Certain abnormalities of the X chromosome or an autosome are associated with dysgenetic male pseudohermaphroditism (see Fig. 22-19 and Table 22-4 ). Duplications of the Xp21.3 region that contains the DAX1 gene can cause dysgenic male pseudohermaphroditism as well as other extragenital anomalies and mental retardation (Table 22-36). Mutations in DAX1 cause X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism. DAX1 encodes a protein with three and one-half repeats of a motif that may be a DNA-binding domain. The gene is expressed in the ovaries, testes, hypothalamus, and pituitary gland and has a steroidogenic factor (SF1) response element in its promoter. Mutations in DAX1 in XY males have no apparent effect on either the differentiation of the testes or male differentiation of the external genitalia. DNA analysis of 46,XY phenotypic females has failed to detect an abnormality in the DAX1 gene. Deletion of DAX1 does not impair testicular determination and differentiation, but duplications of the DAX1 region impair testicular differentiation in 46,XY individuals. This observation has led to the suggestion that DAX1 may function as a repressor of male differentiation; the conversion to DHT is mediated by the type 1 5-reductase isozyme. However, DAX1 expression is also detected in other tissues, such as the brain, suggesting a more complex role for this gene.

46,XY dysgenetic male pseudohermaphroditism has been associated with mental retardation and thalassemia, the "ATRX syndrome." Mutations in a gene called XH2, located at Xq13.3, that encodes a DNA helicase are described in patients with an atypical form of this syndrome. Terminal deletions at chromosome 10q (10q26-qter) and at 9p24-pter are associated with dysgenetic male pseudohermaphroditism and dysmorphic features. The putative gene on the long arm of chromosome 10 autosomes involved in testes development has not been ascertained. However, accumulating evidence suggests that haploinsufficiency of a gene related to double sex in Drosophila, DMRT1, in chromosome 9p24.3 leads to defective testis differentiation. Less common is the association of dysgenetic male pseudohermaphroditism with

Anomalies of the urinary tract are common in patients with abnormalities of genital differentiation. Less common is the association of dysgenetic male pseudohermaphroditism with
congenital or early-onset renal disease (diffuse mesangial sclerosis) and the development of Wilms’ tumor in the first decade (i.e., the Denys-Drash syndrome) or the childhood onset of renal disease and gonadal tumors (the Frasier syndrome).

XY individuals with Denys-Drash syndrome usually present in the newborn period with ambiguous genitalia, although both normal male and normal female genitalia have been reported (Table 22-37). The karyotype is 46,XY, albeit affected 46,XX females with renal disease and normal genitalia have been reported. Gonadal development in males varies from streak gonads to dysgenetic testes. The differentiation of the müllerian ducts varies depending on the functional status of the Sertoli cells of the gonads. Diffuse mesangial sclerosis, leading to renal failure, is seen on renal biopsy. Wilms’ tumor occurs in the first decade of life, and 4% of patients with Denys-Drash syndrome develop a gonadoblastoma. Frasier and associates described a pair of 46,XY monozygotic twins with streak gonads and gonadoblastoma, one of whom developed renal failure: these patients appear to represent a component of the spectrum of the Denys-Drash syndrome (Table 22-38). DNA analysis of patients with Denys-Drash syndrome has revealed heterozygous mutations of the Wilms’ tumor suppressor gene (WT1) located on 11p13. The WT1 gene encodes a transcription factor with four CysCys/HisHis zinc fingers that is expressed in the fetal kidney, gonad, and genital ridge. Heterozygous mutations, mostly missense mutations, are most common in exon 9 of the WT1 gene, with Arg394Trp being the most frequent in patients with Denys-Drash syndrome. The majority of WT1 mutations in Denys-Drash syndrome are de novo and appear to act as dominant negative mutations.

The Frasier syndrome, a variant of the Denys-Drash syndrome, is characterized in XY individuals by XY complete gonadal dysgenesis, with streak gonads resulting in female external and internal genital structures, late-onset glomerulopathy, focal glomerular sclerosis with renal failure occurring in the second decade, and predisposition to the development of a gonadoblastoma rather than Wilms’ tumor. The syndrome is associated with a heterozygous mutation in the WT1 gene at the donor splice site of intron 9. DNA analysis of patients with Denys-Drash syndrome has revealed heterozygous mutations of the Wilms’ tumor suppressor gene (WT1) located on 11p13.

TABLE 22-38 — Clinical Features of Frasier Syndrome in 46,XY Males.

| Karyotype: | 46,XY |
| Inheritance: | Autosomal dominant: mutation in splice donor site in intron 9 of the WT1 gene on 11p13 affecting the inclusion of 3 amino acids (KTS) and thus altering the normal balance of ± KTS isoforms. |
| Genitalia: | Female (hypoplastic male with cryptorchidism, rare) |
| Wolffian duct derivatives: | Absent (hypoplastic, rare) |
| Müllerian duct derivatives: | Present hypoplastic |
| Gonads: | Streak dysgenetic hypoplastic testes |
| Other features: | Late-onset renal disease from focal and segmental sclerosis of the kidney; increased incidence of gonadal tumors, especially gonadoblastoma; Wilms’ tumor rare (4%) |
| Hormone profile: | Elevated plasma LH, FSH levels |

LH, luteinizing hormone; FSH, follicle-stimulating hormone.

*Frasier’s syndrome and Denys-Drash syndrome may be variants of the same underlying syndrome.

as interrelated disorders of the WT1 gene and two extremes of a spectrum of clinical features rather than separate disease entities. (See section on sex differentiation.)

The genitourinary anomalies in the WAGR syndrome include renal agenesis, horseshoe kidney, urethral atresia, hypospadias, and cryptorchidism, and they are usually less severe than those observed in the Denys-Drash syndrome. (A mutation or deletion of WT1 has not been found in SR-Y-positive patients with dysgenetic gonads who do not have evidence of renal disease.)

Heterozygous mutations of the autosomal SOX9 gene cause campomelic dysplasia, often a lethal skeletal malformation, in which three fourths of affected 46,XY patients have dysgenetic male pseudohermaphroditism (Table 22-38; see also Fig. 22-17).

TABLE 22-39 — Clinical Features of SOX9 Deficiency in 46,XY Males

| Karyotype: | 46,XY |
| Inheritance: | Autosomal dominant: heterozygous loss of function mutations in the SOX9 coding region on chromosome 17q24.317q25.1 or break points with translocation 50 kb or more 5’ to the SOX9 gene |

| Wolffian duct derivatives: | Absent hypoplastic present |
| Müllerian duct derivatives: | Normal hypoplastic absent |
| Gonads: | Testes dysgenetic testes ovotestes ovaries (rare) |
| Habitus: | Campomelic dysplasia, usually lethal bony dysplasia associated with male-to-female sex reversal in two thirds of affected males; testes in one third with male external genitalia |
| Prominent features of campomelic dysplasia: bowing of femora and tibiae, hypoplastic scapulae, 11 pairs of ribs, pelvic malformations, clubfeet, cleft palate, micrognathia, etc. |

disorder has an incidence of 0.05 to 1.6 per 10,000 live births. Manifestations include bowed long bones, hypoplastic scapula, a deformed pelvis, 11 pairs of ribs, a small thoracic cage, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. Death from respiratory distress usually occurs in the neonatal period, but long-term survival has been reported. The external genitalia of affected 46,XY males varies from that of normal males with descended testes through ambiguous genitalia to female external genitalia, depending on the functional status of the fetal gonads. Affected 46,XX females have normal external genitalia and apparently normal ovaries. Histologic examination of the gonads from 46,XY patients with ambiguous or female external genitalia showed varying degrees of testicular dysgenesis extending to streak gonads with primordial follicles.

Tommenup and co-workers mapped the sex-reversal locus associated with campomelic dysplasia to 17q24.3q25.1 from studies of three patients with balanced de novo reciprocal translocations. The break point in these patients was distal to the growth hormone locus and proximal to the thymidine locus on 17q. Because
the murine gene. Sox9 had been localized to a region in the murine genome that is homologous to 17q and this gene is expressed in skeletal tissue, the corresponding human gene Sox9 was considered to be a candidate for campomelic dysplasia. Subsequently, missense, nonsense, frameshift, and splice junction mutations were detected in the Sox9 gene in patients with campomelic dysplasia with or without gonadal dysgenesis. However, no correlation between the mutations and the gonadal phenotype (sex reversal) has been found. In one family, the same Sox9 mutation resulted in siblings with campomelic dysplasia as a result of a germ-cell mosaicism for a Sox9 mutation in the father. However, the gonadal phenotype varied in the two 46,XY males from dysgenetic gonads to "normal" ovaries, and the affected 46,XX female had "normal" ovaries. In all patients studied, the mutation has been identified in only one SOX9 allele (heterozygous), which suggests that both the campomelic dysplasia and sex reversal are caused by haplosufficiency of the SOX9 gene. The absence of sex reversal in approximately one fourth of 46,XY individuals with campomelic dysplasia and in patients with translocations that involve break points in 17q more than 130 kb from the SOX9 gene in which no mutations have been found is unexplained.

The SOX9 gene has three exons and two introns, the first of the SOX genes to have introns, and encodes a 509-residue protein that localizes to the nucleus and contains an HMG box with 71% homology to that of the SRY protein. The HMG box binds to the same DNA motif CAA-CACAAGC as other HMG transcription factors and trans-activates transcription of a downstream target gene or genes. The trans-activation function of Sox9 appears to reside in the carboxy-terminal domain of the protein. Sox9 is expressed in the developing gonad, rete testis, and seminiferous tubule and in the mesenchyme that gives rise to skeletal tissue. During choriongenesis, Sox9 is co-expressed with COL2A1, the gene that encodes type II collagen; the SOX9 protein binds to regulatory gene sequences in the COL2A1 gene and regulates its expression. It is apparent from the study of patients with campomelic dysplasia that SOX9 is an integral part of testicular development cascade.

Steroidogenic factor 1 (SF1, or Ad4BP, adrenal 4 binding protein), a zinc finger "orphan" nuclear receptor, is a member of the steroid hormone/thyroid hormone receptor superfamily of transcription regulatory factors. SF1 encoding a gene on chromosome 9q33 and binds to a DNA motif consisting of an estrogen receptor half-site, AGGTCA, and to nucleotides S to this half-site (see Fig. 21-1A). The presence of this motif in the promoters of CYP steroid hydroxylase genes, as well as in vivo expression studies, suggests that SF1 is a key regulator of CYP steroidogenic enzymes in the adrenals and gonads. However, in the placenta the expression of CYP1A1 (P450umc) and other CYP steroidogenic genes occurs in the absence of expression of the SF1 gene, as is the case in the central nervous system where neurosteroids are produced locally. The SF1 gene is critical to the in vivo expression of AMH and the subunit of LH.

SF1 and the embryonal long terminal repeat binding protein (ELP, a protein that suppresses expression of Moloney murine leukemia virus in mouse undifferentiated embryonal carcinoma cells) are isoforms transcribed from the same gene by alternative promoter usage and splicing. SF1 and ELP are the mouse homologue of the human genes SF1 and ELP, which are co-expressed in skeletal muscle, reproductive organs, and gonads. All male and female knockout mice die of presumed adrenal insufficiency in the neonatal period. The external genitalia are female in both XX and XY mice, müllerian duct derivatives are normally developed, and the ventromedial nucleus of the hypothalamus is aplastic or hypoplastic. The expression of SF1 in the developing gonad is sexually dimorphic. At 12.5 days of embryonic development, when the bipotential gonad develops into an ovary or testis in the mouse and before expression of the CYP steroidogenic genes, SF1 expression persists in the Leydig and Sertoli cells of the testes but is extinguished in the primordial ovary.

In SF1 knockout mice the genital ridges developed normally until 10.5 days after coitus and thereafter underwent apoptosis. Therefore, SF1 appears to play a critical role in the development of the adrenals, ovaries, testes, hypothalamus, and gonadotropes and in modulation of AMH and CYP steroidogenic enzymes. As discussed previously, SF1 deficiency in three humans has been shown to cause severe adrenal insufficiency with impairment of testicular determination. Whether it affects ovarian determination is still to be determined (Table 22-40). Patients with 46,XY syndrome and putative haploinsufficiency of DMRT1 also manifest male pseudohermaphroditism, as discussed previously (Table 22-41).

Vanishing Testes Syndrome (Embryonic Testicular Regression Syndrome)

Various terms (XY gonadal dysgenesis, XY gonadal agenesis, rudimentary testis syndrome, congenital anorchia) have been used to describe the spectrum of genital anomalies resulting from cessation of testicular function during the middle phase of male sex differentiation, between 8 and 14 weeks of gestation. We first used the term vanishing testes syndrome for this form of male pseudohermaphroditism in 1957 because the genitalia in these cases suggested that the testes functioned initially and then “vanished” (for obscure reasons) at some time during the process of male sex differentiation. These patients have a 46,XY karyotype. Gonadal elements are absent, and differentiation of the genital ducts, urogenital sinus, and external genitalia is variable. At one end of the spectrum is the group of 46,XY individuals with female external and internal genitalia in whom the deficiency of embryonic testicular function presumably occurred before 8 weeks of gestation. These individuals have either no gonads (46,XY agonalism) or streak gonads. Loss of function of the fetal testes at 8 to 10 weeks of gestation would lead to ambiguous genitalia and variable development of the genital ducts, from complete absence of both müllerian and Wolffian ducts to partial development of either, a constellation referred to by some as the XY gonadal agenesis syndrome. Loss of testicular function after the critical phase of male differentiation (12 to 14 weeks) results in anorchia, a syndrome characterized by normal male differentiation both internally and externally but no gonadal tissue. The presence of normal male genitalia and absence of müllerian duct derivatives implies that fetal testicular function was normal before its loss. Sporadic and familial forms of unilaterial and bilateral anorchia, including monozoic gonads concordant and discordant for anorchia, have been described. Fetal testicular insufficiency and incomplete regression of the fetal testes after 12 to 14 weeks would be expected to produce a syndrome similar to that described by Bergada and colleagues, that is, small, rudimentary testes with microphallic and male ejaculatory ducts.

The nature of the underlying defect, which in some cases leads to absence or regression of genital ducts as well as testes and in some cases other congenital

*One 46,XX female reported with Arg255Leu heterozygous mutation; adrenal insufficiency; normal female genitalia; normal ovaries.*
anomalies, is not known. Several sibships with multiple affected individuals have been described. Josso and Briand reported on two siblings, one of whom was a normally differentiated male with microphallus and anorches. The other sibling had a 46,XY karyotype but was raised as a female. She had a normal clitoris, fused labioscrotal folds, a single perineal opening that led into a urogenital sinus, and a vagina. At laparotomy, absent gonads with coexistent müllerian and wolfian structures were found. This patient's phenotype was compatible with a diagnosis of XY gonadal agenesis. Despite the absent gonads, the patients had distinct phenotypic differences in the internal and external genitalia. The coexistence of so-called XY gonadal agenesis and anorches in the same sibship suggests that the disorders are related and are caused by embryonic testicular regression occurring at different stages of male development in utero; the familial cases support the operation of a rare, mutant gene in at least some patients with this syndrome. All eight boys with bilateral congenital anorches confirmed at surgical exploration were SRY positive.

The diagnosis of "true" anorches (in contrast to the testicular regression syndrome with ambiguous external genitalia) can be suspected in normally differentiated males with bilateral cryptorchidism, elevated gonadotropin levels, and low plasma AMH and inhibin levels. It is infrequently familial. We have demonstrated a diaphasic childhood pattern of gonadotropin levels in anorches males similar to that seen in females with the syndrome of gonadal dysgenesis. In particular, plasma FSH levels are elevated in infancy, decrease into the normal range in middle childhood, and rise into the agonal range after age 9 to 10 years. LHRH-induced increases in plasma FSH and LH concentrations are elevated throughout infancy and childhood. Hence, the LHRH test may be helpful diagnostically in middle childhood, when basal gonadotropin levels are normal or near normal. It has been proposed that the finding of elevated plasma FSH levels in conjunction with lack of a plasma testosterone response to HCG (1500 U/m2 intramuscularly every 48 hours × 7) establishes the diagnosis of anorches and obviates the need for laparotomy. This approach has been called into question by the finding of testes at laparotomy in two prepubescent males in whom no testosterone response to HCG was elicited. Immunoassay of plasma AMH in infancy and childhood is a useful additional test to assess for the presence of a testis; the concentration of plasma AMH in anorches is very low, as is the determination in plasma of another Sertoli cell secretion, inhibin B. Indeed, the concentration of plasma inhibin B highly correlates with the testosterone response to HCG and may well substitute for the HCG test, and it is more cost effective. Furthermore, CT or MRI, ultrasonography, and laparoscopy are useful procedures for evaluation of the patient with suspected anorches. We have deferred laparoscopic exploration of males with presumed "true" anorches (phenotypic males with nonpalpable testes, elevated gonadotropin levels, and no rise in the plasma concentration of testosterone in response to HCG) until the time of insertion of prosthetic testes. The typical findings at laparoscopy are a nubbin of testicular tissue adfixed to spermatic vessels exiting the internal inguinal ring. No recognizable testicular elements are evident in the nubbin. The true vanishing testes syndrome typified by normal male genital development has been attributed to a prenatal torsion event. An interesting case study described antenatal ultrasound findings of a male fetus with a left hydrocele and a normal right testes but at birth the right testis was nonpalpable. At surgical exploration, there was torsion of the spermatic cord on the left side and a normal testis, whereas on the right side the spermatic cord ended in a nubbin of testicular tissue. No recognizable testicular elements are evident in the nubbin. The true vanishing testes syndrome was not bilateral because the left hydrocele had a protective effect on the vascularity during the antenatal testicular torsion. The vanishing testes syndrome can be unilateral, occurring after descent but before fixation of the tunica vaginalis to the scrotal wall.

**AMH/MIS**, a 148-kd glycoprotein homodimer, is secreted by the Sertoli cells of the testes beginning with differentiation of the fetal seminiferous tubules and continuing until pubertal maturation. AMH is not secreted by the fetal ovary, but postnatally (see section on sex differentiation) it is expressed in the granulosa cells of antral and preantral ovarian follicles. AMH, a member of the TGF- superfamily of growth and differentiation factors, is processed intracellularly and secreted in its mature, bioactive form. AMH binds to the AMH type II serine/threonine kinase receptor located in the mesenchyme surrounding the müllerian ducts before 8 weeks of gestation (when the müllerian ducts respond to AMH), causing epithelial-mesenchymal interaction, apoptosis of the müllerian duct epithelium, and regression of the müllerian duct. Studies in the bovine freemartin and in transgenic mice overexpressing AMH indicate that AMH can cause regression of germ cells in the ovary and reorganization of the ovary into cord-like seminiferous tubules and can inhibit CYP19 activity. Five of 21 transgenic male mice that chronically expressed human AMH exhibited mammary gland development, arrested wolffian duct differentiation, and undescended testes. These observations suggest that high levels of AMH can impair Leydig cell function and steroidogenesis in the testes. AMH levels are measurable in the normal male plasma until pubertal maturation.

AMH is encoded by a 2.75-kb gene containing five exons in the region of chromosome 19p13.3. The gene has an upstream regulatory element, the estrogen response element, half-site AGGTCA type, to which SF1 binds to regulate AMH secretion.

The AMH/MIS receptor, a serine/threonine kinase with a single transmembrane domain, is a member of the family of type II receptors for TGF--related proteins (see Fig. 22-27). The AMH type II receptor binds ligand but requires the ubiquitous type I receptor for signal transduction.

The AMH II receptor is encoded by a gene that contains 11 exons. The AMH type II receptor binds ligand but requires the ubiquitous type I receptor for signal transduction.

The AMH II receptor is encoded by a gene that contains 11 exons. This receptor is expressed in adult granulosa and Sertoli cells, which suggests a possible autocrine action of AMH in these cells.

**Persistent Müllerian Duct Syndrome (Female Ducts in Otherwise Normal Men; Hernia Uteri Inguinalis)**

AMH/MIS, a 148-kd glycoprotein homodimer, is secreted by the Sertoli cells of the testes beginning with differentiation of the fetal seminiferous tubules and continuing until pubertal maturation. AMH is not secreted by the fetal ovary, but postnatally (see section on sex differentiation) it is expressed in the granulosa cells of antral and preantral ovarian follicles. AMH, a member of the TGF- superfamily of growth and differentiation factors, is processed intracellularly and secreted in its mature, bioactive form. AMH binds to the AMH type II serine/threonine kinase receptor located in the mesenchyme surrounding the müllerian ducts before 8 weeks of gestation (when the müllerian ducts respond to AMH), causing epithelial-mesenchymal interaction, apoptosis of the müllerian duct epithelium, and regression of the müllerian duct. Studies in the bovine freemartin and in transgenic mice overexpressing AMH indicate that AMH can cause regression of germ cells in the ovary and reorganization of the ovary into cord-like seminiferous tubules and can inhibit CYP19 activity. Five of 21 transgenic male mice that chronically expressed human AMH exhibited mammary gland development, arrested wolffian duct differentiation, and undescended testes. These observations suggest that high levels of AMH can impair Leydig cell function and steroidogenesis in the testes. AMH levels are measurable in the normal male plasma until pubertal maturation.

AMH is encoded by a 2.75-kb gene containing five exons in the region of chromosome 19p13.3. The gene has an upstream regulatory element, the estrogen response element, half-site AGGTCA type, to which SF1 binds to regulate AMH secretion.

The AMH/MIS receptor, a serine/threonine kinase with a single transmembrane domain, is a member of the family of type II receptors for TGF--related proteins (see Fig. 22-27). The AMH type II receptor binds ligand but requires the ubiquitous type I receptor for signal transduction.

The AMH II receptor is encoded by a gene that contains 11 exons. Exons 1 to 3 for the signal sequence and the extracellular domain of the AMH receptor, exon 4 for the transmembrane domain, and exons 5 through 11 for the intracellular serine/threonine domain. In addition to the mesenchyme surrounding the fetal müllerian ducts (but not the epithelial cells), this receptor is expressed in adult granulosa and Sertoli cells, which suggests a possible autocrine action of AMH in these cells.

**A Distinctive disorder, persistent müllerian duct syndrome (PMDS), has been described in which 46,XY men and boys have well-developed testes, normal male ducts and external genitalia, and müllerian duct derivatives (Fig. 22-84). The diagnosis often is not made until a fallopian tube and uterus are encountered in patients undergoing inguinal hernia repair, orchioepxy, or abdominal surgery. Because of the trend for early surgical repair of an inguinal hernia or undescended testes, more cases are detected in infancy. The two anatomic forms. In the more prevalent form, there is a hernia containing a partially descended or scrotal testis and the ispsilateral tube and uterus are in the hernia. In some instances the contralateral testes and tube are present in the hernial sac as well. The presence of transverse testicular ectopia should suggest PMDS.** In the second form, the uterus, tubes, and testes are in the pelvis.
PMDS is a heterogeneous condition that is inherited in a sex-limited autosomal recessive manner. Females homozygous for null mutations in the AMH gene have normal müllerian ducts, external genitalia, and ovarian function, including fertility. Therefore AMH does not appear to play a critical role in ovarian differentiation or formation.

The retention of müllerian structures in normally differentiated males can result from failure of the testes to synthesize or secrete AMH or from a defect in the response of the duct to AMH because of an AMH receptor defect or possibly an abnormality in the timing or secretion of the hormone. Mutations in the AMH gene can lead to absence of AMH as a cause of PMDS (Fig. 22-85). AMH mutations are most common in Mediterranean and Arab countries with high rates of consanguinity, and most familial mutations are homozygous; on the other hand, mutations in the gene encoding the AMH type II receptor (AMHR-II) are more common in France and Northern Europe and are often heterozygous mutations.

In an extensive study of 69 families with PMDS, 28 mutations in the AMH gene were detected in 31 families (see Fig. 22-85). Both homozygous and compound heterozygous mutations were found in affected families, including splicing, missense, nonsense, and deletion mutations affecting the whole gene but mostly involving exons 1 and 3 of exon 5. In 27 families, deleterious mutations in the type II AMH receptor were detected, including deletion, missense, and nonsense mutations (Fig. 22-86). The most common mutation was a 27-base pair deletion in exon 10, which was found on at least one allele in 10 out of 16 families and stands in contrast to the diverse mutations in the AMH gene. In 11 families (16% of the total number), no abnormality in AMH or AMH receptor genes was detected. Patients with PMDS caused by mutations of the AMH gene have low or undetectable levels of serum AMH; in contrast, AMH concentrations are high or elevated in patients with mutations of the AMH receptor.

Treatment of PMDS is directed toward attempting to ensure fertility in males, a difficult issue because of the anatomic findings. Testicular differentiation and function are normal in these patients, but an increased prevalence of testicular degeneration has been described, which is probably secondary to torsion of the testes. Anatomic abnormalities of the epididymis and the vas deferens are common. Infertility may result from late orchiopexy or from mechanical problems associated with entrapment of the vas deferens in the müllerian derivatives, which is usually present. Early orchiopexy, proximal salpingectomy (leaving the epididymis attached to the fimbriae of the fallopian tube), dissection of the vas deferens from the lateral walls of the uterus, and a complete hysterectomy are recommended as a useful surgical approach. Despite these recommendations, men with high pelvic testes rarely have successful orchiopexy, and many of these individuals are androgen deficient.

Progestagens and synthetic estrogens, alone or in combination, have been implicated as rare causes of male pseudohermaphroditism. Courrier and Jost demonstrated an androgenic effect on the male fetus induced by a synthetic progestagen, ethisterone. Neumann and colleagues observed that relatively high doses of progesterone or of synthetic progestagens impaired urethral groove fusion in fetal male rats. Aarskog reported on 130 patients with hypospadias who were studied retrospectively. A history of maternal ingestion of oral progestagens in early pregnancy was obtained in 11 cases. In 6, the agent was administered for threatened abortion, and in 5 the progestagen in combination with estrogens was given as a pregnancy test. Hypospadias occurred anywhere from the glans to the base of the penile shaft; the location correlated with the week of gestation in which therapy was initiated. Other studies have also suggested an association between progestagens and hypospadias, although this relationship has been questioned.

Aarskog postulated that maternal progestagens may inhibit testosterone synthesis by the fetal testes and impair the reduction of testosterone to DHT at the target tissue and thereby lead to failure of urethral groove fusion and hypospadias. Some progestagens can inhibit 5-reductase activity in vitro. Inhibition of this enzymatic activity at an early fetal stage (e.g., through placental transfer of drugs given to the mother) could impair masculinization of the male external genitalia. Alternatively, progestagens may bind to androgen receptors and impair androgen action.

Kaplan described male pseudohermaphroditism in a boy whose mother received large doses of diethylstilbestrol during early pregnancy. However, no additional reports of this association have appeared. Because of the report of Herbst linking maternal diethylstilbestrol therapy during pregnancy with vaginal and cervical adenocarcinoma in daughters, abnormalities in the genital tract have been sought in males. Increased incidences of meatal stenosis, epididymal cysts, hypospadias, and abnormal semen have been observed, but hypospadias has not been reported.

Environmental Chemicals

An increase in the prevalence of disorders of the development and function of the male reproductive system, especially hypospadias and cryptorchidism, and in some European countries a fall in the sperm count and a rise in cancer of the testis, has occurred during the past 50 years. Some investigators have speculated that the increase in reproductive abnormalities observed in human males is related to an increase in the exposure in utero to exogenous estrogenic chemicals, so-called environmental estrogens, in the maternal diet, either as a natural occurrence or as a result of chemical contamination. Administration of diethylstilbestrol or the putative environmental estrogen, 4-octylphenol, to pregnant rats resulted in decreased expression of CYP17 mRNA and protein in Leydig cells of XY male offspring. Suppression of CYP17 may play a role in the putative adverse effect of environmental estrogens on fetal masculinization. The
dichlorodiphenyltrichloroethane (DDT) metabolite \( p,p' \text{DDE} \) (1,1-dichloro2,2-bis-(\( p \)-chlorophenyl) ethylene), unlike DDT itself, has little ability to bind to the estrogen receptor, \footnote{Further studies on the levels and risks of natural and environmental estrogens and antiandrogens in humans are necessary before the putative increased prevalence of certain abnormalities of the reproductive tract can be attributed to these agents as well as their putative role in the pathogenesis of the testicular dysgenesis syndrome.} but it binds to the androgen receptor and inhibits androgen action in the developing urogenital tract of rodents. \footnote{Further studies on the levels and risks of natural and environmental estrogens and antiandrogens in humans are necessary before the putative increased prevalence of certain abnormalities of the reproductive tract can be attributed to these agents as well as their putative role in the pathogenesis of the testicular dysgenesis syndrome.}
Other Sexual Abnormalities in Males

Hypospadias

Hypospadias, which may be defined as incomplete fusion of the penile urethra, is one of the common congenital anomalies. It has an estimated incidence of 4 to 8 per 1000 male births. As noted previously, the rate appears to have doubled in some countries in the 1970s and 1980s. Analysis of the family histories of patients with hypospadias revealed an increase in the occurrence of hypospadias in males in the pedigrees. This finding suggested a multifactorial mode of inheritance in some instances; the cause in most instances is unknown. Aarskog carried out a careful prospective study of 100 consecutive patients with hypospadias without other somatic anomalies, most of which were referred from a surgery clinic. One patient was a genetic female with virilizing CAH, five had sex chromosome abnormalities, one had the incomplete form of 46,XY gonadal dysgenesis, and nine were from pregnancies in which the mother had taken synthetic prostaglandin agents during the first trimester. Thus, in 15% of the patients, a pathogenetic mechanism was found or suspected. Both maternal cocaine use and environmental estrogens and androgens have also been implicated in the development of hypospadias. Even though androgen receptor defects have been suggested to play a significant role in the origin of hypospadias, androgen receptor defects are a rare cause of isolated hypospadias.

Hypospadias is a feature of many malformation syndromes, such as the Opitz syndrome. The cardinal manifestations of this syndrome are widely spaced eyes and hypospadias. This disorder is genetically heterogeneous; an X-linked form involves a locus at Xp22, and an autosomal form involves a locus at 22q11.2. Hypospadias is also a feature of the hand-foot-genital syndrome in males. Limb anomalies include short first metacarpals, short distal phalanges of the thumbs, and a short great toe. A mutation in the HOXA13 gene was detected in a pedigree with this syndrome.

The mildest and most common form of hypospadias is glandular or coronal and occurs in about 85% of cases; with surgical repair, these boys, at least in middle childhood, are not at risk for the development of "gender-atypical" behavior. Even though rare cases have been reported of 5-reductase deficiency and androgen receptor defects with isolated, simple hypospadias, extensive endocrine and cytogenetic evaluation of the otherwise normal male with glandular hypospadias and no somatic anomalies is not warranted. More severe hypospadias with or without cryptorchidism and somatic anomalies is an indication for complete evaluation, including karyotype analysis.

hCG stimulation studies, and visualization of the genitourinary tract.

Cryptorchidism

Undescended testes, the most common urogenital abnormality in malformation syndromes, is associated with more than 40 syndromes. Although normal testes may fail to descend to the scrotum because of coincidental anatomic abnormalities, in many instances cryptorchidism is caused by a defective testis. Fetal pituitary gonadotropin deficiency, either partial or complete, may play a role in some instances of cryptorchidism as well as microphallus. Cryptorchidism and its management are considered in greater detail in Chapter 16 and in several reviews.

Ambiguous Genitalia in 46,XY Males with Multiple Anomalies

The presence of ambiguous genitalia is associated with many malformation syndromes. In malformation syndromes such as the Aarskog and Opitz syndromes, the genital anomaly is of diagnostic significance. Other reports of rare causes of male pseudohermaphroditism include a patient with a putative "biologically inactive" but immunologically reactive LH and a group of familial cases in which a defect was postulated in fetal Leydig cell maturation with inadequate fetal testosterone production and impaired differentiation of germinal elements. The latter patients had ambiguous genitalia at birth but normal utilization at puberty and may represent examples of SRD5A2 deficiency, 17-HSD 3 deficiency, or partial androgen resistance.

Other Sexual Abnormalities in Females

The association of congenital absence of the vagina with normal or absent müllerian structures has been recognized for more than 100 years and is usually known as the Mayer-Rokitansky-Küster-Hauser syndrome. Congenital absence of the vagina occurs in 1 in 5000 female births. It was the second most common cause of primary amenorrhea in a series of 538 patients reviewed by Ross and van de Wiel. The principal features of the syndrome are primary amenorrhea in 46,XX females with well-developed female secondary sexual characteristics, an absent or hypoplastic vagina, and müllerian derivatives that vary from a normal uterus to bicornuate cords to absence of the uterus. Ovarian function is usually normal, and patients exhibit cyclic gonadotropin secretion with ovulation. Renal and skeletal anomalies may be present. Hearing loss, both conductive and sensorineural, occurs in 25% of patients with the Mayer-Rokitansky-Küster-Hauser syndrome. Clitoromegaly is not a feature and that distinguishes it from the adrenal and nonadrenal forms of female pseudohermaphroditism. The 46,XX karyotype and normal plasma gonadal steroid values differentiate this disorder from androgen insensitivity. Familial aggregates of women with anomalous müllerian differentiation may be explained by multifactorial inheritance.

It has been suggested that patients with skeletal and renal anomalies should be considered as a separate group, the GRES (genital-renal-ear-skeletal) syndrome. The association of uterine anomalies with malformations of the extremities is well described. The association of absence of the uterus and the upper part of the vagina, renal anomalies, and cervical somite dysplasia (Klippel-Feil syndrome) has been called the MURCS association (müllerian duct aplasia, renal agenesis/ectopia, and cervical somite dysplasia). Ultrasonography and CT and MRI scans are useful for determining the presence of a uterus and its structure.
Hematocolpos is a preventable complication if surgical reconstruction is begun before puberty is advanced. If the vagina is too small for sexual intercourse, nonsurgical or surgical correction should be undertaken at an appropriate age. Vaginal lubrication, orgasm, and coitus have been reported to be satisfactory in adults who have had successful vaginal reconstruction.
MANAGEMENT OF PATIENTS EXHIBITING AMBISEXUAL DEVELOPMENT

The advances in the management of patients with intersexuality have undergone a dramatic change over the past 50 years. A major deficiency in promoting guidelines for the modern management of intersexuality is the lack of critical outcome data or the selective nature of the available data. A background for these changes is the dramatic shift in our society's attitude toward sexual identity has come out of the closet and discarded many formerly deeply embedded Victorian attitudes. Before 1953, when one of us became committed to the clinical, scientific, and management aspects of intersex, these patients were largely managed by surgeons and urologists. Some were paternalistic authoritarians who had little tolerance for anyone questioning their empirical decision. The gonad was a cardinal criterion for determination of sex of rearing. The mantra was "It's an anatomical anomaly, fix it or cut it out."

A sea change in this approach began with Lawson Wilkins and his associates at the Harriet Lane Home of Johns Hopkins Hospital in the early 1950s. This was the beginning of group decision making by an evolving team that initially was composed of Dr. Howard Jones, a gynecologic surgeon; Drs. Joan and John Hampson, child and adult psychiatrists; John Money, a psychologist newly arrived from Boston, Wilkins and his fellows Judson Van Wyk and Melvin M. Grumbach, George Clayton, and Alfred Bongiovanni, a young faculty member in the group and the director of the pediatric endocrine laboratory. Social workers provided important family care skills. After the departure of the Hampsons for the University of Washington in the late 1950s and Lawson Wilkins' death in 1964, Money's extended studies led him to propose the gender socialization hypothesis of gender identity later referred to by his disciples as the "optimal-gender policy." The notion was that "sex of assignment and rearing were consistently and conspicuously a more reliable prognosticator" of the gender identity of an intersex patient than the chromosomal sex, gonadal sex, hormonal sex, the sex of the internal genital organs, or the degree of ambiguity of the external genitalia. Money and his associates stressed the importance of a decision about the sex of assignment in infancy.

Beginning in 1959 with the report by Phoenix and Young of "masculinization" of the female guinea pig brain by prenatal administration of testosterone, mounting evidence, at first a trickle but later virtually a torrent of experimental and behavioral studies, indicated the effect of androgens on sex dimorphic behavior. Further concern had arisen about the recommendations that infants with micropenis but normally found external genitalia and testes be assigned a female sex. Furthermore, the Intersex Society of North America raised important issues about the management of intersexuality. The article by John Colapinto in Rolling Stone and his later book, As Nature Made Him: The Boy Who Was Raised as a Girl, served to accelerate the re-examination of the clinical care of the intersex patient. This reassessment was led by psychologists, psychiatrists, and pediatric endocrinologists, as well as a number of informed pediatric surgeons and urologists. The Winter 1998 (Vol. 9, No. 4) issue of the Journal of Clinical Ethics was devoted to "Intersexuality." In a historical perspective on hermaphroditism, Dreger has emphasized how ingrained are our attitudes about "gender normality" but it also exemplifies how much our attitudes have changed.

Considerations Governing Choice of Sex for Rearing

With early, carefully weighed assignment of sex for rearing and appropriate continued management with an emphasis on continuity of care, individuals with ambiguities of the genitalia have the potential to lead well-adjusted lives and ultimately a satisfactory sex life. To obtain this favorable result, it is incumbent on the physician to make a correct diagnosis as early as possible and to provide the parents with pros and cons of sex assignment so that they may acquire sufficient knowledge to arrive at an informed decision on the sex for rearing. Lucid, simple, comprehensive discussions with the parents, taking into account their anxieties, religious views, social mores, cultural factors, and level of understanding, are critical for an appropriate gender assignment. The detection of genital ambiguity in a newborn infant can be seen as an urgent neonatal psychosocial necessity, beginning with how the parents are informed about the genital ambiguity. Once the sex for rearing is assigned, the gender role is reinforced by the use of whatever appropriate surgical, hormonal, and psychological measures are indicated.

Studies of patients reared in a sex discordant with their chromosomal sex, gonadal sex, hormonal sex, and even external genital organs have shown that no one parameter is an infallible basis on which to assign sex for rearing. A large body of evidence supports the masculinizing effect of exposure of the female as well as the male fetus to androgens; however, the magnitude of this influence cannot be predicted with certainty in the individual case. In intersex patients the degree of masculinization of the external genitalia does not correlate strongly with that of the central nervous system. The physician should consider the modern surgical advances in genital repair, including repair of hypospadias, and the use of exogenous testosterone in the treatment of androgen-sensitive microphallicus. In some cultures, the social, cultural, and economic benefits of a male gender are more compelling than phallic adequacy and are a prevailing, if not the most important, factor in the parental decision on the sex of rearing (Table 22-42).

The hormonal sex expected at maturity and the increasing possibility of fertility with advances in assisted reproduction technology are of importance. With the exception of female pseudohermaphroditids and true hermaphroditids reared as females, ambiguities of the external genitalia are caused by lesions that severely compromise but do not eliminate the possibility of fertility in view of the advances of modern reproductive techniques. A major goal in intersex patients should be the possibility of achieving cosmetic and functionally normal genitalia by surgical and endocrinologic means. In considering a decision to recommend a male sex of rearing, emphasis should be placed on the size of the phallus and glans and its potential for growth. All phenotypic males with micropenis (stretched penis length < 2.5 cm at birth) should be given a trial of testosterone enanthate in oil, 25 to 50 mg intramuscularly monthly for three doses, to ascertain the potential of the phallus for further growth before a decision on sex of rearing is made. Failure of the phallus to lengthen significantly (mean response, 2.0 ± 0.6 cm) raises the possibility of inadequate growth of the phallus in later childhood and at puberty. The parents should be made aware of the difficulties in making a dogmatic recommendation with the limited data on outcome. Principles governing the differential diagnosis and the surgical, hormonal, and psychological management of patients with genital ambiguity are treated more extensively in the following sections.

| TABLE 22-42 — Management of Ambiguous Genitalia |
| Get help! Team approach: pediatrician, endocrinologist, child mental health expert, social worker, and surgeon. |
| Arrive at a (prompt) definitive diagnosis if possible |
| Inform the parents of your diagnosis: the natural history of the disorder, prognosis, and the therapeutic options. Full disclosure! |
| Consider the parents’ level of understanding, cultural background, and religious views in order to allow them to come to a decision on the "sex" of their child and to provide truly "informed consent." |

Abnormalities of sex differentiation should be suspected not only in infants with ambiguous genitalia (Fig. 22-87) but also in apparent females with inguinal masses, inguinal hernias, or slight clitoral enlargement. Apparent males with cryptorchidism, hypospadias, or unusually small genitalia or gonads likewise deserve close scrutiny. Sufficient investigation should be carried out in the newborn period to ascertain, if at all possible, an etiologic diagnosis to permit an informal decision by the parents on the assignment of sex. A karyotype or FISH analysis of sex chromosomes is an imperative first step in all such newborns (Fig. 22-88).
Infants with a 46,XX Karyotype

All infants with sexual ambiguity and a 46,XX karyotype should receive sufficient study in the neonatal period to differentiate the various forms of female pseudohermaphroditism (Table 22-18) from true hermaphroditism and the rare XX male.

Congenital Adrenal Hyperplasia

Female pseudohermaphrodites with virilizing CAH are reared as females in most cultures (Table 22-43). If female pseudohermaphroditism is secondary to CAH (primarily CYP21 deficiency), plasma levels of 17-hydroxyprogesterone and androstenedione and excretion of urinary 17-ketosteroids should be markedly elevated. A plasma 17-hydroxyprogesterone level higher than 90 nmol/L (3000 ng/dL) in an infant with ambiguous genitalia who is 24 hours of age or older is virtually diagnostic of 21-hydroxylase deficiency. However, premature and stressed infants may have elevated plasma 17-hydroxyprogesterone levels for 4 to 5 days. The diagnosis of CAH is sometimes difficult in the newborn period and may require multiple steroid determinations and the use of an intravenous bolus of ACTH to stimulate plasma 17-hydroxyprogesterone for the detection of 21-hydroxylase deficiency and 11-deoxycorticisol for 11-hydroxylase deficiency. Any infant with ambiguous external genitalia who fails to thrive or who develops vomiting, dehydration, and signs of hypoglycemia during the first few weeks of life should be suspected of having a severe salt-losing form of CAH. If such an infant has hyperkalemia associated with acidosis and hypocalcemia, the diagnosis is virtually assured, and vigorous therapy with hydrocortisone, salt, and mineralocorticoids should be instituted on an urgent basis to prevent collapse and sudden death. Once the diagnosis of adrenal hyperplasia is established, glucocorticoid therapy should be instituted and continued for life.

Other Forms of Female Pseudohermaphroditism

A small proportion of 46,XX female pseudohermaphrodites have aromatase (CYP19) deficiency. A history of virilization of the mother during pregnancy and elevated levels of androgens, androgen precursors, and FSH and unmeasurable levels of estrogen and estradiol are diagnostic. 46,XX infants may be presumed to have nonadrenal-induced female pseudohermaphroditism if adrenal hyperplasia, aromatase deficiency, and a glucocorticoid receptor defect have been excluded and if there is a reliable history of the mother receiving androgens or pregnancy. Patients with female pseudohermaphrodism usually have a normal uterus and fallopian tubes with ovaries in the normal location. For this reason, the diagnosis should be viewed with suspicion if there is an inguinal hernia or if gonad-like masses are palpable in the groin. Such masses are frequently testes. The presence of a uterus can often be detected in the newborn period by digital examination via the rectum; however, the use of pelvic ultrasonography is now routine because it is more informative and less stressful. If there is uncertainty, MRI of the pelvis is useful.

True Hermaphroditism

Most patients with true hermaphroditism have a 46,XX karyotype, and it may be difficult to distinguish some of them from patients with the rare nonadrenal causes of female pseudohermaphroditism. True hermaphrodites, however, often have gonads located in the labia or inguinal canals, a bipartite gonad is highly suggestive of ovotestes. In true hermaphroditism the assignment of sex should be deferred until the nature of the internal genital structures and gonads can be determined by ultrasonography, MRI, urethroscopy, or radiologic study with contrast media and, if necessary, laparoscopy. Most 46,XX true hermaphrodites are raised as females. Not infrequently, the heterologous gonadal tissue can be removed. It is important to emphasize the risk of malignant degeneration of the dysgenetic testicular tissue that is retained. In general, assignment of female sex and an attempt to preserve an ovary or ovarian tissue are appropriate except in those rare true hermaphrodites who have a 46,XY karyotype, no uterus, and adequate phallic development (Table 22-44).
Infants with a 46,XY Karyotype

Male pseudohermaphroditism is a heterogeneous group of disorders in which ambiguous genitalia result from either androgen deficiency or androgen resistance during the critical period of sex differentiation (see Fig. 22-88) (Table 22-45). The existence of both complete and partial defects in androgen biosynthesis, metabolism, and action; the occurrence of more than one gene encoding a protein with the same enzymatic activity but with different tissue specificities or developmental expression (e.g., 3-HSD, 17-HSD, 5-reductase); and the presence of different phenotypes in some patients with the same molecular genetic defect confound the clinical picture and the predictions about the natural history of these disorders.

A great effort should be made to establish an etiologic diagnosis, because this may have an important bearing on subsequent management, including family counseling. A detailed family history with construction of a pedigree is important, because many sexual abnormalities are hereditary and because this type of historical information is not always volunteered. For example, a history of aunts who have never menstruated or of an inguinal hernia or labial mass in a phenotypic female first-degree relative may suggest the diagnosis of androgen resistance. The mother should also be asked about signs of virilization during pregnancy and drugs or hormones that she may have taken during the early part of pregnancy.

Studies during the newborn period should always include an examination of the karyotype. A sufficient number of metaphase plates should be examined to reduce the possibility of overlooking mosaicism. The morphology of the sex chromosome and the autosomes should be determined and selective FISH analysis carried out.

Pelvic ultrasonography or MRI, radiographic contrast studies of the urogenital sinus, and fiberoptic endoscopic examination may aid in this initial evaluation. Laparoscopy or laparotomy is rarely indicated in the neonatal period except in infants suspected of having true hermaphroditism. Before an informal decision about sex assignment is made by the parents it is important to evaluate fully karyotypic studies, the pattern of plasma gonadal steroids before and after hCG stimulation, and other measures to identify a specific type of male pseudohermaphroditism.

Urinary steroids and plasma androgens should be measured before and after administration of corticotropin (0.15 to 0.25 mg intravenously) and hCG (1500 U/m² intramuscularly daily × 3 doses or every 48 hours × 7) to ascertain whether the patient has a block in testosterone synthesis or 5-reductase deficiency. The testosterone response to hCG may result in measurable phallic enlargement. Therefore, in addition to providing objective information about the functional capacity of the Leydig cells to secrete testosterone, the test may also provide evidence for the capacity of androgen-sensitive target tissues to respond to androgens. In the patient with male pseudohermaphroditism and no evidence of a testosterone biosynthetic error, 5-reductase-2 deficiency, or dyssgenetic male pseudohermaphroditism, clinical or biochemical evidence of testosterone responsiveness should be assessed before a sex assignment is made.

Male infants with congenital hypopituitarism or isolated hypogonadotropic hypogonadism frequently have micropenis and unilateral or bilateral cryptorchidism, and this diagnosis should be excluded by appropriate studies of pituitary function before considering sex reassignment. It is our view that all male infants with micropenis should be given a trial of testosterone parenterally before a conclusion is made that the phallus lacks the capacity for growth. Administration of a dose of 25 mg (100 mg/m²) of testosterone enanthate intramuscularly once a month for 3 months in the newborn should provide an adequate androgen stimulus to make this assessment. Rarely, this treatment may cause a slight advancement of the skeletal age, but this consideration is trivial when weighed against the momentous question of deciding the future sex of rearing. It is also important to assess penis size periodically and to repeat the course of testosterone therapy to maintain phallic size within the normal range for age. It has been suggested by inference from studies in rats that early exposure of the penis to androgens in childhood may result in a significant reduction in adult phallic size. However, data obtained by us and others suggest that early exposure to androgens does not cause a decrease in the developmentally programmed, final penile length.

In many patients, a precise etiologic diagnosis and appropriate sex assignment can be made on the basis of the criteria just stated. In the rare patient with no evidence of defective testosterone synthesis, end-organ unresponsiveness to androgen, or testicular dysgenesis, true hermaphroditism should be considered. In these patients the demonstration of both ovarian and testicular tissue at laparoscopy establishes the diagnosis. All of the findings (anatomic, karyotypic, genetic, and hormonal), along with the natural history of the specific disorder and the possibilities for surgical reconstruction and normal sexual function, need to be discussed with the parents. Their informed consent, understanding, and cooperation are critical to a successful gender assignment. Once the parental decision is made to rear the infant as a boy or as a girl, it is important to support the parents and patient in reinforcing this decision and to obtain mental health counseling. It is critical to assist the parents in addressing uncertainties and doubts that may arise during follow-up visits.

Reassignment of Sex After the Newborn Period

Children may be assigned an inappropriate sex because of errors in diagnosis or ignorance of the principles that should properly determine this choice. In such cases, the knotty decision to change the sex of rearing or to leave matters undisturbed depends largely on the age of the child and the degree to which the gender identity has been established. Money has stated that a change in the sex of rearing is feasible until the age of 18 months and is sometimes successful until 30 months, but thereafter, in our culture, serious and sometimes complex psychiatric and social consequences may be encountered. This concept has been challenged. Nevertheless, change of gender assignment in children should be undertaken after 18 months only after a review of alternatives and with the provision of close supervision and long-term counseling of the patient, parents, and siblings.

Before, at, or during adolescence, the patient may reach the decision that he or she has been reared in the wrong sex and may request assistance in changing his or her sex of assignment. If there are sufficient grounds for this belief, the request should be considered seriously and honored. Some patients may have serious psychological disturbances, and both psychiatric and legal counsel should be sought.
Reconstructive Surgery

Because the presence of ambiguous external genitalia is likely to reinforce doubt about the sexual identity of the infant or child, it is desirable to initiate reconstructive surgery as early as is medically and surgically feasible. The functional result, rather than the cosmetic, is paramount. It is highly desirable that surgery on the external genitalia be initiated before 6 months of age when practicable.

The management of clitoromegaly in female pseudohermaphrodites and in male pseudohermaphrodites reared as females has been controversial. Two different operative approaches have been used: clitoral recession, first reported by Lattimer in 1961 to replace the then widely used clitorectomy, and clitoroplasty. Clitoridectomy has long been abandoned as a mutilating procedure. Documentation of the role of the clitoris as an erotic organ in women makes it clear that clitoridectomy must be avoided. Clitoral recession has significant drawbacks mainly because of painful clitoral erections. Clitoroplasty, as recommended by Donahoe, Rink, Hutson, and Baskin, requires excision of the shaft and corpora with retention of the glans. This procedure and modifications of it are used most widely at present. Long-term data are still necessary to evaluate the efficacy of this procedure with respect to appearance and sexual function.

The extent of the initial repair of the urogenital sinus and vagina depends in large part on the skill and experience of the surgeon. These are not procedures that should be undertaken by surgeons or urologists who have not had training and experience with these techniques and are not part of a team of professionals that address clinical issues. Even when the initial repair has been done in the past by an experienced surgeon, it has not been uncommon for patients who have had vaginoplasties performed at age 18 months or earlier to require secondary operations because of stenosis of the introitus. We believe that reconstruction of a vagina in male pseudohermaphrodites reared as females and in female pseudohermaphrodites can be deferred until adolescence or until requested by the patient. A small vaginal pouch often can be enlarged by daily manipulations with a suitable mold. Even if the vagina remains too shallow for satisfactory coitus, manual dilatation makes it easier to carry out subsequent surgical correction.

</table>

A male with hypospadias no longer requires multiple procedures to create a phallic urethra. In recent years, new surgical techniques have reduced the number of operations and the length of hospitalization and have increased the success rate and parental expectations for "normality" in both the short and the long term. Circumcision should be avoided to preserve as much tissue as possible. Laparoscopy can be undertaken (if necessary) simultaneously with the initial operation. It is often desirable to insert prosthetic testes to give the scrotum dependency and to improve cosmetic appearance. These may be changed to adult-sized prostheses in adolescence.
Removal of the Gonads

A high incidence of gonadal tumors in patients with certain forms of gonadal dysgenesis and dysgenetic male pseudohermaphroditism especially makes it mandatory that an evaluation of this risk be given priority in deciding whether and when the gonads should be removed. Although the incidence of gonadoblastomas and germinomas (seminomas or dysgerminomas) increases near the normal time of adolescence, tumors are sometimes discovered during the first decade. Because temporizing serves no useful purpose and may expose the child to hormone secretions inappropriate to the chosen sex for rearing, it is advisable to proceed with gonadectomy concurrently with the initial repair of the external genitalia in patients who are at high risk, especially in the instance of intra-abdominal rudimentary testes. We are evaluating the use of MRI of the pelvis every 1 to 2 years to screen for gonadal neoplasms in children at risk.

Although prevalence of gonadal tumors has been reported to be as high as 9% in patients with the androgen resistance syndrome based on studies over three decades ago, some patients who developed tumors may have had atypical forms of gonadal dysgenesis; a modern survey is not available. The prevalence of gonadal malignancy before age 25 years in patients with androgen resistance appears to be relatively low. If the patient has a hernia and surgical repair is indicated, we recommend gonadectomy at that time to avoid a second operation. Otherwise, in the patient with complete androgen resistance, the undesended testes may be left in situ until after puberty. Thereafter, a frank and open discussion with the patient of the pathophysiology of androgen resistance and an assessment of the risk of gonadal malignancy needs to be undertaken to obtain informed consent for gonadectomy (Table 22-46).

There is a risk of some degree of virilization at the time of puberty in patients with the partial form of androgen resistance and in those with other forms of male pseudohermaphroditism with retained testes in whom a female sex for rearing has been assigned. In these cases, gonadectomy before puberty has been advanced and should be considered and discussed with the patient and parents. In some male pseudohermaphrodites who are raised as males, at least partial development of male secondary sexual characteristics will occur at the expected time of puberty. Provided the testes are not dysgenetic and are sufficiently descended to permit palpation, it is reasonable to leave the testes in situ. Such patients should be carefully examined at regular intervals for the presence of a tumor. MRI, ultrasonography, and examination of testicular biopsy specimens are useful in the early diagnosis of CIS and testicular neoplasm.

Hormone substitution therapy in hypogonadal patients should be prescribed in such a way that secondary sexual characteristics emerge appropriately in both timing and sequence. The goal of therapy should be to approximate normal adolescent development as closely as possible.

In females, including patients with the syndrome of gonadal dysgenesis, estrogenic hormone substitution therapy is initiated with low oral doses of estrogen (0.3 mg conjugated estrogens or 5 µg ethinyl estradiol daily) or a transdermal estradiol patch. Breast enlargement and growth of the uterus frequently occur within 3 months. Usually, cyclic therapy with estrogen and an oral progestagen is begun after 6 to 12 months of estrogen therapy or sooner if breakthrough bleeding occurs (see section on treatment of gonadal dysgenesis).

Development of male secondary sexual characteristics is usually better with repository injections of testosterone or a transdermal testosterone patch than with oral preparations. Few data are available on the use of dermal testosterone therapy in childhood or adolescence. Many oral synthetic androgens have the added disadvantage of predisposing to biliary stasis, jaundice, and hepatic tumors. Rapid virilization is usually inadvisable, and it is preferable to promote virilization gradually over many months in a manner similar to that in normal boys. The effect of gonadal steroids on skeletal maturation is dose related, whereas the effect on linear growth is less so. The relation between attained stature and skeletal maturation at the inception of therapy and the dose of androgen prescribed determines the ultimate effect of this therapy on adult height. An initial intramuscular dose of 50 mg of testosterone enanthate or other long-acting testosterone ester may be given monthly, beginning at age 12 to 13 years. Thereafter, the dose should be increased gradually over 3 to 4 years to the adult replacement dose of 200 mg every 2 weeks, usually reaching the adult level after a bone age of 17 years has been attained (see Table 22-45). In selected patients we have used the transdermal testosterone patch; initially the 2.5-mg patch is applied overnight for 8 hours. Subsequently the length of application is gradually increased to 24 hours.
Psychological Management

The newborn with ambiguous genitalia presents a clinical, social, and psychological challenge. Initially, in infants with ambiguous genitalia it is best for the physician to admit uncertainty regarding the "true sex" of the child and to urge the parents not to immediately assign a name and send out birth announcements. The filing of the birth certificate with the name should be delayed until a definite gender assignment and name has been given to the child. Clinical, cytogenetic, hormonal, and radiologic evaluation should be undertaken expeditiously. Thereafter, clearly presented, comprehensive, and informative discussions with the parents should ensue with all members of the team (i.e., endocrinologist, infant's physician, geneticist, surgeon, mental health specialist, social worker) present, if possible. This discussion should take into account the anxieties, religious views, social mores, cultural background, and level of understanding of the parents to make the best gender assignment for the infant and to obtain informed consent for the decision from the parents. A simple explanation of the normal process of sexual differentiation with appropriate illustrative material is useful because it lays the groundwork for the concept that all fetuses are bipotential initially and that sex differentiation is a complex process that may not be completed in utero. An analogy to other so-called birth defects (e.g., cleft lip, congenital heart disease) is accurate, easily understood, and less psychologically threatening. It should be stated clearly that the anatomic abnormalities can be surgically repaired by an experienced surgeon, that hormone replacement can be given if necessary, and that psychological support is available (Table 22-47). Continuing follow-up by the team members should address any questions that arise during infancy and childhood. In this age of "freedom of information," it is prudent to discuss in an age-appropriate manner and in progressive stages all aspects of the diagnosis, pathophysiology, management, and treatment of the ambiguous genitalia with the patient as soon as his or her level of increased understanding allows for this.

The implications of these observations for the management of intersex are debated in a series of published papers in the Journal of Clinical Ethics.

Chapter 23 - Normal and Aberrant Growth

Edward O. Reiter
Ron G. Rosenfeld

NORMAL GROWTH

ASSESSMENT OF GROWTH

Childhood is a time of growth, a process that is complex and involves the interaction of multiple, diverse factors—the "cumulative sum of millions of unsynchronized cell replications." Growth is common to all multicellular organisms and occurs by cell replication and enlargement along with the nonhomogeneous processes of cell and organ differentiation. The overall morphologic development, the rates of cellular division in different organ systems at different times, and the ultimate outcome are determined by the genetic composition of the individual interacting with external factors, including nutrition and psychosocial and economic factors.

The very nature of linear height growth, whether occurring as a continuous process or with periodic bursts of growth and arrest, has been hard to characterize definitively. During 1 year of growth monitoring, there may be marked seasonal variations of height and weight gain, with several monthly bursts of weight and then height growth. Some normal children may have a broad growth channel, with many showing diverse but characteristic tracks. Nonetheless, even though the process of growth is multifactorial and complex, children usually grow in a remarkably predictable manner. Deviation from such a normal pattern of growth can be the first manifestation of a wide variety of disease processes, including both endocrine and nonendocrine disorders and involving virtually any organ system of the body. Frequent and accurate assessment of growth is, therefore, of primary importance in the care of children.

Phases of Normal Growth

Growth occurs at differing rates during intrauterine life, early and middle childhood, and adolescence, prior to its cessation after fusion of long bone and vertebral epiphyseal growth plates. Prenatal growth averages 1.2 to 1.5 cm/week but varies dramatically (Fig. 23-1); midgestational length growth velocity of 2.5 cm/week falls to almost 0.5 cm/week immediately prior to birth. Growth velocity (Fig. 23-2 and Fig. 23-3) averages about 15 cm/year during the first 2 years of life and slows to about 6 cm/year during middle childhood. Pubertal growth begins earlier in girls than in boys but is 3 to 5 cm greater in magnitude in boys than in girls. The peak height velocity during the pubertal growth spurt is comparable to the rate of growth during the second year of life. The time of onset of the pubertal growth spurt varies in normal children, reflecting the concept of a tempo of growth or rate of maturation, as emphasized by Tanner and associates. In most normal children, the final height is not influenced by the chronologic time of the onset of the pubertal growth spurt, although the sex-related differences in adult height of approximately 13 cm are due to an earlier cessation of growth in females. Growth ceases when the skeleton achieves adult maturity.

Karlberg and associates have resolved the normal linear growth curve into three additive, partially superimposable phases. The components of this model include (1) an infancy phase, starting in midgestation and then rapidly decelerating to about 3 to 4 years of age; (2) a childhood phase, slowly decelerating during early adolescence; and (3) a sigmoid-shaped puberty phase that involves the adolescent growth spurt.

Hormonal concomitants of these phases have been suggested, but as seen in this chapter, the interplay of the growth hormone (GH)/insulin-like growth factor (IGF) axis, gonadal steroids, and thyroxine (T4) is complex, and an attempt to

![Figure 23-1 Rate of linear growth and weight gain in utero and during the first 40 weeks after birth. Length velocity is expressed in centimeters per week. The solid line depicts actual linear growth rate; the dashed line connecting the prenatal and postnatal length velocity lines depicts the theoretical curve for no uterine restriction late in gestation. The lighter dashed line depicts weight velocity. (Data from Tanner JM. Fetus into Man. Cambridge, Mass, Harvard University Press, 1978.)](https://example.com/figure23-1)

define individual predominance of one hormone at any time of life is likely an oversimplification.
Measurement

Assessment of growth requires accurate and reproducible determinations of height. Supine length is routinely measured in children younger than 2 years of age, and erect height is assessed in older children. The inherent inaccuracies involved in measuring length in infants are often obscured by the rapid skeletal growth during this period. For measurement of supine length, it is best to use a firm box with an inflexible board against which the head lies with a movable footboard on which the feet are placed perpendicular to the plane of the supine length of the infant. Optimally, the child should be relaxed, the legs should be fully extended, and the head should be positioned in the Frankfurt plane, with the line connecting the outer canthus of the eyes and the external auditory meatus perpendicular to the long axis of the trunk.

When children are old enough (and physically capable) to stand erect, it is best to employ a wall-mounted "Harpenden" stadiometer, similar to that designed by Tanner and Whitehouse for the British Harpenden Growth Study. Free-standing stadiometers are also available but require frequent recalibration. The traditional measuring device of a flexible arm mounted to a weight balance is notoriously unreliable and does not provide reliably accurate serial measurements.

As with length measurements in infants, positioning of the child in the stadiometer is critical. The child should be fully erect, with the head in the Frankfurt plane; the back of the head, thoracic spine, buttocks, and heels should touch the vertical axis of the stadiometer, and the heels should be together. Every effort should be made to correct discrepancies related to lordosis or scoliosis. Ideally, serial measurements should be made at the same time of day because standing height may undergo diurnal variation.

A trained individual, rather than an inexperienced member of the staff, should determine height. We recommend that lengths and heights be measured in triplicate, that variation is no more than 0.3 cm, and that the mean height is recorded. To determine height velocity, when several measurements are being made within a short period, the same individual should perform the determinations to eliminate interobserver variability. Even when every effort is made to obtain accurate height measurements, a minimum interval of 6 months is necessary for meaningful height velocity computation. Nine to 12 months' data are preferable so that errors of measurement are minimized and the seasonal variation in height velocity is assimilated into the data.
Growth Charts

Evaluation of a child's height must be done in the context of normal standards. Such standards can be either cross-sectional or longitudinal. Most pediatric endocrine clinics in the United States continue to use the cross-sectional data, provided by the National Center for Health Statistics (NCHS), originally introduced in 1977. Epidemiologic limitations exist in these growth charts. The original infant charts, for example, were derived from a private study of a group of subjects who were primarily white, formula-fed, middle-class infants from southwestern Ohio. Data employed for older children came from national health examination surveys conducted from 1963 to 1974.

The NCHS, now part of the Centers for Disease Control and Prevention (CDC), has recently provided a set of 16 new growth charts (8 each for boys and girls), representing revisions of 14 existing charts, and has introduced new charts for body mass index:

\[ \text{BMI} = \frac{\text{weight}}{\text{height}^2} \]

The charts show little change in average height over the last 25 years despite the perception that today's children are taller than those from three decades ago.

These charts compare individual children with the 5th, 10th, 25th, 50th, 75th, 90th, and 95th percentiles of normal children in the United States. There are, however, two major limitations of these charts when applied to the individual child.

First, they do not satisfactorily define children below the 5th or above the 95th percentiles, the very children in whom it is most critical to define the degree to which they deviate from the normal growth centiles. The NCHS data are useful in computing standard deviation scores (SDSs), which are more helpful, because a short child can be described as, for example, -4.2 or -2.5 SDS from normal. A height SDS for age is calculated as follows:

Because these are defined by cross-sectional data, however, childhood SDSs are not directly comparable with SDS during adolescence, when variation in growth rate and maturational tempo can be large.

Second, cross-sectional data are of greater value during infancy and childhood than in adolescence because differences in the timing of pubertal onset can considerably influence normal growth rates.

To address this issue, Tanner and colleagues developed longitudinal growth charts, combining longitudinal data to construct the curve shapes with centile widths obtained from a large cross-sectional survey, thus accounting for variability in the timing of puberty. Such charts are of particular value in assessing growth during adolescence and puberty and for plotting sequential growth data on any given child.

The data from cross-sectional and longitudinal growth studies have been employed to develop height velocity standards, enhancing the value of linear growth velocity measurements in an individual. Carefully documented height velocity data are invaluable in assessing the child with abnormalities of growth. Although there is considerable variability in the normal height velocity in children of different ages, between age 2 years and the onset of puberty, children
normally grow with remarkable fidelity relative to the normal growth curves. The physician should note any "crossing" of height percentiles during this age period, and abnormal height velocities always warrant further evaluation.

![Figure 23-7 Head circumference for-age and weight-for-length percentiles for boys (birth to 36 months). Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000).](http://www.cdc.gov/growthcharts)

Syndrome-specific growth curves have been developed for a number of clinical conditions associated with growth failure (e.g., Turner's syndrome, achondroplasia, Down's syndrome). Such growth profiles are invaluable for tracking the growth of children with these clinical conditions. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying cause.
Body Proportions

Many abnormal growth states, including both short stature and excessive stature, are characterized by disproportionate growth. The following determinations should be made as part of the evaluation of short stature:

1. Occipitofrontal head circumference.
2. Lower body segment: distance from top of pubic symphysis to the floor.
3. Upper body segment: sitting height (height of stool should be subtracted from standing height).

Published standards exist for these body proportion measurements, which must be evaluated relative to the patient’s age. The upper segment/lower segment ratio, for example, ranges from 1.7 in the neonate to slightly below 1.0 in the adult.
Skeletal Maturation

The growth potential in the tubular bones can be assessed by evaluation of the progression of ossification within the epiphyses. The ossification centers of the skeleton appear and progress in a predictable sequence in normal children, and skeletal maturation can be compared with normal age-related standards. This forms the basis of bone age or skeletal age, the only readily available quantitative determination of net somatic maturation and thus a mirror of the tempo of growth and maturation. It is not clear which factors determine this normal maturational pattern, but it is certain that genetic factors and multiple hormones, including T<sub>4</sub>, GH, and gonadal steroids, are involved.

Recent studies in patients with mutations of the gene for the estrogen receptor or for the aromatase enzyme have shown that estrogen is primarily responsible for epiphyseal fusion, although it seems unlikely that estrogen is solely responsible for all aspects of skeletal maturation.

After the neonatal period, a radiograph of the left hand and wrist is commonly used for comparison with the published standards of Greulich and Pyle. An alternative method for assessing bone age from radiographs of the left hand involves a scoring system for developmentally identified stages of each of 20 individual bones, a technique that has been adapted for computed assessment. The left hand is used because radiographs of the entire skeleton would be tedious and expensive and would involve additional radiation exposure. However, the hand does not contribute to height, and accurate evaluation of growth potential sometimes calls for radiographs of the legs and spine.

A number of important caveats concerning bone age must be considered. Experience in determination of bone age is essential to minimize intraobserver variance, and clinical studies involving bone age generally benefit from having a single reader perform all interpretations. The normal rate of skeletal maturation differs between boys and girls and among different ethnic groups. The standards of Greulich and Pyle are separable by sex but were developed in American white children between 1931 and 1942. Finally, both the Greulich and Pyle and the Tanner and Whitehouse standards involved normal children and may not be applicable to children with skeletal dysplasias, endocrine abnormalities, or other forms of growth retardation.
Prediction of Adult Height

The extent of skeletal maturation observed in an individual can be employed to predict the ultimate height potential. Such predictions are based on the observation that the more delayed the bone age (relative to chronologic age), the longer the time before epiphyseal fusion prevents further growth.

The most commonly used method for height prediction, based on Greulich and Pyle's *Radiographic Atlas of Skeletal Development,* [37]

---

was developed by Bayley and Pinneau [42] and relies on bone age, height, and a semiquantitative allowance for chronologic age (Table 23-1). The system of Tanner and colleagues [38, 43] employs height, bone age, chronologic age, height and bone age increments during puberty in the previous year, and menarchal status. Roche and associates [44] employ the combination of height, bone age, chronologic age, midparental height, and weight. Further, attempts have been made to calculate final height predictions without requiring the use of skeletal age [45, 46] by using multiple regression analyses with available data such as height, weight, birth measurements, and midparental stature. All of these systems are, by nature, empirical and are not absolute predictors. The more advanced the bone age, the greater the accuracy of the adult height prediction because a more advanced bone age places a patient closer to final height.

All methods of predicting adult height are based on data from normal children, and none has been documented to be accurate in children with growth abnormalities. For this kind of precision, it would be necessary to develop disease-specific (e.g., achondroplasia, Turner's syndrome) atlases of skeletal maturation.
Parental Target Height

Because genetic factors are important determinants of growth and height potential, it is useful to assess a patient's stature relative to that of siblings and parents. Tanner and associates developed a growth chart modifying the heights of children, aged 2 to 9 years, by the midparental height. Further, the child's predicted adult height (see earlier) may be related to a parental target height, or the mean parental height with the addition or subtraction of 6.5 cm for boys and girls, respectively. The two standard deviation (2 SD) range for this calculated parental target height is about ± 10 cm, so that calculated target heights, like predicted adult heights, are approximations.

Recent statistical reassessment shows a tendency for regression to the mean of the children's height as related to the midparental target height. Failure to realize this may lead to inappropriately using short parental height as an explanation for marked short stature in a child. Nevertheless, when a child's growth pattern clearly deviates from that of parents or siblings, the possibility of underlying pathology should be considered. Although it is certainly important to measure the heights of parents and siblings, rather than accept their statural claims, one must recall as well that it is not always possible to know the heights of the true biologic parents.
ENDOCRINE REGULATION OF GROWTH

The Pituitary Gland

The concept of the pituitary as a "master gland," controlling the endocrine activities of the body, has been replaced by recognition of the importance of the brain and, particularly, the hypothalamus in regulating hormonal production and secretion. Nevertheless, the pituitary gland is central to understanding the regulation of growth.

Embryologically, the pituitary gland is formed from two distinct sources: Rathke's pouch, a diverticulum of the primitive oral cavity (stomodeal ectoderm), gives rise to the adenohypophysis. The neurohypophysis (posterior pituitary) originates in the neural ectoderm of the floor of the forebrain, which also develops into the third ventricle. The adenohypophysis normally constitutes 80% of the weight of the pituitary and consists of anterior, intermediate, and infundibular lobes. In humans, the anterior lobe is the largest component and houses the most hormone-producing cells.

Rathke's pouch, the origin of the adenohypophysis, can be identified in the 3-mm embryo during the 3rd week of pregnancy. GH-producing cells can be found in the adenohypophysis by 9 weeks of gestation. Vascular connections between the anterior lobe of the pituitary and the hypothalamus develop about this time, although hormone production can occur in the pituitary in the absence of connections with the hypothalamus. Somatotrophs can frequently be demonstrated in the pituitary in anencephalic newborns. Nevertheless, the initiation of development of the anterior pituitary is probably dependent on responsiveness of the oral ectoderm to inducing factors from the ventral diencephalon and hypothalamus.

A complex orchestration of temporarily sequenced and geographically restricted expression of multiple extracellular signaling peptides and intracellular transcription factors regulates this developmental process. The developing pituitary gland and hypothalamus are in close anatomic juxtaposition, and their embryonic development is likely to be codependent. Some of the diencephalic factors that have been identified to be critical in formative and patterning of Rathke's pouch, which, in the mouse, is initiated on embryonic day 8 (e8), are bone morphogenic proteins 4 and 2 (BMP-4/2), Wnt5a, and fibroblast growth factor 8 (FGF-8). The dorsal neuroepithelial signal, BMP-4, is needed for "organ commitment" of the pituitary, whereas a BMP-2 (ventral) and FGF-8 (dorsal) gradient determines pituitary cell phenotypes [i.e., somatotrophs and the Pit-1-dependent lines, somatotrophs, lactotrophs, and thyrotrophs (ventral) and melanotrophs and corticotrophs (dorsal)]. It seems that reciprocal interaction of at least two transcription factors, Pit-1 and GATA-2, are important in implementing the cell-determination signals of BMP-2 and FGF-8.

Explant studies in the mouse have demonstrated that if Rathke's pouch is removed from the oral ectoderm on e10.5 and incubated in appropriate culture medium, differentiation of each of the pituitary cell types continues, indicating that by that point, organogenesis of the anterior pituitary is no longer dependent on hypothalamic signals, although such signals may remain critically involved in pituitary hormone production.

A number of pituitary-specific transcription factors are involved in the determination of pituitary cell lineages and cell-specific expression of anterior pituitary hormones. To date, defects in several homeodomain transcription factors shown to be involved in human anterior pituitary development and differentiation have now been associated with various combinations of pituitary hormone deficiencies (see Fig. 23-14 and Table 23-5). Because additional gene defects have been implicated in abnormal murine pituitary development, it seems likely that the number of human genetic defects will expand.

In the adult, the mean pituitary size is 13 × 9 × 6 mm. The mean weight is 600 mg (range, 400 to 900 mg), is slightly greater in women than in men, and increases during pregnancy. In the newborn, pituitary weight averages about 100 mg. Normally, the pituitary resides in the sella turcica, immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica is a good index of pituitary size and may be reduced in the child with pituitary hypoplasia. The adult mean pituitary size is 13 × 9 × 6 mm.
Growth Hormone

Chemistry

Human GH is produced as a single chain, 191amino acid, 22-kd protein (Fig. 23-16). It is not glycosylated, but it does contain two intramolecular disulfide bonds. GH shares sequence homology with prolactin, choriionic somatomammonio-tropin (CS) (placental lactogen), and a 22-kd GH variant (GH-V) secreted only by the placenta that differs from pituitary GH by 13 amino acids. The genes for these proteins have probably evolved from a common ancestral gene, even though the genes are located on different chromosomes (chromosome 6 for prolactin, chromosome 17 for GH). The genes for GH, prolactin, and placental lactogen share a common structural organization, with four introns separating five exons. In fact, the GH subfamily contains five members, whose genes are located on a 78-kb section of chromosome 17; the 5’ to 3’ order of the genes are GH, a CS pseudogene, CS-A, GH-V, and CS-B.

Normally, about 75% of GH produced by the pituitary is of the mature, 22-kd form. Alternative splicing of the second codon results in deletion of amino acids 32 to 46, yielding a 20-kd form, which normally accounts for 5% to 10% of pituitary GH. The remainder of pituitary GH includes desamidated and N-acetylated forms and various GH oligomers.

Secretion

The pulsatile pattern characteristic of GH secretion largely reflects the interplay of two hypothalamic regulatory peptides, growth hormonereleasing hormone (GHRH) and somatostatin (somatotropin resease-inhibiting factor [SRIF]), with presumed modulation by putative other GH-releasing factors. GHRH activity is species-specific, presumably reflecting the specificity of binding to a G protein-receptorvated receptor on the pituitary somatotrophs. Regulation of GH production by GHRH is mediated largely at the level of transcription and is enhanced by increases in intracellular cyclic adenosine monophosphate (cAMP) levels.

The GHRH receptor is a member of the G protein-coupled receptor family B-III, also called the secretin family, and has partial sequence identity with receptors for vasactive intestinal polypeptide, secretin, calcitonin, and parathyroid hormone.

In the dwarf transgenic mouse model with diminished GHRH production, pituitary somatotroph proliferation is markedly decreased. Mutations of the GHRH gene itself have not yet been reported, but anatomic and functional abnormalities of the connection between the hypothalamus and the anterior pituitary, which prevent interaction of GHRH with its receptor on the somatotroph, are the most important causes of clinical growth hormone deficiency (GHD).

The Gsh-1 homeobox gene, which is expressed in the developing central nervous system (CNS) but not in the pituitary, plays an important role, nonetheless, in mouse pituitary development. Mice with mutations in this gene do not produce GHRH and, presumably, do not produce gonadotropin-releasing hormone (GnRH) because anterior pituitary hypoplasia and deficiencies of GH, prolactin, and luteinizing hormone (LH) are present. The effects of this gene on hypothalamic releasing factors are analogous to those of the Pit-1 or PROPl genes (see later) at the pituitary level.

Instead of regulating GH synthesis, somatostatin appears to affect the timing and amplitude of pulsatile GH secretion. The pulsatile secretion of GH in vivo is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increase in GHRH release. Conversely, a trough of GH secretion occurs when somatostatin is released in the face of diminished GHRH activity.

The regulation of the reciprocal secretion of GHRH and somatostatin is imperfectly understood. Multiple neurotransmitters and neuropeptides are involved in the regulation of the release of these hypothalamic factors.

Synthetic hexapeptides capable of stimulating GH secretion are termed GH secretagogues (GHSs). These peptides stimulate GH release and enhance the GH response to GHRH, although they work at receptors distinct from those for GHRH, at hypothalamic and pituitary sites. Finding 40% to 60% homology to the G protein-coupled GHS receptor in the pufferfish indicates that structure and function of this receptor have been highly conserved for about 400 million years, certainly suggesting a fundamental role for the natural ligand of this receptor.

Kojima and co-workers identified a putative endogenous ligand, a 28amino acid with the serine 3 residue N-octanoylated, referred to as ghrelin. It is found primarily in the stomach (and throughout the gastrointestinal tract) but also in...

*Average: Bone age within 1 year of chronologic age.

The developmental abnormality holoprosencephaly, which can be associated with GHD, may be caused by gene defects affecting PACAP and PACAP receptor expression.

The hypothalamus, heart, lung, and adipose tissue. Administration of ghrelin stimulates food intake and obesity and raises plasma GH concentrations and, to a lesser extent, adrenocorticotropic hormone (ACTH). These data suggest that ghrelin is an important stimulus for nutrient allocation for growth and metabolism and a central component of the GH regulatory system. Pituitary adenylate cyclase-activating peptide (PACAP), a hypothalamic peptide possibly involved in the regulation of GH secretion, is a member of the PACAP/glucagon superfamily. The developmental abnormality holoprosencephaly, which can be associated with GHD, may be caused by gene defects affecting PACAP and PACAP receptor expression.
The synthesis and secretion of GH are also regulated by the IGF peptides. Inhibition of GH secretion by IGF-I and IGF-II have been identified in varied pituitary cell systems. Inhibition of GH secretion by IGF-I and IGF-II in rat anterior pituitary cells has been demonstrated in a perfusion system, and spontaneous GH secretion is diminished in humans treated with synthetic IGF-I.

The episodic release of GH from pituitary somatotrophs results in intermittent increases in serum levels of GH that are separated by periods of low or undetectable levels, during which time GH secretion is minimal. The pulsatile nature of GH secretion has been demonstrated by frequent serum sampling, coupled with the use of immunofluorometric or chemoluminescent assays of GH. Under normal circumstances, serum GH levels are less than 0.04 µg/L between secretory bursts. Consequently, it is impractical to assess GH secretion by random serum sampling. Extensive sampling studies in people at different ages, in healthy people, and in many patients with abnormal conditions have defined GH pulses, basal secretion, and diurnal variability.

Computer programs have been developed to indicate whether changes in GH levels in various life periods and under diverse clinical circumstances occur because of a change in a secretory mass or pulse frequency, an altered clearance, or a combination of these processes. A model-free measure, is applied to quantify the degree of orderliness of GH release patterns. The impact of the specific nature of pulsatile GH secretion on its biologic actions is under study. For example, it appears that better statural growth is associated with large swings of GH output but of relatively uniform magnitude in an irregular sequence (high approximate entropy).

By 9 to 12 weeks of gestation, GH-secreting cells have been identified, and by 7 to 9 weeks, immunoreactive pituitary GH is present. By 5 weeks of gestation, fetal pituitary cells secrete GH in vitro, before the hypothalamic-portal vascular system is differentiated. By at least 6 weeks of gestation, Pit-1 messenger RNA (mRNA) and Pit-1 protein are expressed; its abundant presence early in gestation suggests an important role in cytodifferentiation and cell proliferation.

By the end of the first trimester, GH can be identified in fetal serum, with peak levels of around 150 µg/L in midgestation. Throughout the latter part of pregnancy, serum levels fall and are lower in term than in premature infants, perhaps reflecting feedback by the higher serum levels of IGF peptides characteristic of the later stages of gestation.

Through childhood and early puberty, mean levels of GH decrease from values of 25 to 35 µg/L in the neonatal period to approximately 5 to 7 µg/L. During adolescence, 24-hour GH secretion peaks, undoubtedly contributing to the high serum levels of IGF-I characteristic of puberty. During mid to late puberty, the increase in GH production is due both to enhanced pulse amplitude and increased mass of GH per secretory burst rather than a change in pulse frequency.

In the face of stable levels of the GH-binding protein (GHBP), the enhanced pubertal GH production is associated with higher levels of free GH. After adolescence, GH and IGF production begins to decline and continues to fall throughout adult life. Normal young adult men generally experience 6 to 10 GH secretory bursts per 24 hours, a value similar to that in younger children and in adolescents. In contrast, 24-hour GH production rates for normal men range from 0.25 to 0.52 mg/m² surface area about 20% to 30% of pubertal levels; this is largely due to decreased GH pulse amplitude with age. Indeed, puberty may be considered, with some justification, a period of "acromegaly," whereas aging, with its decrease in GH secretion, has been termed the somatopause.

Physiologic states that affect GH secretory function include obesity, fasting, and exercise. Stress and gonadal steroids. Maximal GH secretion occurs during the night, especially at the onset of the first slow-wave sleep (stages III and IV). Rapid-eyemovement sleep, however, is associated with low GH secretion. A circadian rhythm of somatostatin secretion, on which is superimposed episodic bursts of GHRH release, may help explain the nocturnal augmentation of GH production. When testosterone was administered to boys with delayed puberty, spontaneous GH release was enhanced, but such a change was not duplicated by administration of nonaromizable androgens, emphasizing the possible unique importance of estrogen on GH secretion.

The effects of testosterone on serum IGF-I levels may, in part, be independent of GH because individuals with mutations of the GH receptor (GHR) still experience a rise in serum IGF-I during puberty.

With a combination of deconvolution analysis, approximate...
entropy, and cosine regression analysis, Velthuis and associates \cite{94,103} carefully evaluated intensive GH sampling data, derived from measurements in sensitive GH assays, in prepubertal and pubertal boys and girls. In addition to the amplified secretory burst mass originating from jointly increased GH pulse amplitude and duration, they found that sex steroids selectively affected faceted of GH neurosecretory control; estrogen increases basal GH secretion rate and irregularity of GH release patterns, whereas testosterone stimulates greater GH secretory burst mass and IGF-1 concentrations.

Obesity is characterized by markedly decreased GH production, reflected by nearly a marked decrease in number of GH secretory bursts and of half-life. Obesity in childhood and adolescence, similarly, is characterized by decreased GH production but normal IGF and increased GHB levels and often increased linear growth. The hyponatremia associated with obesity causes lowered IGF-binding protein (IGFBP)-1 and, perhaps, higher free IGF-I levels. Endogenous GH secretion and levels achieved during provocative tests in these obese subjects \cite{104} approximate the diagnostic range of GHD. Fasting increases both the number and amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion and enhanced GHRH release while lowering GHBP concentrations. Rapid changes in levels of IGFBPs in response to altered nutrition and changes of insulin levels may modify the effect of IGF-I on its negative feedback and effector sites. \cite{105,106}

Body mass also influences GH production in normal prepubertal and pubertal children and adults. \cite{107,108}

**Growth Hormone Receptor/Growth Hormone Binding Protein**

Leung and colleagues \cite{124} cloned both the rabbit and human complementary DNAs (cDNAs) for the GHR. Each contains an open reading frame of 620 amino acids and encodes a mature receptor of 620 amino acids and a predicted molecular weight of 70 kd before glycosylation. There are three domains: (1) an extracellular, hormone-binding domain, (2) a single membrane-spanning domain, and (3) a cytoplasmic domain.

In humans, the most important circulating GH-binding protein appears to be derived from proteolytic cleavage of the extracellular domain of the receptor. \cite{126} In the mouse \cite{127} and rat, \cite{128} however, there are multiple transcripts for the GHR; the larger, 3.4 to 4.8 kb, transcript codes for the intact receptor and the 1.2 to 1.9 kb transcript codes for the soluble GHBP.

The coding and 3' untranslated regions of the human GHR are encoded by nine exons, numbered 2 to 10. \cite{129} The gene for the human GHR is located on chromosome 5p13.1-p12, where it spans more than 87 kb. \cite{130} The GHR shows sequence homology with the prolactin receptor and with receptors for interleukin (IL)-2, IL-3, IL-4, IL-6, and IL-7, as well as receptors for erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), and interferon. \cite{131} The GHR is a member of the class 1 hematopoietic cytokine family. \cite{132} Examination of the crystal structure of the GH/GHR complex revealed that the complex consists of one molecule of GH bound to two GHR molecules, indicating a GH-induced receptor dimerization, which is necessary for GH action. \cite{133}

**Growth Hormone Receptor/Growth Hormone Binding Protein**

After binding to its receptor, GH stimulates phosphorylation of a protein with an apparent molecular weight ratio of 120 kd. \cite{134} Although it was originally suspected that the GHR might be capable of autophosphorylation, it is now apparent that the major tyrosine-phosphorylated protein is associated with the receptor rather than being the receptor itself. JAK2 has been recently identified as the critical GH-R-associated tyrosine kinase. \cite{135} The presumed sequence of steps in GH action is shown in Figure 23-20 (Figure Not Available):

1. Binding of GH to the membrane-associated GHR.
2. Sequential dimerization of the GHR through binding to each of two specific sites on GH.
3. Interaction of the GHR with JAK2.
4. Tyrosine phosphorylation of both JAK2 and the GHR.
5. Changes in cytoplasmic and nuclear protein phosphorylation and dephosphorylation.

GH-dependent and JAK2-dependent phosphorylation have been demonstrated for many cytoplasmic signaling molecules that, after forming homo- and heterodimers, translocate into the nucleus, bind DNA, and activate transcription. \cite{136,137,138} How all of these seemingly redundant pathways intersect to mediate the various anabolic and metabolic actions of GH remains to be elucidated.

The major GHBP in human plasma binds GH with high specificity and affinity but with relatively low capacity, because about 45% of circulating GH is bound. \cite{139,140,141} The GHBP is, in essence, the extracellular domain of the GHR and has an apparent molecular weight ratio of approximately 55 kd. An additional GHBP, not
that is, low levels are associated with states of growth hormone insensitivity (GHI). In the rapidly growing child, however, levels of GHBP are quite low. Initial assays for GHBP involved incubation of serum with \(^{125}\text{I}\)-GH and separation of bound from free radioligand. Carlson and co-workers have developed a ligand-mediated immunofunctional assay for measurement of GHBP.

Levels of GHBP are low in early life, rise through childhood, and plateau during the pubertal years and adulthood. Once puberty is reached, levels are usually constant for a given individual. Impaired nutrition, diabetes mellitus, hypothyroidism, chronic liver disease, and a spectrum of inherited abnormalities of the GHR are associated with low levels of GHBP, whereas obesity, refeeding, early pregnancy, and estrogen treatment can cause elevated levels of GHBP.

A direct correlation exists between GHBP levels and body mass index. Serum GHBP levels correlate inversely with 24-hour GH production; this reciprocal relationship between GH production and GHBP in normal subjects and in subjects with idiopathic short stature (ISS) may result from adjustments of GH secretion to accommodate GH levels that may be genetically determined or modulated by environmental factors such as nutritional status. Assays of serum levels of GHBP are useful in identifying subjects with GH insensitivity due to genetic abnormalities of the GHR. Patients with GHI due to nonreceptor abnormalities, defects of the intracellular domain of the GHR, or inability of the receptor to dimerize may, however, have normal serum levels of GHBP.

Inhibition of GH signaling by several members of the GH-inducible suppressors of cytokine signaling (SOCS) family has been reported. The importance of SOCS proteins in controlling growth is demonstrated by the finding of gigantism in SOCS-2 knockout mice. Endotoxin and proinflammatory cytokines, such as IL-1 and tumor necrosis factor (TNF-), which can also induce SOCS proteins, produce GHI. SOCS-3 induced by IL-1 and TNF- or by endotoxin in vivo may play a role in the GHI induced by sepsis. Critically ill patients with septic shock treated with GH had increased mortality, possibly related to induction of GHI in specific tissues as a consequence of endotoxemia and cytokinemia.

**Growth Hormone Actions**

According to the somatomedin hypothesis, the anabolic actions of GH are mediated through the IGF peptides. Although this theory is largely true, GH is also capable of inducing effects that are independent of IGF activity. Indeed, the actions of GH and IGF are, on occasion, contradictory, as evident in the diabetogenic effects of GH and IGF-1 and tumor necrosis factor (TNF-), which can also induce SOCS proteins, produce GHI. SOCS-3 induced by IL-1 and TNF- or by endotoxin in vivo may play a role in the GHI induced by sepsis. Critically ill patients with septic shock treated with GH had increased mortality, possibly related to induction of GHI in specific tissues as a consequence of endotoxemia and cytokinemia.

2. Bone: stimulation of osteoclast differentiation and activity, stimulation of osteoblast activity, and increase of bone mass by endochondral bone formation.
3. Adipose tissue: acute insulin-like effects, followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone-sensitive lipase, decreased glucose transport, and decreased lipogenesis.
4. Muscle: increased amino acid transport, increased nitrogen retention, increased lean tissue, and increased energy expenditure.

The concept of IGF-independent actions of GH is supported by in vivo studies, in which GH-I cannot duplicate all of the effects of GH, such as nitrogen retention and insulin resistance. The administration of GH for 1 to 3 weeks to calorically restricted normal or obese men results in significant nitrogen retention, although this effect does not persist with prolonged therapy. The effects of GH in normal human aging and in catabolic states are subjects of active investigation.
Insulin-Like Growth Factors

Historical Background

The IGFs (or somatomedins) are a family of peptides that are, in part, GH-dependent and that mediate many of the anabolic and mitogenic actions of GH. Originally identified in 1957 by their ability to stimulate $^35$S sulfate incorporation into rat cartilage and termed sulfation factor, concurrent investigations indicated that only one component of the insulin-like activity of normal serum could be blocked by the addition of anti-insulin antibodies. The remaining activity, termed nonsuppressible insulin-like activity (NSILA), was subsequently demonstrated to contain two soluble, low-molecular-weight (7-kd) forms, named NSILA-1 and NSILA-II. A third line of investigation arose from studies by Dulak and Temin on the mitogenic nature of bovine serum; the mitogenic factor was termed multiplication-stimulating activity (MSA) and shares metabolic and mitogenic activities with both sulfation factor and NSILA.

In 1972, the restrictive labels of sulfation factor and NSILA were replaced by the term somatomedin. The following criteria for a somatomedin were established:

1. The concentration in serum must be GH-dependent.
2. The factor must possess insulin-like activity in extraskeletal tissues.
3. The factor must promote the incorporation of sulfate into cartilage.
4. The factor must stimulate DNA synthesis and cell multiplication.

Purification yielded two somatomedin peptides: a basic peptide (somatomedin-C) and a neutral peptide (somatomedin-A). In 1978, Rinderknecht and Humble described two active somatomedins from human plasma, and after demonstrating a striking structural resemblance to proinsulin, renamed them insulin-like growth factors (IGFs).

IGF Structure and Molecular Biology

IGF-I, a basic peptide of 70 amino acids, correlates with somatomedin-C, and IGF-II is a slightly acidic peptide of 67 amino acids. The two peptides share 45 of 73 possible amino acid positions and have approximately 50% amino acid homology to insulin. Like insulin, both IGFs have A and B chains connected by disulfide bonds. The connecting C-peptide region is 12 amino acids long for IGF-I and 8 amino acids for IGF-II, bearing no homology with the C-peptide region of proinsulin. IGF-I and IGF-II also differ from proinsulin in possessing carboxy-terminal extensions, or D-peptides, of 8 and 6 amino acids, respectively. This structural similarity explains the ability of both IGFs to bind to the insulin receptor and of insulin to bind to the type 1 IGF receptor (see later). On the other hand, structural differences probably also explain the failure of insulin to bind with high affinity to the IGFBPs (see later).

IGF Variants

There are several variants of the two IGF peptides. Rinderknecht and Humble reported that up to one fourth of the IGF-II isolated from human plasma lacked the N-terminal alanine. Jansen and colleagues demonstrated that an IGF-II cDNA isolated from a human liver library predicted an IGF-II variant in which Ser was replaced by Arg-Leu-Pro-Gly, and Zumstein and associates identified this variant peptide subsequently in human plasma. Zumstein and associates isolated a 10-kd IGF-II variant from human plasma that contains a 21-residue carboxy extension, representing a portion of the E domain of pro-IGF-II (see later). In one peptide fragment isolated, Ser was replaced by Cys-Gly-Asp. A 25-kd IGF-II variant was isolated by Gowan and colleagues, presumably representing a carboxy-terminal extension.

The significance of "big" IGF-II forms is still uncertain. In general, these variants appear capable of binding to IGF and insulin receptors and to IGFBPs and can participate in formation of the 150-kd IGF/IGFBP-3/acid-labile subunit (ALS) ternary complex. Big IGF-II can be produced by mesenchymal tumors and can cause nonsiled-cell tumor hypoglycemia (NICTH).

Daughaday and co-workers described a patient with a leiomyosarcoma and recurrent hypoglycemia, in whom 70% of serum IGF-II was in higher-molecular-weight forms. Removal of the tumor eliminated big IGF-II from the serum and corrected the hypoglycemia. The presence of big IGF-II in NICTH has been confirmed in multiple laboratories, but it is unclear why hypoglycemia occurs in the face of normal total serum IGF-II levels.

Zapf has proposed that NICTH occurs when secretion of big IGF-II results in suppression of GH, insulin, and 7-kd IGF-II, leading to decreased production of IGF-I, IGFBP-3, and the ALS and increased production of IGFBP-2. This leads to a shift in the distribution of IGF-II from the 150-kd ternary complex to the 40- to 50-kd molecular-weight complex, composed of IGFBP-3, IGFBP-2, and a number of other low-molecular-weight IGFBPs. It is presumed that this results in increased bioavailability of IGF-II to target tissues, enhanced glucose consumption, and decreased hepatic glucose production.

Big forms of IGF-I have not been as thoroughly documented as with IGF-II. Powell and associates, however, have reported that IGF-I forms with an apparent molecular weight ratio as high as 19 kD may be found in uredine serum. Large molecular forms of IGF-I have also been identified in conditioned media of human fibroblast cell lines.

Two IGF-I precursor molecules have been identified. The first 134 amino acids of each are identical, comprising the signal peptide (48 amino acids), the mature IGF-I molecule (70 amino acids), and the first 16 amino acids of the E domain of the precursor. IGF-I A has additional 19 amino acids, and IGF-I B has additional 61 amino acids (total 195 residues). Alternative splicing of the IGF-I gene presumably generates the two mRNAs. The primary IGF-I translation product in human, rat, and mouse contains 180 amino acids, including a 24-residue signal peptide, the 67-amino acid mature IGF-II sequence, and a carboxy-terminal E peptide of 89 amino acids.

The IGF-I Gene

The IGF genes (Fig. 23-21) are expressed differently in the embryo, fetus, child, and adult. Single large genes encode both IGF-I and IGF-II. The human IGF-I gene is located on the long arm of chromosome 12, and it contains at least six exons. Exons 1 and 2 encode alternative signal peptides, probably each containing several transcription start sites. Exons 3 and 4 encode the remaining signal peptide, the remainder of the mature IGF-I molecule, and part of the trailer peptide (E peptide). Exons 5 and 6 encode, alternatively, used segments of the trailer peptide (resulting in the IGF-IA and IGF-IB forms) and 3' untranslated sequences with multiple different polyadenylation sites. The wide diversity of IGF-I mRNAs thus reflects the following:

1. Multiple leader exons and transcription start sites.
3. Multiple polyadenylation sites in exon 6.

The IGF-II Gene

The human IGF-II gene (Fig. 23-22) is located on the short arm of chromosome 11, adjacent to the insulin gene and spans 35 kb of genomic DNA, containing 9 exons. Exons 1 to 6 encode 5' untranslated RNA; exon 7 encodes the signal peptide and most of the mature protein; and exon 8 encodes the
carboxy-terminal portion of the protein and part of the trailer peptide, whose coding is completed in exon 9.

Thus, multiple mRNA species exist for both IGF-I and IGF-II, allowing for tissue-specific expression of specific transcripts and for developmental and hormonal regulation. The mechanisms involved in the regulation of IGF gene expression include the existence of multiple promoters, heterogeneous transcription initiation within each of these promoters, alternative splicing of various exons, differential RNA polyadenylation, and variable mRNA stability. Translation of IGF-I genes may also be under complex control.

**Regulation of IGF Gene Expression**

GH appears to be the primary regulator of IGF-I gene transcription, which begins as early as 30 minutes after intraperitoneal injection of GH into hypophysectomized rats. Transcriptional activation by GH affects both IGF-I promoters equivalently, resulting in a 20-fold rise in IGF-I mRNA. This coordinated, rapid induction of all IGF-I mRNA species coincides with induction of Spi 2.1 gene by GH, although the relationship between these two processes is still not clear. Furthermore, there may be tissue-to-tissue variability in GH-induced expression of IGF-I mRNA. Other factors that influence IGF-I gene expression include estrogen, which stimulates IGF-I mRNA expression in the uterus but inhibits GH-stimulated IGF-I transcription in the liver. The pubertal rise in serum IGF-I levels reflects the effect of gonadal steroids on IGF-I transcription, some of which results from the pubertal rise in GH secretion and some of which is due to a direct effect of gonadal steroids on IGF synthesis or secretion, because a pubertal rise in serum IGF levels is also observed in patients with GH deficiency.

The factors involved in the regulation of IGF-II gene expression are less clear. In humans and rats, IGF-II gene expression is high in fetal life and has been detected as early as the blastocyst stage in mice. Serum levels of IGF-II are high in midgestation in pregnant rabbits. Fetal tissues generally have high IGF-II mRNA levels that decline postnatally, although brain IGF-II mRNA remains high in the adult rat. IGF-II mRNA is expressed constitutively in a number of mesenchymal and embryonic tumors, including Wilms' tumor, rhabdomyosarcoma, neuroblastosarcoma, pheochromocytoma, hepatoblastoma, leiomyoma and leiomyosarcoma, liposarcoma, and colon carcinoma. Production of big IGF-II by these tumors may cause NICTHE (see earlier).

A tumor suppressor gene associated with Wilms' tumor (WT1) has been mapped to 11p13, close to the IGF-II locus (11p15.5), consistent with the possibility of a direct effect of WT1 on IGF-II gene transcription and suggesting an autocrine role for IGF-II in some tumors. This may be relevant in the embryonal tumors of Beckwith-Wiedemann syndrome (BWS), in which there may be loss of heterozygosity in the 11p15 maternally derived chromosome and paternal isodisomy, consistent with parental imprinting and a twofold increase in gene dosage of the active IGF-II allele.

**IGF Imprinting**

Gene regulation for the IGF system may also be subject to genomic imprinting, a process that influences the expression of specific genes. Namely, certain autosomal genes are expressed only from one of the two theoretically available alleles, in a manner that is specific for the parent of origin. The result is a heritable difference in gene expression, depending on whether a specific allele is inherited from the mother or the father. Allele-specific imprinting is exemplified by abnormalities of chromosome 15q11-13, where deletions of the paternal chromosome result in Prader-Willi syndrome, and deletions of the maternal locus are associated with Angelman syndrome, two phenotypically distinct conditions. The molecular mechanisms responsible for genomic imprinting involve variable DNA methylation. The first evidence for imprinting in the IGF axis emerged from studies of targeted gene disruption of Igf2 in the mouse which caused fetal growth retardation only when the disrupted allele was inherited from the father (i.e., maternally imprinted). The human IGF-II gene is similarly imprinted. In tissues where only maternal chromosomes are present, such as ovarian teratomas, no IGF-II expression is observed, whereas gene expression is observed in tissues where only paternal chromosomes are present (complete hydatidiform mole). Loss of imprinting (or relaxation of imprinting) of the IGF-II gene has been observed in rhabdomyosarcomas, lung cancers, Wilms' tumors, and choriocarcinoma. In such situations, IGF-II may act as an autocrine or paracrine growth factor for neoplastic tissue. Furthermore, in Wilms' tumor, loss of imprinting of the IGF-II gene is associated with reduced expression of the putative tumor suppressor gene H19. The H19 gene appears to be imprinted in a reciprocal manner to Igf2/Igf2, and the two genes may be coordinately regulated, because the genes are located near each other on the same chromosome.

The genes for the type II IGF receptor, which is the same as the cation-independent mannose-6-phosphate (M6P) receptor, are also imprinted, although in a different manner. Thus, the mouse Igf2 receptor gene and the human IGF type 2 receptor gene are both expressed by the maternal allele (i.e., paternally imprinted). If IGF-II functions as a fetal growth factor, there is potential for both maternal and paternal regulation of fetal size.

**Targeted Disruption of IGF Genes**

The role of the IGF axis in fetal growth has been firmly established by a series of studies involving IGF and IGF receptor null mutations. Unlike GH and GHR knockouts, which are near normal size at birth, mice with knockouts of the gene for either IGF-I or IGF-II have birth weights approximately 60% of normal. Mouse mutants lacking both IGF-I and the GHR are only 17% of normal. These observations indicate that both IGF-I and IGF-II are important embryonic
and fetal growth factors but that GH itself does have some independent role as well. Although fetal size was proportionately reduced in both situations and although morphogenesis was grossly normal, a higher neonatal death rate was observed following disruption of the gene for IGF-I. Growth delay began on day e11 for IGF-II knockouts and on day e13.5 for IGF-I knockouts. Those mice with IGF-I gene disruptions who survived the immediate neonatal period continued to have growth failure postnatally, with weights 30% of normal by 2 months of age. Indeed, postnatal growth was poorer than that observed in mice with GHR, GHRH receptor mutations, or Pit-1 mutations, indicating that both GH-dependent and GH-independent factors are necessary for normal growth.

A similar prenatal and postnatal growth phenotype has been observed in the one reported case of an IGF-I gene deletion. When the genes for both IGF-I and IGF-II were disrupted, weight at birth was only 30% of normal, and all animals died shortly after birth, apparently from respiratory insufficiency secondary to muscular hypotonia. Specific ablation of hepatic IGF-I production through the Cre/loxP recombination system confirmed that the liver is the principal source of circulating IGF-I but demonstrated that an 80% lowering of serum IGF-I levels had no apparent effect on postnatal growth. Presumably, either local (paracrine) chondrocyte production of IGF-I or other tissues (possibly adipose) maintain adequate endocrine sources of IGF-I to account for growth preservation.

Supportive data for the predominant role in growth of locally produced IGF-I are the modest decrement of postnatal growth seen in ALS null mice. These murine models are complex as IGFBP-3 levels are reduced despite increased GH and, in contrast with the human, rise after treatment with exogenous IGF-I. Further, the free IGF-I levels are normal in these animals but do not prevent an increment of GH production.

In another study, knockout of the gene for the type 1 IGF receptor resulted in birth weights 45% of normal and 100% neonatal lethality. Concurrent knockout of genes for IGF-I and the type 1 IGF receptor resulted in no further reduction in birth size (45% of normal), consistent with the concept that all IGF-I actions in fetal life are mediated through this receptor. On the other hand, simultaneous knockout of the genes for IGF-II and the type 1 IGF receptor resulted in further reduction of birth size to 30% of normal (as with simultaneous knockouts of IGF-I and IGF-II), suggesting that some of the fetal anabolic actions of IGF-II are mediated by a secondary mechanism (perhaps placental growth). This pathway does not appear to involve the type 2 IGF receptor, because knockout of this paternally imprinted gene results in an increased birth weight but death in late gestation or at birth. Because this receptor normally degrades IGF-II, increased growth reflects excess IGF-II acting through the IGF-I receptor; there is, however, variable accumulation of IGF-II in such mouse tissues. Knockout of the type 2 IGF receptor plus IGF-II causes a birth weight 60% of normal (as is the case with knockout of IGF-II alone) but allows fetal survival.

Several conclusions can be drawn from these studies:

1. IGF-I is important for both fetal and postnatal growth.
2. IGF-II is more important than GH for postnatal growth.
3. IGF-II is a major fetal growth factor.
4. The type 1 IGF receptor mediates anabolic actions of both IGF-I and IGF-II.
5. The type 2 IGF receptor is bifunctional, serving to both target lysosomal enzymes and to enhance IGF-II turnover.
6. IGF-I production is involved in normal fertility.
7. Placental growth is impaired only with IGF-II knockouts.

Whether these studies in mice are fully applicable to humans is yet unknown.

**IGF Peptide Assays**

Bioassays methods for IGF activity included stimulation of [35S] sulfate incorporation, using various modifications of the original method described by Salmon and Daughaday. A wide variety of other bioassays used stimulation of the synthesis of DNA, RNA, or protein or of glucose uptake. Such assays are cumbersome, subject to interference by IGFBPs, and incapable of distinguishing between IGF-I and IGF-II. When somatomedin-C (and later, IGF-I and IGF-II) were purified, it became possible to develop radioreceptor assays (RRAs) and competitive proteinbinding assays; development of specific antibodies permitted the development of accurate and specific measurement of IGF-I and IGF-II.

The issue of IGFBPs must be addressed in any IGF assay. For example, the discrepant results found in uremic sera assayed for IGF by bioassay, RRA, and immunassay are due to the interference of IGFBPs in RRA; such interference is a particular problem in conditions with a relatively high IGFBP/IGF peptide ratio and at the extremes of the assay (i.e., GHD or acromegaly). The most effective way to deal with IGFBPs is to separate them from IGF peptides by chromatography under acidic conditions; however, this is a labor-intensive procedure and has been occasionally replaced by an acid extraction procedure. Although this latter method may be reasonably effective for most serum samples, it is problematic in conditions of high IGFBP/IGF peptide ratios, such as conditioned media from cell lines and sera from newborns and from subjects with GHD or uremia.

Alternative methods include the use of antibodies generated against synthetic peptides, such as the C-peptide region of IGF-I or IGF-II, which does not bind to IGFBPs. In general, such antibodies have high specificity but relatively low affinity. An alternative approach, developed by Blum and colleagues, involves use of an antibody with high specificity for IGF-II, which permits the addition of excess unlabelled IGF-I, to saturate endogenous IGFBPs.

Bang and co-workers have bypassed the interference of IGFBPs by employing a truncated IGF-I radioligand, which has decreased affinity for IGFBPs. Currently, the most practical and effective way to perform accurate IGF assays with minimal interference by IGFBPs is to use the sandwich assay method. These assays, which can be performed in either enzyme-linked immunosorbent assay (ELISA) or immunoradiometric assay, do not employ a radiolabeled IGF molecule, which can bind to IGFBPs, as in conventional radioimmunoassays, and lead to erroneous readings if IGFBP levels are elevated. The absolute IGF values obtained in many of the assays may be falsely high because of low purity and inconsistent amino acid analyses of local standards, but this can be avoided by the use of the World Health Organization International Reference Reagent 87/518 calibration standard.

**Serum Levels of IGF Peptides**

In human fetal serum, IGF-I levels are relatively low and are positively correlated with gestational age. Some but not all groups have reported a correlation between fetal cord serum IGF-I levels with birth weight. IGF-I levels in human newborn serum are generally 30% to 50% of adult levels. Serum levels rise during childhood and attain adult levels at the onset of sexual maturation. During puberty, IGF-I levels rise to two to three times the adult range. Thus, levels during adolescence correlate better with Tanner stage (or bone age) than with chronologic age. Girls with gonadal dysgenesis show no adolescent increase in serum IGF-I, clearly establishing the role of the pubertal rise in IGF-I with the production of gonadal steroids. The pubertal rise in gonadal steroids may stimulate IGF-I production directly, by first leading to a rise in GH secretion, but patients with GH due to GHR mutations show a pubertal rise in serum IGF-I despite a decline in GH levels, thereby suggesting a direct effect of gonadal steroids on IGF-I.

After adolescence, or at least after 20 to 30 years of age, serum IGF-I levels demonstrate a gradual and progressive age-associated decline. a decline that is possibly responsible for the negative nitrogen balance, decrease in muscle mass, and osteoporosis of aging. This provocative hypothesis is unproven but has generated interest in the potential use of GH and IGF-I therapy in normal aging.

Human newborn levels of IGF-II are generally 50% of adult levels. By 1 year of age, however, adult levels are attained, with little, if any subsequent decline, even up to the seventh or eighth decade. This pattern of IGF-II levels in humans is different than that in the rat or mouse, in which serum IGF-II levels are also high in the fetus but rapidly decline postnatally to undetectable levels in the adult.

**Measurement of IGF Levels in Growth Disorders**

The GH dependency of the IGFs was established in the initial report from Salmon and Daughaday and further clarified with the development of sensitive and
specific immunoassays that distinguish between IGF-I and IGF-II. IGF-I levels are more GH-dependent than are IGF-II levels and are more likely to reflect subtle differences in GH secretory patterns. However, serum IGF-I levels, as stated earlier, are influenced by age, degree of sexual maturation, and nutritional status. As a result, construction of age-defined normative values may be misleading. IGF-I levels in normal children younger than 5 years of age are low, and there is overlap between the normal range and values in GH-deficient children. Assessment of serum IGF-II levels is less age-dependent, especially after 1 year of age, but IGF-II is less GH-dependent than is IGF-I.

Moore and associates performed GH stimulation tests in 78 children with heights below the 5th percentile and serum IGF-I levels lower than 0.5 U/mL. Although 19 of these children were subsequently discovered to have GH deficiency on the basis of standard provocative tests, there was an overlap of serum IGF-I levels between GH-deficient children and children with other forms of short stature and normal provocative GH levels. It was only in children with bone ages greater than 12 years that serum IGF-I levels permitted discrimination between GHD and normal short children. Similarly, Reiter and Lovinger found that 4 of 16 children with low provocative GH levels had normal serum IGF-I levels, whereas 7 of 25 children with normal provocative GH levels had low serum IGF-I levels.

Rosenfeld and colleagues evaluated the efficacy of IGF-I and IGF-II measurements in 68 GH-deficient patients, 197 children with normal stature, and 44 normal children with short stature (Fig. 23-24 and Fig. 23-25). Eighteen percent of the GH-deficient children had serum IGF-I levels within the normal range for age, and 32% of normal short children had low IGF-I levels. Low IGF-II levels were found in 52% of GH-deficient children and in 35% of normal short children. However, the use of combined IGF-I/IGF-II assays provided better discrimination. Only 4% of GH-deficient children had normal plasma levels of both IGF-I and IGF-II. Furthermore, only 0.5% of normal children and 11% of normal short children had low serum levels of both IGF-I and IGF-II.

The observation that many "normal short" children have low serum levels of IGF-I, IGF-II, or both calls into question the criteria by which the diagnosis of GHD is made. Given that provocative GH testing is both arbitrary and nonphysiologic and the inherent variability in GH assays, it is not surprising that the correlation between IGF-I levels and provocative GH levels is imperfect. These points are further supported by recent observations with immunoassays for IGFBP-3 (see later).

**IGF Receptors**

A study was published in which the binding of IGFs to the insulin receptor provided an explanation for their insulin-like activity. Shortly thereafter, Megyesi and co-workers identified distinct receptors for insulin and IGF in rat hepatic membranes. At least two classes of IGF receptors exist; insulin, at high levels, competes for occupancy of one form of IGF receptor but has essentially no affinity for the second form of receptor.

Structural characterization of these receptors documented the differences in the two forms of receptor (Fig. 23-26). The type 1 IGF receptor is closely related to the insulin receptor; both are heterotetramers comprised of two membrane-spanning subunits and two intracellular subunits. The subunits contain the binding sites for IGF-I and are linked by disulfide bonds. The subunits contain a transmembrane domain and an adenosine triphosphate (ATP)-binding site and a tyrosine kinase domain that constitute the presumed signal transduction mechanism for the receptor. One mole of the full heterotetrameric receptor appears to bind one mole of ligand.

Although the type 1 IGF receptor has been commonly termed the IGF-I receptor, the receptor binds both IGF-I and IGF-II with high affinity, and both IGF peptides appear capable of activating tyrosine kinase by binding to this receptor. In studies involving transfection and overexpression of the type 1 IGF receptor cDNA, the Kd for IGF-I is typically in the range of 0.2 to 1 nM, affinity for IGF-II is usually slightly less but varies from study to study. The affinity of the type 1 receptor for insulin is generally 100-fold less, thereby explaining the relatively weak mitogenic effect of insulin.

Ullrich and associates deduced the structure of the human type 1 IGF receptor from cDNA; the mature peptide constitutes 1337 amino acids with a predicted molecular mass of 151,869. The translated heterodimer is subsequently cleaved at an Arg-Lys-Arg-Arg sequence at positions 707 to 710, and the released and subunits are linked by disulfide bonds to form the mature (1,2)-receptor in which two alpha chains are joined by secondary disulfide bonds. The subunits are extracellular and contain a cysteine-rich domain, which is critical for IGF binding. As is the case with the insulin receptor, the subunit has a short extracellular domain, a hydrophobic transmembrane domain, and the intracellular tyrosine kinase domain and ATP-binding site. Like the insulin receptor, the type 1 IGF receptor undergoes ligand-induced autophosphorylation, principally on tyrosines 1131, 1135, and 1136. Both receptors are believed to have evolved from a common ancestor protein but are encoded by genes on separate chromosomes (chromosome 15 for the type 1 IGF receptor and chromosome 19 for the insulin receptor).

The type 1 IGF receptor gene spans greater than 100 kb of genomic DNA, with 21 exons; the genomic organization resembles that of the type 1 IGF receptor gene. By Northern blot hybridization, human mRNA reveals two bands of 11 and 7 kb; rat tissues contain only the 11-kb band. Type 1 IGF receptor mRNA is most abundant in embryonic tissues and appears to decrease encoded by exons 4 to 10. The peptide cleavage site involved in generation of the and subunits is encoded by exon 11, and the tyrosine kinase domain of the subunit is encoded by exons 16 to 20. It is in the latter region that the type 1 IGF receptor and insulin receptor share the greatest sequence homology, ranging from 80% to 95%; interspecies homology in this region of the receptors is also high. Exon 21 encodes 3 untranslated sequences.

Type 1 IGF receptor mRNA has been identified in virtually every tissue except liver. By Northern blot hybridization, human mRNA reveals two bands of 11 and 7 kb; rat tissues contain only the 11-kb band. Type 1 IGF receptor mRNA is most abundant in embryonic tissues and appears to decrease encoded by exons 4 to 10. The peptide cleavage site involved in generation of the and subunits is encoded by exon 11, and the tyrosine kinase domain of the subunit is encoded by exons 16 to 20. It is in the latter region that the type 1 IGF receptor and insulin receptor share the greatest sequence homology, ranging from 80% to 95%; interspecies homology in this region of the receptors is also high. Exon 21 encodes 3' untranslated sequences.

with age. The type 1 IGF receptor is present at the embryonic eight-cell stage (the type 2 IGF receptor is first demonstrable at the 2-cell stage) and becomes widely expressed postimplantation, consistent with the observation that this receptor is essential for normal fetal growth.

As with other growth factor receptor tyrosine kinases, binding of ligand (IGF-I or IGF-II) induces receptor autophosphorylation of critical tyrosine residues in the type 1 receptor.\textsuperscript{326} Mutations of the ATP-binding site or of critical tyrosine residues in the subunit result in loss of IGF-stimulated thymidine incorporation and glucose uptake.

Autophosphorylation appears to occur by transphosphorylation of sites on the opposite subunit.\textsuperscript{327} The activated type 1 IGF receptor is capable of phosphorylating other tyrosine-containing substrates, such as insulin receptor substrate 1 (IRS-1), a 185-kd protein that is the predominant substrate of the insulin receptor kinase and IRS-2 (Fig. 23-28) (Figure Not Available).\textsuperscript{328} IRS-1 contains specific phosphorysosyRNA motifs that can associate with proteins containing SH2 (src homology 2) domains, such as PI3-kinase (phosphatidylinositol-3 kinase),\textsuperscript{329} Grb2 (growth factor receptor-bound protein 2),\textsuperscript{330} Syp (a phosphotyrosine phosphatase),\textsuperscript{331} and Nck (an oncogenic protein).\textsuperscript{332} The substrates, which are phosphorylated by the IGF receptor, include the members of the IRS family, particularly IRS-1 and IRS-2, as both of the knockout mice models for these genes result in poor growth (as well as insulin resistance).\textsuperscript{333} Other IRS molecules may have a negative feedback role in regulating IGF action.\textsuperscript{334}

Activation of the type 1 IGF receptor also leads to tyrosine phosphorylation of Shc (src homology domain-containing protein),\textsuperscript{335} which then associates with Grb2 and activates Ras, leading to a cascade of protein kinases, including Raf, MAP kinase kinases, MAP kinases, and S6 kinase.\textsuperscript{336} Thus, phosphorylation of IRS-1 by either the type 1 IGF or insulin receptor activates multiple signaling cascades that ultimately influence nuclear transcription and gene expression. It is, presumably, at this level that the IGF peptides exert their mitogenic and anabolic actions. Given that insulin and IGF peptides activate similar, if not identical, signaling pathways through their own specific receptors, it is unclear how the cell distinguishes between these overlapping ligands. Whether this merely reflects the relative levels of receptors or whether divergent downstream pathways exist for insulin and IGF action remain questions for future investigation.\textsuperscript{337}

Although targeted disruption of the gene for the type 1 IGF receptor causes fetal growth retardation, a clear role for this receptor in the cell cycle has not been established. Fibroblast cell lines derived from mouse embryos homozygous for the knockout gene still undergo cell cycle-dependent division, although at a slower rate.\textsuperscript{338} On the other hand, the transformed phenotype of some cells may be critically dependent on expression of the type 1 IGF receptor. The SV40TAg is capable of inducing a transformed phenotype in a cell only in the presence of intact type 1 IGF receptors.\textsuperscript{339} NIH 3T3 cells and Rat-1 fibroblasts that are made to overexpress the type 1 IGF receptor develop IGF-dependent neoplastic transformation with colony formation in soft agar and tumor formation in nude rats.\textsuperscript{340} Prager and colleagues\textsuperscript{341} have shown that truncation of the type 1 IGF receptor at the amino terminal increases transforming potential, suggesting that the subunit normally restricts this function and that the binding of IGF to the receptor represses the effects of mitogenic stimulation.

Variants of both the a and subunits are present in placenta,\textsuperscript{342} muscle,\textsuperscript{343} and brain.\textsuperscript{344} These variants may explain seemingly anomalous competitive binding studies.\textsuperscript{345} The molecular mechanisms for the formation of such receptor variants have not been identified; nor is it clear if they differentially bind IGF-I, IGF-II or insulin. The formation of IGF-insulin receptor hybrids that contain an IGF hemireceptor disulfide-linked to an insulin hemireceptor (see Fig. 23-26)\textsuperscript{346} appears to be ligand-dependent,\textsuperscript{347} and studies with monoclonal antibodies specific for the insulin or type 1 IGF receptor suggest that such receptors develop in cells with abundant native receptors, such as muscle and placenta.\textsuperscript{348} Such hybrids have near-normal affinity for IGF-I but decreased affinity for insulin. The physiologic significance of such hybrid receptors is unknown.

The type 2 IGF receptor bears no structural homology with either the insulin or type 1 IGF receptors. It has an apparent molecular mass of 220,000 under physiologic significance of such hybrid receptors is unknown. Fibroblast cell lines derived from mouse embryos homozygous for the knockout gene still undergo cell cycle-dependent division, although at a slower rate. On the other hand, the transformed phenotype of some cells may be critically dependent on expression of the type 1 IGF receptor. The SV40TAg is capable of inducing a transformed phenotype in a cell only in the presence of intact type 1 IGF receptors. NIH 3T3 cells and Rat-1 fibroblasts that are made to overexpress the type 1 IGF receptor develop IGF-dependent neoplastic transformation with colony formation in soft agar and tumor formation in nude rats. Prager and colleagues have shown that truncation of the type 1 IGF receptor at the amino terminal increases transforming potential, suggesting that the subunit normally restricts this function and that the binding of IGF to the receptor represses the effects of mitogenic stimulation.

Such hybrids have near-normal affinity for IGF-I but decreased affinity for insulin. The physiologic significance of such hybrid receptors is unknown.
production of inositol triphosphate and diacylglycerol in proximal tubules and canine kidney membranes. Tally and co-workers reported that IGF-II stimulates the growth of a K562 human erythroleukemia cell line, an action not duplicated by either IGF-I or insulin. Minnilli and colleagues reported that IGF-II appears capable of acting as an autocrine growth factor and cell motility factor for human rhabdomyosarcoma cells, actions apparently mediated through the type 2 receptor, and IGF-II may activate a calcium-permeable cation channel via the type 2 IGF receptor, perhaps through coupling to a permissus toxicinsensitive, guanine nucleotide-binding protein (G protein). IGF-II is found in cells transfected with the human type 2 IGF receptor cDNA, IGF-II decreased CAMP accumulation promoted by cholera toxin or forskolin. Mutations or truncation of the small cytoplasmic domain of the receptor prevented these IGF-II actions. The type 2 IGF receptor also binds other molecules such as Msp-containing enzymes (e.g., cathepsin and urokinase), which may be important in the removal of these enzymes from the cellular environment, thus modulating tissue remodeling. In addition, the type 2 IGF receptor binds retinoid x and may mediate some of the growth inhibitory effects of retinoids.

As discussed earlier, knockout of the type 2 IGF receptor results in excessive growth. This receptor, therefore, may act as a growth inhibitory component of the IGF system responding to and mediating multiple antimitogenic systems.

**IGF-Binding Proteins** (Fig. 23-29) (Figure Not Available)

In contrast with insulin, the IGFs circulate in plasma complexed to a family of binding proteins that extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interaction of the IGFs with surface membrane receptors. The identification and characterization of IGF-binding proteins (IGFBPs) in body fluids and in conditioned media from cultured cells have been facilitated by the development of a number of biochemical and assay techniques, including gel chromatography, RRAAs, affinity cross-linking, Western ligand blotting, immunoblotting, and specific radioimmunoassays. However, study of the molecular biology of the IGFBPs has provided the most information concerning their structural inter-relationship.

**IGF-Binding Protein Structure** (Fig. 23-29)

To date, the cDNAs for six distinct human and rat IGFBPs have been cloned and sequenced. Their structural characteristics are summarized in Figure 23-30. The amino acid sequences of the six cloned mammalian IGFBPs are highly conserved. Within a species, the IGFBPs share an overall amino acid sequence homology in the order of 50%, and between species there is more than 80% sequence homology for individual IGFBPs. Perhaps the most impressive similarity in structure is the conservation of the number and placement of the cysteine residues. The total number of cysteines varies from 16 to 20 (18 are conserved in human IGFBP-3) to 5; IGFBP-6 conserves 16 of the 18, and IGFBP-4 has 2 additional cysteines in the middle region of the protein), and each of the IGFBPs has cysteine-rich regions at the amino-terminus and carboxyl-terminus. Conservation of the spatial order of the cysteines presumably indicates that the secondary structure of the IGFBPs, which is dependent on disulfide bonding, must also be conserved.

Disulfide bonding is essential for formation of the IGF

**IGF-Binding Proteins** (Fig. 23-28) (Figure Not Available)

Schematic representation of the insulin-like growth factor I receptor (IGF-IR). On binding IGF-I, the IGF receptor undergoes autophosphorylation at multiple tyrosine residues. The intrinsic kinase activity of the receptor also phosphorylates insulin receptor substrate 1 (IRS-1) at multiple tyrosine residues. Various SH domain-containing proteins, including PI 3-kinase, Syp, Fyn, and Nick, associate with specific phosphotyrosine-containing motifs within IRS-1. These docking proteins recruit diverse other intracellular substrates, which then activate a cascade of protein kinases, including Raf-1 and one or more related kinases. These protein kinases, in turn, activate various other elements, including nuclear transcription factors. Alterations in expression of various IGF-I-responsive genes results in longer-term effects of IGF-I, including growth and differentiation. This model of signal transduction cascades also shows a potential mechanism for the inhibition of apoptosis. (From Le Roth D, Bondy C, Yaker S, et al: The somatomedin hypothesis. Endor Rev 1991; 20:573. © The Endocrine Society.)

**IGF-Binding Protein Structure** (Fig. 23-30)

Figure 23-30 Amino acid sequences of insulin-like growth factor-binding proteins (IGFBPs) 1 to 6, deduced from nucleotide sequences. Sequences in the amino-terminal and carboxyl-terminal residues are aligned to show maximal similarities. Dashes indicate gaps. Residues that are identical in five or six of the six IGFBPs are shaded. (From Rechler MM: Insulin-like growth factor binding proteins. Vitam Horm 1993; 47:114.)

properties of the IGFBPs, such as cell association, IGF enhancement, and IGF-independent actions (see later) may be dependent on specific sequences in these midregions. An RGD (arginine-glycine-aspartic acid) sequence near the carboxyl-terminus of IGFBP-1 and IGFBP-2 is the minimum sequence required for the binding of many extracellular matrix proteins to membrane receptors of the integrin protein family, and IGFBPs may associate with the cell surface through such amino acid sequences. However, IGFBP-3, which lacks an RGD sequence, also binds to cell membranes, possibly to specific receptors (see later).

Under most conditions, the IGFBPs appear to inhibit IGF action, presumably by competing with IGF receptors for binding IGF peptides. For example, IGF analogues with decreased affinity for IGF receptors have increased biologic potency. In studies involving transfection of the human IGF-I-responsive gene into fibroblasts, increased expression of IGFBP-3 inhibited cell growth, even in the absence of added IGF, suggesting a direct inhibitory role of the binding protein. Under some conditions, however, the IGFBPs appear to enhance IGF action, perhaps by facilitating the delivery of IGF to target receptors.

The discovery of several groups of cysteine-rich proteins that contain domains similar to the amino-terminus of the IGFBPs has led to the proposal of an IGFBP superfamily, which includes the family of six high-affinity IGFBPs, as well as a number of IGFBP-related proteins (IGFBP-Ps). Three of the IGFBP-Ps (Mac25/IGFBP-P1; connective tissue growth factor, CTGF/IGFBP-P2; Nov/IGFBP-P3) have been shown to bind IGFs, although with considerably lower affinity than the IGFBPs. Like the IGFBPs, the IGFBP-Ps are modular proteins and the highly preserved amino-terminal domain appears to represent the consequence of exon shuffling of an ancestral gene. The role, if any, of the IGFBP-Ps in normal IGF physiology is unclear, but they seem likely that they influence cell growth by IGF-independent and IGF-dependent mechanisms.

Analysis of IGFBPs is further complicated by the presence of IGFBP-proteases, which degrade IGF, initially reported in the serum of pregnant women, proteases for IGFBP-2, IGFBP-3, IGFBP-4, and IGFBP-5 are present in serum, seminal plasma, cerebrospinal fluid and urine. It is likely that multiple IGFBP-proteases exist, including calcium-dependent serine proteases, kallikreins, cathepsins, and matrix metalloproteases. Proteolysis of IGFBPs complicates their assay and must be taken into consideration when measuring the various IGFBPs in biologic fluids. The physiologic significance of limited proteolysis of IGFBPs remains to be determined, although protease activity usually decreases the affinity of the IGFBP for IGF peptides (Fig. 23-31) and may enhance the mitogenic and anabolic effects of IGF peptides in this way. In prostate epithelial cells and prostate-specific antigen acts as a potent IGF-3 protease (Fig. 23-32) and Fig. 23-32).

The identification and characterization of IGFBPs in body fluids and in conditioned media from cultured cells have been facilitated by the development of a number of biochemical and assay techniques, including gel chromatography, RRAAs, affinity cross-linking, Western ligand blotting, immunoblotting, and specific radioimmunoassays. However, study of the molecular biology of the IGFBPs has provided the most information concerning their structural inter-relationship.

In prostate epithelial cells and prostate-specific antigen acts as a potent IGF-3 protease (Fig. 23-32) and Fig. 23-32).
IGF-Binding Proteins as Carrier Proteins

Given the high affinity of the IGFs for IGF-I and IGF-II (Kₐ = 10⁻¹⁰ M⁻¹), virtually all IGF-I and IGF-II in serum is complexed to IGF-BPs. In normal adult serum, 75% to 80% of the IGF-I and IGF-II peptides are carried in a ternary complex consisting of one molecule of IGF plus one molecule of IGFBP-3 plus one molecule of an 8-kd protein termed the acid-labile subunit (ALS). Binding of ALS to form the full ternary complex occurs after the binding of IGF by IGFBP-3 or IGF-BP-5, although ALS may bind to IGFBP-3 even in the absence of IGF. The 150-kd ternary complex is too large to leave the vascular compartment and extends the half-life of IGF peptides from approximately 10 minutes to 1 to 2 hours for IGF in the IGFBP-3 ternary complex to 12 to 15 hours for IGF in the ternary complex. The presence of cell membrane proteins or receptors that specifically bind IGFBP-3 provides a potential mechanism for IGF-independent growth inhibitory actions of IGFBP-3.

IGF peptides in the 40- to 50-kd molecular-weight peak may not be restricted to the vascular compartment. IGFBP-1, IGFBP-2, and IGFBP-4, at least, can probably cross endothelial barriers. In the fetus and neonate, whose IGFBP-3 levels are relatively low, and in GHD and GH, binding of IGFs by IGFBP-1, IGFBP-2, IGFBP-4, and IGFBP-5 may predominate over binding to IGFBP-3. Similarly, in tumorinduced hypoglycemia associated with increased serum levels of IGF-II, ternary complex formation may be decreased, and most IGF peptides are found in the low-molecular-weight peak.

IGF-Binding Proteins as Modulators of IGF Action

In general, the binding affinity of IGF-BPs for IGF peptides is higher than that of IGF receptors, implying that IGF-BPs can modulate IGF binding to its receptors, thereby modulating IGF biologic actions. Coincubation of cells with IGF-I and a molar excess of IGFBP-3 results in an inhibition of IGF-stimulated thymidine incorporation in human fibroblasts, lipogenesis in rat epididymal adipocytes, and glucose consumption in mouse fibroblasts. Termination of inhibition apparently requires dissociation of IGFs from the IGF-IGFBP complex by mass action, proteolysis, or other mechanisms. IGF-BP proteases have been identified in a variety of body fluids and cell culture media and are postulated to play a role in altering IGF availability by lowering the affinities of IGF-BPs for their ligand, thereby increasing the availability of IGFs to cell membrane receptors (see earlier).

Under certain conditions, the IGF-BPs potentiate IGF action. In human and bovine fibroblasts, DNA synthesis and -aminoisobutyric acid transport are potentiated when cells are preincubated with IGFBP-3, whereas IGFBP-3 is inhibitory if added at the same time as IGF-I. These observations have suggested that cell association of IGFBP-3 during preincubation is essential for its IGF-potentiating effect, perhaps allowing IGFBP-3 to serve as a reservoir for IGFs and bringing the ligand into closer proximity to the type 1 IGF receptors. This cell surface association of IGFBP-3 may involve interaction with heparin and heparin sulfate proteoglycans on the cell membrane or specific IGFBP-3 receptors.

IGF-Independent Actions of IGF-Binding Proteins

The IGF-BPs are bioactive molecules that, in addition to binding IGF, have a variety of IGF-independent functions. These include growth inhibition in some cell types, direct induction of apoptosis, and modulation of the effects of other non-IGF growth factors. These effects of IGF-BPs are mediated by binding to their own receptors. The IGF-BP signaling pathways are currently being unraveled and involve interaction of IGF-BPs with nuclear retinoid receptors as well as with other molecules on the cell surface and in the cytoplasm.

IGFBP-3, itself, appears to have intrinsic inhibitory effects on cells, independent of its interaction with IGF. Vailland and co-workers found that the stimulation of DNA synthesis by basic FGF is inhibited by simultaneous treatment with IGFBP-3, even in the presence of levels of insulin, suggesting that sequentialization of IGF peptides from type 1 IGF receptors is not the only means whereby IGFBP-3 inhibits cell growth. IGFBP-3 is also more effective than immunoneutralization of IGF-I in inhibiting serum-stimulated DNA synthesis, and IGFBP-3 inhibits FSH-stimulated DNA synthesis in cultured ovarian granulosa cells, with or without added IGF. Under the same conditions, IGFBP-2 is less inhibitory, despite its higher affinity for IGF peptides. Expression of a transfected human IGFBP-3 cDNA in mouse fibroblasts inhibits both IGF-stimulated and insulin-stimulated cell proliferation. Similar studies of fibroblasts derived from mouse embryos homozygous for a targeted disruption of the type 1 IGF receptor again demonstrated inhibition with overexpression of IGFBP-3. These studies strongly support an IGF-independent action for IGFBP-3.

IGFBP-3 binds with high affinity to the surface of various cell types, including human breast cancer cells and rat chondrocytes, and inhibits monolayer growth of these cells in an IGF-independent manner. Furthermore, transcausal regulation of IGFBP-3 expression may be the mechanism for the inhibition of breast cancer cell growth by both transforming growth factor 2 and retinoic acid (Reduction of IGFBP-3 production may be a common pathway for multiple hormones and growth factors involved in the modulation of cell growth. For example, estrogen inhibits expression and secretion of IGFBP-3, whereas antestrogens stimulate production of IGFBP-3 in estrogen receptorpositive human breast cancer cells. Similarly, the mitogenic action of epidermal growth factor (EGF) in human cervical epithelial cells is associated with inhibition of IGFBP-3 expression, and the inhibitory effect of retinoic acid is accompanied by increased IGFBP-3 expression. Regulation of IGFBP-3 gene expression plays a role in signaling by p53, a potent tumor suppressor protein.

The presence of cell membrane proteins or receptors that specifically bind IGFBP-3 provides a potential mechanism for IGF-independent growth inhibitory actions of IGFBP-3.
IGFBP-3 is the predominant IGFBP in adult serum, where it carries approximately 75% of the total IGF, primarily as part of the 150-kd ternary complex. Serum levels capable of ternary complex formation are increased in insulin resistance.

Analyses and radioimmunoassays for IGFBP-3 reflect the altered affinity of IGFBP-3 fragments for IGF ligands, although some proteolytic fragments of IGFBP-3 are also produced.

The mature IGFBP-3 protein has a molecular weight of approximately 29 kd; however, because it is nonglycosylated, its affinity for IGF-I and IGF-II is decreased.

IGFBP-1 affinity for IGF-I and thereby inhibit IGF action. The ability of IGFBP-1 to inhibit or potentiate IGF action may depend on post-translational modifications of IGFBP-1, such as phosphorylation, which appears to enhance its ability to inhibit IGF-I.

Although most in vitro studies are consistent with an inhibitory effect of IGFBP-1 on IGF actions, presumably reflecting interference with IGF ligand-receptor interactions, IGFBP-1 potentiates IGF effects in certain cell systems, probably as the result of the binding of IGFBP-1 to cell membranes through its Arg-Gly-Asp (RGD) sequence. RGD is an integrin receptor recognition sequence that presumably allows IGFBP-1 to associate with the integrin (fibronectin) receptor. The ability of IGFBP-1 to inhibit or potentiate IGF action may depend on post-translational modifications of IGFBP-1, such as phosphorylation, which appears to enhance its ability for IGF-I and thereby inhibit IGF action.

Figure 23-33

The acute modulation of serum IGFBP-1 levels may regulate the free IGF-I pool and thereby influence the ability of IGF-I to bind to the type I IGF receptor (lanes 11 and 12 in Figure 23-33A). Otherwise, knockout of the IGFBP-2 gene or overexpression of IGFBP-1 in transgenic mice appears to have little effect on phenotype, possibly reflecting "redundancy" in the IGF system, in which one IGFBP can compensate for loss of another.

The existence of a low-molecular-weight IGFBP in cerebrospinal fluid was inferred from studies demonstrating a 34-kd IGFBP that did not react with antibodies to IGFBP-1 (or IGFBP-3). This IGFBP appeared to be consistent with a previous observation of CSF IGFBPs with preferential affinity for IGF-II.

Figure 23-34

Affinity cross-linking of [125I]IGF-I (A) and [125I]IGF-II (B) to membranes from HepG2 breast cancer cells. In the absence of unlabeled insulin-like growth factor (IGF) peptide (lane 1), IGF-I and IGF-II were not detected.

The mature IGFBP-3 protein has a molecular weight of approximately 28 kd; however, because it is nonglycosylated, it normally migrates as a doublet of 40 to 46 kd. Glycosylation does not alter its affinity for IGF-I or IGF-II. IGFBP-3 also undergoes serine phosphorylation of IGFBP-3, although its physiologic significance is uncertain. Perhaps the most significant post-translational modification of IGFBP-3 is proteolysis (see earlier). Discrepancies between immunoblot analyses and radioimmunoassays for IGFBP-3 reflect the altered affinity of IGFBP-3 fragments for IGF ligands, although some proteolytic fragments of IGFBP-3 are capable of inhibiting IGF action. In pregnancy serum levels of IGFBP-3 remain elevated, as do levels of IGFBP-3 in the conditioned media of prostatic epithelial cells. Interestingly, IGFBP-2 gene expression is markedly reduced in prostatic stromal cells from patients with benign prostatic hyperplasia, suggesting that IGFBP-2 may inhibit stromal growth.

Serum levels of IGFBP-2 are frequently elevated in patients with prostate carcinoma.

The mature IGFBP-3 protein is GH-dependent, due to either a direct GH effect or regulation by IGF. GH administration to hypophysectomized rats increases serum levels of IGFBP-3 in a manner similar to that seen with IGF-I administration. The protein was actually identified and purified from several different tissues, including amniotic fluid and Hep G2 conditioned media. Placental membranes (placental protein 12), and endometrium (pregnancy-associated 47k, -globulin). Its gene is 5.2 kb long, located on the short arm of chromosome 7, and composed of four exons. The mature protein is 30 kd and is nonglycosylated. mRNAs for IGFBP-3 are expressed in decidua (although not in placental trophoblasts), liver, and kidney.

IGFBP-1 may be involved in reproductive functions, including endometrial cycling, ovocyte maturation and fetal growth. It is the major IGFBP in fetal serum in early gestation, reaching levels as high as 3000 µg/L by the second trimester. Levels of IGFBP-1 in newborn serum are inversely correlated with birth weight, consistent with an inhibitory role on fetal IGF action.

IGFBP-1 also appears to have an important metabolic role, because its gene expression is enhanced in catabolic states, and serum levels undergo diurnal variation. Insulin suppresses and glucocorticoids enhance IGFBP-1 mRNA levels. Its gene is 5.2 kb long, located on the short arm of chromosome 7, and composed of four exons. The mature protein is 30 kd and is nonglycosylated. mRNAs for IGFBP-3 are expressed in decidua (although not in placental trophoblasts), liver, and kidney.

The IGFBP-2 is similar to IGFBP-1 in its lack of N-glycosylation and in the presence of an RGD sequence, perhaps allowing cell association and potentiation of IGF action. Nevertheless, knockout of the IGFBP-2 gene or overexpression of IGFBP-1 in transgenic mice appears to have little effect on phenotype, possibly reflecting "redundancy" in the IGF system, in which one IGFBP can compensate for loss of another.

The existence of a low-molecular-weight IGFBP in cerebrospinal fluid was inferred from studies demonstrating a 34-kd IGFBP that did not react with antibodies to IGFBP-1 (or IGFBP-3). This IGFBP appeared to be consistent with a previous observation of CSF IGFBPs with preferential affinity for IGF-II.

IGFBP-2 is expressed in secretory endometrium and endometrial tumors and is the major IGFBP in seminal fluid and in the conditioned media of prostatic epithelial cells. Interestingly, IGFBP-2 gene expression is markedly reduced in prostatic stromal cells from patients with benign prostatic hyperplasia, suggesting that IGFBP-2 may inhibit stromal growth.

Serum levels of IGFBP-2 are frequently elevated in patients with prostate carcinoma.

The IGFBP-3 gene is located on chromosome 7 in proximity to the gene for IGF-I. It contains four exons homologous to those of IGFBP-1 and IGFBP-2 and a fifth exon, consisting of 3' untranslated sequences. In all human tissues studied to date, a single 2.6-kb mRNA has been observed, whereas an additional 1.7-kb mRNA species suggests alternative splicing in baboons. mRNAs levels are high in liver, but IGFBP-3 is secreted by hepatic endothelia (portal venous and sinusoidal) and Kupffer cells, whereas ALS is synthesized in hepatocytes.

IGFBP-3 is GH-dependent, due to either a direct GH effect or regulation by IGF. GH administration to hypophysectomized rats increases serum levels of IGFBP-3. Serum levels of IGFBP-2 are frequently elevated in patients with prostate carcinoma. On the other hand, IGF-I treatment of patients with GHI does not alter serum IGFBP-3 levels, whereas GH treatment of GH-deficient patients does increase serum levels. Whether these observations mean that GH has a direct effect on IGFBP-3 or reflect GH regulation of ALS and ternary complex formation is unclear.

Figure 23-33

The effect of insulin-like growth factor binding protein 3 (IGFBP-3) proteolysis by prostate-specific antigen (PSA) on the ability of IGF-I to inhibit IGF-I (A) and IGF-II (B) action. (From Cohen P, Puehl DM, Graves HC, Rosenfeld RG. Biological effects of prostate-specific antigen as an insulin-like growth factor binding protein-3 protease. J Endocrinol 1994; 142:407415.)

Figure 23-34

Affinity cross-linking of [125I]IGF-I (A) and [125I]IGF-II (B) to membranes from HepG2 breast cancer cells. In the absence of unlabeled insulin-like growth factor (IGF) peptide (lane 1), IGF-I was markedly displaced by unlabeled IGF-I or IGF-II (lanes 2 to 5) but not by unlabeled IGF-II/insulin hybrid molecule (lanes 6 and 7) or by an IGF analogue with decreased affinity for IGFBP-binding proteins (QALY, lanes 9 and 10 in A). However, addition of [Leu27] IGF-II, which has decreased affinity for the type I IGF receptor (lanes 11 and 12 in A and lanes 7 and 9 in B), resulted in "unmasking" of the 130-kd subunit of the type I IGF receptor (A) and the 250-kd type II IGF receptor. (From Oh Y, Muller HL, Lamson G, Rosenfeld RG. Insulin-like growth factor [IGF] independent action of IGFBP-binding protein 3 in HepG2 human breast cancer cells: cell surface binding and growth inhibition. J Biol Chem 1993; 268:1496414971.)

The mature IGFBP-3 protein has a molecular weight of approximately 28 kd; however, because it is nonglycosylated, it normally migrates as a doublet of 40 to 46 kd. Glycosylation does not alter its affinity for IGF-I or IGF-II. IGFBP-3 also undergoes serine phosphorylation of IGFBP-3, although its physiologic significance is uncertain. Perhaps the most significant post-translational modification of IGFBP-3 is proteolysis (see earlier). Discrepancies between immunoblot analyses and radioimmunoassays for IGFBP-3 reflect the altered affinity of IGFBP-3 fragments for IGF ligands, although some proteolytic fragments of IGFBP-3 are capable of inhibiting IGF action. In pregnancy serum levels of IGFBP-3 remain elevated, as do levels of IGFBP-3 in the conditioned media of prostatic epithelial cells. Interestingly, IGFBP-2 gene expression is markedly reduced in prostatic stromal cells from patients with benign prostatic hyperplasia, suggesting that IGFBP-2 may inhibit stromal growth.

Serum levels of IGFBP-2 are frequently elevated in patients with prostate carcinoma. On the other hand, IGF-I treatment of patients with GHI does not alter serum IGFBP-3 levels, whereas GH treatment of GH-deficient patients does increase serum levels. Whether these observations mean that GH has a direct effect on IGFBP-3 or reflect GH regulation of ALS and ternary complex formation is unclear.

IGFBP-3 is the predominant IGFBP in adult serum, where it carries approximately 75% of the total IGF, primarily as part of the 150-kd ternary complex. Serum levels
are reduced in patients with GHD or GHI, conditions in which assays for serum IGFBP-3 have important diagnostic value (see later).

IGFBP-3 associates with cell membranes. Affinity cross-linking studies employing [125I]IGF-I and a human breast cancer cell line have demonstrated no binding to the type 1 IGF receptor but rather to membrane-associated 45-kd IGFBP-3 (see Fig. 23-34). When IGF analogues with selective affinity for IGFBPs were added, a typical 125I-subunit of the type 1 IGF receptor was uncovered, demonstrating that membrane-associated IGFBP-3, with its high affinity for IGF peptides, normally "mask" the IGF receptors. Oh and associates [24] demonstrated that the binding of IGFBP-3 to cell membrane proteins was specific, cation-dependent, and of high affinity. Whether these proteins constitute genuine IGFBP-3 receptors remains to be demonstrated, although they may mediate IGF-independent actions of IGFBP-3. Alternatively, IGFBP-3 may associate with heparin-containing proteoglycans both in the extracellular matrix and in the cell membrane, because both IGFBP-3 and IGFBP-5 contain heparin-binding consensus sequences in their COOH termini. However, treatment of cell monolayers with heparinase or chondroitinase has only minor effect on IGFBP-3 binding.

Like other IGFBPs, IGFBP-3 inhibits IGF action, especially when the binding protein is present in excess. Presumably, inhibition of IGF action by IGFBP-3 reflects a sequestering of IGF peptides away from the type 1 receptor. Proteolysis of IGFBP-3, resulting in a decrease in affinity for IGF ligands, decreases the inhibitory effects of the binding protein.

**IGF-Binding Protein 4**

The **IGFBP-4** gene, located on chromosome 17, contains four exons. A single 2.6-kb mRNA has been identified with high expression in liver. The protein is the smallest of the IGFBPs with 237 amino acids in humans, including 20 cysteines and one N-linked glycosylation site. In immunoblots of most biologic fluids, IGFBP-4 is a 24/28-kd doublet; deglycosylation eliminates the 28-kd band. IGFBP-4 appears to interact with connective tissues, but there is no evidence of membrane association, consistent with a primary role for IGFBP-4 as a soluble, extracellular IGFBP.

IGFBP-4 was initially isolated on the basis of its ability to inhibit IGF-stimulated cell proliferation in bone. There is no evidence for any IGF-potentiating effects. The inhibitory effects of IGFBP-4 are reduced by proteolysis of the protein, much as has been observed with IGFBP-3 degradation. IGFBP-4 proteases are produced by a wide variety of cells, including neuroblasts, smooth muscle, fibroblasts, osteoblasts, and prostatic epithelium. Activation of IGFBP-4 proteolysis occurs in the presence of IGF-I or IGF-II, presumably reflecting a conformational change in IGFBP-4 resulting from IGF occupancy. The clinical use of IGFBP-4 measurements is minor.

**IGF-Binding Protein 5**

Complementary DNAs for IGFBP-5 have been isolated and sequenced from rat ovary and human placenta and from a human osteosarcoma. The gene is located on chromosome 5 and contains four exons. A single 6.0-kb mRNA is expressed in a wide variety of tissues, particularly in kidney. Mature IGFBP-5 is produced as a 252-amino acid protein with no N-linked glycosylation sites but with one O-linked glycosylation site.

The addition of excess IGFBP-5 to human osteosarcoma cells inhibits IGF-stimulated DNA and glycosyn synthesis. However, when IGFBP-5 adheres to fibroblast extracellular matrix, it potentiates the growth-stimulatory effects of IGF on DNA synthesis. The affinity of IGFBP-5 for IGF-I is reduced approximately sevenfold when the binding protein is associated with extracellular matrix, providing a potential mechanism for release of IGFs to cell surface receptors. Association of IGFBP-5 with extracellular matrix also appears to protect it from proteolysis. Addition of IGFBP-5 to conditioned medium from fibroblasts results in proteolysis to a 21-kd fragment that does not potentiate IGF action, whereas the deposition of IGFBP-5 in extracellular matrix of fibroblasts makes it relatively resistant to degradation. Andreass and Bimbarm [55] purified a 23-kd IGFBP-5 fragment from U-2 osteosarcoma cells that has reduced affinity for IGFs but enhances IGF-stimulated mitogenesis. The 23-kd IGFBP-5 fragment stimulates mitogenesis in an IGF-independent manner, presumably by binding to a specific "receptor" on the cell membrane.

Unlike proteolysis of IGFBP-4, which is enhanced by addition of IGFs, degradation of IGFBP-5 is inhibited by the binding of IGF peptides. Proteolysis of IGFBP-5 results in the formation of 15- to 23-kd fragments demonstrated on immunoblots. Degradation of IGFBP-5 may have particular importance in the regulation of granulosa cell activity. In healthy ovarian follicles, neither IGFBP-4 nor IGFBP-5 is expressed, whereas both binding proteins are expressed in atretic follicles, thereby providing a mechanism for intrafollicular regulation

**IGF-Binding Protein 6**

The human IGFBP-6 gene is located on chromosome 12 and contains four exons. IGFBP-6 transcripts include a major 1.3-kb mRNA and a minor 2.2-kb transcript. The mature peptide contains 216 amino acids and has a molecular mass of approximately 23 kd, although it may migrate at a higher molecular weight on SDS gels, presumably reflecting O-glycosylation. Although IGFBP-6 binds both IGF-I and IGF-II, it has a significantly greater affinity for IGF-I. IGFBP-6 is found in relatively high levels in cerebrospinal fluid, as is also the case for IGFBP-2, which also binds IGF-II with selectively high affinity. IGFBP-6 may also have a role in regulating ovarian activity, perhaps by functioning as an antigonadotropin.
Gonadal Steroids

Although androgens and estrogens do not contribute substantially to normal growth before puberty, the adolescent rise
Thyroid Hormone

Thyroid hormone is a major contributor to postnatal growth, although, like GH, it is of relatively little importance to growth of the fetus. Hypothyroidism postnatally can cause profound growth failure and virtual arrest of skeletal maturation. In addition to a direct effect on epiphyseal cartilage, thyroid hormones appear to have a permissive effect on GH.

GH, growth hormone; GHD, growth hormone deficiency; IGF, insulin-like growth factor.

Patients with hypothyroidism have decreased spontaneous GH secretion and blunted responses to GH provocative tests. Treatment with thyroid hormone results in rapid "catch-up" (accelerated) growth, which is typically accompanied by marked skeletal maturation, potentially causing overly rapid epiphyseal fusion and compromise of adult height.
GROWTH RETARDATION

A classification of growth retardation is shown in Table 23-2. Growth disorders are subdivided into these categories:

1. Primary growth abnormalities, in which the defect(s) appears to be intrinsic to the growth plate.
2. Secondary growth disorders, or growth failure resulting from chronic disease or endocrine disorders (the newly introduced category of "IGF deficiency" can result from GHRH deficiency, GHD, or GH or IGF insensitivity).
3. ISS, including variants of normal (constitutional delay of growth and maturation [CDGM] and genetic short stature), heterozygous mutations of the GH receptor gene (GHR gene, a variant of GHI) and as yet unclarified mutations throughout the growth-related genome.
PRIMARY GROWTH ABNORMALITIES

Osteochondrodysplasias

The osteochondrodysplasias encompass a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage or bone, or both. These conditions share the following features:

1. Genetic transmission.
2. Abnormalities in the size and shape of bones of the limbs, spine, and/or skull.
3. Radiologic abnormalities of the bones (generally).

More than 100 osteochondrodysplastic conditions have been identified to date on the basis of physical features and radiologic characteristics, and biochemical, molecular, and genetic studies of these conditions will undoubtedly lead to the recognition of additional types. An international classification for the osteochondrodysplasias, developed in 1970 and revised in 1978 and 1992, is summarized in Table 23-3. Of note, the category of dysostosis has been dropped from the classification, which focuses on developmental disorders of bone and cartilage.

Diagnosis of osteochondrodysplasias can be difficult. Although the underlying molecular and biochemical defects have been identified in many of these conditions, clinical and radiologic evaluation remain central to the diagnosis. Frequently, the clinical features are characteristic, and the diagnosis can be made at birth or even prenatally by ultrasonography. The family history is critical, although many cases are due to fresh mutations, as is generally the case in the classical autosomal dominant achondroplasia and hypochondroplasia. Measurement of body proportions should include arm span, sitting height, upper and lower body segments, and head circumference. Clinical and radiologic evaluation should be used to determine whether involvement is of the long bones, skull, and vertebrae and whether abnormalities are primarily at the epiphyses, metaphyses, or diaphyses.

Two of the more common osteochondrodysplasias are achondroplasia and hypochondroplasia.

<tr>
<th>II. Disorganized Development of Cartilaginous and Fibrous Components of the Skeleton</th>
</tr>
</thead>
<tbody>
<tr>
<td>Achondroplasia</td>
</tr>
</tbody>
</table>

Achondroplasia is the most common of the osteochondrodysplasias, with a frequency of about 1:26,000. Although transmitted as an autosomal dominant disorder, 80% to 90% of cases appear to be due to new mutations. Achondroplasia is due to a mutation in a transmembranous domain of the gene for FGF receptor 3 (FGF-R3) located on the short arm of chromosome 4p16.3.

Most cases identified to date are caused by activating mutations at a "hot spot" at nucleotide 1138 (codon380, gly380arg) of the FGF-R3 gene and because these mutations create new recognition sites for restriction enzymes, they can be easily diagnosed. The mutation rate reported at this site indicates that it may be the most mutable gene in the human genome. The homogeneity of mutation in achondroplasia probably explains the minimal heterogeneity in its phenotype. Infants homozygous for this condition have severe disease, typically dying in infancy from respiratory insufficiency due to the small thorax. Diminished growth velocity is present from infancy, although short stature may not be evident until after 2 years of age. Mean adult heights in males and females are 130 and 120 cm, respectively. Growth curves for achondroplasia have been developed and are of value in following patients.

With increasing age, the diagnosis of achondroplasia becomes easier because these patients have characteristic abnormalities of the skeleton, including...
megaloecephaly, low nasal bridge, lumbar lordosis, short trident hand, and rhizomelia (shortness of the proximal legs and arms) with skin redundancy. Radiologic findings include small, cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance. The iliac wings are small, with narrow sciatic notches. The small foramen magnum may lead to hydrocephalus, and spinal cord and/or root compression may result from kyphosis, stenosis of the spinal canal, or disc lesions. GH secretion in these children is comparable to that in normal children.

In a mouse with an equivalent FGF-R3 mutation showing many features of human achondroplasia, there is ligand-independent dimerization and phosphorylation of FGF-R3 with activation of STAT proteins and up-regulation of cell cycle inhibition. Additionally, such mutant mice also exhibit down-regulation of expression of the Indian hedgehog and PTHrP receptor genes, which are also involved in bone formation. As a result of the overexpression of this receptor activity, there is abnormal chondrogenesis and osteogenesis during endochondral ossification.

Hypochondroplasia

Hypochondroplasia is an autosomal dominant disorder, previously described as a "mild form" of achondroplasia, that frequently results from a mutation (Asn540Lys) in the FGF-R3 gene. The two disorders do not occur in the same family. About 70% of affected individuals are homozygous for a mutation in the FGF-R3 gene, but locus heterogeneity exists as other unidentified mutations cause a similar phenotype. Mullis and co-workers, using restriction enzyme analysis, suggested that the IGF-I gene may be a candidate gene for hypochondroplasia, but other molecular abnormalities are likely to be found.

The facial features of achondroplasia are absent, and both the short stature and rhizomelia are less pronounced. Adult heights typically are in the 120- to 150-cm range. In contrast with achondroplasia, poor growth may not be evident until after 2 years of age, but stature then deviates progressively from normal. Occasionally, the disproportionate short stature is not apparent until adulthood. Outward bowing of the legs may be accompanied by genu varum. Lumbar interpedicular distances diminish between L1 and L5, and, as with achondroplasia, there may be flaring of the pelvis and narrow sciatic notches. The diagnosis is exceedingly difficult to make in young children. Mild variants of the syndrome may not be clinically distinguishable from normal, and radiologic studies should be performed if a question arises.
Mild intrauterine growth retardation (IUGR), with mean birth weights and lengths of 2800 g and 48.3 cm, respectively. Clinical trials of GH therapy in such cases are currently in progress.

Deletion of the long arm of chromosome 18 has an estimated prevalence of 1 in 40,000 live births. In a review of 50 cases, 64% of children (mean age 5.8 ± 4.5 years) had heights greater than 2 SD below the mean, with only 6% greater than 0 SDS. Fifteen percent had serum IGF-I concentrations, and 9% had IGFBP-3 concentrations below -2 SD. Seventy-two percent of children had reduced GH responses to provocative testing, although such testing was not always rigorous. Clinical trials of GH therapy in such cases are currently in progress.

**Chromosomal Abnormalities**

Abnormalities of autosomes or sex chromosomes may cause growth retardation, frequently associated with somatic abnormalities and mental retardation, as in deletion of chromosome 5 or trisomy 16 or 13. Such abnormalities, however, may be subtle, and the diagnosis of Turner's syndrome must be considered in any girl with unexplained short stature. In many cases, the precise cause of growth failure is not clear because the genetic defects do not affect known components of the GH-IGF system. The chromosomal lesion may directly influence normal tissue growth and development or, indirectly, modulate local responsivity to IGF.

**Down's Syndrome**

Trisomy 21, or Down's syndrome, is probably the most common chromosomal disorder associated with growth retardation, affecting approximately 1 in 600 live births. On average, newborns with Down's syndrome have birth weights 500 g below normal and are 2 to 3 cm shorter. Growth failure continues postnatally and is typically associated with delayed skeletal maturation and a delayed and incomplete pubertal growth spurt. Adult heights range from 135 to 170 cm in men and 127 to 158 cm in women. The cause of growth failure in Down's syndrome and in other autosomal defects is unknown.

Attempts to find underlying hormonal explanations for growth retardation have been unsuccessful, even though hypothryoidism due to Hashimoto's thyroiditis is more common than normal in Down's syndrome and should be sought. Marginal levels of GH secretion and low serum levels of IGF-I have been reported in Down's syndrome, and exogenous GH may be efficacious in the short term. It is more likely, however, that the growth failure reflects a generalized biochemical abnormality of the epiphyseal growth plate.

**Gonadal Dysgenesis**

In girls with gonadal dysgenesis (Turner's syndrome), short stature is the single most common feature, occurring more frequently than delayed puberty, cubitus valgus, or webbing of the neck. In large series of such individuals, short stature occurs in 95% to 100% of girls with a 45,X karyotype. Several distinct phases of growth have been identified in girls with Turner's syndrome:

1. Mild intrauterine growth retardation (IUGR), with mean birth weights and lengths of 2800 g and 48.3 cm, respectively.
2. Slow growth during infancy falling to -3 SDS by 3 years of age.
3. Delayed onset of the "childhood phase" of growth and progressive decline in height velocity from 3 years of age until approximately 14 years of age, resulting in further deviation from normal height percentiles.
4. A prolonged adolescent growth phase, characterized by a partial return toward normal height, followed by delayed epiphyseal fusion.

Mean adult heights in the United States and Europe range from 142.0 to 146.8 cm (lower in Asia). There are important genetic and ethnic influences on growth in these girls. Parental height correlates well with final patient height, and a cross-cultural study in 15 countries demonstrated a strong correlation between adult height and midparental height. In girls with gonadal dysgenesis and Turner's syndrome, adult heights range from 135 to 167 cm in women. Parental height correlates well with final patient height, and a cross-cultural study in 15 countries demonstrated a strong correlation between adult height and midparental height.

**(r = 0.91)** between final height in Turner's syndrome and in the normal population with an approximate 20-cm deficit.

The cause of growth failure in Turner's syndrome remains unclear. Girls have a skeletal dysplasia and are haploinsufficient for the SHOX gene (short stature homeobox-containing gene) located in the pseudoautosomal region of the short arm of the X chromosome. Mutations and deletions of this gene are associated with poor height growth and several syndromes of skeletal dysplasia including Madelung's deformity, which is also seen in Turner's syndrome. The incidence of IUGR is much greater in girls lacking two copies of the SHOX gene (46% versus 7%).

Most patients have normal GH and IGF levels during childhood; reports of low GH or IGF levels in adolescents with Turner's syndrome are likely due to low serum levels of gonadal steroids. Growth impairment is evident prior to the period when activity of the GH-IGF axis is decreased. Nevertheless, GH therapy is capable of both accelerating short-term growth and increasing adult height. This diagnosis must be considered in all girls with unexplained growth failure and especially in girls who are short for family but are growing between the 5th and 10th percentiles in the first decade of life. Nonetheless, a recent study found that the mean age at diagnosis lagged 5.3 years behind the age at which patients with Turner's syndrome fell below the 5th percentile, where its frequency is approximately 1/1000. Such data affirm the need for vigorous assessment of all girls who are either absolutely short or relatively small for family heights.

**18q Deletions**

Deletion of the long arm of chromosome 18 has an estimated prevalence of 1 in 40,000 live births. In a review of 50 cases, 64% of children (mean age 5.8 ± 4.5 years) had heights greater than 2 SD below the mean, with only 6% greater than 0 SDS. Fifteen percent had serum IGF-I concentrations, and 9% had IGFBP-3 concentrations below -2 SD. Seventy-two percent of children had reduced GH responses to provocative testing, although such testing was not always rigorous. Clinical trials of GH therapy in such cases are currently in progress.
Intrauterine Growth Retardation

Infants with IUGR comprise a heterogeneous group with birth weight and/or length below the 3rd or 10th percentile for gestational age, depending on the study. They may also be referred to as small-for-gestational-age (SGA) infants, in contrast with those who are appropriate for gestational age (AGA). The importance of this distinction, in addition to a number of issues influencing neonatal morbidity, is in the prediction of later growth: Most AGA low-birth-weight infants experience catch-up growth during the first 2 years of life, in contrast with the slower, attenuated growth of SGA infants who may have persistent height deficits throughout childhood and adolescence. First-trimester growth failure has been closely associated with low birth weight and low-birth-weight percentile. The earlier in gestation that fetal growth is impaired, the less likely that complete recapture of lost growth will occur.

IUGR can arise from abnormalities in the fetus, the placenta, or the mother (Table 23-4). Factors affecting fetal growth include nutrition provided by the maternal-placental system, alterations of fetal IGF production, and as yet unclarified genes. Although it is understandable why uterine constraint or twin pregnancies might result in limited fetal growth, the reason for abnormal fetal growth in most cases of IUGR is unclear.

The implications of IUGR may extend beyond fetal life. Although most SGA infants exhibit catch-up growth by 2 years of age, a large subgroup remains small. In a retrospective study of 47 individuals who had IUGR, 23 men had an adult height of 162 cm and 24 women had an adult height of 148 cm. Larger studies demonstrated that SGA children had a fivefold to sevenfold greater chance of short stature than AGA children did. Ten percent to 15% of SGA infants will have short stature, and this group makes up as much as 20% of all short children. In a study of a more severely affected neonatal intensive care unit SGA population, 27% had not yet achieved catch-up by 6 years of age. Final adult height is -0.8 to -0.9 SDS, which is a mean deficit of 3.6 to 4 cm when adjusted for family stature. The endocrinologic mechanisms of the poor growth are varied but may include abnormalities of GH production and secretory patterns and insensitivity to GH and IGF-I action.

The childhood and adolescent endocrine disorders associated with the SGA children include premature adrenarche, insulin resistance, functional ovarian hyperandrogenism, and an attenuated pubertal growth spurt. Furthermore, SGA infants have an increased risk of hypertension, maturity-onset diabetes mellitus, and cardiovascular disease later in life. Not all of these problems appear to occur in those IUGR babies who do not have catch-up growth, although insulin resistance has been described. Whether IUGR is causally related to these disorders or is a symptom of an underlying inborn metabolic disorder is not yet known.

In contrast with the role of the endocrine system in postnatal growth, intrauterine growth is less dependent on fetal pituitary hormones. Athyreotic and agonadal infants are of normal length and weight at birth. Pituitary GH is synthesized and secreted by the latter half of the first trimester, with midgestational levels peaking at 150 µg/L and then falling to around 30 µg/L at term. Because the anencephalic fetus is normal in size, the pituitary was thought to be unnecessary for fetal growth. However, documentation of birth size of rats and humans with congenital GHD and of human newborns with mutations of the GH or GHR genes indicate that GH from the fetal pituitary makes a small contribution to birth size. Infants with neonatal GHD are around -0.5 to

---

**Intrinsic Fetal Factors**
Other syndromes associated with moderate to profound growth failure include Bloom's syndrome, de Lange's syndrome, leprechaunism (mutations of the insulin syndrome caused by hypothalamic dysfunction. Hypertension, and congestive heart failure. Skeletal hypoplasia results in severe growth retardation, which usually becomes evident by 6 to 18 months of age. Subcutaneous fat, accompanied by alopecia, hypoplasia of the nails, joint limitation, early onset of atherosclerosis, typically followed by angina, myocardial infarction, The senile appearance characteristic of progeria be delayed or incomplete. Mental retardation of variable degrees is present in approximately 25% to 50% of patients. Although birth weight is generally within the normal range, mean growth in length and weight is below the 3rd percentile through much of childhood with a falling height velocity not dissimilar to that seen in Turner's syndrome except for the late and attenuated pubertal increments. GH secretory abnormalities do not account for the short stature, although endogenous GH production may be reduced somewhat. Exogenous IGF-I administration increases neonatal growth rate and protein and fat accretion in pigs with IUGR. Hepatic levels of GHR mRNA and of GHR are low, perhaps explaining the modest impact of GH on IGF production and linear growth. In neonates with IUGR, GH levels are elevated, and exogenous GH treatment has little or no effect on growth, body composition, or energy expenditure, further supporting a state of relative insensitivity to GH at this developmental stage. With defects of the GHR, neonatal IGF levels are low, suggesting a role for GH in regulating IGF production. Similarly, IGFBP-1's are identifiable in serum and other biological fluids in the fetus and newborn. However, serum levels of IGFBP-3 and ALS, the major serum carriers of IGF peptides in the adult, are low in the fetus and newborn. Thus, the components of the IGF system are apparently regulated directly by glucose levels or indirectly by fetal insulin secretion, with less impact of GH levels.

The role of insulin production in fetal growth is demonstrated by somatic overgrowth of the hyperinsulinemic infants of mothers with diabetes and of infants with the syndrome of persistent neonatal hyperinsulinemic hypoglycemia (nosedobilastosis). In contrast, infants with pancreatic agenesis or with abnormalities of the insulin receptor in the "leprechaun" syndrome are SGA. Further, the inverse relationship of insulin and IGFBP-1 levels and the finding that fetal IGFBP-1 levels are elevated in IUGR support an important role for insulin in fetal growth regulation. In addition to these well-characterized endocrine profiles, cord blood cortisol levels and neonatal insulin levels are inversely related to IGF-I and directly to IGFBP-3 concentrations. In infants with IUGR, a close correlation (r = -0.54) was observed between cord blood cortisol levels and length growth during the first 3 months of life. This is a period during which substantial catch-up growth occurs in some, but clearly not all, IUGR infants.

Infants with IUGR exhibiting poor postnatal growth, particularly when the abnormalities are intrinsic to the fetus, have frequently been categorized as having "primordial growth failure." Several syndromes are briefly noted in the following sections.

**Russell-Silver Syndrome**

Russell-Silver syndrome (RSS) is a condition that was independently described by Russell and by Silver and associates. Although this syndrome is probably due to a heterogeneous group of disorders, the common findings include IUGR, postnatal growth failure, congenital hemihypertrophy, and small, triangular facies. Nonspecific findings include clinodactyly, precocious puberty, delayed closure of the fontanelles, and delayed bone age. Adults are short, with final heights about 4 SD below the mean. Endogenous GH secretion in prepubertal children with RSS is similar to that in other short IUGR children and less than in AGA short children.

Because no genetic or biochemical basis for this disorder has been identified, RSS is often used incorrectly as a designation for IUGR of unknown etiology. Maternal uniparental disomy of chromosome 7 exists in 7% to 10% of cases. Candidate genes in chromosome region 7p11-13, such as those for IGFBP-1, IGFBP-3, and IGF-R, all show biallelic expression, but a growth suppression gene, GB10, which binds to the insulin and IGF-I receptors and replicates asynchronously, remains a candidate gene for overexpression. Paternally expressed imprinted genes at 7q32, PEG/MEST, and g2-COP are other candidates.

**Seckel's Syndrome**

Originally described by Mann and Russell in 1959. The condition most commonly termed Seckel's syndrome is also known as Seckel's bird-headed dwarfism. The syndrome is an autosomal recessive disorder characterized by IUGR and severe postnatal growth failure, combined with microcephaly, prominent nose, and micrognathia. Final height is typically 90 to 110 cm, with moderate to severe mental retardation. The nature of the underlying defect is unknown, although the gene defect may be at 3p22.1-q24.

**Noonan's Syndrome**

Although Noonan's syndrome shares certain phenotypic features with Turner's syndrome, the two disorders are clearly distinct. In Noonan's syndrome, the sex chromosomes are normal and transmission is apparently autosomal dominant; neither the gene locus nor product has been identified, although linkage with chromosome 12 has been demonstrated. Both males and females may be affected, which may explain the misleading terms Turner-like syndrome and male Turner's syndrome. Affected individuals typically have webbing of the neck, a low posterior hairline, ptosis, cubitus valgus, and malformed ears. Cardiac abnormalities are primarily right-sided (pulmonary valve) rather than the left-sided lesions (aorta, aortic valve) characteristic of Turner's syndrome.

Although birth weight is generally within the normal range, mean growth in length and weight is below the 3rd percentile through much of childhood with a falling height velocity not dissimilar to that seen in Turner's syndrome except for the late and attenuated pubertal increments. GH secretory abnormalities do not account for the short stature, although endogenous GH production may be reduced somewhat. Microphallus and cryptorchidism are common, and puberty may be delayed or incomplete. Mental retardation of variable degrees is present in approximately 25% to 50% of patients.

**Progeria**

The senile appearance characteristic of progeria (Hutchinson-Gilford syndrome) is generally apparent by 2 years of age. There is a progressive loss of subcutaneous fat, accompanied by alopecia, hypoplasia of the nails, joint limitation, early onset of atherosclerosis, typically followed by angina, myocardial infarction, hypertension, and congestive heart failure. Skeletal hypoplasia results in severe growth retardation, which usually becomes evident by 6 to 18 months of age.

**Cockayne's Syndrome**

Cockayne's syndrome, like progeria, is characterized by a premature senile appearance. Retinal degeneration, photosensitivity of the skin, and impaired hearing may also be present. Growth failure typically appears at 2 to 4 years of age. Transmission is as an autosomal recessive disorder.

**Prader-Willi Syndrome**

Growth failure in Prader-Willi syndrome may be evident at birth and is more impressive postnatally. It is considered at length in the discussion of IGF deficiency syndrome caused by hypothalamic dysfunction. Other syndromes associated with moderate to profound growth failure include Bloom's syndrome, de Lange's syndrome, leprechaunism (mutations of the insulin receptor gene), Ellis-van Creveld syndrome, Aarskog's syndrome, Rubinstein-Taybi syndrome, multiple endocrine (Perner's syndrome), Dubowitz's syndrome, and Johanson-Blizzard syndrome. It is interesting that the gene for the ghrelin receptor is close to the mapped location of de Lange's syndrome.
Maternal and Placental Factors

Maternal factors and placental insufficiency can impair fetal growth. Although such affected infants have better growth potential compared with infants with "primordial growth failure," postnatal growth is not always normal. Maternal nutrition is an important contributor to fetal growth and to the child's growth during the first year of life. Fetal growth retardation may also result from alcohol consumption during pregnancy and from use of cocaine, marijuana, and tobacco. The mechanisms of such drug-induced fetal growth retardation are unclear but probably include uterine vasoconstriction and vascular insufficiency, placental abruption, and premature rupture of membranes. Although maternal tobacco use is, statistically, a major contributor to reduced fetal size, it is unlikely, by itself, to result in severe IUGR.

The maternal hormonal milieu is affected by placental steroids and peptides, especially placental GH and human placental lactogen (hPL), also called human chorionic somatomammatropin (hCS), which influence the production of maternal IGF-I. Maternal IGF affects placental function and may facilitate transport of nutrients to the fetus and maternal IGF-I levels correlate with fetal growth. Hasegawa and colleagues have found increased levels of free (non-IGFBP bound) IGF-I levels during normal human pregnancy, possibly due to accelerated proteolysis of IGFBP-3.

The placenta has multiple functions, including the transport of nutrients, oxygen, and waste and production of hormones, and it consumes oxygen and glucose brought to it by the uterine circulation. Placental GH affects maternal IGF production that in turn affects placental function. The finding of normal levels of placental GH and IGF-I in a woman with Pit-1 deficiency supports the importance of placental GH action. Additionally, ghrelin message and peptide are present in human placentae during the first trimester.

hPL is a major regulator of glucose, amino acid, and lipid metabolism in the mother, aiding in the mobilization of nutrients for transport into the fetus. Damage to the placenta by vascular disease, infection, or intrinsic abnormalities of the syncytiotrophoblasts can impair these important functions. Sometimes, but not always, examination of the placenta can reveal diagnostic information as to the pathogenesis of IUGR. An X-linked homeobox gene, Esx1, detected only in extraembryonic tissues and human testis, is a chromosomally imprinted regulator of placental morphogenesis. Heterozygous and homozygous mutant mice were born 20% smaller than normal and had large edematous placentae. Vasculature was abnormal at the maternal-fetal interface, presumably causing the growth retardation.
SECONDARY GROWTH DISORDERS

Malnutrition

Given the worldwide presence of undernutrition, it is not surprising that inadequate caloric and protein intake is the most common cause of growth failure. Marasmus refers to cases with an overall deficiency of calories, including protein malnutrition. Subcutaneous fat is minimal, and protein wasting is marked. Kwashiorkor refers to inadequate protein intake, although it may also be characterized by some caloric undernutrition. In both conditions, multiple deficiencies of vitamins and minerals are apparent. Frequently, the two conditions overlap. Decreased weight growth generally precedes the failure of linear growth by a very short time in the neonatal period and by several years at older ages. Stunting of growth in early life has life-long consequences, resulting in diminished height growth.

Both acute and chronic malnutrition affects the GH-IGF system. The impaired growth is usually associated with elevated basal and stimulated serum GH levels, but in generalized malnutrition (marasmus) GH levels may be normal or low. In both conditions, serum IGF-I levels are reduced. Malnutrition may consequently be considered a form of GHI, with serum IGF-I levels reduced despite normal or elevated GH levels. GHBP levels, as a reflection of GHR content, are decreased. GH may be an adaptive response, whereby protein is spared by the lipolytic and anti-insulin actions of GH. Reduced serum IGF-I levels would serve to shift calories from anabolic to survival requirements. These adaptive mechanisms are accompanied by changes in serum IGFBPs to further limit IGF action during periods of malnutrition.

Inadequate calorie and protein intake complicates many chronic diseases that are characterized by growth failure. Anorexia is a common feature of renal failure and inflammatory bowel disease and occurs with cyanotic heart disease, congestive heart failure, CNS disease, and other illnesses. Some of these conditions, furthermore, may be characterized by deficiencies of specific dietary components, such as zinc, iron, and vitamins, necessary for normal growth and development.

Undernutrition may also be voluntary, as with dieting and food fads. Caloric restriction is especially common in girls during adolescence, when it may be associated with anxiety concerning obesity, and in gymnasts and ballet dancers. Anorexia nervosa and bulimia are extremes of "voluntary" caloric deprivation and are commonly associated with impaired growth, prior to epiphyseal fusion, that may result in diminished final adult height. Adolescent bone mineral accretion is impaired and significant osteopenia may persist into adulthood. Later in adolescence, malnutrition may cause delayed puberty and menarche and a variety of metabolic alterations. In anorexia nervosa, hormonal profiles are similar to those in protein-energy malnutrition, with high basal levels of GH but low levels of IGF-1, IGFBP-3, and GHBP. GHBP and IGFBP-3 levels correlate with body mass index, as in normal children. The hormones of the GH-IGF axis return to normal levels with refeeding.
Chronic Diseases

Malabsorption and Gastrointestinal Diseases

Intestinal disorders that impair absorption of calories or protein cause growth failure, for many of the reasons cited earlier. Growth retardation may predate other manifestations of malabsorption and chronic inflammatory bowel disease. Accordingly, celiac disease (gluten-induced enteropathy) and regional enteritis (Crohn's disease) should be considered in the differential diagnosis of unexplained growth failure. Serum levels of IGF-I may be reduced, reflecting the malnutrition, and it is crucial to discriminate between these conditions and GHD or related disorders causing IGF-I deficiency. Documentation of malabsorption requires demonstration of fecal wasting of calories, especially fecal fat, along with other measures of gut dysfunction such as the D-xylene or breath hydrogen studies.

In celiac disease (Fig. 23-42), impaired linear growth may be the first manifestation of disease. In European studies, celiac disease is the cause of unexplained growth impairment in 5% to 20% of unselected patients. The onset and progression of puberty may be delayed, and menarche may be late. Accordingly, a screening test for celiac disease is needed to obviate the standard diagnostic tests involving multiple intestinal biopsies in assessments of asymptomatic patients.

Both immunoglobulin G (IgG) and IgA antiendomysial antibodies have relatively high sensitivity and specificity but have been largely supplanted by IgA tissue transglutaminase antibodies. IgA deficiency is the most common immunodeficiency in assessments of antibody data. Nonetheless, the diagnosis of celiac disease ultimately requires demonstration of the characteristic mucosal flattening in small bowel biopsy. Changes in the serologic profiles mirror the clinical status obviating the need for subsequent biopsies. Gluten withdrawal is a highly effective treatment for celiac disease and results in rapid catch-up growth and decreased clinical symptoms during the first 6 to 12 months of treatment. Low IGF-I and IGFBP-3 levels return to normal during this period. Most children who receive appropriate dietary management ultimately achieve a normal final height.

Growth failure in Crohn's disease is probably due to a combination of malnutrition from malabsorption and anorexia, chronic inflammation, inadequacy of trace minerals in the diet, and use of glucocorticoids. IGF-I levels are low, especially with impaired growth. One third to two thirds or more of children with Crohn's disease have impaired growth at diagnosis, and occasional patients have significant growth failure as the first evidence of Crohn's disease. Osteopenia is common. An elevated erythrocyte sedimentation rate, anemia, and low serum albumin are useful clues, but diagnosis ultimately requires colonoscopy and biopsy along with gastrointestinal imaging studies.

Long-term treatment includes enteral and parenteral nutrition, anti-inflammatory agents, alternate-day steroid therapy, and judicious operative intervention. Newer therapeutic alternatives may include GH. Permanent impairment of linear growth and deficits of final height may occur in 30% of patients.

Chronic Liver Disease

Impaired linear growth and short stature with chronic liver disease in childhood are caused by decreased food intake, fat and fat-soluble vitamin malabsorption, trace element deficiencies, and abnormalities of the GH-IGF system. Decreased levels of IGF-I, IGFBP-3, and increased GH secretion define the acquired GH syndrome.

A close correlation between GH-dependent peptides and liver function indicates the dominant regulatory role of damaged hepatocytes in end-stage liver failure. Low levels of full-length and truncated GHRs in the cirrhotic liver and consequent diminished release of GHB P substantiate the GHI. Despite provision of adequate calories, insensitivity to the action of GH persists.

Liver transplantation prolongs life expectancy, but linear growth is variably improved in the early post-transplantation years. Exogenous glucocorticoid administration presumably plays a major role in the continued growth retardation; GH and IGFBP-3 production are normal, but the amount of "free IGF" may be decreased because IGFBP-3 levels are relatively high. Post-transplantation growth is inversely correlated with age and directly correlated with degree of growth improvement at transplantation. Exogenous GH treatment, for a period of 18 months, enhances growth rates and increases median height SDS by 0.7 unit.

Cardiovascular Disease

Congenital heart disease with cyanosis or chronic congestive failure can cause growth failure. As many as 27% of children with varied cardiac lesions were below the 3rd percentile for height and weight in one survey, and 70% were lower than the 50th percentile in another. Because cardiac defects are usually congenital, many infants have dysmorphic features and IUGR.

Inadequate cardiac intake is the most common cause of growth impairment in children with congenital heart disease frequently associated with anorexia and vomiting. Chronic congestive heart failure is associated with malabsorption that includes protein-losing enteropathy, intestinal lymphangiectasia, and steatorrhea. Greater cardiac and respiratory work and the relatively higher ratio of metabolically active, energy-utilizing brain and heart to the growth-related body mass (cardiac cachexia) causes an increased basal metabolic rate in these children. Food intake that appears adequate for the child's weight is thus inadequate for normal growth. The degree of cyanosis or hypoxia does correlate with the degree of growth impairment. Decreased levels of IGF-I and IGFBP-3 and normal levels of GH and hepatic GHRs in chronically hypoxic newborn sheep suggest GHI distal to the GHR. Linear growth and pubertal maturation depend on left ventricular function in children and adolescents with complicated rheumatic heart disease.

Corrective surgery may restore normal growth, frequently after a phase of catch-up growth with normalization of energy expenditure. Surgery must, on occasion, be delayed until the infant reaches an appropriate size, resulting in the conundrum that surgery corrects growth failure but cannot be performed because the infant is too small. In these situations, meticulous attention to caloric support and alleviation of hypoxia and heart failure is necessary to promote growth prior to surgery. Fortunately, this problem has diminished because of operative successes in the neonatal period.

The nutritional management of these infants includes calorie-dense feedings, because of the need to restrict fluids; calcium supplementation, because of the use of...
diuretics that may cause calcium loss in the urine, and iron, to maintain an enhanced rate of erythropoiesis.

**Renal Disease**

All conditions that impair renal function can impair growth. Uremia and renal tubular acidosis can cause growth failure before other clinical manifestations become evident. The growth impairment results from multiple mechanisms, including inadequate formation of 1,25-dihydroxycholecalciferol (1,25 [OH]2 D) with resultant osteopenia, decreased calcitic intake, loss of electrolytes necessary for normal growth, metabolic acidosis, protein wasting, insulin resistance, chronic anemia, and compromised cardiac function as well as from impaired GH and IGF production and action. In nephrotic cytostasis, acquired hypothyroidism contributes to the inadequate growth. Sixty percent to 75% of patients with chronic renal failure treated prior to the GH therapeutic era had a final adult height more than -2 SD below the mean.

Children and adolescents have normal or elevated circulating levels of GH, depending on the degree of renal failure. In children with end-stage renal disease (ESRD) on dialysis or preterminal chronic renal failure (CRF), the half-life of GH is prolonged twofold. The number of secretory bursts was increased in ESRD by twofold to threefold over chronic renal failure and controls and mean levels of GH were 2.5-fold higher in ESRD than in chronic renal failure patients or controls. Overall, children with ESRD produced substantially more GH than either chronic renal failure patients or controls. Early reports of decreased serum IGF-I levels in uremia were an artifact due to inadequate separation of IGF from IGFBPs prior to assay. Decreased hepatic IGF production is possibly due to low hepatic irinocortisol gene expression. Additionally, the uremic state may cause a postreceptor defect in GH signal transduction by diminishing phosphorylation and nuclear translocation of GH-activated STAT proteins. Serum IGF-I and -II levels are, however, usually normal, but increases in serum IGFBPs, especially IGFBP-1, may inhibit GH action.

In patients with nephrotic syndrome, serum levels of IGF-I and IGFBP-3 are low because of urinary loss of IGF-IGFBP complexes. Chronic glucocorticoid therapy for a variety of renal disorders can exacerbate growth retardation by diminishing GH release and blunting IGF-I action at growth plates. Chronic renal disease, especially ESRD, with increased GH levels and production, low levels of IGF-I, and poor growth is thus a state of relative resistance to GH and, in some instances, to IGF-I. Overall, serum IGF-I levels in ESRD may be normal. In the large cohort of patients in the North American Pediatric Renal Transplant Cooperative Study, the mean height increased after transplantation by only 0.11 SD in the first 4.5 years. The youngest age group (≤2 years) had the largest deficit and the most catch-up growth (0.94 SD); children between 6 and 17 years of age showed no improvement in SD score. Although the mortality rate in the younger age group was 16%, more recent studies suggest that transplantation may have an acceptable risk in such patients. Growth-retarded post-transplantation children, whether receiving daily or alternate-day glucocorticoid treatment, have decreased GH secretion, normal levels of IGF-I and IGFBP-1, and increased levels of IGFBP-3. They differ from patients with ESRD in that IGFBP-1 levels are not strikingly elevated, perhaps because of altered glucose tolerance and hyperinsulinism due to chronic glucocorticoid therapy.

Even after successful renal transplantation, growth height may not be normal. After successful renal transplantation, mean height increased after transplantation by only 0.11 SD in the first 4.5 years. The youngest age group (<2 years) had the least growth. The number of secretory bursts was increased in ESRD by twofold to threefold over chronic renal failure and controls and mean levels of GH were 2.5-fold higher in ESRD than in chronic renal failure patients or controls. Overall, children with ESRD produced substantially more GH than either chronic renal failure patients or controls. Early reports of decreased serum IGF-I levels in uremia were an artifact due to inadequate separation of IGF from IGFBPs prior to assay. Decreased hepatic IGF production is possibly due to low hepatic irinocortisol gene expression. Additionally, the uremic state may cause a postreceptor defect in GH signal transduction by diminishing phosphorylation and nuclear translocation of GH-activated STAT proteins. Serum IGF-I and -II levels are, however, usually normal, but increases in serum IGFBPs, especially IGFBP-1, may inhibit GH action.

In patients with nephrotic syndrome, serum levels of IGF-I and IGFBP-3 are low because of urinary loss of IGF-IGFBP complexes. Chronic glucocorticoid therapy for a variety of renal disorders can exacerbate growth retardation by diminishing GH release and blunting IGF-I action at growth plates. Chronic renal disease, especially ESRD, with increased GH levels and production, low levels of IGF-I, and poor growth is thus a state of relative resistance to GH and, in some instances, to IGF-I. Overall, serum IGF-I levels in ESRD may be normal. In the large cohort of patients in the North American Pediatric Renal Transplant Cooperative Study, the mean height increased after transplantation by only 0.11 SD in the first 4.5 years. The youngest age group (≤2 years) had the largest deficit and the most catch-up growth (0.94 SD); children between 6 and 17 years of age showed no improvement in SD score. Although the mortality rate in the younger age group was 16%, more recent studies suggest that transplantation may have an acceptable risk in such patients. Growth-retarded post-transplantation children, whether receiving daily or alternate-day glucocorticoid treatment, have decreased GH secretion, normal levels of IGF-I and IGFBP-1, and increased levels of IGFBP-3. They differ from patients with ESRD in that IGFBP-1 levels are not strikingly elevated, perhaps because of altered glucose tolerance and hyperinsulinism due to chronic glucocorticoid therapy.

Overall, height SDS at the time of transplantation and use of alternate-day glucocorticoid therapy after transplant correlate positively with final height, and longer duration of reduced GFR and higher cumulative dose of prednisone have a negative impact; other factors, such as gender, age at transplant, diagnosis, and number of transplants, do not seem to have a significant impact on adult height. The importance of height at the time of transplantation in determining final adult height, despite complex post-transplantation health issues, confirms the value of improving growth velocity and absolute height prior to transplantation. Children who receive tacrolimus (FK-506)-based immunosuppression, allowing discontinuation of glucocorticoids, have normal growth and absence of obesity.

Although the growth failure of renal disease in the pretransplantation period is not specifically due to either GH or IGF deficiency, GH therapy accelerates skeletal growth and is approved by the U.S. Food and Drug Administration (FDA) for use. Such treatment probably increases the molar ratio of IGF peptides to IGFBPs and may override the inhibitory actions of IGFBPs. GH administration may also be useful for treatment of post-transplantation growth failure.

**Hematologic Disorders**

Chronic anemia, such as sickle cell disease, is characterized by growth failure. In general, the decrease in height and weight is greater in adolescent years than earlier because the onset of the adolescent growth spurt is delayed and menarche is late. The adolescent growth and final adult height in sickle cell disease, however, may be normal. The causes of growth retardation probably include impaired oxygen delivery to tissues, increased work of the cardiovascular system, energy demands of increased hematopoiesis, and impaired nutrition. The GH-IGF system probably does not have an important role in the growth impairment of sickle cell anemia.

In thalassemia, in addition to the consequences of chronic anemia, endocrine deficiencies can result from chronic transfusions and accompanying hemosiderosis. Despite vigorous efforts to maintain hemoglobin levels near normal and to avoid iron overload, growth failure is still a common feature of thalassemia, even in transfusion-dependent adolescents. The pathophysiological defects include disproportional growth with truncal shortening but normal leg length. It is likely that anemia, impaired IGF-I synthesis, hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism all contribute to growth failure in this disorder. GH is suggested by generally adequate GH production with low IGF-I levels. In most patients, GH treatment increases growth at least initially. About half of the patients in the International Fanconi Anemia Registry have short stature. GH was demonstrated by provocative testing (22 of 48) or with assessment of endogenous secretion (13 of 13) in a group with mean height of -2.23 SDS. A longitudinal study of 46 children whose diabetes began before 10 years of age indicated that initial heights at diagnosis were normal and that the final height SDS was minimally reduced from that at onset. In boys, despite a delay of about 2.5 years in onset of puberty, total pubertal height gain was normal. In girls with diabetes mellitus, however, total pubertal height gain was diminished and the adolescent growth spurt was not delayed; the effects of increased insulin and IGF-I levels on ovarian function have not been assessed in such patients. Chronic metabolic control did not correlate with the pubertal height gain or with the normal final heights. Nevertheless, good glycomic control at certain maturational periods, such as puberty, may improve growth during those intervals.

**Diabetes Mellitus**

Although weight loss may occur immediately before the onset of clinically apparent IDDM, children with new-onset diabetes are frequently taller than their peer group, possibly because GH and insulin levels are increased during the preclinical evolution of the disease. Most children with IDDM grow quite normally, even those with marginal control, especially in prepubertal years, although growth velocity may decrease during puberty. Growth failure, however, can occur in diabetic children with long-standing disease. Growth failure in those with IDDM, severe growth failure, and hepatosplenomegaly may be due to excess hepatic glycol gen deposition. This type of growth retardation has become increasingly rare.

Many pathophysiologic processes, including malnutrition, chronic intermittent acidosis, increased gluco norticoid production, hypothyroidism, impaired calcium balance, and “end-organ uteropituitaryness” to either GH or IGF, may contribute to growth failure in those with IDDM. Reflecting acquired GHI, GHBP levels are decreased, supporting the concept of impaired GH function or number. Further, IGFBP-1 is normally suppressed by insulin, and hypoinsulinemia results in elevated serum IGFBP-1 levels, which may inhibit IGF action. In contrast to the situation in adolescents and adults, IGFBP-1 levels are not elevated in well-growing prepubertal children. On the contrary, increased IGFBP-3 proteolysis may enhance the bioactivity of the available IGF-I. Most children with IDDM, however, attain normal cellular nutrition and growth factor action despite intermittent hypoinsulinemia and derangements of peripheral indices of the GH-IGF system.

Although glycomic control is inversely correlated with IGF-I levels, the correlation between glycomic control and growth is weak. With conflicting reports as to the influence of glycomic regulation on growth, a longitudinal study of 46 children whose diabetes began before 10 years of age indicated that initial heights at diagnosis were normal and that the final height SDS was minimally reduced from that at onset. In boys, despite a delay of about 2.5 years in onset of puberty, total pubertal height gain was normal. In girls with diabetes mellitus, however, total pubertal height gain was diminished and the adolescent growth spurt was not delayed; the effects of increased insulin and IGF-I levels on ovarian function have not been assessed in such patients. Chronic metabolic control did not correlate with the pubertal height gain or with the normal final heights. Nevertheless, good glycomic control at certain maturational periods, such as puberty, may improve growth during those intervals.

**Inborn Errors of Metabolism**
Inborn errors of metabolism are often accompanied by growth failure that may be pronounced. Glycogen storage disease, the mucopolysaccharidoses, the glycogeninases, and the mucolipidoses are characterized by poor growth. Many inborn metabolic disorders are also associated with significant skeletal dysplasia. In a small number of patients with organic acids (e.g., methylmalonic and propionic acidurias), IGF-I levels are low and GH levels are normal, suggesting a possible state of GHR related to nutritional status. Preliminary data suggest that exogenous GH treatment may improve the metabolic status of such children.

**Pulmonary Disease**

Growth can be retarded in children with asthma who have not received glucocorticoid therapy. Mean height and growth velocity and degree of growth failure are related to the severity of the asthma. Delayed pubertal maturation in such patients is also associated with growth deceleration in early adolescence. Impaired nutrition and increased energy requirements along with chronic stress, especially with nocturnal asthma and enhanced endogenous glucocorticoid production, cause poor linear growth. The lowered growth in asthmatic children does not appear to be associated with abnormalities of the GH-IGF axis. Glucocorticoid therapy, generally given to more severely affected patients, further impairs growth throughout childhood. Synthetic glucocorticoids, such as prednisone or dexamethasone, may have a greater growth-suppressive effect than equivalent therapeutic doses of cortisol, presumably because the biopotency of the synthetic agents may be underestimated. Alternate-day or aerosolized glucocorticoid therapy often ameliorates growth retardation and can be associated with an accelerated catch-up phase.

The use of spacer devices and effective nebulizer solutions may permit use of inhaled glucocorticoids in young children without growth impairment. Clearly, however, sufficient glucocorticoid delivered by any route can diminish growth and impede the function of the adrenal gland. Nonetheless, judicious utilization of inhaled glucocorticoid results in normal adult height despite long-term exposure and an initial decrement of linear growth velocity. Indeed, examination of near adult heights of Swedish men with asthma demonstrated an improvement in the mean difference between “severe” asthmatics and normal controls in the era of inhaled corticosteroid use. Overall, normal adult height is usually achieved.

Bronchopulmonary dysplasia (BPD), a sequel of hyaline membrane disease and prematurity, is characterized by an incidence as high as 35% in very-low-birth-weight infants (<1500 g). The use of dexamethasone in the neonatal treatment of BPD causes a transient cessation of growth and has engendered long-term concern for neurodevelopment and somatic growth. Growth in surviving infants is poor through early childhood, but the defect generally disappears by 8 years of age. Long-term hypoxia, poor nutrition, chronic pulmonary infections, and reactive airway disease are responsible for the poor early growth.

In patients with cystic fibrosis (CF), chronic pulmonary infection with bronchiectasis, pancreatic insufficiency with exocrine and endocrine inadequacy, malabsorption, and malnutrition all contribute to decreased growth and late sexual maturation. In 17,857 patients with CF, mean height was at the 21st percentile and mean weight was at the 9th percentile. Early impairment of height and weight growth and retardation of skeletal maturation may progress or plateau during middle childhood years but become most marked in the preadolescent period when growth and maturational changes are delayed.

The degree of growth retardation is related most closely to the severity and variability of the pulmonary disease rather than to pancreatic dysfunction. The degree of steatorrhea does not correlate well with growth impairment, although improved nutrition programs enhance the overall clinical picture. Adult heights in surviving patients with CF approach the normal range. Endocrine abnormalities, such as failure of both alpha and beta islet cells with decreased glucagon and insulin production do not seem to influence prepubertal growth patterns in children with CF. The incidence of diabetes mellitus increases as patients live past the second decade. Alterations of vitamin D metabolism, although potentially affecting skeletal mineralization, do not diminish growth. Delayed sexual maturation in which GnRH administration evokes a prepubertal pattern of pituitary gonadotropin secretion in adolescent patients is similar to that in CDGM. The GH-IGF axis shows evidence for acquired GH with lowered mean IGF-I and elevated GH levels.

GHT treatment of prepubertal children with CF for 1 year resulted in anabolic effect with greater growth velocity and nitrogen retention and increased protein and decreased fat stores. Pulmonary function improved in most patients. A 4-year longitudinal study using the National Cystic Fibrosis Foundation Registry found that improved nutrition status and growth were associated with a slower age-related decrement of pulmonary function.

**Chronic Inflammation and Infection**

Poor growth is a characteristic feature of chronic inflammatory disease and recurrent serious infection. We have discussed impaired growth associated with disorders such as Crohn’s disease, CF, and asthma in which inflammatory processes may be significant. De Benedetti and co-workers, studying juvenile rheumatoid arthritis in humans and a transgenic murine model expressing excessive IL-6, demonstrated an IL-6-mediated decrease in IGF-I production to be a credible mechanism by which chronic inflammatory disease could lead to poor growth. The close relationship of the GHR to that of multiple cytokines makes this an interesting hypothesis. A complex cascade of cytokines, as part of the inflammatory response to acute and chronic infection, can impact the endocrine system at many levels, impairing mineral and nutrient metabolism and the growth and remodeling of bone.

Exposure to human immunodeficiency virus (HIV) in children and adolescents occurs through perinatal transmission, blood transfusions, drug usage and sexual contact, most commonly via perinatal transmission from HIV-infected mothers. Growth failure is a cardinal feature of childhood acquired immunodeficiency syndrome (AIDS). Mean height and weight measurements during early childhood years are at or below -1 SD below the mean, but weight-for-height data may be normal in contrast with the “wasting” syndrome described in adult patients with AIDS.

In a drug treatment study of 88 HIV-infected children (mean age, 3.1 years), more than 90% were below the 50th percentile for both height and weight. Only 44% of this group survived 4 years after initiation of the study. Height or growth velocity is not a useful predictive indicator for survival. In hemophilic boys with HIV growth impairment, delayed pubertal onset and progression, and lower skeletal age were common. Despite this delayed pubertal maturation, serum testosterone levels were not significantly decreased. In many developing countries, chronic infection with parasites (e.g., schistosomiasis, hookworm, roundworm) contributes to nutritional debilitation and growth failure.
Endocrine Disorders

Hypothyroidism

Growth may be retarded in children with hypothyroidism, but the development of newborn screening programs for congenital hypothyroidism has resulted in more prompt diagnosis and treatment of such newborns (1/4100 live births). Growth in appropriately treated infants and children with congenital hypothyroidism is normal for age.\(^{[900]}\) so that skeletal maturation approximates chronologic age.\(^{[901]}\) These data do demonstrate the essential role of T\(_4\) in linear growth during the first year of life.\(^{[902]}\) Pubertal growth and maturation and final adult height are normal in well-treated congenital hypothyroidism.\(^{[903]}\)

Many features of adult myxedema are present in children with hypothyroidism. The most prominent manifestation of acquired hypothyroidism is growth failure, which may be profound.\(^{[904]}\) In acquired hypothyroidism, growth retardation may take several years to become clinically evident; once present, however, it is typically severe and progressive. The poor growth is more apparent in height than in weight gain, so those children tend to be overweight for height.

Rivkees and associates\(^{[905]}\) reported a mean 4.2-year delay between slowing of growth and the diagnosis of hypothyroidism. At diagnosis, girls were 4.04 SD below and boys 3.15 SD below mean heights for age. (This is one of several situations in which the diagnosis of short stature is later in girls than in boys.) Body proportion is immature, with an increased upper body to lower body segment ratio. Skeletal age is usually markedly delayed. Although chronic hypothyroidism is usually associated with delayed puberty, precocious puberty and premature menarche can occur in hypothyroid children (see Chapter 24).

The diagnosis of primary hypothyroidism is usually straightforward. Serum levels of T\(_4\) are reduced, and thyrotropin levels are elevated. The presence of antithyroid antibodies (usually thyroperoxidase antibodies) is consistent with a diagnosis of Hashimoto's thyroiditis, the most common cause of acquired childhood hypothyroidism in the United States. Isolated secondary or tertiary hypothyroidism, due to thyrotrpin or thyrotropin-releasing hormone (TRH) deficiency, respectively, is a rare cause of hypothyroidism.

Replacement therapy results in rapid catch-up growth. Nevertheless, accelerated growth may not restore full growth potential because rapid skeletal maturation is rapid during the first 18 months of treatment.

In one study of profoundly hypothyroid children, those treated at a mean chronologic age of 11 years had adult heights approximately -2 SD below the mean, final heights that were lower than midparental and predicted adult heights.\(^{[906]}\) The deficit in adult stature correlated with the duration of hypothyroidism before initiation of treatment.

In a separate study of hypothyroid children treated at a mean age of 9 years and with a 3-year delay of bone age, mean height SDS for bone age fell from +0.59 to -0.55 in girls and from +1.6 to -0.87 in boys. Catch-up growth may be particularly compromised when therapy is initiated near puberty.\(^{[907]}\)

On the basis of these studies, it may be appropriate to use lower than usual replacement dosages of levothyroxine and to consider a pharmacologic delay of puberty in children treated at a young age.\(^{[908]}\) Replacement therapy results in rapid catch-up growth. However, accelerated growth may not restore full growth potential because rapid skeletal maturation is rapid during the first 18 months of treatment.

Cushing's Syndrome

Glucocorticoid excess impairs skeletal growth,\(^{[909]}\) interferes with normal bone metabolism by inhibiting osteoblastic activity, and enhances bone resorption.\(^{[910]}\) Regardless of whether Cushing's syndrome is due to ACTH hypersecretion, adrenal tumor, or glucocorticoid administration. The effects of glucocorticoids are probably at the level of the epiphysis because GH secretion and serum concentrations of IGF peptides and IGFBPs are usually normal.

GH treatment cannot completely overcome the growth-inhibiting effects of excess glucocorticoids, although short-term GH or IGF-I administration can diminish many of the catabolic effects.\(^{[911]}\) Linear growth in children receiving glucocorticoids falls during GH therapy if the exogenous prednisone dose is greater than 0.35 mg/kg per day.\(^{[912]}\) The “toxic” effects of glucocorticoids on the epiphysis may persist, in part, after correction of chronic glucocorticoid excess, and patients frequently do not attain target heights.\(^{[913]}\) The longer the duration and the greater the intensity of glucocorticoid excess, the less likely is catch-up growth to be completed. Therefore, exposure to glucocorticoids should be limited as much as the underlying condition allows, frequently by the use of alternate-day therapy.

Adrenal tumors secreting large amounts of glucocorticoids can produce excess androgen, which may mask growth-inhibitory effects of glucocorticoids. In addition, Cushing's syndrome in children may not cause all the clinical signs and symptoms associated with the disorder in adults and may present with growth arrest. However, Cushing's syndrome is an unlikely diagnosis in children with obesity, because exogenous obesity is associated with normal or even accelerated skeletal growth and growth deceleration is generally evident by the time other signs of Cushing's syndrome appear (Fig. 23-43). In a series of 10 children and adolescents treated for Cushing's disease with surgery and cranial radiation, mean final height was -1.36 SDS. Post-therapy GHD was common, and GH replacement contributed to a positive change of the difference between height and target height from diagnosis to final height (-0.72 to -0.93).\(^{[914]}\)\(^{[915]}\)

![Figure 23-43](image)

Figure 23-43 Growth curves of two boys with obesity. The boy depicted by the circles had cortisol excess related to Cushing's disease. An onset of rapid weight gain was associated with a decrease in linear growth velocity at 7 years of age. The diagnosis was established, and an adrenalectomy (arrow) was performed at the age of 8½ years, with an almost immediate increase in growth rate and striking catch-up. The boy whose growth is depicted by triangles had exogenous obesity. At the age of 9½ years, his weight was approximately the same as that of the patient with Cushing's disease, but his height was at the 97th percentile, reflecting the enhancement of linear growth in this individual with exogenous obesity.

Hypoparathyroidism

Pseudohypoparathyroidism (detailed in Chapter 26) is mentioned here because growth failure is a common feature.\(^{[916]}\) This condition typically combines growth failure, characteristic dysmorphic features, and hypocalcemia and hyperphosphatemia secondary to end-organ resistance to parathyroid hormone. Affected children are short and have truncal obesity with short metacarpals, subcutaneous calcifications, round facies, and mental retardation.

Rickets

In the past, hypovitaminosis D was a major cause of short stature often associated with other causes of growth failure, such as malnutrition, prematurity, malabsorption, hepatic disease, or chronic renal failure (see Chapter 27). In isolated vitamin D deficiency, breast-fed infants typically have poor exposure to sunlight and are not nutritionally supplemented with vitamin D. Characteristic skeletal manifestations of rickets include frontal bossing, craniolabes, rachitic rosary, and bowing
of the legs. Such children usually begin to synthesize 1,25(OH)\(_2\)D as they become older, broaden their diet, and have increased exposure to sunlight with amelioration of the transient early decrease of linear growth velocity.

The association of vitamin D receptor gene polymorphism with birth length, growth rate, adult stature, and bone mineral density.

**Primary Defects of IGF Synthesis**

| IGF1        | AR          | IGF-I deficiency; IUGR and postnatal growth failure | 270 | Igif | 277 |

ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHBP, GH-binding protein; GHD, GH deficiency; GHR, GH receptor; GHRH, GH-releasing hormone; GHRHR, GHRH receptor; IGF, insulin-like growth factor; IGHD, isolated GHD; LH, luteinizing hormone; PRL, prolactin; TSH, thyrotropin (thyroid-stimulating hormone).

Vitamin D-resistant (hypophosphatemic) rickets is an X-linked dominant disorder that is due to decreased renal tubular reabsorption of phosphate related to mutations in the phosphate-regulating endopeptidase gene (PHEX, Xq22.1) (see Chapter 27). The presence of high-affinity binding sites for the vitamin D receptor DNA-binding domain in the GH promoter suggests that the vitamin D receptor may actually modulate GH expression. Vitamin D-resistant rickets.

Treatment requires oral phosphate replacement, but such therapy may result in poor calcium absorption from the intestine. The addition of calcitriol to oral phosphate increases intestinal phosphate absorption and prevents hypocalcemia and secondary hyperparathyroidism. Such combined therapy does improve the rickets but does not necessarily correct growth. There is no clear association between endogenous GH secretion, IGF-I, or phosphate levels and height in this disorder. Nevertheless, GH therapy, in eight trials including 83 patients, has resulted in an enhancement of skeletal growth and improvement in bone mineral density.

IGF-I Deficiency

Because IGF-I is a major mediator of skeletal growth, its deficiency can result in severe growth failure. Causes of IGF-I deficiency include:

1. Central hypothalamic-pituitary dysfunction with failure of pituitary GH production (i.e., hypopituitarism or GHD). It may be impossible to discriminate between hypothalamic and pituitary dysfunction if both organs have the same pathologic process.
2. Primary or secondary GH insensitivity (GHI).

We use the term insulin-like growth factor I (IGF-I) deficiency syndrome to describe the generic condition, whether caused by GHD, dysfunction, or insensitivity, to illustrate this unifying concept.

It is not always possible to discriminate completely between hypothalamic and pituitary dysfunction because both organs may be involved in the same pathologic process. In addition, as described earlier, embryonic development of the hypothalamus and pituitary appears to be codependent. A number of factors produced in the developing ventral diencephalon function as molecular signals for initial formation and development of Rathke's pouch; subsequent differentiation of each of the various
anterior pituitary cell types appears to be primarily regulated by a strict temporal and spatial pattern of pituitary transcription factors. It is somewhat of a semantic issue as to whether to label some of the molecular defects either “hypothalamic” or “pituitary”; nevertheless, some arbitrary classification decisions have been made in the following discussions. Table 23-5 presents our current classification of molecular defects of the GH-IGF axis, whereas the sites of defined and likely sites of genetic defects are shown in Figure 23-44. The murine homologues of these gene defects are also listed in Table 23-5.

A potential system for analysis of the known and potential genetic errors in patients with IGF deficiency syndrome is shown in Figure 23-45. It is to be anticipated that significant development will be made in our understanding of these defects over the next few years and that this classification will require frequent updating and modification.

Clinical Features

IGF-I deficiency due to hypothalamic dysfunction with abnormalities of GHRHR, endogenous GHS or SRIF synthesis or secretion, primary or secondary decreased pituitary GH production, or GHI share a common phenotype. The similarity among these patients emphasizes the role of IGF-I in mediating most of the anabolic and growth-promoting actions of GH. This point is further supported by the capability of IGF-I therapy to correct growth in children with mutations of the GHR gene.

Accordingly, the typical clinical features of severe IGF deficiency are shared by all of these conditions. If GH or IGF deficiency is acquired, clinical signs and symptoms appear at a later age.

Birth size is normal or near normal in most children with IGF-I deficiency but low in severe congenital GHD and GHI and in the single case of a deletion of the IGF-I gene. Typically, birth length and weight are within 10% of normal, and severe IUGR is not part of typical IGF deficiency but is present in infants with profound IGF-I deficiency, confirming the critical role of IGF-I in intrauterine growth. Infants with early-onset GHD may have birth lengths of around 2 SD below the mean.

Although at least 50% of infants diagnosed before 2 years of age have birth lengths more than 2 SD below the mean (both in isolated GH and in multiple pituitary hormone deficiencies), mean birth weight is about -1 SD, lending an appearance of relative adiposity, even in the neonatal period. These data further support an intrauterine role of the GH-IGF system in growth regulation along with the high frequency of abnormalities of the hypothalamic-pituitary area defined by magnetic resonance imaging (MRI). Anatomic abnormalities include dysgenesis of the pituitary stalk, ectopic placement of the posterior pituitary inferior to the median eminence, and diminished volume of the anterior pituitary. There is high frequency of breech deliveries and perinatal asphyxia. Neonatal morbidity can include hypoglycemia and prolonged jaundice with direct hyperbilirubinemia due to cholestasis and giant cell hepatitis. When GHD is combined with deficiency of ACTH and thyrotropin, hypoglycemia may be severe. The combination of GHD with gonadotropin deficiency can cause microphallus, cryptorchidism, and hypoplasia of the scrotum. GHD (or GHI) should, therefore, be considered in the differential diagnosis of neonatal hypoglycemia and of microphallus/cryptorchidism.

Postnatal growth is abnormal in severe congenital IGF deficiency. Most surveys of GHD and GHI indicate that growth failure can occur during the first months of life.

Figure 23-44 The hypothalamic-pituitary-IGF axis: sites of established and hypothetical defects. The established defects are shown as Roman numerals in the gray-shaded circles or ovals, and the hypothetical defects are shown in the white circles or ovals. ALS, acid-labilesubunits; GH, growth hormone; GHB, growth hormone-binding protein; GHRH, growth hormone-releasing hormone; IGF, insulin-like growth factor; IGFBP, IGF-binding protein; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; STAT, signal transducer and activator of transcription. (From Lopez-Bermejo A, Buckway CK, Rosenfeld RG. Genetic defects of the growth hormone-insulin-like growth factor axis. Trends Endocrinol 2000; 11:43.)

Figure 23-45 Decision tree for the investigation of genetic defects in patients with IGF deficiency. Hypothetical genetic defects are presented in parentheses. In these defects shown with a * sign, abnormalities in other organs and structures besides the hypothalamic-pituitary-IGF axis are expected to occur as a result of these genetic defects: ACTH, adrenocorticotropic hormone; CPHD, combined pituitary hormone deficiencies; FSH, follicle-stimulating hormone; GH, growth hormone; GHI, GH receptor; GHRHR, GH-releasing hormone receptor; IGF, insulin-like growth factor; IGFIR, IGF-I receptor; LH, luteinizing hormone; PRL, prolactin; STAT5, signal transducer and activator of transcription 5; TSH, thyrotropin (thyroid-stimulating hormone). [From Lopez-Bermejo A, Buckway CK, Rosenfeld RG. Genetic defects of the growth hormone-insulin-like growth factor axis. Trends Endocrinol 2000; 11:43.]

Figure 23-46 Magnetic resonance image of infundibular dysgenesis. A, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area in a normal 8-year-old girl. The anterior pituitary (AP) and posterior pituitary (PP) lobes and the pituitary stalk (PS) are marked. B, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area of a 17-year-old boy with isolated human growth hormone deficiency. The anterior pituitary (AP) lobe is hypoplastic, the posterior pituitary (PP) lobe is ectopic, and the pituitary stalk is absent. (From Rozd AJ, Martinez CR. Magnetic resonance imaging in patients with hypopituitarism. Trends Endocrinol Metab 1990; 3:293287.)

Figure 23-47 Height measurements for Ecuadorian children with insulin-like growth factor deficiency resulting from growth hormone insensitivity. (From Rosenfield RG, Rosenblom AL, Guevara-Aguilar J. Growth hormone [GH] resistance due to primary GH receptor deficiency. Endocr Rev 1994; 15:369390. © The Endocrine Society.)

Skeletal proportions tend to be relatively normal but correlate better with bone age than with chronologic age. Skeletal age may be delayed to less than 60% of the chronologic age but in the absence of hypothyroidism is similar to the height age. In acquired GHD, as from a CNS tumor that causes increased intracranial
pressure, bone age may approximate the chronologic age; delayed skeletal maturation, therefore, should not be required for the diagnosis of GHD.

Assessment of volumetric bone mineral density reveals decreased mineralization beyond that dependent on small size. Weight-to-height ratios tend to be increased, and fat distribution is often "infantile" or "doll-like" in pattern. Musculature is poor, especially in infancy and can cause delay in gross motor development and to lead the erroneous impression of mental retardation in an immature-appearing child. Facial bone growth may be particularly retarded, with an underdeveloped nasal bridge and frontal bossing. Fontanel closure is often delayed, but the overall growth of the skull is normal, leading to cephalofacial disproportion and the appearance of hydrocephalus. The voice is infantile because of hypoplasia of the larynx. Hair growth is sparse and thin, especially during early life; nail growth is also slow. Even with normal gonadotropin production, the penis is small and puberty is usually delayed.

Final height data in patients with untreated GHD are not plentiful. Wit and colleagues summarized data from 22 untreated men and 14 women with severe isolated GHD with a mean final height SDS of -4.7. In 19 patients with multiple pituitary hormone deficiencies, thus lacking in gonadal steroids, mean final height was -3.1 SDS.

Etiology

Two surveys of nearly 63,000 GH-treated patients, in databases managed by Pharmacia (Pharmacia International Growth Database [KIGS]) and Genentech (National Collaborative Growth Study [NCGS]), cared for by pediatric endocrinologists throughout the world include more than half of the internationally treated patients. The patients are diverse and include subjects with GHD and with Turner's syndrome and miscellaneous other disorders. About 59% of the total group (37,000 patients) had GHD (as defined by a stimulated GH level of < 10 µg/L) of whom 78% had "idiopathic" GHD and 22% had "acquired" or "organic" (neoplasms, trauma, inflammation, miscellaneous) causes of GHD. The latter group includes patients with congenital (developmental) GHD-associated syndromes. The organic/acquired group is probably underestimated because many of the patients classified as idiopathic had not had definitive imaging assessments of the hypothalamic-pituitary region and possibly have congenital structural abnormalities.

With the availability of synthetic IGF-I for treatment of patients with inherited abnormalities of the GHR, approximately 200 patients with primary GHD have been identified. This is an exceedingly small number of subjects, even with the addition of the potentially larger group of individuals with heterozygous abnormalities of the GHR. In contrast, patients with secondary GHI, including those with malnutrition or chronic systemic disease, must be considered as potentially a huge number, on a worldwide basis.

An incidence of GHD of 1:6,000 live births has been reported from the United Kingdom, and a survey of Scottish schoolchildren indicated prevalence as high as 1:4,000. The best estimate in the ultimate human population is approximately 1:3,480. It is likely, however, that childhood GHD is an overdiagnosed condition. In particular, the diagnosis of acquired, idiopathic, isolated GHD should always be suspect. Although one might argue that (1) destructive or inflammatory lesions of the hypothalamus or pituitary may affect only GH secretion or (2) isolated GHD due to a mild mutation or deletion of the GHRH receptor gene or GH gene may appear late or (3) combined pituitary hormone deficiencies (CPHDs) may first present with what appears to be isolated GHD, such circumstances appear to be rare. In the absence of anatomic abnormalities evident on imaging studies, or biochemical evidence of CPHD, the diagnosis of acquired, isolated, idiopathic GHD demands careful and thorough documentation, with greater skepticism as children approach adolescence. The entity of partial, transient GH insufficiency related to sex steroid deficiency in delayed puberty is particularly confounding.

Central Hypothalamic-Pituitary Abnormalities

Many of the disorders that affect hypothalamic regulation of GH synthesis and secretion also have a direct impact on pituitary function. Consequently, it is not always possible to definitively establish the primary of hypothalamic or pituitary dysfunction, hence the term idiopathic. Nevertheless, congenital (developmental) or functional abnormalities of the hypothalamus account for most idiopathic cases of hypopituitarism, and many such cases of GHD prove to have a molecular basis. Acquired structural damage to this area (such as from neoplasm and trauma) causes about 25% of GHD cases.

Hypothalamic Dysfunction: Genetic Abnormalities.

Hypothalamic factors involved in regulating GH synthesis and secretion include, but may not be limited to, GHRH, GHSs, endogenous GH-releasing peptides such as ghrelin, PACAP, galanin, and somatostatin. Mutations of the genes encoding these or other hypothalamic peptides may explain some cases of IG deficit due to hypothalamic dysfunction. To date, however, mutations of the genes encoding GHRH have not been identified. Targeted disruption of the murine homeobox gene Tebp, expressed in the ventral diencephalon but not in Rathke's pouch or in the pituitary during embryogenesis, results in early ablation of the pituitary primordium.

A Gsh-1 homeobox gene, expressed in varied parts of the developing murine CNS, plays an important role in pituitary development because mutant strains have impaired production of GHRH with anterior pituitary hypoplasia and GHD. The broad impact of defects of this gene on hypothalamic releasing factors may be similar to mutations of the Pit-1 gene because deficiencies of prolactin and LH also occur. Deletions of the murine dopamine transporter (DAT) result in increased dopaminergic tone, anterior pituitary hypoplasia, and dwarfism. This suggests an important role for hypothalamic dopamine in pituitary development.

Congenital Malformations Involving the Hypothalamus.

Hypothalamic dysfunction from congenital malformations of the brain or hypothalamus is a common cause of hypopituitarism. As noted earlier, patients with early diagnosed congenital GHD frequently have an abnormal pituitary stalk, ectopia of the posterior pituitary, and hypoplasia of the anterior pituitary. Anencephaly results in a pituitary gland that is small or abnormally formed and is frequently ectopic. Despite the loss of hypothalamic regulation, somatotrophs differentiate and proliferate diminished overall mass.
parallel to each other. GH GHD can occur by itself or in combination with deficiencies of thyrotropin, ACTH, and gonadotropins. About 50% of children with severe anatomic defects have hypopituitarism, and the diagnosis should be considered in any child with growth failure associated with pendular or rotary nystagmus or impaired vision and a small optic nerve disc. In some patients, hypoplastic or interrupted pituitary stalks and ectopic posterior pituitary placement have been identified by MRI. It is not clear whether this disorder is inherited, but there is an increased incidence in offspring of young mothers and in first-born children.

Mutations of HESX1, a paired-like homeodomain gene, expressed early in pituitary and forebrain development, are associated with familial forms of septo-optic dysplasia. Three of 228 patients with a broad spectrum of congenital pituitary defects ranging from pituitary hypoplasia and septo-optic dysplasia were found to have heterozygous mutations of the HESX1 gene. Transgenic mice lacking this gene exhibit a variety of anterior midline CNS defects (e.g., abnormalities of the corpus callosum and septum pellucidum and microphthalmia) and pituitary dysplasia.

In most patients, so-called idiopathic hypopituitarism or GHD is due to abnormalities of synthesis or secretion of the hypothalamic hypophysiotropic factors. In a number of reports, idiopathic GHD is associated with MRI findings of an ectopic neurohypophysis, pituitary stalk dysgenesis, and hypoplasia or aplasia of the anterior pituitary.

In multiple series involving 397 children with isolated GHD or with CPHDs, 54% had the characteristic MRI findings; 93% of CPHD patients were abnormal in contrast with 32% of patients with isolated GHD.

Abrahams and co-workers studied 35 patients with idiopathic GHD and found that those with MRI abnormalities could be divided into two groups: (1) 43% had an ectopic neurohypophysis (neurohypophysis located near the median eminence), absent infundibulum, and absence of the normal posterior pituitary bright spot; and (2) 43% had a small anterior pituitary, either as an isolated finding or combined with an ectopic neurohypophysis. Overall, those patients with the most striking abnormalities of the hypothalamic-pituitary region, those with MRI abnormalities of the hypothalamic-pituitary region, had the smallest anterior pituitary glands.

Patients with more severe deficiencies of GH have greater frequency of significant morphologic abnormalities.

Although the increased incidence of breech presentation and birth trauma with neonatal asphyxia in congenital idiopathic hypopituitarism has led some to suggest an etiologic role for these occurrences, the syndrome of pituitary stalk dysgenesis with congenital hypopituitarism is probably due to abnormal development, and the perinatal difficulties are likely the consequence rather than the cause of the abnormalities. Findings of a similar MRI appearance in patients with septo-optic dysplasia, in association with type I Arnold-Chiari syndrome and syringomyelia, and perhaps also in holoprosencephaly and the occurrence of microcephaly with this syndrome, all support the concept that congenital hypopituitarism is a genetic or developmental malformation, not a birth injury.

A single report of an apparent autosomal dominant mutation of early brain development with infundibular dysgenesis associated with GH deficiency supports the primary nature of the abnormality. Further indirect evidence in studies of isolated, complete anterior pituitary aplasia indicates that hypothalamic hypopituitarism and breech delivery are consequences of congenital midline brain defects, although perinatal residua of breech delivery may exacerbate ischemic damage to the hypothalamic-pituitary unit.

The MRI findings described earlier for patients with an early diagnosis of hypopituitarism are also found in children diagnosed at a later age. Most of these children have hypothalamic dysfunction as the cause of diminished pituitary hormone secretion. In the older group, as in the infants, structural, acquired hypothalamic, stalk, or pituitary abnormalities must be considered.

Patients with myeloencephalocele with long-term survival have growth failure, decreased bone mineral density, and pubertal abnormalities. Diminished growth is due to maldevelopment of the vertebral-skeletal system and to diverse midline CNS developmental anomalies such as hydrocephalus and Arnold-Chiari malformation. Many have hypothalamic-pituitary dysfunction including GHD and precocious puberty. GH treatment does improve growth in these patients, although most of the growth is in the trunk and arms in children with shunted hydrocephalus, nearly two thirds have endocrine abnormalities. As a group, prepubertal patients were about 1 SDS below control populations and had a higher body mass index. Sixteen (30%) of 54 patients had inadequate GH production.

pituitary heights found on MRI. Early and accelerated pubertal maturation contributes to reduced final height.

Trauma of the Brain and Hypothalamus.

Head trauma may cause isolated GHD or multiple anterior pituitary deficiencies, and some series of patients with GHD indicate an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery. Although GHD may be a consequence of a difficult delivery or hypoxic perinatal period, it is more commonly an associated developmental abnormality deficiency (see earlier) or due to head trauma later in life. In a series of 22 head-injured adolescents and adults, nearly 40% had some degree of hypopituitarism.

Inflammation of the Brain and Hypothalamus.

Bacterial, viral, or fungal infections may result in hypothalamic or pituitary insufficiency, and the hypothalamus, pituitary gland, or both may also be involved in sarcoidosis.

Tumors of the Brain and Hypothalamus.

Brain tumors are a major cause of hypopituitarism insufficiency, especially midline brain tumors such as germinomas, meningiomas, gliomas, ependymomas, and optic nerve gliomas. Although short stature and GHD are most often associated with suprasellar lesions in neuroblastoma, they may also exist without such lesions; whether growth impairment antedates the pathologic findings is not clear. Metastases from extracranial carcinomas are rare in children, but hypothalamic insufficiency can result from local extension of craniopharyngeal carcinoma or Hodgkin’s disease of the nasopharynx.

The laboratory diagnosis of GHD in children with brain tumors may be difficult because levels of both IGF-I and IGFBP-3 are poor predictors, especially in pubertal patients. Cranial radiotherapy and histiocytosis can cause hypothalamic dysfunction, as described elsewhere ("Pituitary Growth Hormone Deficiency").

Radiation of the Brain and Hypothalamus.

Cranial radiation appears to be an increasing cause of hypothalamic-pituitary dysfunction. Taken in aggregate, there may be as many as 4000 pediatric cancer survivors whose GH has resulted from the broad range of cancer treatments.

Radiation may impair both hypothalamic and pituitary function, and often it is not easy to discriminate between damage at the two levels. The hypothalamus is more radiosensitive than the pituitary and is more often the site of damage, especially in the dose range usually given to children with malignancy. Thyroidal and gonadal function may also be directly impaired by certain radiation therapies. The degree of pituitary dysfunction is relative to the dose of radiation received. Low doses typically cause isolated GHD, and higher doses cause multiple pituitary deficiencies. GH develops in most long-term survivors, with the adverse effect of radiotherapy directly related to the biologically effective dose to the hypothalamus. Within 5 years of radiation, nearly 100% of children receiving more than 30 Gy over 3 weeks to the hypothalamic-pituitary axis had subnormal GH responses to provocative tests, whereas GHD may not become apparent for a decade or more after lower doses (18 to 24 Gy).

The degree of pituitary deficiency is also a function of the length of time after radiation; children who test normally at 1 year post-therapy may develop pituitary deficiencies later. Prior to development of GH secretory deficiency, GHI with low levels of IGF-I, IGFBP-3, and GHB (presumably caused by the malignancy and the intensive chemotherapy and radiation therapy regimens) may decrease growth velocity.
Chemotherapy regimens by themselves may impair final adult height, although not nearly to the extent seen after radiation. When such therapy is stopped, prepubertal children experience some degree of catch-up growth but also have persistent abnormalities of the IGF/IGFBP system. Even when serum GH responses to provocative testing are normal, spontaneous GH secretion may be blunt at x-ray doses as low as 18 to 24 Gy. Although acquired GHD impairs final height, the relation of diminished GH production to levels of the GH-dependent peptides, IGF-I, and IGFBP-3 is variable. With long-term follow-up, however, correlations have been found between nocturnal GH secretion, levels of IGF-I and IGFBP-3, and pituitary size.

Poor linear growth from decreased GH secretion may be exacerbated by the impact of radiation itself, with inadequate pubertal acceleration of spinal growth. Surprisingly, cranial radiation can result in precocious puberty, especially in children undergoing radiation therapy at young ages, causing early epiphyseal fusion. Sexual precocity appears to occur more frequently with low doses of radiation and gonadotropin deficiency is likely at high doses. The rate of pubertal progression, however, does not appear to be accelerated.

Treatment with GnRH analogues may be necessary to suppress the hypothalamic-pituitary-gonadal axis in an attempt to attain normal final height. Three possibilities must be considered in following children after craniospinal radiation: (1) evolving hypopituitarism, (2) decreased spinal growth potential, and (3) early puberty with premature epiphyseal fusion. Children with documented GHD and growth failure are candidates for exogenous GH treatment. There is no evidence for enhanced relapses of the primary neoplasm in patients receiving GH, but there appears to be a variable growth response to GH. Spinal growth impairment, inadequate or delayed treatment, and sexual precocity may limit linear growth.

Bone marrow transplantation (BMT) for patients with inborn errors of metabolism, aplastic anemias, and malignancies requires preparative regimens that include total body irradiation, often with chemotherapy and sometimes including cranial radiation. Children whose clinical condition required modest treatment programs before BMT experienced minimal loss of growth after BMT. In children who underwent cranial radiation followed by high-dose chemotherapy and total body radiation, especially in a single dose, as preparative regimens, growth failure was almost inevitable 2 to 5 years after BMT. Fetal growth was most affected. If the total body radiation was fractionated and if cranial radiation was not previously needed, growth velocity and height were not compromised 3 years after BMT.

In the absence of cranial radiation, there was poor correlation between GH production and levels of IGF-1 or IGFBP-3 and growth in children after BMT suggesting the importance of factors such as nutrition and radiation-induced vertebral dysplasia or hypothyroidism. Growth failure may be evident at birth and is more impressive postnatally, with mean adult heights more than 2 standard deviations below the mean. Mean final heights in 28 long-term survivors of BMT were about 1 SDS lower than at the time of the transplantation but still within the normal range in all but one patient. Such data suggest a conservative approach with regard to exogenous hormonal treatment.

Psychosocial Dwarfism.

An extreme form of failure to thrive is termed psychosocial dwarfism or emotional deprivation dwarfism. Most cases of failure to thrive can be traced back to a poor home environment and inadequate parenting, with improved weight gain and growth on removal of the infant from the dysfunctional home. Some children have dramatic behavioral manifestations beyond those in the typical infant with failure to thrive, namely bizarre eating and drinking habits, such as drinking from toilets, social withdrawal, and primitive speech.

Hyperphagia and abnormalities of GH production are associated. GH secretion is low in response to pharmacologic stimuli but returns to normal on removal from the home. Concomitantly, eating and behavioral habits returned to normal and a period of catch-up growth ensued. Careful assessment of endogenous GH secretion showed reversal of the GH insufficiency within 3 weeks, including enhancement of GH pulse amplitude and a variable increase of pulse frequency. The reversibility of GH secretion and the later growth increment in the context of the clinical findings described earlier confirm the diagnosis of psychosocial dwarfism.

The neuroendocrinologic mechanisms involved in psychosocial dwarfism remain to be elucidated. GH secretion is abnormal, and ACTH and thyrotropin levels may also be low, although some patients have high plasma cortisol levels. Even when GH secretion is reduced, treatment with GH is not usually beneficial until the psychosocial situation is improved. Management of the emotional causes of the growth failure is imperative and often associated with substantial growth. In our experience, although psychosocial dysfunction is a common cause of failure to thrive in infancy, the constellation of bizarre behaviors described in psychosocial dwarfism is rare.

The fact that GH production is impaired in adults with varied psychiatric disorders and the presence of growth aberrations of functional GHD with psychosocial dwarfism suggest that children with emotional problems may have impaired GH secretion and growth. Indeed, depression in children, as in adults, can lower GH production and anxiety disorders in girls predict a modest height loss in adults.

Growth Hormone Neurosecretory Dysfunction.

Because tests of GH secretion following pharmacologic provocation may not accurately reflect normal GH secretion, it has been argued that a subset of children with GH neurosecretory dysfunction may be identified by frequent or continuous serum sampling over a 12- to 24-hour period. This condition is characterized by short stature and poor growth, normal serum GH response to provocative testing, but reduced IGF-I and 24-hour serum GH levels. Prior cranial radiation may be the most common cause of these findings. Patients with ISS (see later) do not appear to have diminished 24-hour GH production rates, especially when the very broad range of data in normal and short normal children are considered. There appears to be little doubt that some of children with GH neurosecretory dysfunction secrete insufficient amounts of GH, even if they pass provocative GH testing; whether they should be identified by 24-hour GH sampling or by determination of the GH-dependent peptides is unclear.

Prader-Willi Syndrome.

Prader-Willi syndrome is a genetically determined syndrome complex, with a frequency of 1 in 10 to 25,000 live births. Profound neonatal hypotonia and subsequent developmental delay and strength are seen. Growth failure may be evident at birth and is more impressive postnatally, with mean adult heights more than 2 SD below the mean and almost always below the midparental height target range. Cryptorchidism and microphallus are present in the neonate and hypogonadotropic hypogonadism may persist into adult life. With advancing age, hyperphagia and obesity become prominent.

The genetic defect in Prader-Willi syndrome is a functional deletion of the paternal allele within chromosome 15q11-13. Most patients with the syndrome have deletions of the long arm of the paternal derived chromosome 15, in some both copies of 15q may be maternally derived (uniparental disomy), whereas rarely there may be mutations of the imprinting center of chromosome 15q.

The probable cause of the short stature in Prader-Willi syndrome is deficient GH production due to as yet undefined hypothalamic dysfunction. MRI assessment of the hypothalamic-pituitary area does not yield evidence for congenital structural abnormalities. The body habitus and composition are similar to those in classic GHD, including small hands and feet, increased fat mass, and low muscle mass. Low mean serum GH levels or inadequate responses after provocative testing may reflect the impact of obesity, but serum levels of GH-dependent peptides are low in Prader-Willi syndrome, in contrast with the findings in obesity, a condition in which these factors are produced normally despite diminished GH production. Thus, Prader-Willi syndrome is an IGF deficiency condition due to inadequate GH production, although the possibility of failure of up-regulation of GH action, as seen in obesity, may yet be found to play a role.

GH treatment of growth failure in patients with Prader-Willi syndrome is now an FDA-approved indication for GH use. Treatment results in improved growth velocity, normalization of final height potential, increased muscle mass and strength, and decreased fat mass. In view of the risk for development of obesity-related insulin resistance and diabetes mellitus, glycemic status must be monitored closely during GH therapy.
In most pediatric endocrine centers, many children receiving GH are classified as having acquired, idopathic, isolated GHD. As noted earlier, this diagnosis should always be considered somewhat suspect, especially prepubertally, although some patients may actually have undiagnosed gene defects in GH production or secretion or may be exhibiting the first manifestation of CPHD.

Multiple studies have reported data on retesting patients with GH-treated GHD during or after cessation of therapy. All the vagaries of different GH assays and GH provocative tests, varied “cut-off” levels of GH normality, diagnostic categorization of patients, and radiologic interpretation of MRI findings certainly affect these evaluations. Nonetheless, several clear conclusions emerge. In 464 patients with isolated GHD, 207 (44%) had normal GH levels during provocative retesting. In contrast, approximately 96% of 148 patients with CPHD, with or without structural abnormalities of the hypothalamic-pituitary area, had sustained GHD. The presence of multiple anterior pituitary hormone deficiencies or structural disease would seem to obviate the need for subsequent retesting. Whether these results simply cast doubt on the validity of the initial GH tests (or GH provocative testing in general) or whether children with earlier GHD may truly normalize is not clear. The entity of partial, transient GHD associated with delayed puberty certainly may be an example of this latter situation.

**Pituitary Growth Hormone Deficiency.**

As discussed earlier, many of the disease processes that impair hypothalamic regulation of GH secretion also impair pituitary function. Another group of abnormalities specifically affects pituitary somatotroph development and function.

As many as 3% to 30% of patients with GHD have an affected parent, sibling, or child, and multiple genetic causes of GHD have been recently described. We discuss inborn errors of genes for nuclear transcription factors affecting hypothalamic-pituitary development, the GHRH receptor, and the GH gene, each of which can cause GHD and IGF deficiency.

**Genetic Abnormalities Resulting in Combined Pituitary Hormone Deficiency:**

Septo-optic dysplasia and its relationship to HESX1 have been discussed earlier. The gene PRO1 (denoting prophet of Pit1) encodes a paired-like 226amino acid homeodomain protein, which is involved in the early determination and differentiation of multiple anterior pituitary cell forms and is necessary for POU1F1 (Pit1) expression. Mutation of this gene is responsible for a form of murine pituitary-dependent dwarfism, the Ames mouse. Abnormalities of human PRO1 result in CPHD, characterized by variable and often age-dependent degrees of deficiency of GH, prolactin, thyrotropin, FSH, LH, and, occasionally, ACTH.

Gonadotropin abnormalities are particularly diverse because about 30% of patients undergo spontaneous pubertal development, including menarche, before ultimately developing hypogonadotropic hypogonadism. Striking variability has been described in pituitary size, with very large glands having a hyperintense T1-weighted signal occasionally demonstrated by MRI. These pituitary glands may then undergo involution, leaving a large empty sella in a patient with complete anterior hypopituitarism, including ACTH deficiency. At least eight PRO1 (chromosome 5q35, OMIM01536) gene abnormalities have been identified and include missense, frameshift, and splicing mutations. A GH repeat in exon 2 (295-CGA-GAG-AGT-303) has been reported to be a “hot spot” in the PRO1 gene; any combination of a GA or AG deletion in this repeat region results in a frameshift in the coding sequence and premature termination at codon 109.

Similar abnormalities result from homozygous lesions at other sites on exon 2 affecting codons 73, 88, and 149. Further, compound heterozygosity for two mutations was detected in 36% of children from four families because two different common deletions both led to a stop codon at position 109. These mutations all result in loss of the DNA-binding and C-terminal trans-activating domains of PRO1. There does not appear to be strong correlation between phenotype and genotype. Large-scale screening of patients with CPHD has found 54% with PRO1 mutations in two series of patients with multiple affected individuals, however, PRO1 mutations accounted for all of the 25 siblings. Such frequencies far exceed those reported for POU1F1 mutations and emphasize a central role for PRO1 in pituitary cellular differentiation.

The POU1F1 (Pit-1, GHF-1) gene (chromosome 3p11, OMIM 173110) encodes Pit1, a member of a large family of transcription factors, referred to as POU-domain proteins, and is responsible for pituitary-specific transcription of genes for GH, prolactin, thyrotropin, and the GHRH receptor. Additionally, the 280amino acid Pit-1 protein activates transcription of genes that regulate differentiation, proliferation, and survival of somatotrophs, lactotrophs, and thyrotrophs. Both Snell (dw/dw) and Jackson (dw/dwJ) dwarf mice have GH, prolactin, and thyrotropin deficiency and mutations or rearrangements of the murine Pit-1 gene. Many different mutations (at least 12 point mutations and deletions in the POU1F1 gene) have been found internationally in families with GHD and prolactin deficiency and variable defects in thyrotropin secretion. The most common mutation is an R271W substitution affecting the POU homeodomain protein, which is involved in the early determination and differentiation of multiple anterior pituitary cell forms and is necessary for POU1F1 (Pit1) expression.

**Molecular Defects of GHRH.**

Despite extensive assessment, mutations of the gene encoding GHRH, which would cause the IGF deficiency phenotype, have not been identified. Although expression of GHRH is suppressed in mutations of murine neural genes GnF1 and DAT1, the failure to demonstrate a GHRH mutation remains a surprise because this gene would appear to be a likely candidate for familial GHD. Abnormalities of the endogenous "GHSs" or their receptors remain to be identified. Mutations causing constitutive or enhanced ligand-mediated activation of the G protein-related somatostatin receptor to yield chronic inhibition of GH also have not yet been reported.

**Molecular Defects of the GHRH Receptor.**

Although no defects of the GHRH gene have yet been reported, multiple kindreds have been found with homozygous mutations of the GHRH receptor gene. Wajnrajch and associates reported the first human cases of a mutation in the GHRH receptor gene (chromosome 7) in two cousins with IGF deficiency and growth failure. These patients had a severely truncated GHRH receptor protein that lacked the membrane-spanning regions and the G protein-binding site. The affected children exhibited undetectable GH release during standard provocative tests and after exogenous GHRH administration but responded to GH treatment.

Another series of 18 patients with the same point mutation was found in Pakistan ("dwarfish of Sind") and in two members of a Tamoulean family from Sri Lanka. The largest kindred with a mutation of GHRH receptor has been identified in Brazil; a donor splice mutation in position 1 of exon 1 also results in a severely truncated GHRH protein.

The patients in all of the groups have striking short stature (often more than -5 SDS), lack other features of GHD such as microphallus, truncal obesity, and...
hypoglycemia, but have profound abnormalities of the GH-IGF axis. The absence of the GHRH receptor in the tests does not preclude fertility. The patients respond well to exogenous GH without antibody formation. Heterozygotes may have minimal height deficits but do show moderate biochemical deficiencies of the GH-IGF axis.

Despite extensive study, the geographic separation and ethnic differences do not suggest recent (>200 years) contact among the families from the Indian subcontinent. The most probable explanation for all four families is that of a "founder effect," or one-time mutations in each group with propagation within geographically isolated gene pools. In an analysis of 30 families with isolated GHD type IB, Salvatori and colleagues found new missense mutations in transmembrane and intracellular domains of GHRH receptor in three families (10%) with two affected members in each. Transfection experiments indicated normal cellular expression of these mutant receptors.

Mutation of the gene for GHRH receptor in its ligand binding domain has also been identified in the little mouse (little). leading to dwarfism and decreased numbers of somatotrophs. This in model, the fetal somatotroph mass is normal and hypoplasia, but not absence, of the somatotrophs is evident only after birth. Such data suggest that GHRH is not an essential factor for fetal differentiation of the somatotrophs and that GHRH-independent cells persist or that mutation does not cause total loss of GHRH function.

**Genetic Abnormalities of Growth Hormone Production and Secretion Resulting in Isolated Growth Hormone Deficiency.**

Four isomeric GHD due to errors of the GH gene have been reported (see Table 23-5). The gene encoding GH (GH1) is located on chromosome 17q23 in a cluster that includes two genes for hpl: (1) a pseudogene for hpl and (2) the hpl gene that encodes placental hpl. GH1 and GH2 differ in mRNA splicing pattern: GH1 generates 20- and 22-kd proteins (of approximately equal bioactivity), whereas GH2 yields a protein differing from GH1 in 13 amino acid residues.

Isolated GHD type IA (GH1-IA) results primarily from large deletions, with rare microdeletions and single base-pair substitutions of the GH1 gene that prevent synthesis or secretion of the hormone. GH1-IA is inherited as an autosomal recessive trait and affected individuals have profound congenital GHD. Because GH is not produced even in fetal life, patients are immunologically intolerant of GH and, typically, develop anti-GH antibodies when treated with either pituitary-derived or recombinant DNA-derived GH. When antibodies prevent patients from responding to GH, GH1-IA can be viewed as a form of GHI, and such patients are candidates for IGF-I therapy.

The less severe form of autosomal recessive GHD (isolated GHD type IB) also may result from mutations or rearrangements of the GH1 gene. These mutations cause production of an aberrant GH molecule that retains some function or at least generates immune tolerance. Patients usually respond to exogenous GH therapy without antibody production. The very low frequency (1.7%) of GH1 gene mutations in familial type IB isolated GHD suggests the importance of studying the GH1 gene promoter region.

In a group of 65 children with isolated GHD-IB, the GHRH receptor gene was normal in domains coding for the extracellular region, but more recently, mutations in the transmembrane and intracellular gene domains were found in 10% of families with isolated GHD-IB.

Isolated GHD-IL is inherited as an autosomal dominant trait. Such patients may have splice site, intronic, and missense mutations of the GH1 gene. The most common cause appears to be those mutations that inactivate the 5’ splice donor site of intron 3, resulting in skipping of exon 3. It is likely that they function in a dominant-negative manner with the GH mutant suppressing intracellular accumulation and secretion of wild-type GH.

In patients with missense mutations in exon 4 or 5, clinical presentation is quite variable with some evidence for reversibility of the impairment of intracellular GH storage and secretion by GH treatment.

Type III GHD, transmitted as an X-linked trait with associated hypogammaglobulinemia, has not yet been related to a mutation of the GH1 gene.

**Bisubunit Growth Hormone.**

Serum GH exists in multiple molecular forms, the consequences of alternative post-transcriptional or post-translational processing of the mRNA or protein, respectively. Some of these forms are presumed to have defects in the amino acid sequences required for binding of GH to its receptor and different molecular forms of GH may have varying potencies for stimulating skeletal growth, although this remains to be rigorously proven.

Short stature with normal GH immunoreactivity but reduced biopotency has been suggested, but the molecular abnormalities have been characterized only in a few such situations. In one child with extremely short stature (-6.1 SDS), a mutant GH caused by a single missense heterozygous mutation (cys to arg, codon 77 of GH1 gene) bound with greater affinity than normal to GHBP and the GHR and inhibited the action of normal GH. The child grew more (6 versus 3.9 cm/year) during a period of therapy with exogenous GH in moderate dosage. Strangely, the father had the same genetic abnormality but did not express the mutant hormone. In the second patient, with marked short stature (-3.6 SDS), a heterozygous A-to-G substitution on exon 4 of GH leads to a glycine to arginine substitution. This mutation is located in site 2 of GH molecular binding with its receptor and leads to failure of appropriate sequential receptor dimerization and subsequent diminished tyrosine phosphorylation and the GH-mediated intracellular cascade of events. Bioactivity determined in a mouse B cell lymphoma line was about 33% of immunoreactivity. Exogenous GH substantially increased growth velocity (4.5 to 11.0 cm/year).

There remain other patients, however, in whom diminished bioactivity by sensitive in vitro assays is not reflected by comparable immunoreactivity, but who do not have GH1 mutations, suggesting the importance of abnormal post-translational modifications of GH or other peripheral mechanisms.

**Trauma.**

See earlier topics.

**Inflammation.**

See earlier topics.

**Tumors Involving the Pituitary Gland.**

Many tumors that impair hypothalamic function also impair pituitary secretion of GH. In addition, craniopharyngiomas are a major cause of pituitary insufficiency. These tumors arise from remnants of Rathke’s pouch, the diverticulum of the roof of the embryonic oral cavity that normally gives rise to the anterior pituitary. Genetic defects in this condition, although certainly reasonable to suspect, have not yet been identified. This tumor is a congenital malformation present at birth and gradually grows over the ensuing years. The tumor arises from nests of squamous cells at the junction of the adenohypophysis and neurohypophysis, and it forms a cyst as it enlarges, which contains degenerated cells and may calcify but does not undergo malignant degeneration. The cyst fluid ranges from a “machinery oil” to a shimmering cholesterol-laden liquid, and the calcifications may be microscopic or gross. About 75% of craniopharyngiomas arise in the suprasellar region, the remainder resembling pituitary adenomas.

Craniopharyngiomas can cause manifestations at any age from infancy to adulthood but usually in middle childhood. The most common presentation is due to increased intracranial pressure, including headaches, vomiting, and ocular motor abnormalities. Visual field defects result from compression of the optic chiasm and papilledema or optic atrophy may be present. Visual and ophthalmic hallucinations have been reported, as have seizures and dementia. Most children with craniopharyngiomas show evidence of growth failure at the time of presentation.

GH and the gonadotropins are the most commonly affected pituitary hormones in children and adults, but deficiency of thyrotropin and/or ACTH may also occur; diabetes insipidus is present in 25% to 50%. Fifty percent to 80% of patients have abnormalities of at least one anterior pituitary hormone at diagnosis.
The initial report of primary GHI by Laron and colleagues described abnormalities of the Growth Hormone Receptor. Antibodies to GH; and (4) antibodies to the GHR. Illness-related GHI is discussed in the specific text sections.

Secondary GHI domain; (2) postreceptor abnormalities of GH signal transduction; (3) primary defects of IGF-I biosynthesis; and (4) genetic insensitivity to IGF-I action.

Primary GHI describes patients with the phenotype of GHD but with normal or elevated serum GH levels and diminished production of IGF-I.

Growth Hormone Insensitivity.

Partial GH insensitivity. GH insensitivity in the absence of dysmorphic features described by Laron et al.

IGF-I, insulin-like growth factor I; GH, growth hormone.

To supplement this revised classification, the following definitions are proposed:

GH insensitivity: Clinical and biochemical features of IGF-I deficiency and resistance to exogenous GH, associated with GH secretion that would not be considered abnormally low.

GH insensitivity syndrome: GH insensitivity associated with the recognizable dysmorphic features described by Laron et al.

Partial GH insensitivity. GH insensitivity in the absence of dysmorphic features described by Laron et al.

Operative intervention either via craniotomy or transsphenoidal resection may result in partial or almost complete removal of the lesion. Postoperative radiation, especially when tumor resection is incomplete, is commonly used. In some patients, especially those who become obese, a syndrome of normal linear growth without GH may occur. The circulating growth-promoting substances in this condition include insulin and other poorly characterized mitogens. The long-term childhood and adolescent consequences of craniohypophysealoma are substantial, with many quality of life issues exacerbating the hypopituitarism.

Pituitary adenomas (see Chapter 8) are infrequent during childhood and adolescence, accounting for fewer than 5% of operated patients at large centers. Nearly two thirds of tumors immunochemically stain for prolactin, and a small number stain for GH. GH-secreting pituitary adenomas are exceedingly unusual in youth. There is a variable experience as to the invasive nature of pituitary adenomas, although the prevailing opinion is that they are less aggressive in children than in adults. In 56 patients at the Mayo Clinic with non-ACTH secreting adenomas removed transsphenoidally, macroadenomas were about one third more frequent than microadenomas, with girls outnumbering boys 3.3 to 1. The incidence of hypopituitarism in patients with macroadenomas was about 50%, compared with none in patients with microadenomas; long-term cure rates were 55% to 65% for both tumor sizes.

These syndromes are characterized by an infiltration and accumulation of Langerhans cells in the involved areas, such as skull, hypothalamic-pituitary stalk, CNS, and viscera. Although these disorders, especially Hand-Schüller-Christian disease, are classically associated with diabetes insipidus, approximately 50% to 75% of patients in selected series have growth failure and GHD at the time of presentation. These individuals clearly have IGF-I deficiency.

Operative intervention either via craniotomy or transsphenoidal resection may result in partial or almost complete removal of the lesion. Postoperative radiation, especially when tumor resection is incomplete, is commonly used. In some patients, especially those who become obese, a syndrome of normal linear growth without GH may occur. The circulating growth-promoting substances in this condition include insulin and other poorly characterized mitogens. The long-term childhood and adolescent consequences of craniohypophysealoma are substantial, with many quality of life issues exacerbating the hypopituitarism.

The localized or generalized proliferation of mononuclear macrophages (histiocytes) characterizes Langerhans cell histiocytosis, a diverse disorder occurring at all ages, with peak incidence at ages 1 to 4 years. Endocrinologists are more familiar with the term histiocytosis X, which includes three related disorders: (1) solitary bony disease (eosinophilic granuloma), (2) Hand-Schüller-Christian disease (chronic disease with diabetes insipidus, exophthalmos, and multiple calvarial lesions), and (3) disseminated histiocytosis X (Letterer-Siwe, with widespread visceral involvement).

These syndromes are characterized by an infiltration and accumulation of Langerhans cells in the involved areas, such as skull, hypothalamic-pituitary stalk, CNS, and viscera. Although these disorders, especially Hand-Schüller-Christian disease, are classically associated with diabetes insipidus, approximately 50% to 75% of patients in selected series have growth failure and GHD at the time of presentation. In contrast, only 1% of unselected children with Langerhans cell histiocytosis living in Canada during a 15-year period had GHD. Isolated GHD or deficiencies of other anterior pituitary hormones may occur.

The initial report of primary GHI by Laron and colleagues described...
Osteopenia

Birth length: may be slightly decreased

Postnatal growth: severe growth failure

Bone age: delayed, but may be advanced relative to height age

Genitalia: microopenis in childhood; normal for body size in adults

Puberty: delayed 37 years

Sexual function and fertility: normal

**Craniofacies**

- Hair: sparse before age 7 years
- Forehead: prominent; frontal bossing
- Skull: normal head circumference; craniofacial disproportion due to small facies
- Faces: small
- Nasal bridge: hypoplastic
- Orbit: shallow
- Dentition: delayed eruption
- Scleras: blue
- Voice: high-pitched

**Musculoskeletal/Metabolic/Miscellaneous**

- Hypoglycemia: in infants and children; fasting symptoms in some adults
- Walking and motor milestones: delayed
- Hips: dysplasia; avascular necrosis of femoral head
- Elbow: limited extensibility
- Skin: thin, prematurely aged
- Osteopenia

"three siblings with hypoglycemia and other clinical and laboratory signs of GHD, but with abnormally high levels of immunoreactive serum GH." To date, approximately 250 cases have been identified worldwide, most from the Mediterranean region or from Ecuador (probably from Spanish Conversos, or Jews who converted to Christianity during the Inquisition). These individuals do not respond to exogenous GH, in terms of growth, metabolic changes, or increases in serum levels of IGF-I and IGFBP-3. Cellular unresponsiveness to GH was demonstrated in vitro by the failure of GH to stimulate erythroid progenitor cells from the peripheral blood of patients. Direct evidence of receptor dysfunction was provided by the demonstration that microsomes obtained by liver biopsy do not bind radiolabeled GH. GHBP activity is usually (in 75% to 80% of cases) undetectable in the sera of patients with this disorder.

Studies of the GHR gene in Israeli patients indicate that some, but not most, contained gene deletions, and a wide variety of homozygous point mutations in this gene (missense, nonsense, and abnormal splicing) have been identified subsequently. Most of the mutations are in the extracellular (GH binding) domain of the GHR; at least one mutation of the extracellular domain does not affect GH binding but prevents dimerization of the receptor. Mutations of the intracellular and transmembrane domains are much less frequent.

One patient had two separate amino acid substitutions in the intracellular domain, but because both mutations are on the same allele, which comes from the unaffected mother, the diagnosis of GHI in this patient was not certain. Chujo and associates, additionally, found that a specific heterozygous missense exon 10 (which codes for most of the GHR intracellular domain) mutation was present in 14 of 96 volunteers; there was no significant effect on stature, suggesting that this mutation represents a normal polymorphism. Another subject with compound heterozygous mutations in exon 10 was extremely short (-4 SDS) but grew in response to a very high dose of GH. At this time, data are inadequate to determine whether these intracellular domain substitutions represent genuine mutations or innocent polymorphisms.

Another profoundly short patient, fully resistant to GH but highly responsive to IGF treatment, had coexistent heterozygous mutations affecting exons 6 and 9. A similarly short girl (-8 SDS) had compound heterozygosity in exons 8 and 10.

Woods and colleagues described two cousins with severe GHR and homozygous mutations at the 5' splice donor site of intron 8, resulting in a mutant GHR without functional transmembrane or intracellular domains. A similar defect was found in a Druse girl with a mutation of the 3' acceptor site of intron 7. Serum levels of GHBP were elevated because the mutant receptor protein apparently becomes detached from the cell receptor surface.

Two defects directly affecting the intracellular domain have been reported to result in dominantly inherited GHI. A, B The
patients and their mother had a heterozygous point mutation that disrupted the 5’ splice donor site of intron 9, causing skipping of exon 9 and the appearance of a premature stop codon in exon 10 and resulting in the same GH 1277 receptor molecule as described by Ayling and co-workers. Under in vitro conditions, the Japanese mutation has been shown to result in a GHR molecule that behaves in a dominant negative manner, inhibiting GH-induced tyrosine phosphorylation of STAT5.

Heterozygosity for defects of the GHR may cause relative GHRI, with modest growth occurring only in response to high doses of GH. Such observations raise the important question of whether heterozygosity for GHRI can result in a clinically important phenotype and whether some children labeled as “diopathic short stature” (ISS) may harbor such mutations. Given the requirement for dimerization of the GHR, there is the potential for an abnormal protein to have varying degrees of dominant negative effect. Ross and associates described a truncated (1-279) GHR splice variant whose differential production could act to regulate GHBP production and, more importantly, to modulate GHR signaling in a negative fashion.

In summary, the clinical features of GHR due to GHR deficiency are identical to those of other forms of severe IGFI deficiency, such as congenital GHDI. As with GHDI, however, there is a wide range of clinical phenotypes. Basal serum GH levels are typically elevated in children but may be normal in adults. Most patients have decreased serum GHBP levels, but a normal or even elevated serum GHBP concentration does not exclude the diagnosis of GHRD because mutations of the GHR dimerization domain and in the intracellular domain have been described. Patients with measurable GHBP tend to be taller. Serum IGFI-I, IGFI-II, and IGFBP-3 levels are profoundly reduced, but partial clinical and biochemical phenotypes have been described, typically but not always related to milder mutations of the GHR gene, resulting in only a modest reduction in binding activity and receptor action.

Primary Defects of IGFI Biosynthesis.

Woods and colleagues described a 15-year-old boy with a partial deletion of the IGFI-gene yielding a truncated IGFI-molecule. Severe prenatal and postnatal (-6.7 SDS) growth retardation and insensitivity to exogenous GH were consistent with the expectations of the phenotype of IGFI-deficiency. Somnolineal deafness, mental retardation, and microcephaly suggest a role for prenatal IGFI in CNS development. Hyperinsulinism and insulin resistance were presumably due to overproduction of GH. IGFI-I levels were exceedingly low, but IGFBP-3 and GHBP levels were normal. The patient was homozygous for deletions of exons 4 and 5 of the IGFI-gene, with both parents being heterozygous carriers and perhaps mildly affected themselves. Although unresponsive to GH therapy, the patient was able to achieve accelerated growth velocity, improved body composition, increased bone mineralization, and decreased insulin resistance on treatment with IGFI-I.

Primary Defects of IGFI Transport and Cleavage.

In fibroblasts from a single short child of 127 studied, Tollesen and co-workers found a marked resistance to IGFI-stimulated -amininosobutyric acid uptake and thymidine incorporation. And IGFI-variant with 60-fold lower binding affinity for IGFBPs stimulated the fibroblasts of this child and normal children, thus eliminating a primary IGFI-receptor defect. This patient's fibroblasts secreted more IGFBPs than normal and had a 10-fold increase in a cell surface protein similar in size though not immunoreactivity to IGFBP-1.

Barreca and associates studied a short boy (-6 SDS) with increased GH, normal IGFI-I, and 20- to 30-fold elevated IGFBP-1 levels. Growth failure seemed due to inhibition of IGFI-action by IGFBP-1. Short-term treatment with GH led to suppression of IGFBP-1, increased ternary-complexed IGFI-I, and a marked increase of growth rate.

Primary Defects of IGFI-Receptor Production or Responsiveness.

In mouse knockout models, homozygous mutations of the IGFI-receptor result in profound growth failure and neonatal mortality. Heterozygous mutations are phenotypically similar to wild-type mice. In the African Efe pygmies, a series of studies demonstrated extreme insensitivity to the in vitro growth-enhancing effects of IGFI-I, Reduced IGFI-I receptor transplants and sites with resultant diminished tyrosine phosphorylation and postreceptor signaling, although no definable receptor mutation, are suggested explanations.

In leprochaunism, a syndrome of growth failure and insulin receptor dysfunction, IGFI-insensitivity is variable. The profound abnormality of the insulin receptor suggests that heterodimeric insulin-receptor and IGFI-receptor combinations could possibly lead to failed activation of the IGFI-signaling cascade. As the IGFI-receptor gene resides at 15q26.3, deletions of the distal long arm of chromosome 15 or ring chromosome 15 may lead to hemizygosity for the IGFI-receptor. Although such patients may have IGFR1 and skipping postnatal growth failure, lack of a biologic response to IGFI-I has not been conclusively demonstrated. Whether growth failure in such patients is due to altered levels of IGFI-receptor or represents the net effect of the loss of other genes located on 15q remains to be determined.

Figure 23-51 Serum levels of insulin-like growth factor I (IGFI-I), IGFI-II, IGFI-binding protein 2 (IGFBP-2) and IGFBP-3 in patients with GH receptor deficiency from Ecuador. GH deficiency, growth hormone deficiency; GHRH, growth hormonereleasing hormone; IM, intramuscular; IV, intravenous.

*Tests should be performed after an overnight fast. Many investigators suggest that prepubertal children should be "primed" with gonadal steroids, e.g., a 5 mg Prenalin orally the night before and the morning of the test with 500 mg of 10 mg/kg ethinyl estradiol orally 3 consecutive days before testing. This, of course, alters the patient's steady state and performs the provocative test in a steroid-rich environment. Patients must be euthyroid at the time of testing.

Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. Documentation of appropriate lowering of blood glucose is recommended. If GHD is suspected, the lower dosage of insulin is usually administered, especially in infants. Glucagon should be available.

involves at least two hypothalamic factors—GHRH and somatostatin—and multiple other peptides and neurotransmitters. Spontaneous GH secretion varies with gender, age, pubertal stage, and nutritional status, all of which must be factored into the evaluation of GH production.

Between normal pulses of GH secretion, serum GH levels are low (often <0.1 µg/L), below the limits of sensitivity of most conventional assays (usually <0.2 µg/L). Accordingly, measurement of a random serum GH concentration is virtually useless in diagnosing GHD but may be useful in the diagnosis of GHI and GH excess. Measurement of GH "secretory reserve," therefore, relies on the use of physiologic or pharmacologic stimuli, and such provocative tests have been the basis for the diagnosis of GHD for more than 30 years. Physiologic stimuli include fasting, sleep, exercise, and pharmacologic stimuli include levodopa, clonidine, glucagon, propranolol, arginine, and insulin.

Stimulation tests have often been divided into screening tests (exercise, fasting, levodopa, clonidine), which are characterized by ease of administration, low toxicity, low risk, and low specificity, and definitive tests (arginine, insulin, glucagon). To improve specificity, provocative tests are customarily combined or given sequentially. We have, for example, often used fasting plus oral clonidine as a screening test, to be followed by fasting plus intravenous sequential arginine, oral clonidine, levodopa, or insulin as a definitive test. It is generally accepted that a child must "fail" provocative tests with at least two separate stimuli to be considered GHD. Standard provocative GH tests are summarized in Table 23-8.

Although provocative GH testing has been the foundation for the diagnosis of GHD since GH assays first became available, they have come under criticism for a number of reasons:

1. Provocative GH testing is nonphysiologic. None of the standard pharmacologic provocative tests satisfactorily mimic the normal secretory pattern of pituitary GH. Even when normal secretory regulatory peptides are used for stimuli, the routine, route of administration, and interactions with other regulatory factors are artificial. Furthermore, because most endocrine centers use several different stimulation tests, there is no validated means of resolving conflicting data from two or more provocative tests. To emphasize this point, Guyda reported on 6373 GH stimulation tests performed on 3233 short French children; 11 different pharmacologic tests were employed, with 62 of the possible 66 pairs employed at least once and the most frequent combination of tests used only in 12.7% of patients.

2. Arbitrary definitions of "subnormal" response to provocative tests. Different centers vary in the definition of a "normal" response to stimulation tests. Although early reports generally employed a cut-off level of 2.5 µg/L, this cut-off was gradually increased to 7 µg/L and with the availability of recombinant DNA-derived GH, increased to 10 µg/L, although there are no data for validating higher arbitrary cut-off values. The initial levels of GH that were used to define GHD were based on the study of patients with profound classic findings or organic destruction of the adenohypophysis. The lack of documentation of defined normal responses can be seen in the use of vague terminology such as "lack of adequate endogenous growth hormone secretion" and "inadequate secretion of normal endogenous growth hormone." There are multiple new GH assays that measure GH immunoreactivity at 33% to 50% of earlier assays, but there has not been a systematic reassessment of "new normal" GH cut-off levels nor recognition by many endocrinologists of which assay their center might be using.

3. Age dependency and use of gonadal steroids. Serum GH levels typically rise during puberty, typically because of an increase in pulse amplitude rather than an increase in pulse frequency. GH secretion may normally be so low as to blur the differentiation between GHD and CDGM. Many children who "fail" provocative testing before the onset of puberty prove to have normal GH secretion after puberty or after administration of exogenous gonadal steroids. In a placebo-controlled comparison of estrogen priming in children with GHD and ISS, supramaximal provocative tests performed 3 days before the tests performed (using 9 µg/L as a cut-off with a polyclonal GH assay) had a diagnostic efficiency of 98%. A well-controlled study of provocative GH testing in children of normal stature documented the inherent problems of such testing and the need for standardization of gonadal steroid administration during stimulation tests in peripubertal children. When exercise and arginine-insulin stimulation tests were administered to these normal children, the lower limit of normal (-2 SD) for peak serum GH concentration in prepubertal children was only 1.9 µg/L, whereas in children of Tanner stage 5 puberty, this level was 9.3 µg/L. When estrogen was administered prior to provocative testing, the lower 95% confidence limit for the normal serum GH range rose to 7.2 µg/L. When estrogen was not administered, the serum GH level did not rise above 7 µg/L, during three provocative tests. These normally growing children could, potentially, be erroneously labeled as GHD in 61% of normal prepubertal children. Furthermore, the finding of similar GH values in slow-growing, short children emphasizes the difficulty of basing this important diagnosis on provocative test data that use a "magic" number as an arbitrary cut-off for normal.

4. Variability of GH assays limit discriminatory power. Several studies have demonstrated as much as threefold variability in the measurement of serum GH levels among established laboratories. This is explained, at least in part, by the presence of several molecular forms of GH in serum and by the use of different monoclonal antibodies in contrast with older polyclonal antibodies and variations in the choice of standards, labeling techniques, and assay buffers (matrix). The consequence is that children labeled as GHD by one assay are considered normal by another. This is an unacceptable situation for clinicians, who must remain aware of the type and source of GH assay being used by a given laboratory. A highly sensitive immunofunctional GH assay has now been developed that measures concentrations of GH capable of binding to GHBP. It is not clear, however, that such assays necessarily have any advantages over standard radioimmunoassays for routine GH measurements. When arginine/levodopa or arginine/insulin stimulation tests were used, approximately 50% of normal children had peak GH concentrations below 7 ng/mL and 30% were below 5 ng/mL, whether GH was measured by immunofunctional assay or ELISA.
5. Expense, discomfort, and risks of provocative GH testing. Provocative testing typically requires multiple timed blood samples and the parental administration of drugs. The resulting expense and discomfort to the patient are self-evident. In addition, tests involving insulin administration carry the risk of hypoglycemia and seizures and should be performed only by experienced medical personnel under appropriate supervision. Deaths have been reported from insulin-induced hypoglycemia and from its overly vigorous correction with parental glucose. 1029

6. Poor reproducibility of provocative tests. The reproducibility of provocative GH tests has never been adequately documented, even when GH levels are measured with the same assay. 1030

Another diagnostic approach involves measurement of spontaneous GH secretion. This can be done either by multiple sampling (every 5 to 30 minutes) over a 12- to 24-hour period or by continuous blood withdrawal over 12 to 24 hours. 1031 The former method allows one to evaluate and characterize GH pulsatility, whereas the latter permits only determination of mean GH concentration. Both approaches are subject to many of the same limitations as provocative GH testing. The expense and discomfort of such testing are obvious, and although it was thought that this approach is more reproducible than provocative GH tests, variability is a problem. 1032 The ability of such tests to discriminate between GHD and normal short children is also an issue.

Rose and colleagues reported that measurement of spontaneous GH secretion identified only 57% of children with GHD as defined by provocative testing. Similarly, Lanes reported that one fourth of normally growing children had low overnight GH levels, and a longitudinal study of normal boys through puberty demonstrated a wide intersubject variance, including many "low" 24-hour GH production rates, despite fully normal growth. 1033

Given the problems with GH testing, it is not surprising that provocative tests and 24-hour GH profiles do not always correlate. It is likely that 12- to 24-hour GH profiles can identify most children with GHD and is superior, both in sensitivity and specificity, to provocative GH testing. "Neurosecretory dysfunction" probably does exist in children after cranial radiation and likely does characterize a subgroup of children with GHD and IGF deficiency. The expense and discomfort of such tests is likely to outweigh their value.

The measurement of GH levels in urine is an alternative means of estimating integrated GH secretion (or, at least, excretion). This technique requires timed urine collections and anti-GH antibodies of high affinity, because urinary GH levels are normally low. Adequate age- and gender-related standards have not been developed, and the diagnostic use of urinary GH determination remains to be defined.

An alternative means of diagnosing GHD involves assessment of IGF-I and IGF-II and their binding proteins. Bone loss is not uncommon in children with GHD, and normal serum IGF-I levels had reduced IGFBP-3 levels, and 10 (43%) of 23 normal short children had decreased serum IGFBP-3. For example, in one study, the sensitivity of the IGFBP-3 assay in complete GHD (peak GH <5 µg/L) was 93%; however, it was only 43% in partial GHD (peak GH 5 to 10 µg/L). The utility of IGFBP-3 assays in the diagnosis of GHD was evaluated by Blum and colleagues, who found that serum IGFBP-3 levels were below the 5th percentile in 80% of children with GHD and normal serum IGF-I levels had reduced IGFBP-3 levels, and 10 (43%) of 23 normal short children had decreased serum IGFBP-3. In the latter study, 18% of patients with low provocative GH levels had IGFBP-3 concentrations in the normal range, but only 4% of "GHD" patients had normal serum levels of both IGF-I and IGF-II. Serum levels of IGF-I and IGF-II were both reduced in only 0.5% of normal children and in 11% of normal short children.

The assay of GH-dependent IGFBP-3, normally the major serum carrier of IGF, is an additional means of diagnosing IGF deficiency caused by GHD because the concentrations of IGFBP-3 correlate with the sum of the levels of IGF-I and IGF-II:

1. The immunoassay of IGFBP-3 is technically simple and does not require separation of the binding protein from IGF peptides.
2. Normal serum levels of IGFBP-3 are high, typically in the range of 1 to 5 mg/L, so that assay sensitivity is not an issue. However, IGFBP-3 assays do have the following potential limitations:
   1. IGFBPs may interfere with radioimmunoassays, RIA, and bioassays. These binding proteins either must be removed by acid gel chromatography (which is labor-intensive) or must be blocked by the addition of excess IGF-II (which requires a high-affinity, high-specificity antibody for IGF-I). An alternative approach is to employ a radiolabeled IGF-1 analogue with reduced affinity for IGFBPs.
   2. Serum IGF-I levels are age-dependent, being lowest in young children (<5 years of age), during which one must wishes to have an accurate diagnostic test.
   3. Serum IGFBP-3 levels may be low in conditions other than GHD, such as primary GH (Laron's syndrome) and secondary GHI (e.g., malnutrition, liver disease).
   4. Serum concentrations of IGF-I (and IGFBP-3) are often normal in adult-onset GHD and in children with GHD resulting from brain tumors and cranial radiation. 1034
   5. Interlaboratory differences of absolute IGF values, although not as striking as with GH, may be substantial.

Even when these caveats are considered, the correlation between serum IGF-I levels and provocative or spontaneous GH measurements is imperfect. In a group of children younger than 10 years of age, IGF-I levels were below -2 SD in only 8 of 15 children with a diagnosis of GHD based on provocative testing (53.3% sensitivity) and normal in 47 of 48 children with a normal GH response (97.9% specificity). In one study, 18% of patients with low provocative GH levels had IGFBP-3 concentrations in the normal range, but only 4% of "GHD" patients had normal serum levels of both IGF-I and IGF-II. Serum levels of IGF-I and IGF-II were both reduced in only 0.5% of normal children and in 11% of normal short children.

The correlation between IGF-I and IGFBP-3 levels and assessments of spontaneous GH secretion is also imperfect. Even in normal children, the correlation between 24-hour GH secretion and serum IGF-I and IGFBP-3 levels is modest (r = 0.78 and 0.62, respectively). It is not possible to resolve fully conflicts between assay of IGF-I levels and measurement of GH secretion, since there is no definitive way to diagnose GHD; however, studies of patients with GHI have developed useful methods to diagnose GHD and to estimate the degree of GHI. Although such patients may have normal or elevated serum GH levels, mutations or deletions of the GHI gene render them unresponsive to GH, making them functionally deficient. In approximately 70 instances of GHI gene mutations, all had markedly reduced serum levels of both IGF-I and IGFBP-3. Even so, both IGF-I and IGFBP-3 correlated significantly with height. Measurements of IGF-I and IGFBP-3 levels have been used in other studies to establish the diagnosis of GHD.
velocity. Figure 23-52 provides an algorithm for the evaluation of the child with growth failure.

The many illness-related causes of diminished growth have been discussed in prior sections. The possibility of hypothalamic or pituitary dysfunction should always be considered in children with documented growth deceleration, particularly in the face of known or suspected CNS pathology (e.g., tumors, radiation, malformations, infection, trauma, blindness, nystagmus). Similarly, the neonate with hypoglycemia or microphallus warrants evaluation of pituitary function (including MRI), and children with documented thyropin, ACTH, antidiuretic hormone, or gonadotropin deficiency are candidates for GHD. For children with proportional short stature and documented growth deceleration, assessment of serum IGF-I and IGFBP-3 is warranted, and, based on the results, the possibilities of hypothalamic dysfunction, pituitary insufficiency, and GHI can be investigated.

Recent recommendations by the Growth Hormone Research Society (GRS) for defining GHD recognize no "gold standard" for that diagnosis and propose that in a child with slow growth, whose history and auxology suggest GHD (Table 23-9), testing for GH/IGF-I deficiency requires the measurement of IGF-I and IGFBP-3 levels as well as GH provocation tests (after hypothryoidism has been excluded). In cases of suspected isolated GHD, two GH provocation tests (sequential or on separate days) are required: in those with defined CNS pathology, history of radiation, CPHD, or a genetic defect, one GH test will suffice. In patients who have had cranial radiation or malformations of the hypothalamic-pituitary unit, GHD may evolve over years, and its diagnosis requires serial testing. Some patients with auxology suggestive of GHD, however, may have IGF-I and/or IGFBP-3 levels below the normal range on repeated tests but GH responses in provocation tests above the cut-off level. Such children do not have classic GHD but nonetheless may have an abnormality of the GH-IGF axis and, after the exclusion of systemic disorders affecting the synthesis or action of IGF-I, might be considered for GH treatment. A cranial MRI, with particular attention to the hypothalamic-pituitary region, should be carried out in any child given a diagnosis of GHD. These recommendations stress the importance of rational clinical judgment rather than specific tests in characterization of childhood GHD.

Ultimately, the diagnosis of GHD (or IGF deficiency) should be made by on the basis of combined clinical and laboratory criteria. Short children who have well-documented normal height velocities do not, generally, require evaluation of GH secretion, and the finding of normal serum levels of IGF-I and IGFBP-3 is confirmatory. Children with Turner's syndrome and short stature should not be required to undergo GH testing to qualify for GH therapy, because such treatment is not predicated on abnormal GH secretion. On the other hand, the child with documented growth deceleration requires further evaluation, even if tests of GH secretion appear normal. Documentation of decreased serum IGF-I and IGFBP-3 levels would then substantiate the diagnosis of IGF deficiency, and the differential diagnoses of GHD and GHI would need to be considered.

The child with a history of cranial irradiation, decreased height velocity, and reduced serum levels of IGF-I and IGFBP-3 should be considered to have GHD (or GHI), even in the face of normal provocative tests. Alternatively, such patients may have normal IGFBP-3 levels with low GH levels in pharmacologic tests. This approach still leaves a place for measurements of GH secretion. Such determinations are critical for distinguishing between GHD and GHI as causes of IGF deficiency. Documentation of abnormal pituitary GH secretion raises the possibility of intracranial tumors and the potential for deficiency of other pituitary hormones. Evaluation

for GHD permits concomitant assessment of ACTH/cortisol secretion during insulin-induced hypoglycemia.

The diagnosis of GHD in a newborn is especially challenging. The presence of microopenis in a male newborn should always lead to an evaluation of the GH-IGF axis. A GH level must be measured in the presence of neonatal hypoglycemia occurring in the absence of a metabolic disorder, such as hyperammonemia or carnitine deficiency syndromes. A level below 20 mg/L in a polyclonal radioimmunoassay suggests GHD. The use of standard GH stimulation tests, except for the glucagon test, is not recommended in neonates. Normative data are not available for stimulated serum GH levels, but a cut-off of 25 ng/mL is probably appropriate and stimulated values lower than 20 ng/mL certainly should raise suspicion. MRI is essential when the diagnosis is suspected, and useful clinical information defining developmental abnormalities of the hypothalamic-pituitary area may be available sooner than GH assay data. An IGFBP-3 level is of value for the diagnosis of neonatal GHD, but IGF-I levels are rarely helpful. In fact, serum IGFBP-3 should be performed as the test of choice in suspected neonatal GHD.

In summary, a child should be considered a candidate for GH therapy if he or she meets one of these auxologic criteria, supported by biochemical evidence of GHD based on sex steroidprimed provocative tests or evidence of IGF deficiency based on measurement of IGF-I and IGFBP-3 concentrations. Such patients should also

undergo MRI studies of the hypothalamus-pituitary and assessment of other pituitary hormone deficiencies. It is understood that this approach will result in GH treatment of some children with idiopathic, isolated GHD or IGF deficiency and that such cases require careful monitoring of both pituitary status and responsiveness to GH treatment. The latter can be assessed relatively to recently developed predictive models [1251,1252] and the diagnosis of GHD reconsidered in the child with idiopathic, isolated GHD, normal MRI findings, and a subnormal clinical response to GH.

**Diagnosis of IGF Deficiency Syndrome: Growth Hormone Insensitivity**

The combination of decreased serum levels of IGF-I, IGF-II, and IGFBP-3 plus increased serum levels of GH suggests a diagnosis of GHI. [1253] The possibility of GHR deficiency is supported by a family history consistent with autosomal recessive transmission. Savage and associates [1254,1255] devised a scoring system for evaluating short children for the diagnosis of GHR deficiency, based on five parameters:

1. Basal serum GH higher than 10 µL (5 µg/L).
2. Serum IGF-I below 50 µg/L.
3. Height SDS below -3.
4. Serum GHBP less than 10%, based on binding of (125)GH.
5. A rise in serum IGF-I levels after GH administration of less than twofold the intra-assay variation (10%).

Blum and colleagues [1256] proposed that these criteria could be strengthened by:

1. Evaluating GH secretory profiles, rather than isolated basal levels.
2. Employing an age-dependent range and the 0.1 percentile as the cut-off level for evaluation of serum IGF-I concentrations.
3. Using highly sensitive IGF-I immunosassays and defining a failed GH response as the inability to increase serum IGF-I levels by at least 15 µg/L.
4. Measuring both basal and GH-stimulated IGFBP-3 levels.

These criteria fit well with the population of patients with GHR deficiency in Ecuador, but that is a homogeneous population with severe GHI. [1257] The applicability of these criteria elsewhere remains to be evaluated. An important biochemical marker is the response of IGF-I (and, possibly, IGFBP-3) to GH stimulation. Normal ranges and age-defined responses of serum IGF-I levels have not been established. [1258,1259]

Decreased serum levels of GHBP suggest the diagnosis of GHR deficiency, but some individuals with GHR deficiency have normal serum concentrations of GHBP. [1260,1261,1262] Such cases represent mutations in the dimerization site or in the intracellular domain of the receptor or abnormalities of postreceptor signal transduction mechanisms. On the other hand, polymorphisms of the GHR gene, without associated reductions in levels of IGF-I or IGFBP-3, should not be considered examples of GHI. At this point, definitive diagnosis of GHI requires (1) the classic phenotype, (2) decreased serum levels of IGF-I and IGFBP-3, and (3) identification of an abnormality of the GHR gene.

**Idiopathic Short Stature**

Many children and early adolescents are short (<3rd percentile), with slowed linear growth velocity (<25th percentile). They may have delayed skeletal maturation and an impaired or attenuated pubertal growth spurt, with or without a family history manifesting some or all of these clinical features, and have no chronic illnesses or apparent endocrinopathies. Such children usually have normal GH secretory dynamics, although provocative test results may be blunted under some circumstances; GH-dependent peptides are lower than expected on a chronologic, although usually not skeletal, age basis; treatment with exogenous GH usually augments linear growth.

Such children are usually considered to have variants of normal growth and achieve a final adult height within the range considered acceptable for the family. In most of these children, the cause of the slowed childhood growth and commonly delayed pubertal spurt has not been established. Because this is the largest group of short children, continuing efforts are under way to develop a rational categorization and the means of distinguishing between these children from children with an abnormality of the GH-IGF axis. Several groups of patients, including those with CDGM, genetic or familial short stature, and heterozygous abnormalities of the GHR, are described later. Additional causes of ISS will likely be identified at each level of the hypothalamic-pituitary-IGF axis. [1263]

---

**Constitutional Delay of Growth and Maturation**

The term constitutional delay [1264,1265,1266] describes children with a normal variant of maturational tempo; characterized by short stature but relatively normal growth rates during childhood; delayed puberty with a late and attenuated pubertal growth spurt; and attainment of normal adult height. Most children with constitutional delay begin to deviate from the normal growth curve during the early years of life, and they are at or slightly below the 5th percentile for height by age 2 years. [1267] During middle childhood years, height SDS may gradually drift lower, but this does not appear to affect adult height outcome. [1268] Final height, although usually within the normal population range, is often in the lower part of the parental height target zone, [1269,1270] with few patients exceeding that target height. The predicted final height, especially when the skeletal age is extremely delayed, is greater than that usually achieved. [1271,1272,1273]

The delayed growth spurt may adversely affect growth of the spine and mineralization of the vertebrae, which is not overcome when the pubertal growth acceleration finally occurs, thus limiting the final height. [1274] The osteopenia reported in men with a history of delayed puberty may be due to a profound alteration of normal pubertal bone mineral accretion or to a prepubertal and continuing deficit in bone mass that is an intrinsic part of CDGM. [1275,1276]

GH secretion may be decreased with transient partial GHD at the time of the delayed pubertal growth spurt, apparently the consequence of inadequate production of gonadal steroids. [1277,1278] Such children would be expected to have delayed skeletal ages, normal or slightly low serum IGF-I but usually normal IGFBP-3 levels for skeletal age, and normal GH provocative tests (if pretreated with gonadal steroids). Overnight GH secretion is generally normal in these children when control groups are carefully matched. [1279] By definition, children with pure CDGM should have bone ages sufficiently delayed to result in normal predicted adult heights (>163 cm in males and >150 cm in females) (Table 23-10), although the correlation between predicted and final height is imperfect and must be viewed with caution. [1280,1281] When CDGM occurs in the context of familial short stature (see later), however, children may experience both a delayed adolescent growth spurt and a short final height.

As stated earlier, some have attributed the diminished growth in the peripubertal period in CDGM to a transient GHD or to a “lazy” pituitary, a concept that is probably due to the delay in the expected growth spurt.

to the inadequacies of GH testing, especially to the failure to pretreat patients with a brief course of gonadal steroids. Low serum levels of IGF-I and IGFBP-3 or a poor GH response to provocative testing (after priming with gonadal steroids) should mandate an investigation for underlying pathology, such as intracranial tumors.

Genetic (Familial) Short Stature

The control of growth in childhood and the final height attained are polygenic in nature. For this reason, familial height affects an individual's growth, and evaluation of a specific growth pattern must be placed in the context of familial growth and stature. Formulas have been developed for determination of parental target height, and growth curves that relate a child's height to parental height are available. As a general rule, a child who is growing at a rate that is inconsistent with that of siblings or parents warrants further evaluation.

Furthermore, many organic diseases characterized by growth retardation are genetically transmitted. This list includes multiple causes, such as GHI due to mutations of the GHR gene, GH gene deletions, mutations of the Pprop1 or Pouf1 gene, pseudohypoparathyroidism, diabetes mellitus, and some forms of hypothyroidism. Inherited nonendocrine diseases characterized by short stature include osteochondrodysplasias (see earlier), dysmorphic syndromes associated with IUGR (see earlier), inborn errors of metabolism, renal disease, and thalassemia (see later). Identifying short stature as inherited thus does not, by itself, relieve the physician of responsibility for determining the underlying cause of growth failure.

Nonetheless, a constellation of clinical findings describes a normal variant referred to as genetic short stature (GSS) (or familial short stature) that differs from the syndrome of CDGM discussed earlier. In GSS, childhood growth is at or below the 5th percentile but the velocity is generally normal. The onset and progression of puberty are normal or even slightly early and more rapid than normal, so that skeletal age is concordant with chronologic age. Parental height is short (both parents are often below the 10th percentile), and pubertal maturation is normal. Final heights in patients with GSS are short and in the target zone for the family. The GHIGF system is normal, but exogenous GH therapy during middle childhood years may increase linear growth velocity substantially without disproportionate augmentation of skeletal maturation. Whether long-term GH treatment enhances final height outcome, however, is not clear.

Heterozygous Mutations of the Growth Hormone Receptor

The level of the GHR may be genetically determined, although modulated by such factors as nutritional status. GH production appears to be inversely related to GHR/GHBP levels. Accordingly, GHBP levels have been assessed in subjects with ISS. Serum levels of GHBP in 90% of children with ISS are lower than the normal mean, 20% being below the normal range, especially a subgroup with low IGF-I and higher mean 12-hour levels of GH. Such data raise the possibility that an abnormality of GHR content or structure might impair GH action.

The inverse relationship of GHBP levels to GH production is consistent with this hypothesis. In a small group of patients with growth failure, low levels of IGF-I, and poor response to exogenous GH, heterozygous GHR mutations were present in 28%. In contrast with the rarity of homozygous GHR mutations in GHR, heterozygosity is more common and may be a frequent cause of short stature. In heterozygotes, protein from the mutant allele may disrupt the normal dimerization that occurs when GH interacts with its receptor, leading to diminished GH action and growth impairment.

The IGF-I/IGFBP-3 generation test following 4 days of GH administration may reveal individual patients with findings of low basal and provoked peptides and modestly elevated GH levels that might represent partial GHI. Biochemical confirmation of insensitivity is mandatory in such cases.
TREATMENT OF GROWTH RETARDATION

When growth failure is the result of a chronic underlying disease, such as renal failure, CF, or malabsorption, therapy must be directed at treatment of the underlying condition. Although growth acceleration may occur in such children with GH or IGF-I therapy, complete catch-up requires correction of the primary medical problem. If treatment of the underlying condition involves glucocorticoids, growth failure may be profound and is unlikely to be correctable until steroids are reduced or discontinued.

Correction of growth failure associated with chronic hypothyroidism requires appropriate thyroid replacement. As discussed earlier, thyroid therapy causes dramatic catch-up growth but also markedly accelerates skeletal maturation, potentially limiting adult height. More gradual thyroid replacement or the use of gonadotropin inhibitors to delay puberty, or both, may be necessary to obtain maximal final height.

Treatment of Constitutional Delay

CDGM is a normal variant, with (by definition) potential for a normal (although delayed) pubertal maturation and a normal (albeit diminished for target zone) adult height. Most subjects can be managed by careful evaluation to rule out other causes of abnormal growth and delayed puberty combined with appropriate explanation and counseling. The skeletal age and Bayley-Pinneau table are often helpful in explaining the potential for normal growth to the patient and parents. A family history of constitutional delay is also a source of reassurance. On occasion, however, the stigmata of short stature and delayed maturation may be psychologically disabling for the preadolescent or teenager.

Some adolescents with delayed puberty have poor self-images and limited social involvement. In such patients and in some in whom pubertal delay is predicted on the basis of the overall clinical picture, there is a role for the judicious use of short-term gonadal steroids.

Two aspects of this syndrome are addressed by androgen treatment: short stature, especially in boys between ages 10 and 14, and delayed puberty after age 14 years. In the younger group, in whom CDGM is apparent, the orally administered, synthetic androgens, oxandrolone, has been used extensively. In several controlled studies, oxandrolone therapy for 3 months to 4 years increased linear growth velocity of 3 to 5 cm/year without adverse effects or decreasing either actual or predicted final height. The growth-promoting effects of oxandrolone appear related to its androgenic and anabolic effects rather than to augmentation of the GH-IGF axis. Currently recommended treatment is 0.1 mg/kg orally per day. In older boys, in whom delayed pubertal maturation is unbearable and anxiety-provoking, testosterone enanthate has been administered intramuscularly with success.

Criteria for therapy of such adolescents should include:

1. A minimal age of 14 years.
2. Height below the 3rd percentile.
3. Prepubertal or early Tanner G2 stage with a early morning serum testosterone lower than 3.5 nmol/L (<1 ng/mL).
4. A poor self-image that does not respond to reassurance alone.

Therapy consists of intramuscular testosterone enanthate, 50 to 200 mg every 3 to 4 weeks, for a total of four to six injections. Patients typically show early secondary sex characteristics by the fourth injection and grow an average of 10 cm in the ensuing year. Despite attempts to choose subjects carefully for treatment programs in CDGM, a spectrum of activation of the reproductive system is inevitable; growth responses to short courses of therapy are best in the boys who have early pubertal gonadotropin secretory patterns. Testosterone enhances growth velocity by direct actions and increases GH production. Brief testosterone regimens do not cause overly rapid skeletal maturation, compromise adult height, or suppress pubertal maturation. It is important to emphasize to the patient that he is normal, that therapy is short-term and designed to provide some pubertal development earlier than he would on his own, and that treatment will not increase adult height. In such situations, the combination of short-term androgen therapy, reassurance, and counseling helps the boys with constitutional delay to cope with a difficult adolescence.

The availability of several new forms of testosterone, which are approved for adults with hypogonadism, provides adolescents with an opportunity for a choice among different androgen replacement therapies. Although effectiveness of these preparations has not been demonstrated in children with constitutional delay, we have personal experience with their successful use, finding an equivalent response to that obtained with testosterone injections. Testosterone gel is painless and easy to apply and has proven popular since its release. Testosterone patches also avoid the need for injections, but they work best when applied to the scrotum and are often accompanied by complaints of itching. The dosing of these alternative forms of therapy in children and adolescents has not yet been established. In view of the important role of estrogen in the process of skeletal maturation, aromatase inhibitors might be used in conjunction with androgen therapy to prevent an acceleration of bone age and further enhance final adult height.

Patients must be reevaluated to ensure that they enter "true" puberty. One year after testosterone treatment, boys should have testicular enlargement and a serum testosterone in the pubertal range. If this is not the case, the diagnosis of hypothalamic-pituitary insufficiency or hypogonadotropic hypogonadism should be considered. Although the diagnosis of constitutional growth delay remains most likely in such patients, some eventually prove to be gonadotropin-deficient, especially if they are still prepubertal late in adolescence.

Referrals for constitutional delay are more common in boys than girls, undoubtedly reflecting our cultural values. When constitutional delay is a problem in girls, short-term estrogen therapy can be employed, but the advancement of bone is a greater hazard at doses that enhance growth velocity and sexual maturation. The use of GH in patients with constitutional delay is discussed in the following sections.
Treatment of Growth Hormone Deficiency

Nomenclature and Potency Estimation

The nomenclature for the various biosynthetic GH preparations reflects the source and the chemical composition of the product. Somatropin refers to GH of the same amino acid sequence as that in naturally occurring human GH. Somatropin from human pituitary glands is abbreviated GH or pit-GH; recombinant-origin somatropin is termed recombinant GH (rGH). Somatrem, abbreviated met-rGH, refers to the methionine derivative of rGH. Although the latter preparation is a more antigenic preparation, that propensity is not clinically relevant; despite the presence of anti-GH antibodies, growth responses to met-rGH are similar to those seen in patients treated with rGH.1209,1210 We refer to these biosynthetic preparations as GH in the subsequent discussions.

The biopotency of commercially available biosynthetic GH preparations, expressed as International Units per milligram of the new WHO rGH reference reagent 88/624 for somatropin, is 3 IU/mg.1229 It was necessary to standardize the early GH preparations by bioassay because of variable production techniques (such as extraction and column purification). The most common bioassays have been the hypophysectomized rat weight gain assay, the tibial width assay, and the more sensitive Nb2 rat lymphoma proliferation assay.1213,1214,1215 With the availability of purified and essentially equivalent rGH products, the requirement for bioassays has become an FDA requisite to substantiate biologic activity rather than to assess potential differences between preparations. It is likely that the bioassays will be replaced by in vitro binding assays using GHRs or GHBP derived from molecular techniques.1229

Historical Perspective

Because untreated patients with IGF deficiency syndrome have profound short stature (averaging nearly -5 SDS1216,1217,1218), the clinical urgency to use GH therapy as soon as it was available has been apparent.1219 The action of GH is highly species-specific, and humans do not respond to animal-derived GH.1220,1221,1222,1223 Unlike most other hormones, the only GH that is biologically active in humans is primate GH. For many years, human cadaver pituitary glands were the only practical source of primate GH for treatment of GHD, and more than 27,000 children with GHD worldwide were treated with pit-GH.1224 The limited supplies of pit-GH, low doses, and interrupted treatment regimens resulted in incomplete growth increments; usually therapy was discontinued in boys whose height reached 5 feet, 5 inches in height and in girls who reached 5 feet in height. Nonetheless, this treatment did increase linear growth and in many patients enhanced final adult height. The dose-response relationship and the relation of age to GH response were recognized during this period.1225

Distribution of pit-GH was halted in the United States and most of Europe in 1985 because of concern about a causal relationship with Creutzfeldt-Jakob disease (CJD), a rare and fatal spongiform encephalopathy that had been previously reported to be capable of iatrogenic transmission through human tissue.1226,1227 In North America and Europe, the incidence of this disorder is approximately 1 case per million in the general population; it is exceedingly rare before age 50 years. To date, more than 100 young adults who had received human cadaver pituitary products have been identified as cases of CJD, with the sad likelihood that all will die of the disease.1228,1229,1230 In patients in the United States, the onset of CJD was 14 to 33 years after starting treatment, whereas the large cohort of French patients had a median incubation period approximately 5 years shorter.1231,1232 Vigilant surveillance for this dreadful complication continues.

Fortunately, by the time the risks of pituitary-derived GH were discovered, rGH was being tested for safety and efficacy.1233,1234,1235 The original rGH included an N-terminal methionine, added as a start signal for transcription (met-rGH). This preparation mimicked pit-GH in regard to both anabolic and metabolic actions. Subsequent rGH preparations do not contain the additional methionine. rGH has universally replaced pit-GH as the treatment for children with GHD.

Treatment Regimens

The recommended therapy starting dose of GH in GHD is 0.18 to 0.35 mg/kg of body weight per week, administered in seven daily doses, with the mean dose in the United States being 0.3 mg/kg.1236 Alternative regimens include a 6-day/week or 3-day/week schedule, with the same weekly dosage, but they are not as successful. In general, the growth response to GH is a function of the log-dose given, so that increasing dosages further enhance growth velocities,1237,1238 but daily dosing may be the most important treatment parameter.1239 Either subcutaneous or intramuscular administration has equivalent growth-promoting activity;1240 the former is now used almost exclusively. GH is available in several vehicles, and multiple systems are now available for administering GH (Table 23-11).

The standard preparation is lyophilized GH that is highly water-soluble, so that it may be brought into solution with a small volume of diluent. An aqueous solution is ready to use and has 28-day stability. A sustained-release preparation of GH with protein integrity in a poly(lactide-coglycolide) polymer that is biocompatible and biodegradable permits once-monthly or twice-monthly treatments.1241 The pharmacokinetics of this system show an early release of GH and then a sustained release over 12 to 28 days. Average exposure to GH and IGF-I following administration of current treatment regimens of depot GH is approximately half that of daily GH therapy. Either reconstituted or liquid GH is administered in insulin syringes with ultralfine needles that are almost pain-free in skilled hands. Pen devices with internal reconstitution of the GH are frequently used because of ease, accuracy, and "hidden" needles. Needle-free, jet injector systems are available and do yield a normal serum immunoreactive and bioactive GH profile.1242 The sustained-release GH is administered through a short, larger-bore needle, but the injection pain is balanced against the low frequency of treatments. At this time, all of the GH preparations yield comparable short-term growth outcomes, except long-acting GH, in which mean first year growth rates are about 2 cm lower per year.1243,1244

GH treatment should be continued after growth ceases, because GH has other important metabolic effects, including support of normal gonadal function1245,1246 and attainment of normal adult bone mineral density.1247,1248 A report from the Drug and Therapeutics committee of the Lawson Wilkins Pediatric Endocrine Society summarized the society's views on the use of GH in children with diverse syndromes of short stature.1249

Growth responses to exogenous GH vary, depending on the frequency of administration, dosage, age (greater absolute gain in a younger child, though not necessarily of growth velocity SDS), weight, and GH amount, as assessed by serum GHBP levels.1250,1251,1252 On this general regimen, nonetheless, the typical

GH, growth hormone.
GHD child accelerates growth from a pretreatment rate of 3 to 4 cm/year to 10 to 12 cm/year in year 1 of therapy and 7 to 9 cm/year in years 2 and 3. Progressive waning of GH efficacy occurs and is poorly understood. The importance of dosage frequency is illustrated (Fig. 23-53 and Fig. 23-54) by data from a carefully done assessment of growth responses of prepubertal GHD children randomly assigned to receive thrice-weekly or daily GH at the same total weekly dose (0.30 mg/kg per week). The mean total height gain during this period was 9.7 cm greater in the daily-treated patients (38.4 versus 28.7 cm. P < 0.0002) with similar increments in skeletal maturation and no acceleration of the onset of puberty. Mean height SDS at the end of 4 years was +0.2, or at the midpoint of normal for age. At a dosage of 0.30 mg/kg per week, the approximate current cost of GH therapy for a 20-kg child is $12,000 to $15,000 annually.

Sophisticated mathematical models have examined many laboratory and auxologic parameters that influence response to GH therapy. Because age at onset of treatment is inversely correlated with growth responses and the smaller, lighter child requires less GH (with marked economic benefit), growth data in early treated children are important to assess. In short-term studies of 134 patients, treated prior to 3 years of age, marked early catch-up occurred with a mean height gain of around 3 SDS by 4 years of therapy, allowing most children to reach the normal height range by middle childhood. In one study, mean height reached -0.4 SDS after 8 years of treatment. Near adult height data in 13 patients treated before 5 years did not differ from the midparental target height (-0.9 versus -0.7 SDS). If future long-term outcome studies also show excellent growth responses with achievement of genetic target height and adherence to treatment regimen were possible in very young children, strongly worded recommendations for early treatment would surely be appropriate.

**Longer-Term Final Height Results**

Much information on growth has been reported about pGH-treated children, generally thrice-weekly and administered intramuscularly. Five-year data are available from Bundak and co-workers on a group of 58 prepubertal and 20 pubertal children with GHD. The younger group increased its height from -3.6 SDS to -2 SDS, whereas the pubertal children grew to -2.3 SDS. The height SDS for bone age, however, did not increase; thus, further loss of adult height was prevented, but there was no increase in the adult height prediction. The importance of early initiation of treatment is stressed by such data. Similarly, Libber and associates found that GH therapy increased mean height from about -4.2 SDS to -2.3 SDS. Patients treated with daily (QD) and thrice-weekly injections (TIW). The mean annual growth velocity in the QD group was significantly greater during each year, although significance diminished from year 1 to year 4. (From MacGillivray MH, Baptista J, Johanson A, and Genentech Study Group. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal growth hormone-deficient children. J Clin Endocrinol Metab 1996; 81:18061809; reproduced by permission of M. H. MacGillivray.)

![Figure 23-54](image)

Figure 23-54: Height standard deviation score (SDS) (mean + SD) for prepubertal patients with growth hormone deficiency (GHD) before and during 4 years of growth hormone (GH) treatment, contrasting results with daily (QD) and thrice-weekly (TIW) injections. The mean SDS in the QD group was significantly greater throughout the treatment period. Younger patients had the greatest increase in height SDS, and the effect of age was more marked in the QD group. (From MacGillivray MH, Baptista J, Johanson A, and Genentech Study Group. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal growth hormone-deficient children. J Clin Endocrinol Metab 1996; 81:18061809 (1328). Reproduced by permission of M. H. MacGillivray.)

Mean height reached -0.7 SDS, which was equivalent to the midparental target height. Even in these closely followed patients, however, a -0.4 to -0.6 SDS difference from midparental targeted height still occurred. The achievement of the genetic target is possible, however, as a Swedish subgroup (in KIGS) of consistently treated patients reached a median final height SDS of -0.32, which was equivalent to the midparental target height. By multiple regression analysis, factors found to correlate with enhanced adult height were baseline height, younger age at onset of treatment, longer treatment duration, and a greater growth velocity during the first year of treatment. Although the development of rGH

*GH dose is mg/kg per week.*

Patients treated largely with biosynthetic GH have improved actual or near-final adult height SDS, with average final height in more than 1400 patients approximating -1.3 SD below the mean. Even in these closely followed patients, however, a -0.4 to -0.6 SDS difference from midparental targeted height still occurred. The achievement of the genetic target is possible, however, as a Swedish subgroup (in KIGS) of consistently treated patients reached a median final height SDS of -0.32, which was equivalent to the midparental target height.
has solved the problem of supply experienced in the pituitary GH era, delays in diagnosis and initiation of therapy have still compromised adult height.

In an effort to increase final height of patients with GHD, the use of high-dose GH during puberty has been studied based on the rationale that GH secretion normally rises two-fold to four-fold during the pubertal growth spurt with dramatic concomitant increases in serum IGF-I levels and that the pubertal growth spurt normally accounts for approximately 17% of adult male height and 12% of adult female height. Earlier studies by Stanhope and colleagues indicated that little difference in height gain could be observed when adolescent patients were given 30 versus 15 IU/m² of GH weekly (0.04 versus 0.02 mg/kg per day). Mauers and colleagues, however, evaluated higher pubertal GH doses (0.1 versus 0.043 mg/kg per day) and found that the higher dosage resulted in a 4.6 cm increase in near-final height. Mean height SDS achieved in the 0.043 mg/kg per day group (as in the earlier report) was 0.7 ± 0.9 but 0.0 ± 1.2 in the group receiving 0.1 mg/kg per day. The higher GH dosage did not result in more rapid acceleration of skeletal maturation.

Important factors in these improved adult height outcomes include:

1. The use of higher doses of GH.
2. The ability to treat until growth cessation.
3. Early initiation of treatment, progressive weight-related dose increments.
4. Attention to compliance with daily administration.
5. Appropriate thyroid hormone and glucocorticoid replacement therapy.

Since final height correlates with height at the onset of puberty in patients with GHD, every effort must be made to enhance growth velocity during prepuberty.

In data from NCGS and KIGS, the height gained during puberty in patients with GHD was generally comparable to that in healthy children with delayed bone ages. The pubertal height gain is negatively correlated with the age of pubertal onset. When normal or precocious puberty limits the response to GH, it may be appropriate to delay puberty by the use of a GnRH analogue. Use of this strategy in pubertal GHD patient groups, however suggestive, is not yet clearly documented to enhance final height. Nevertheless, the earlier the age of pubertal onset, the lower the final height outcome, and patients with GHD with delayed puberty or hypogonadotrophic hypogonadism have a taller adult height.

Growth Hormone Treatment of Prader-Willi Syndrome

GH treatment of growth failure in Prader-Willi syndrome is now an FDA-approved indication, with a recommended dose of approximately 1 mg/m² per day or 0.24 mg/kg per week. Numerous clinical trials document the efficacy of GH and help to confirm that the characteristic IGF deficiency state is due to GHD. After 5 years of GH therapy, Lindgren and co-workers (at a dose of 0.23 mg/kg per week) showed that mean height SDS approached 0.5, with a gain of nearly 2 SDS. Other shorter-term (6- to 24-month) treatment programs have found increased growth rates but also provide important information on the changes in abnormal metabolic parameters during GH treatment. Such data demonstrate reduction in body fat mass and percentage, increased fat-free mass, improved muscle strength and agility, and increased fat oxidation. Respiratory muscle weakness, which is found in Prader-Willi syndrome, was improved after GH treatment. In view of the association of insulin resistance and type 2 diabetes mellitus with obesity, glycemic status should be monitored in GH-treated patients with Prader-Willi syndrome.

Combined Pituitary Deficiencies

If GHD is part of a multiple pituitary insufficiency, it is necessary to address each endocrine deficiency both for general medical reasons and to ensure maximal effect of GH therapy. Thyrotropin deficiency is often "unmasked" during the initial phase of therapy, and thyroid function should be assessed both before the onset of therapy and during the first 3 months of GH treatment and at least on an annual basis thereafter.

Monitoring Growth Hormone Therapy

Although most pediatric endocrinologists simply document changes in growth velocity as the signal parameter of therapeutic efficacy, this may not be sufficient. Treatment models that predict growth rate with quite narrow confidence limits provide quantitative estimates of whether the individual patient is responding appropriately to GH. A model explaining 61% of growth response variability for the first year of therapy includes inverse relationships with maximum GH response during provocative testing, age and height SDS minus midparental height SDS, and positive correlation with body weight SDS, GH dose, and birth weight SDS. The most important predictive factor for years 2 through 4 is the first-year height velocity. Clearly, after age at diagnosis, GH dose management is the variable most affected by the physician. Changes in levels of the GH-dependent peptides, IGF-I and IGFBP-3, ALS, and the aggregate ternary complex, as well as leptin, correlate with growth responses. Measurement of these may give added information on the growth-promoting and fat-mobilizing actions of GH as well as of the spectrum of childhood responsiveness to exogenous GH. Safety monitoring should include yearly assessment of IGF-I, IGFBP-3, and fasting glucose/insulin ratios.

Poor Growth Responses

The growth response to GH typically attenuates after several years but should continue to be equal to or greater than

the normal height velocity for age throughout treatment. Using the statistical growth treatment models may prove valuable in judging therapeutic efficacy.
A suboptimal response to GH can be due to several causes:

1. Poor compliance.
2. Improper preparation of GH for administration or incorrect injection techniques.
3. Subclinical hypothyroidism.
5. Excessive glucocorticoid therapy.
7. Epiphyseal fusion.

Although 10% to 20% of recipients of GH develop anti-GH antibodies, growth failure is rarely due to such antibodies. Maximal growth response to GH can usually be obtained by early diagnosis and initiation of therapy and by careful attention to compliance and psychological support. Although in many earlier studies, large numbers of boys and especially of girls with idiopathic GHD did not achieve normal adult heights, it is our belief that normal height (i.e., reaching the family-specific target height) can be reached in most cases. The referral of short girls and their ultimate treatment with GH remain less frequent than those of boys.

Despite the efficacy of GH in accelerating growth in GHD children and to bring adult height into the normal range if treatment is begun sufficiently early, several studies have indicated that the long-term prognosis for such patients is guarded, although there is much more follow-up assessment needed in the modern era. The educational, vocational, and social outlook for adults who had childhood GHD is frequently suboptimal. Whether this reflects subtle intellectual deficits or the consequences of lower expectations of patients, families or teachers remains to be determined. In any case, patients with GHD should be followed carefully throughout life.

**Growth Hormone Treatment during the Transition to Adulthood and in Adulthood**

Studies have focused on the clinical consequences of GHD in adults and at the potential benefits of GH therapy in such patients. Signs and symptoms of adult GHD include reduced lean body mass and muscle mass, increased body fat, reduced bone mineral density, reduced exercise performance, and increased plasma cholesterol. GHD adults have been found to have impaired psychological well-being and quality of life, characterized by depression, anxiety, reduced energy and vitality, and social isolation. Several placebo-controlled studies have demonstrated that GH therapy of adult GHD patients results in marked alterations in body composition, fat distribution, bone density, and sense of well-being. Whether these effects of GH therapy will be sustained and, if so, what the optimal GH regimen will be remain to be determined.

On the basis of the data in adults, which suggest profound metabolic derangements associated with untreated GHD, continuation of GH treatment in late adolescent patients who show GHD on retesting has become a clinical issue. In nearly 500 patients with isolated GHD, 207 (44%) had normal GH levels during provocative retesting. In contrast, approximately 96% of patients with CPHD, with or without structural abnormalities of the hypothalamic-pituitary area, had sustained

The presence of multiple anterior pituitary hormone deficiencies or structural disease would seem to obviate the need for subsequent retesting.

One unresolved matter is the strict pharmacologic definition of GHD in that age group: There are no convincing normative data, and it does not seem reasonable to use the much lower GH responses to testing that characterize older adults. This remains to be worked out. Many patients do not wish to continue daily injections, but data support their necessity. Loss of energy and strength is frequent. Total body and abdominal fat in untreated patients increases significantly, whereas lean body mass is lost relative to controls or comparable GH-treated patients or those after reinstatement of therapy. Similarly, resting metabolic rates decreased within 6 months and were predictive of increased fat mass at 1 year after stopping GH treatment. Because bone mass accrual is not completed until the third decade, late adolescence is an important time for GH sufficiency to prevent later osteopenia.

In young adults (mean age, 24 years) in whom GH therapy had been discontinued since late adolescence, 57% had average spine bone mineral density more than -1 SD below the mean. Two years of GH treatment resulted in a 5.2% increase after a transient decrement at 6 months of therapy. After 1 to 2 years off GH therapy, IGFI-1 levels decrease to about 35% and IGFBP-3 to 75% of treated values. Resumption of GH normalizes these levels. These studies affirm the necessity of continuing GH treatment in late adolescence, albeit at non-childhood growth-promoting doses to prevent development of adverse cardiovascular risk, diminished bone mineralization, and an overall lowering of energy level.

Our current method of assessing the late adolescent patient is based on the retesting data discussed earlier and on the recommendations of the Growth Hormone Research Society. An algorithm to guide this transition is shown in Figure 23-55. On completion of skeletal growth, GH therapy should be halted for approximately 3 months and the patient is then retested. When an insulin tolerance test is mandatory for the patient to qualify for further GH therapy, this test should be performed; other pituitary hormones and serum IGFI-1 and IGFBP-3 levels are also measured. The opportunity should be taken to assess body composition, bone mineral density, fasting lipids, insulin, and quality of life, before and after discontinuation of GH therapy. These studies establish baseline data prior to long-term GH treatment and are also used for longitudinal assessment of untreated patients. The likelihood of GHD persisting into adult life in patients with CPHD, structural abnormalities of the hypothalamic-pituitary, or documented hypothalamic-pituitary molecular defects far exceeds that in patients with idiopathic, isolated GHD.

In summary, a conservative approach would suggest that all children classified as having GHD should be retested by insulin-provocative tests on completion of skeletal growth and before a commitment is made for long-term adult treatment. An argument can be made, however, that patients with a high likelihood of persistent GHD do not necessarily require retesting or, at most, should undergo determinations of IGFI-1 and IGFBP-3 concentrations. On the other hand, the child who has carried a diagnosis of idiopathic, isolated GHD should always be retested. When the diagnosis of adult GHD is established, continuation of GH therapy is strongly recommended. One should exercise caution when considering whether to continue GH therapy when there is a known risk of diabetes mellitus or malignancy. The tr guesses to close collaboration between the pediatric and adult endocrinologists, who should discuss the reintroduction of treatment with the patient.
survey of 251 pediatric endocrinologists suggested that 30% to 50% would consider treating short children with a wide array of diagnoses, including Russell-Silver and Noonan's syndromes, IUGR, and steroid-induced growth suppression. Indeed, children with growth failure due to multiple different disorders have received GH and have grown substantially.

Although these data arise from large, uncontrolled NCGBS and KGBS studies, certain trends do emerge. On purely auxologic grounds, it is difficult to discriminate between responses, over at least 4 years, to GH in children with a diagnosis of GHD by current clinical and laboratory criteria or in children with Turner's syndrome from responses in many children with "other conditions." If such data are taken in the context that responsiveness to GH (rather than an arbitrary diagnosis of GHD) should determine appropriateness of GH therapy, prospective evaluations in many clinical states of poor growth should ensue.

The questions of whether such therapy is safe and justifies the cost and potential risks are more complicated. Additionally, questions have been raised about the appropriateness of "cosmetic" hormonal therapy. These are not issues that are presently answered. Guidelines have been developed by the Lawson Wilkins Pediatric Endocrine Society and the Growth Hormone Research Society to provide a rational framework in this area.

The 2001 FDA-approved indications for GH treatment in childhood and adolescence are GHD, Prader-Willi syndrome, chronic renal failure, Turner's syndrome, and growth failure due to prior IUGR. GH insufficiency need not be documented in the latter four conditions of poor growth.

### Chronic Renal Failure

GH accelerates growth in children with chronic renal failure at least over several years of therapy (Fig. 23-56 and Fig. 23-57). Using a GH dosage of 0.05 mg/kg per day.

![Figure 23-56 Annual growth velocity in 20 growth-retarded prepubertal patients with chronic renal insufficiency who were treated with growth hormone. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth-retarded children with chronic renal insufficiency with recombinant human growth hormone. Kidney Int 1996; 49:781785; reproduced by permission of R. N. Fine.)](image1)

![Figure 23-57 Height standard deviation score (SDS) (mean ± SD) in 20 growth-retarded prepubertal patients with chronic renal insufficiency. Note that the basal height is outside the normal range (at -2.5 SDS); enters the normal range within 1 year of treatment, and does not differ from the mean by the 5th year of growth hormone therapy. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth-retarded children with chronic renal insufficiency with recombinant human growth hormone. Kidney Int 1996; 49:781785; reproduced by permission of R. N. Fine.)](image2)

Fine and associates reported a mean first-year growth rate of 10.7 cm in GH recipients and 6.5 cm in the placebo group; in the second year GH-treated patients had a mean growth rate of 7.8 cm/year versus 5.5 cm/year in placebo recipients; this resulted in an improvement of height SDS from -2.9 to -1.5. Twenty patients who were treated for 5 years reached a normal height SDS of -0.7, having had a mean height increase of 40 cm. The youngest patients (<2.5 years of age) had the most impressive growth response to GH therapy (14.1 cm/year). Deleterious effects on renal function or progression of osteodystrophy were not observed.

This treatment regimen does not adversely affect renal graft function after transplantation, nor is there significant "catch-down" growth following the transplantation.

The final height in 38 German children treated with GH for an average of 5.3 years was 1.6 ± 1.2 SDS, an increase of 1.4 SDS over the pretreatment baseline. The final height of an untreated control group was 2.1 ± 1.2 or 0.6 SDS below baseline.

Long-term GH treatment has also been shown to be safe and effective for extremely short (<4.0 SDS) children with nephropathic cystinosis and should be considered if nutrition and cysteamine treatment do not prevent growth failure. Because children are often short at the time of renal transplantation, hormone findings of relative GHI, and receive chronic prednisone therapy, GH is sometimes administered in the post-transplantation period. Data for 1 to 2 years of treatment of such children and adolescents indicate a large increment of growth velocity at year 1 and a smaller benefit at year 2. As with GH treatment of chronic renal failure, the pharmacologic regimen overcomes the relative GHI. Considerable assessment must yet be undertaken to demonstrate whether there is increased height growth over a longer term, that renal function does not deteriorate during therapy, and that the risk of rejection is not enhanced. Initial data suggest that GH treatment does not cause an accelerated decline of allograft function or changes in histopathologic findings but that the exacerbation of chronic rejection by GH therapy remains a possibility. Use of nonsteroid-based immunosuppressive regimens may obviate the need for post-transplantation GH treatment.

### Turner's Syndrome

Patients with Turner's syndrome have a final height of about 143 cm in the United States, which is about 20 cm lower than the mean final height of normal women. Extensive trials of therapy have involved androgens, estrogens, and GH. Androgens have either no effect or cause modest gains in final adult height, despite frequent reports of short-term improvement in growth velocity. Although estrogen deficiency is probably not involved in the growth failure of Turner's syndrome, especially that in infancy and childhood years, low-dose therapy has been unsuccessfully used in an attempt to enhance growth. These studies consistently show modest, transient increments of growth velocity, invariably accompanied by advancement of skeletal maturation. Final height outcome is not improved and often is impaired. Planning for the needed estrogen replacement for ovarian failure must take into account its effects on growth outcome.

Prior to the availability of rGH, data were conflicting concerning the efficacy of pit-GH in this disorder, but the ability of GH to accelerate growth has now been
demonstrated in multiple reports. In 1983, a randomized, controlled North American study of GH (at a dose of 0.375 mg/kg per week), with or without added oxandrolone, was initiated, with mean age of onset of treatment approximately 9 years. Analysis of all 62 girls enrolled in the study at near final height shows a stature of 152.1 cm in the GH plus oxandrolone group (a gain of 10.3 cm, compared with Lyon height predictions), whereas girls receiving GH alone are at 150.4 cm (a gain of 8.4 cm) (Fig. 23-35). In another arm of this study, addition of estrogen to the GH regimen prior to age 15 years lowered the final height gain from 8.4 to 5.1 cm. In a reassessment of North American data in NCGS, early initiation of GH treatment was shown to allow estrogen administration at a physiologic age without loss of adult height.

Several other studies have used higher doses of GH, have shown even greater gains in adult height outcomes. Sas and colleagues, in a multicenter trial using a maximum GH dose of approximately 0.63 mg/kg per week for 4.8 estrogen-free GH treatment years, beginning at mean age 8.1 years, found a gain of 16 cm over the modified Lyon projection. In their group receiving a similar GH dose to the American studies, a height gain of 12.5 cm was achieved by age 16 with 4.8 estrogen-free GH treatment years starting at 7.9 years. Carel and colleagues, using 0.7 mg/kg per week in a group that received 5.1 estrogen-free GH treatment years beginning at 10.2 years, gained 10.6 cm over Lyon projections. Their conventional dose group (0.3 mg/kg per week) gained only 5.2 cm with 3.0 estrogen-free GH treatment years starting at 11 years. The substantial variations in the GH-induced growth increments in these studies are presumably related to GH dose, duration of estrogen-free GH treatment years, the age of initiation of GH and estrogen administration, as well as the population and parental adult heights. In these higher dose treatment studies, hyperinsulinism with presumed insulin resistance was evident, though reversible.

Some uncertainty still exists, however, because none of the studies were placebo controlled to adult height, and many studies have yielded much poorer height outcomes. Nonetheless, in light of historical data on natural growth in Turner’s syndrome, the available treatment results do provide convincing support for the belief that GH can both accelerate growth and increase adult height.

We recommend seeking the diagnosis vigorously in short girls of any age and initiating therapy at that young age (i.e., at diagnosis). We consider the addition of oxandrolone to the regimen in girls with a late diagnosis. We initiate estrogen administration at an appropriate physiologic age in girls who began GH therapy at a young age, but we delay estrogen administration as long as possible in girls who began GH therapy at a late age. The diminished areal bone density in Turner’s syndrome is enhanced by GH, but estrogen therapy is needed to normalize volumetric density (i.e., related not simply to size). Use of statistical prediction models for long-term growth in Turner’s syndrome may permit a more quantitative assessment of the individual therapeutic efficacy.

### Down’s Syndrome

The encouraging results of GH trials in Turner’s syndrome have led to studies of GH in Down’s syndrome. In several preliminary studies, GH accelerated growth in such patients, although ethical issues have been raised concerning the appropriateness of such therapy. In the uncontrolled NCGS experience, 23 children experienced a 1.3 SDS height gain over the first 4 years of GH therapy. No convincing data exist that GH improves neurologic or intellectual function in such patients. The increased risk of diabetes mellitus and leukemia in children with Down’s syndrome might be augmented by GH therapy.

### Intrauterine Growth Retardation

A number of studies employing GH have been performed in short children with IUGR but are hampered by the heterogeneity of this group of patients, whose poor growth may reflect maternal factors, chromosomal disorders, dysmorphic syndromes, toxins, and others. Indeed, the low levels of IGF-I and IGFBP-3 in infants with IUGR, apparently related to fetal malnutrition, do not seem to predict the degree of subsequent growth impairment. Short children with IUGR make up a substantially portion of growth-retarded patients seen in pediatric endocrine practices. Because the height of these children may be in the range seen in growth deficiency syndrome, therapeutic attempts certainly are appropriate if it can be assumed that the insulin resistance noted in these children does not become a clinical issue. Encouraging short-term and long-term responses have been obtained with GH treatment.

A randomized, placebo-controlled, double-blind, two-dose (0.13 and 0.4 mg/kg per week) study on 95 children of GH therapy was serially reported during 3 years of treatment and then after 1 year off GH. After this period, mean height was normal in the high-dose group (1.76 ± 0.17 SDS) and higher than in the low-dose group (2.46 ± 0.39 SDS); skeletal maturation in the two groups advanced 5.3 ± 0.4 and 4.6 ± 0.7 years, respectively, over the 4-year study, but remained 1 to 2 years below chronologic age.

Several other 2-year multicenter trials using doses ranging from 0.23 to 0.7 mg/kg per week also showed enhanced growth velocity (gaining 5 to 10 cm more than control groups), but bone age advanced 2.7 years. These data suggest that height growth may catch up in children with IUGR who are very short during middle childhood years. Perhaps an approximation to the growth velocity of their peers would have enough benefit to justify GH treatment, even if long-term data do not indicate an appreciable enhancement of final adult height. Subsequently, the questions regarding long-term efficacy of GH therapy on final height have been answered.

Sas and co-workers contrasted prepubertal SGA children receiving 0.23 (n = 23) to 0.47 mg/kg per week (n = 16) over a 5-year period. Mean height SDS increment of 3.3 ± 0.7 in the higher dose group exceeded that in the lower (2.4 ± 0.5). Despite a mean skeletal age increase of 7 years during the study, predicted adult height increased 9.1 ± 2.8 and 14.0 ± 5.5 cm in the two groups.

de Zegher and colleagues reported results from the longest GH treatment of SGA children. They used several different regimens, including continuous treatment with 0.23 to 0.45 mg/kg per week for 6 years and a discontinuous program of 0.23 to 0.7 mg/kg per week for 2 years followed by no therapy or one additional 2-year course at these varied doses.

The mean dose in the discontinuous treated children was 0.22 mg/kg per week over the 6 years, but they received 46% fewer injections. Mean height SDS gains were approximately 2.0 cm in these regimens, with mean parent adjusted height SDS at about -0.5. Bone age advanced 7.3 ± 0.1 years over the 6-year period and remained slightly delayed. At 8 years of therapy (personal communication from de Zegher F, 2000), the children are still growing and have now reached approximately 12 cm over predicted adult height. Onset of puberty was not accelerated in either of these studies. It appears that GH therapy for this group of patients, which accounts for about 20% of short children, may become a quantitatively important use as this treatment is now an FDA-approved indication. No evidence of meaningful insulin resistance was found in these study patients, in contrast to its high prevalence in children with IUGR who are growing well and potentially evolving into the adult syndrome.
Osteochondrodysplasias

GH therapy has been studied in several skeletal dysplasias. The largest published study in achondroplasia involved 40 children. During the first year of treatment, height velocity increased from 3.8 to 6.6 cm/year; in year 2, height velocity decreased to approximately 5 cm/year. A modest improvement was seen in the ratio of lower limb length to height. Although GH was well tolerated, atlantoaxial dislocation during GH therapy has been reported in one patient. In another study, normal growth velocity was achieved for up to 6 years in 35 subjects with a significant increment in height SDS for at least 4 years. In this study, vertebral growth was disproportionately greater than limb growth.

Bridges and Brook reported on the effects of GH therapy of 27 patients with hypochondroplasia; response was maximal during the first year of treatment, but substantial benefit was seen through 4 years of treatment in pubertal subjects. Much of the growth response represents an increase of spinal length; with leg-lengthening procedures, some patients may achieve adult height within the normal range. Experience with GH treatment is limited in other skeletal disorders, such as dyschondrosteosis, hereditary multiple exostoses, osteogenesis imperfecta, and Ellis-van Creveld syndrome.

Noonan's Syndrome

Most experience with GH therapy of short stature in Noonan's syndrome has been limited to small, uncontrolled studies in which few patients have reached final height. The clinical diagnosis of a dysmorphic syndrome potentially makes the treatment groups heterogeneous. Overall, treatment results for 3 to 4 years are similar to those attained in Turner's syndrome, with growth velocities improving from baseline rates of approximately 4 cm/year to 8, 7.7, and 6 cm/year over the first 4 years of therapy, gaining from about -3.5 to -2 SDS without inordinate advancement of bone age. Although initial anecdotal experience suggested progression of ventricular hypertrophic cardiomyopathy, such has not been found in larger carefully monitored studies.

Idiopathic Short Stature (or, Possibly Normal Short Children)

A heterogeneous group that includes children with constitutional growth delay, genetic short stature, possible heterozygous mutations of the GHR gene, and an array of conditions still called idiopathic short stature has been very difficult to characterize. Even though these children are placed in one category, this group includes some children who have normal provocative GH responses but are, nevertheless, relatively IGF-deficient, reflecting the inadequacies of GH testing. This group also includes children with undiagnosed syndromes, chronic illnesses, or endocrine disorders. For example, children with heterozygous mutations of the GHR have subnormal growth, diminished IGF and GHBP levels, and impaired responsiveness to exogenous GH administration. These children often experience stressful circumstances, although studies suggest variable relationships of behavioral problems to the short stature. Accordingly, although the specific causes of these disorders are often unknown, GH treatment has been used widely.

The failure to report levels of IGF-I, IGFBP-3, and GHBP in many studies and differing interpretations of endogenous GH secretion studies (according to factors such as assay variance and control group size), in addition to the heterogeneity of the patient groups, confound data assessment. Furthermore, published clinical trials have not contained long-term control groups and have reported variable growth responses. Most normal short children treated with GH experience growth acceleration (catch-up) that generally is sustained over the first several years of therapy, although attenuation of the response occurs as in all other instances of GH treatment. It appears that slower pretreatment growth velocity and higher weight/height ratio, factors suggesting GHD, and a lesser degree of bone age retardation are associated with better early growth responses.

Longer-term data are now available to begin to determine the impact of therapy on adult height. Nearly 3000 children were classified as having ISS in KIGS, with having reached final height in 1999. GH treatment (0.2 to 0.25 mg/kg per week) resulted in achievement of target height in familial (genetic) short stature (FSS) patients, although at a short stature (-1.7 SDS in males and -0.2 SDS in females) with a mean gain during therapy of 0.6 to 0.9 SDS. In non-FSS children, the mean final height was greater in males (-1.4 SDS than in females (-2.3 SDS), with mean gains 1.3 and 0.9 SDS, respectively. These latter heights are, nonetheless, distant from the midparental target heights that were near 0 SDS.

Hintz and associates assessed adult height in 80 North American children with ISS treated for up to 10 years at a GH dose of 0.3 mg/kg per week. Mean height SDS at conclusion was -1.4 with a gain of 1.3 SDS, similar to the broader KIGS experience. Although this study was not placebo-controlled, the data were compared to predicted and actual final heights of two groups of short children followed for similar periods. Treated boys achieved 9.2 cm and girls 5.7 cm greater gain in final height than untreated controls. Careful monitoring did not reveal any discernible metabolic side effects.

Similarly, unpublished data from Sweden showed a mean final height gain of 1.5 SDS, in contrast with 0.6 SDS in an untreated group of short children.

McCaughy and colleagues showed that GH treatment (0.34 mg/kg per week) of 8 prepubertal girls led to a mean height SDS gain of 1.28 after 6.2 years of treatment. This was a 7.6 cm greater gain than in a control group whose mean height SDS did not change during the study.

Taken together, these studies show that GH treatment of prepubertal children with ISS does increase growth velocity and final height, but that the range of results reflects the heterogeneity of the study populations. Girls may be less responsive than boys, and early treatment may enhance growth outcome.

In a collaborative study of 229 untreated children from nine European countries, contrasting data, which challenge the value of GH treatment in such patients, showed final heights of -1.5 SDS in boys and -1.6 SDS in girls. Price found generally similar results in reviewing six studies but stressed the inaccuracy of height predictions and the failure to attain target heights.

Concerns had been raised that GH treatment might accelerate pubertal onset and progression resulting in failure to improve height SDS for bone age, thereby offsetting the positive responses observed during early years of GH treatment of ISS. This has not been substantiated by the studies described earlier. Nonetheless, several small studies assessed the value of delaying puberty with a GnRH agonist in GH-treated children with ISS. Although two trials showed considerable gain (6 to 10 cm) between predicted and final height, others did not. At this time, the added cost along with the potential negative impact of stopping puberty in a child already shorter and less mature than his or her peers diminishes our enthusiasm for such a delaying regimen.

Important questions have been raised about the financial, ethical, and psychosocial impact of GH therapy of normal short children. Given the cost, the financial implications of treating normal short children (whether at the bottom 5%, 3%, 1%, or 0.1%) is considerable. The point is well taken that 5% of the population will always be below the 5th percentile, whether or not we treat with GH, and focusing on short stature potentially handicaps an otherwise normal child, psychologically or socially. No convincing data have been presented to date that GH treatment of normal short children improves psychological, social, or educational function. Furthermore, the final adult height in children with CDGM (probably the most frequent discrimination) will be adequate without any treatment.

Finally, the treatment risks of GH therapy, both known and unknown, must be considered when treatment of otherwise normal children is an issue. There can be no discernible risk associated with therapy in this situation. Yet, given (1) the current limitations in the definitive discrimination between GHD and normal short stature, (2) the inadequate understanding of neurosecretory defects of GH secretion, (3) the inadequate recognition of “partial” GHD or GHI, and (4) the need to move to a more global concept of IGF deficiency, it seems unfair to prevent GH therapy of short children who do not meet a narrow definition of GHI (i.e., provocative testing) that we recognize as inadequate.

As noted earlier, many of these children are comparable clinically and in responsivity to GH to classic GHD patients. Accordingly, we recommend the following approach:

1. Controlled therapeutic trials of normal short stature must continue to be carried out to adult height.
2. Appropriate evaluation should include extensive analysis of the GH-IGF axis (with GHBP levels, IGF responses to GH treatment, and possibly GHRP/GHRH testing) before labeling a short child as “normal.”
3. Proper assessment of pretreatment growth velocity should be over a minimum of a 6-month period and preferably for 12 months.
4. In the otherwise normal child with severe short stature (at least 2.5 SD below the mean for age) and a poor height velocity (e.g., <25th percentile for age)
cm/year before age 4 years; <5 cm/year at age 4 to 8 years; <4 cm/year anytime before puberty), the possibility of a trial of GH therapy should be discussed with the patient and family. This discussion should include an assessment of normal growth patterns, familial growth patterns, and the predicted pubertal and statural development. The inconveniences, discomforts, and potential risks of GH treatment should be fully described. It is the physician's responsibility to ensure that expectations of the child and the parents are realistic in regard to short-term growth and ultimate height. Where appropriate, counseling and psychological support should be provided.

5. If a trial of GH therapy is desired, treatment should be for a minimum of 6 months. There are no perfect guidelines for dosage; we recommend 0.05 mg/kg per day.

6. Therapy with GH should be continued beyond 6 months only if growth is accelerated (an increase in height velocity of at least 2 cm/year). Efficacy of treatment requires continuous monitoring, especially in patients with partial GHR deficiency, in whom the possibility of IGF-I therapy is a future alternative. The use of complex, nonlinear multivariate models to assess growth response is recommended.

7. Growth acceleration with GH treatment does not relieve the physician of child's growth failure. Appropriate studies should be repeated, when indicated.

8. Treatment must be carefully monitored for side effects of GH treatment.

9. Continued psychological support should be provided for the child and family. This includes guiding the patient through puberty and providing post-treatment follow-up.

The evaluation and treatment of a "normal short child" with GH should be conducted by physicians trained in the management of growth disorders.

Miscellaneous Causes of Growth Failure

In addition to the clinical conditions described earlier, GH has been employed to treat short stature associated with various conditions related to postnatal growth failure. In general, such trials have been uncontrolled and have not included sufficient numbers of subjects for efficacy to be evaluated. Continuing examination of such treatment should be noted in the large international databases.

Normal Aging and Other Catabolic States

Detailed consideration of the potential use of GH in normal aging is beyond the scope of this chapter. The rationale for such therapy is based on the concept of the "somatopause," referring to the fact that GH secretion normally declines progressively after 30 years of age, as reflected in decreasing IGF-I levels. Aging can be viewed as a catabolic state, with the potential that GH therapy must reverse or retard the loss of muscle mass and strength and the decrease in bone density with aging. Clinical studies are in progress.

Growth failure, often with impaired final adult height, is a characteristic clinical finding in endogenous or exogenous Cushing's syndrome. Excess glucocorticoids cause a catabolic state characterized by increased proteolysis, decreased protein synthesis, lowered osteoblastic and increased osteolytic activity, and insulin resistance. GH treatment blunts some of these catabolic actions but increases the insulin resistance.

Mauras and Beaufreere found that IGF-I therapy, similarly, induces an anabolic response despite excess glucocorticoids but does not cause insulin resistance. GH treatment in the post-transplantation period and in other glucocorticoid-treated children causes some height increments but not as good a response as in individuals not on glucocorticoids. GH does enhance bone formation and increases osteoblastic activity in such children. GH therapy is also being investigated in catabolic states, such as burns, tumor cachexia, major abdominal surgery, AIDS, sepsis, metabolic acidosis, and situations requiring total parenteral alimentation.
Side Effects of Growth Hormone

For a quarter of a century, pituitary-derived human GH had an enviable safety record but proved to be the agent for transmission of the fatal spongiform encephalopathy, CJD. Although pit-GH was removed from use in the United States in 1985 and later throughout the world, more than 100 patients with GH-derived CJD have been identified, and cases are likely to continue to be discovered over the next several decades. Although this risk does not exist with recombinant DNA-derived GH, the experience with pituitary GH serves as a grim reminder of the potential toxicity that can reside in "normal" products and "physiologic replacement."

Extensive experience with rGH over more than 20 years has been encouraging. Every attempt has been made to seek physiologic replacement rather than pharmacologic therapy, but this is often not possible. Concerns have been raised about a number of potential complications, which clearly require continued follow-up and assessment. This evaluation has been greatly facilitated by the extensive databases established by GH manufacturers, in particular Genentech (NCGS) and Pharmacia (KIGS).

Development of Leukemia

The development of leukemia as a complication of GH therapy was first reported in five cases from Japan in 1988, and to date more than 50 cases of leukemia have been reported in GH-treated cases. Many of the cases are from Japan, but some are from the United States. One difficulty in assessing the role of GH treatment in this disorder is that many children with GHD have conditions that may predispose the development of leukemia, such as a history of malignancy, radiation, or syndrome associated with the development of leukemia (Bloom's syndrome, Down's syndrome, Fanconis anemia). GH-treated patients who develop leukemia do so at a later age than the normal population. Patients have included recipients of both pit-GH and rGH, and leukemia has occurred both during treatment and following termination of therapy. Calculations of relative risk are imprecise but vary from sevenfold in Japan to twofold to fourfold in the United States. Leukemia has been reported in GHD individuals without any history of GH therapy, suggesting that the GH state alone might be a predisposing factor.

We cannot be certain whether GH is a causative agent in the development of leukemia. If it is, the increase in risk appears modest and may arise from the underlying state rather than from GH therapy. The number of cases of new leukemia worldwide in children treated with GH but with no known risk factors is approximately what would be expected on a patient-year basis. This issue should be discussed with all potential recipients of GH, but it appears that the risk is limited to children with several risk factors. Particular care should be used in prescribing GH therapy for children with a history of leukemia or lymphoma or other disorder that conveys an increased risk of leukemia.

In a study of more than 600 children with prior leukemia and who received GH, the relapse rate was within the expected range, consistent with no effect of GH replacement therapy on recurrence of leukemia. In addition, data from 59,158 GH-treated patients with more than 193,000 patient-years at risk did not reveal an increased risk of nonleukemic extracranial neoplasms.

Recurrence of Central Nervous System Tumors

As many recipients of GH therapy have acquired GHD because of CNS tumors or their treatment, the possibility of tumor recurrence with therapy is of obvious importance. Estimates of CNS tumor recurrence rates in non-GH-treated children and adolescents are difficult to obtain, bearing in mind the vast array of treatment programs used in the past three decades.

Of a total of 1363 patients, documented in 11 reports, not treated with GH, 209 (19.3%) had recurrences. Such data in a heterogeneous group, including craniopharyngiomas, gliomas, ependymomas, medulloblastomas, and germ cell tumors, provide a background for assessing recurrence rates in GH-treated youth. Reports from nine centers, encompassing 390 patients, indicate recurrence in 64 (16.4%) at the time of publication, not much different from the much larger number of untreated patients.

In a particularly well-conducted comparative study at three pediatric neuro-oncology centers with data on 1071 patients with a brain tumor (180 received GH for a mean period of 6.4 years, and 31 were observed for more than 10 years), the relative risk of recurrence or death was similar in both groups. Extensive analysis of 4410 patients with brain tumor or craniopharyngioma histories prior to GH therapy in the NCGS and KIGS experiences showed a similar lack of increased tumor recurrence. In the NCGS series, recurrence rates of the most common CNS neoplasms, craniopharyngioma (6.4%), primary neuroectodermal tumors (medulloblastoma, ependymoma) (7.2%), and low-grade glioma (18.1%) were lower or similar to those reported in children not given GH. Despite these comforting data, the relatively short median follow-up times, even in the huge international databases, must temper the willingness to eliminate any relationship of GH therapy to recurrence of intracranial neoplasia.

Pseudotumor Cerebri

Pseudotumor cerebri (idiopathic intracranial hypertension) has been reported in GH-treated patients. The disorder may develop within months of starting treatment or as long as 5 years into the course; it appears to be more frequent in patients with renal failure than in those with GHD. The mechanism for the effect is unclear but may reflect changes in fluid dynamics within the CNS. Pseudotumor has also been described following thyroid hormone replacement in hypothyroidism.

In any case, physicians should be alert to complaints of headache, nausea, dizziness, ataxia, or visual changes. Significant fluid retention with edema or hypertension is rare. Because of the possible association of pseudopapilledema with GHD, perhaps representing a variant of optic nerve hypoplasia, careful ophthalmologic evaluation should be undertaken in patients with suspected GH therapy-associated pseudotumor cerebri to avoid overdiagnosis and invasive treatments.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is associated with both hypothyroidism and GHD. Whether GH therapy plays a role in this condition has been difficult to determine, in part, because the incidence of SCFE varies with age, sex, race, and geographic locale. It has been reported in 2 to 142 cases per 100,000. The data in the KIGS and NCGS studies are in this range. Accordingly, although SCFE cannot be attributed to GH therapy per se, complaints of hip and knee pain or limp should be evaluated carefully.

Diabetes Mellitus

The association of GH treatment with insulin resistance is well documented. A retrospective analysis of the KIGS experience found 43 of 23,333 children with abnormalities of glucose regulation, including 11 with type 1 and 18 with type 2 diabetes mellitus. The heterogeneity of this patient group and the failure to corroborate these findings with a similar retrospective analysis of NCGS data (type 2, 6.2/100,000) put the report into question. Nonetheless, the reduction of insulin sensitivity by GH is a concern that demands close assessment of high-risk patients, such as those with Prader-Willi or Turner's syndromes and a history of IUGR. It seems most likely that the relationship of the development of diabetes mellitus in childhood and adolescent GH recipients is due to a common genetic linkage rather than to a GH side effect.
Miscellaneous Side Effects

Other potential side effects of GH therapy include prepubertal gynecomastia, pancreatitis, growth changes, scoliosis and kyphosis, worsening of neurofibromatosis, hypertrophy of tonsils and adenoids, and sleep apnea. One report of reduced testicular volume and elevated gonadotropin levels in four young adult men previously treated with GH for ISS had not been confirmed by a double-blind, placebo-controlled study or in the international databases. This list, obviously, is only partial. It is best for the clinician to remember that GH and the peptide growth factors it regulates are potent mitogens with diverse metabolic and anabolic actions. All patients receiving GH treatment, even as replacement therapy, must be carefully monitored for side effects.

For the most part, side effects from GH therapy are minimal and rare. When they occur, a careful history and physical examination are adequate to identify their presence. Management of these side effects may include either transient reduction of dosage or temporary discontinuation of GH. In the absence of other risk factors, there is no evidence that the risk of leukemia, brain tumor recurrence, SCFE, or diabetes mellitus are increased in recipients of long-term GH treatment. Any patient receiving GH who has a second major medical condition, such as being a tumor survivor, should be observed in conjunction with an appropriate specialist, such as an oncologist and a neurosurgeon. Although GH does increase the mortality of critically ill patients in intensive care units, there is no evidence that GH replacement therapy needs to be discontinued during intercurrent illness in children with GHD.

The Question of Long-Term Cancer Risk

Several epidemiologic studies suggest an association between high serum IGF-I levels and incidence of malignancy. The calculated risk of cancer in those studies was also increased for patients with low IGFBP-3 levels. Although additional studies are being conducted to verify or disprove these associations, the role of GH should also be carefully examined.

IGF-I levels have not been statistically associated with cancer risk, but the combination of high IGF-I and low IGFBP-3 appears to be related to a heightened risk. Because GH positively influences production of both peptides, this casts doubt on its role as a driving force in the IGF-cancer relationship. Epidemiologic studies assessing the risk of malignancy in patients with acromegaly found differing results, with some, but not others, identifying significant associations between acromegaly and colon cancer risk. Small size, uncontrolled retrospective nature, and multiple possible sources of bias make these reports difficult to interpret.

The largest study, a review of more than 1000 patients, indicated no overall increased cancer incidence in acromegaly. Although colon cancer risk was also not increased in that study, mortality was higher in this population, suggesting an effect of GH or IGF-I on established tumors.

A recent prospective analysis of colon and colonic polyps in patients with acromegaly did not observe an association between these two diseases when using either autopsy series or prospective colonoscopy screening series for the control population. Acromegaly is associated with a marked increase in incidence of benign hyperplasia of several organs, including colonic polyps. Such findings suggest that the GH-IGF axis may lead to symptomatic benign proliferative disease, which might be associated with symptoms such as rectal bleeding that would then lead to a potential detection (or ascertainment) bias.

Children receiving GH do not have a greater risk of de novo or recurrent tumors. No increased incidence of cancer was found in GH recipients among adults who were treated for GHD. These reports represent imperfect, uncontrolled studies, but the experience gained through them strongly suggests that GH therapy is not associated with future development of neoplasms in the absence of other risk factors.

The use of IGF-I and IGFBP-3 in the monitoring of GH recipients, both adult and pediatric, has been recommended and endorsed by international bodies such as the Growth Hormone Research Society. Until the issue of cancer risk in GH therapy is fully resolved, the prudent approach appears to be regular monitoring of both IGF-I and IGFBP-3 and altering the GH dose to ensure that the theoretical risk profile induced by GH therapy is favorable. This can be done by avoiding the unlikely situation of a GH-treated patient having an IGF-I level at the upper end and IGFBP-3 at the lower end of the normal ranges.

In the 21st century, many GH-deficient patients will be receiving lifelong GH replacement, emphasizing importance of long-term, regular monitoring of IGF-I and IGFBP-3. Although many issues still remain in fully discerning the relationship, if any, between the GH/IGF axis and the risk of cancer, current data strongly suggest the safety of present indications for use of GH in children and adults.
Treatment of Growth Hormone Insensitivity Syndrome

The production of IGF peptides by recombinant DNA technology has permitted clinical trials of IGF therapy. IGF-I administration to normal adult male volunteers as a single intravenous injection of 100 µg/kg caused hypoglycemia within 15 minutes. On a molar basis, IGF-I has approximately 6% of the hypoglycemic potency of insulin, presumably reflecting increases in "free" IGF-I. In contrast, intravenous infusions of IGF-I to normal men at a rate of 20 µg/kg/hour resulted in serum IGF-I levels within the normal range and did not produce hypoglycemia but did suppress GH levels, increase creatinine clearance, and decrease plasma urea nitrogen. 

The most obvious clinical use of IGF-I therapy is in patients with GHI. In patients with GHR deficiency, intravenous bolus administration of IGF-I caused acute symptomatic hypoglycemia, presumably because of low serum levels of IGFBP-3. The subcutaneous administration of IGF-I to eight GHR deficiency patients, at a dosage of 150 µg/kg per day for 7 days, did not cause symptomatic hypoglycemia. Vaccarello and co-workers treated six adults with GHR deficiency for 7 days with subcutaneous IGF-I at a dosage of 40 µg/kg every 12 hours. Normal serum IGF-I levels were maintained for 2 to 6 hours after injection, followed by a rapid decline, because of low serum levels of IGFBP-3. Hypoglycemia did not occur, mean 24-hour GH levels were suppressed, and urinary calcium was increased.

A number of short-term growth-related studies with IGF-I treatment at varied doses have been reported. Laron and associates reported growth acceleration to rates of 8.8 to 13.6 cm/year in five children treated with a single daily dose of 150 µg/kg of IGF-I for 3 to 10 months. Similarly, Walker and colleagues found an increase in growth rate from 6.5 to 11.4 cm/year in a GHR deficiency patient treated with twice-daily subcutaneous injections of 120 µg/kg of IGF-I.

Wilton reported collaborative data on the treatment of 30 children, aged 3 to 23 years, with GHI from GHR deficiency or GHD-IA with anti-GH antibodies; the dosage of IGF-I varied from 40 to 120 µg/kg given twice daily. Except for the two oldest individuals, growth rates increased in all subjects by at least 2 cm/year.

In another study, a mean increment of more than 4 cm/year in growth velocity was found in 11 prepubertal children treated with 80 µg/kg twice a day. This study also demonstrated a significant inverse relationship between growth response to exogenous IGF-I and the severity of the GHI phenotype.

Longer-term studies of IGF-I treatment of GHI have demonstrated a persistent but progressively waning effect. Data from a European collaborative trial of 17 patients treated for at least 4 years showed an increase in mean height SDS from -6.5 to -4.9, with two adolescents reaching the 3rd percentile, and emphasize the importance of early diagnosis and initiation of therapy. Side effects included hypoglycemia, headache, convulsions, urolithiasis, and papilledema; the latter, which suggests the possibility of pseudotumor cerebri, resolved spontaneously while IGF-I was being administered. In the longest treatment study, Backeljauw and Underwood showed data similar to the European study, with an initial burst of growth followed by slowing to just above baseline by the 6th year of therapy. Height SDS improved from -5.6 to -4.2 by the end of the 6th year.

A randomized, double-blind, placebo-controlled trial of IGF-I therapy in GHR deficiency has been performed in Ecuador, probably the only place where the patient population is sufficiently large and homogeneous to permit such investigation. The placebo group grew 4.4 cm/year during the same time, and then their growth rate increased to 8.4 cm/year during IGF-I treatment. The incidence of hypoglycemia was equal in the two groups. One recipient of IGF-I developed papilledema, which resolved spontaneously while on treatment.

Although these early studies are promising, little is known about the long-term effects of IGF-I or about the optimal dose or frequency of administration. Taken together, the IGF-I treatment studies show that the growth response is neither as successful nor as long-lived as that of GHD children treated with exogenous GH. The failure of serum levels of IGFBP-3 to increase with IGF-I administration underscores the relevance of the IGFBPs to IGF pharmacokinetics. Nevertheless, these data indicate that the IGF peptides, long considered to function as autocrine or paracrine growth factors, can act as classic endocrine hormones.
EXCESS GROWTH AND TALL STATURE

Although as many children have a height greater than 2 SD above the mean as have a height greater than 2 SD below the mean, referral for tall stature is less common than referral for short stature. This pattern speaks eloquently to the psychosocial pressures to which children with growth disorders are subjected. Nevertheless, it is essential to identify situations in which tall stature or an accelerated growth rate provides a clue for the diagnosis of an underlying disorder (Table 23-14).
STATURAL OVERGROWTH IN THE FETUS

Maternal Diabetes Mellitus

Maternal diabetes mellitus is the most common cause of large-for-gestational-age (LGA) infants (height or weight

GH, growth hormone; IGF-II, insulin-like growth factor II; MEN, multiple endocrine neoplasia.

> the 90th percentile for gestational age). Even in the absence of clinical symptoms or a family history, the birth of an excessively large infant should lead to evaluation for maternal (or gestational) diabetes mellitus.
Sotos’ Syndrome and Beckwith-Wiedemann Syndrome

Two relatively rare syndromes can also cause LGA infants. Children with cerebral gigantism (Sotos’ syndrome) are typically above the 90th percentile for both length and weight at birth. Additional clinical features include a prominent forehead; dolichocephaly; macrocephaly; high-arched palate; hypertelorism with an unusual slant to the eyes; prominent ears, jaw and chin; large hands and feet with thickened subcutaneous tissue; mental retardation; and motor incoordination. Although such children continue to grow rapidly during the early years of childhood, puberty is usually early and causes premature epiphyseal fusion. Most patients have a final height within the normal population range. GH secretion and serum IGF levels are normal, and no cause of the overgrowth in cerebral gigantism has been identified.

Beckwith-Wiedemann syndrome (BWS) is the most common (1/13,700) of a group of disorders. It is associated with excessive somatic and specific organ growth, collectively referred to as overgrowth syndromes, apparently caused by excess availability of the growth factor IGF-II encoded by the gene Igf2. BWS is characterized by fetal macrosomia with omphalocele, with its clinical features due to selective organomegaly, including macroglossia, renal medullary hyperplasia, and neonatal hypoglycemia due to islet cell hyperplasia. As with cerebral gigantism, excessive fetal, neonatal, and childhood growth ultimately leads to early epiphyseal fusion, without an increase in adult height.

Although an association between BWS and disordered regulation of IGF-II gene transcription exists, to date no consistent postnatal abnormality of the GH-IGF axis has been identified. The paternally derived gene for IGF-II is overexpressed, and the maternally transmitted gene is not active. Four children with somatic overgrowth but not the diagnostic features of BWS had Igf2 gene overexpression. Various lines of investigation have localized “imprinted” genes involved in BWS and associated childhood tumors to chromosome 11p15.5. These include, in addition to Igf2, the gene H19, which is involved in Igf2 suppression as well as the gene WT-1 (the Wilms’ tumor gene). Mutations in GPC3, a glypican gene, which codes for an IGF-II neutralizing membrane receptor, cause the related Simpson-Golabi-Behmel overgrowth syndrome.
POSTNATAL STATURAL OVERGROWTH

As stated earlier, both cerebral gigantism and BWS are associated with rapid perinatal growth, but rapid growth usually ends by early to middle childhood. Nevertheless, these conditions should be considered when tall stature in childhood is accompanied by the characteristic phenotypic features or with a history of unexplained fetal overgrowth. As in the case of the child with growth failure, crossing height percentiles between infancy and the onset of puberty is an indication for further evaluation. Although such growth patterns are frequently not of concern to parents, that overly rapid statural growth can indicate serious underlying pathology. Furthermore, as with short stature, children with tall stature must be evaluated in the context of familial growth and pubertal patterns.

Familial (Constitutional) Tall Stature

GH secretion and levels of IGF-I and IGFBP-3 in familial tall stature (FTS) are often in the upper normal range.[1255] Tauber and co-workers[1561] divided 65 children with FTS into a subset with high GH secretion rates (5.4 ± 2.3 mg/L/mm) and frequent secretory bursts (5.1 ± 1.6/day) and another subset with lower GH secretion (2.1 ± 0.5 mg/L/mm) and fewer episodic spikes (3.3 ± 1.3/day). IGF-I levels were higher in the group producing more GH and were normal in the low GH group. The investigators postulated that both enhanced secretion of GH and greater efficiency of GH-mediated IGF-I production might be potential causes of FTS.

Like children with short stature, children with tall stature must be evaluated relative to familial growth patterns and parental target height.[1562] When a family history of tall stature is available, support and reassurance may be all that are required. A careful assessment of pubertal status and bone age facilitates prediction of adult height and usually obviates the need for hormonal therapy. Standard height prediction using Bayley-Pinneau tables, especially for children younger than 12 years of age, tend to overestimate final height with large confidence limits.[1563][1564][1565]

We discourage therapy for boys with predicted adult heights less than 198 cm (6 feet, 6 inches) and girls with predicted adult heights less than 183 cm (6 feet). Indeed, societal changes in attitudes toward tall individuals appear to discourage treatment except in extreme circumstances. The number of patients treated in the United States has fallen markedly since 1970. Therapy, when necessary, is aimed at the acceleration of puberty to cause premature epiphyseal fusion.[1566][1567]

Accordingly, the optimal time for treatment is before the onset of puberty. The earlier the intervention, the more likely that adult height can be decreased, although patients are not usually referred until late childhood or early puberty.

Although some success with lower dosages had been reported, administration of ethinyl estradiol at a dose of 0.15 to 0.3 mg/day is a reasonable starting level in girls and can be increased, if necessary and well-tolerated, to 0.5 mg/day. Conjugated estrogens, 7.5 to 10 mg/day, have also been successful. If breakthrough bleeding occurs, cyclic progestagens may be added to the estrogen therapy. Treatment should be continued until epipyses fuse, because post-treatment growth may be substantial if treatment is stopped early.[1565]

The mechanism of estrogen action is probably complex, because estrogen can affect both GH secretion and serum IGF levels and, more importantly, acts directly on the epiphysis. Estrogen mediates epiphyseal fusion in both girls and boys.[32][33][34] In prepubertal girls, estrogen therapy reduces adult height by as much as 5 to 6 cm, relative to predictions. When therapy is initiated after the onset of puberty, the decrement in adult height is not likely to be as large.

The use of high-dose estrogen in otherwise normal children must be weighed against the known (and unknown) toxicity of such therapy, including nausea, weight gain, edema, and hypertension. During the initial phases of therapy, growth is paradoxically accelerated as the child rapidly progresses through puberty. Other potential problems, such as thromboembolism, cystic hyperplasia of the breast, endometrial hyperplasia, and cancer, have not been definitively related to estrogen therapy in children but should be discussed with the patient and family.

Therapy in boys with tall stature is even more problematic. For the reasons discussed earlier, estrogen is likely to be most efficacious in accelerating epiphyseal fusion but is obviously undesirable in males. Androgens also accelerate skeletal maturation, presumably via aromatization to estrogen but at the price of rapid virilization.
Obesity

Obesity is frequently associated with rapid skeletal growth and early onset of puberty. Patients with obesity tend to have diminished overall GH production but normal high GHBP and IGF-I levels maintaining adequate or enhanced linear growth velocity. Early activation of adrenal androgenesis and premature pubarche are common. Bone age is usually modestly accelerated so that both puberty and epiphyseal fusion occur early and adult height is normal. This association between obesity and growth is so characteristic that the child with obesity and short stature should always be evaluated for underlying pathology, such as hypothyroidism, GHD, Cushing’s syndrome, or Prader-Willi syndrome.
Excess Growth Hormone Secretion

Pituitary gigantism is a rare condition analogous to acromegaly in adults (see Chapter 8). Typically, GH-secreting tumors of the pituitary are eosinophilic or chromophobe adenomas. Their etiology is uncertain, although many result from somatic mutations that generate constitutively activated G proteins with reduced guanosine triphosphatase activity. The resulting increase in intracellular cAMP in the pituitary leads to increased GH secretion.

McCune-Albright syndrome, which is also caused by mutations resulting in constitutive activation of G proteins, may also be characterized by somatotropic tumors and excess GH secretion. GH-secreting tumors have also been reported in multiple endocrine neoplasia and in association with neurofibromatosis and tuberous sclerosis (see Chapter 8). GH excess that occurs prior to epiphyseal fusion results in rapid growth and attainment of adult heights above the expected genetic potential. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades, as in the case of the Alton giant, who reached a height of 280 cm by the time of his death in his 20s. Manifestations typical of acromegaly may also appear, such as soft tissue swelling, enlargement of the nose, ears and jaw with coarsening of the facial features, pronounced increases in hand and foot size, diaphoresis, galactorrhea, and menstrual irregularity.

Serum IGF-I levels are elevated, although high IGF-I levels may also be a normal manifestation of puberty. Basal serum GH levels may be normal or increased, but serum GH is not suppressed by administration of glucose (1.75 g/kg of body weight, up to a maximum of 100 g).

Although abnormalities of the sella turcica are often evident on lateral skull films, the demonstration of increased GH-IGF secretion should lead to radiologic evaluation of the hypothalamus and pituitary by MRI or computed tomography. Definitive therapy requires surgical ablation of the tumor. Fortunately, this can usually be accomplished by a transphenoidal pituitary surgery, although macroadenomas may require a more aggressive surgical approach. As described in Chapter 8, the use of somatostatin analogues, dopamine agonists, and novel GHR antagonists is an important component of treatment programs for GH excess.
Precocious Puberty

Precocious puberty, whether mediated centrally (increased gonadotropin secretion, GnRH-dependent) or peripherally (increased androgen and/or estrogen secretion GnRH-dependent), results in accelerated linear growth in childhood, mimicking the pubertal growth spurt. Because skeletal maturation is also accelerated, adult height is frequently compromised. The diagnostic evaluation and management of precocious puberty are discussed in Chapter 24.
Miscellaneous Causes of Tall Stature

Marfan’s syndrome, an autosomal dominant disorder of collagen metabolism, is characterized by hyperextensible joints, dislocation of the lens, kyphoscoliosis, and dissecting aortic aneurysm and often leads to long, thin bones that result in arachnodactyly and moderately tall stature. Homocystinuria, an autosomal recessive disorder, phenotypically resembles Marfan’s syndrome, although patients are usually mentally retarded. The rate of linear growth may increase modestly in hyperthyroidism. Tall stature has been found in patients with familial ACTH resistance due to a defective ACTH receptor. Dosage effects of the SHOX gene may result in tall stature. In females with three copies of the SHOX gene and gonadal dysgenesis, adult stature was +2 to +2.9 SDS. In women with 47,XXX karyotype, mean final heights are around 5 to 10 cm taller and in men with 47,XXY karyotype (Klinefelter’s syndrome), about 3.5 cm taller than population means. Males with an XYY karyotype may also have moderate tall stature. In addition to the SHOX effects, however, the variable degree of estrogen production in some of these syndromes must influence skeletal maturation and final height.

It is worth commenting that although delayed puberty may be associated with short stature in childhood, failure to enter puberty and complete sexual maturation may result in sustained growth during adult life with ultimate tall stature and a characteristic eunuchoid habitus. The description of tall stature with open epiphyses resulting from mutation of the estrogen receptor or from aromatase deficiency underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth.

Chapter 24 - Puberty: Ontogeny, Neuroendocrinology, Physiology, and Disorders

Melvin M. Grumbach
Dennis M. Styne

Puberty should not be considered as a de novo event but rather as a phase in the continuum of the development of gonadal function and the ontogeny of the hypothalamic-pituitary-gonadal system in the fetus, through puberty, to the attainment of full sexual maturation and fertility. By puberty, secondary sexual characteristics appear and the adolescent growth spurt occurs, which result in the striking sexual dimorphism of mature individuals, fertility is achieved, and profound psychological effects ensue. The changes are a consequence of stimulation of the gonads by pituitary gonadotropins and increases in gonadal steroid output. Adolescence, a term usually considered to relate to the psychosocial aspects of the teenage years, is accompanied by the onset of adult patterns of socioeconomic and economic behavior.

The human being is the most reproductively successful of mammals, and many anthropologists have attributed this success to the prolonged pattern of human growth and development and the delay in attaining full sexual maturity. The evolution of the human scheme of growth involves the development of two stages: a childhood stage and an adolescent stage that includes an adolescent or pubertal growth spurt. Fig. 24-1. Not even our closest biologic relative, the chimpanzee, which matures twice as rapidly as the human, unequivocally exhibits these two stages including the unique human adolescent growth spurt. (The estimated date for divergence of the chimpanzee and human lineages is 4 million to 5 million years ago.)

Evolution theorists proposed that a critical part of human success and of many biosocial characteristics emanates from the learning and practice of adult behaviors related to sex and child rearing, particularly provisioning (not just infants) with food, which is unique to humans. These include learning skills related to production of food, cooperative hunting, division of labor according to sex, sharing food, tool making, and adjusting to the social organization and cultural environment. Given, on the other hand, noting that tool making preceded the evolutionary development of adolescence, suggested that, in addition, the evolution and value of human childhood and adolescence and this unique pattern of growth and development have had a significant role in the comparatively striking reproductive advantage and success of the human being. May has called this process of selection "selection for reproductive success."

Historical evidence suggests that puberty occurs at an earlier age today than in the past, usually reflected by age of menarche, which is removed by several years from the first sign of secondary development in girls. The average age of menarche in industrialized European countries has decreased 2 to 3 months per decade over the past 150 years, and in the United States the decrease has been approximately 2 to 3 months per decade in the last century (Fig. 24-2). However, this secular trend has slowed or ceased in "developed" countries such as the United States, Australia, and Western Europe (e.g., Britain and Holland) since approximately 1940, presumably because of improved socioeconomic status and health and the benefits of urbanization. The social class difference in menarcheal age has narrowed or disappeared in most countries, whereas in Denmark, Spain, and Brazil there remains evidence for a continued decline, at least in certain local regions. In the nomadic Lapp culture, in which the standard of living changed little between 1870 and 1930, no trend toward earlier menarche was found.

According to a 1973 survey by the U.S. National Center for Health Statistics, the age of menarche in the United States is 12.8 years, and data published in 1997 indicate that this age remains true for white but not for black girls, in whom the mean age of menarche is 6 months earlier. At present there remains a difference in the age of attainment of stages of puberty in different countries even if stability was reached; for example, Japanese boys undergo changes in testicular size about 1 year earlier than Swiss boys reach the same stage. Remarkably, there is a reverse secular trend in Northern Italy (in women born between 1950 and 1959) and other areas of Europe leading to a later age of menarche; this has been attributed putatively to a resurgence of physical and psychological stress.

The method of ascertainment of the age of menarche is of importance. Contemporaneous recordings are performed with the probit method of asking, "yes" or "no," are you menstruating? These may be incorrect because of social pressures of the culture and socioeconomic group considered. Recalled ages of menarche are used in other studies and considered to be accurate within 1 year (in 90% of cases) during the teenage years and in older women, too.

Earlier menarche within the normal range may have health consequences. International studies show that earlier age at menarche is associated with a greater risk of development of breast cancer; indeed, the risk for women with menarche at age younger than 12 years is increased by about 50% compared with those with menarche at 16 years. Further, there is indirect evidence relating earlier menarche to increasing likelihood of hepatocellular carcinoma.
If the age of puberty was later in past centuries than at present, the age of attaining adult height was also later. Surveys of army recruits, schoolchildren, and workers in Europe and America, as well as records of slaves in the United States, show that large portions of the population in the past two centuries continued to grow a considerable amount into their early 20s, whereas modern adolescents cease to grow and reach stable heights by about 17 years of age. The adult heights attained during the 18th and 19th centuries were often at modern 25th percentiles or less. The secular trend toward increased height is more marked than the secular trend toward earlier puberty.

Dietary modification may affect the age of menarche and other aspects of puberty. The Harvard Longitudinal Studies of Childhood Health and Development related dietary intake to menarche and found that girls had earlier menarche if they were taller and consumed more animal protein and less vegetable protein as early as 3 to 5 years of age; further, girls had earlier peak growth if they had a history of higher dietary fat intakes at 1 to 2 years of age and higher animal protein intakes at 6 to 8 years. Girls had higher peak velocity if, controlling for body size, they consumed more calories and animal protein 2 years before peak growth. Moderate obesity (up to 30% above normal weight for age) is associated with earlier menarche and conversely adult women with obesity had a history of a tendency toward an earlier age of menarche, which is the cause and which is the effect is not clear. Pathologic obesity is associated with delayed menarche. Black American girls are advanced in secondary sexual development compared with white American girls of the same age during the first three stages of puberty; this may be related, in part, to the higher prevalence of obesity in black girls, although, as stated later, there appears to be a genetic influence in ethnic differences as well.

The interaction of socioeconomic conditions, nutrition, energy expenditure, states of health, and puberty is of particular importance in areas of the world where nutrition is suboptimal. South America and Africa have a pattern in which rural children fare better and have earlier puberty and taller stature than urban children, the opposite of the pattern found in previous eras, demonstrating a disturbing trend of adverse nutritional conditions in crowded urban centers. The onset of secondary sexual development in girls of the Kikuyu in Kenya is 13.0 years with menarche at 15.9 years; in contrast to the age of onset of puberty in black American girls of 8.9 years with menarche at 12.2 years: the Kikuyu start later and have a shorter time of transition to menarche than the American girls. Kikuyu boys enter puberty before or at the same age as Kikuyu girls. Further, boys of the Hadza of Tanzania enter puberty 2 years earlier than girls. In contrast, in the United States and wherever else puberty has been studied in the Western world, girls enter puberty before boys by an average of at least 6 months and often more.

Other studies demonstrate the effect of chronic disease on the age of menarche. Delay can occur in any serious chronic condition that is not adequately treated; for example, celiac disease can delay menarche as well as decrease growth in childhood, as does infection with Helicobacter pylori. The earlier suggestion that blindness may advance the age of menarche is not supported by more recent studies. Puberty starts at a later age and the period of pubertal development lasts longer at high altitudes than at low altitudes even when nutritional status is similar.

Strenuous physical activity in girls, especially, but not necessarily, when associated with low body weight, can delay or arrest puberty. On the contrary, inactive, bedridden children with mental retardation reach menarche at an earlier age and at a lower proportion of body fat value than do similarly retarded children who are more active.

There is evidence that even the living environment might influence menarche. A convergence of the onset of menses in women or girls living together was noted. Several publications followed that studied the timing of the spontaneous onset of menses in women living together or when auxiliary odor scent (presumably containing pheromones) was present in women; some studies noted synchrony and others did not. Subsequently, the methodology of the studies was criticized and the positive findings deemed incorrect. Nonetheless, one group of investigators found and studied menstrual synchrony in a variety of conditions in college women and older subjects and found that closeness of sleeping conditions was not a prerequisite to synchronizing menstrual cycles but that being close friends was of significance in the phenomenon.

Genetic factors play an important role in the onset of puberty, as illustrated by the similar age of menarche in members of an ethnic population and in mother-daughter and sibling pairs.

Further support for the influence of genetics on the age of menarche is found in the concordance of the ages of pubertal developmental stages and menarche, which are closer between monozygotic than dizygotic twins. Secondary sexual development occurs earlier in black girls than in white girls in the United States, and although we have alluded to the influence of body mass index (BMI) upon menarche, genetics appears of importance although there is no apparent effect of social or economic factors on this relationship (see later). Thus, when socioeconomic and environmental factors lead to good nutrition, general health, and infant care, the age of onset of puberty in normal children is determined largely by genetic factors.

The influence of genetics on mother-daughter comparisons of age of menarche may be subject to complicating factors. In one study of white girls, there was a trend for maternal age at menarche to predict adolescent’s age at menarche, but breast development, weight, family relations (including the absence of a father), and depressive affect were predictive of age at menarche in this group with family relations more strongly predicting the age at menarche than the influence of breast development or weight. This study also raised the question of whether psychological stress can decrease the age of menarche or whether stress is likely to occur because of the earlier menarche. On the other hand, another study of age of menarche confirmed the influence of the age of menarche in mothers on the age of menarche in daughters but found no influence of stress related to family problems upon early menarche. Thus, environmental influences should be considered in the study of the age of menarche, although only some of these influences appear to have greater significance than genetic patterns.
PHYSICAL CHANGES OF PUBERTY

Secondary Sexual Characteristics

Comparative description of the physical changes between individuals and populations requires an objective and reproductible method of describing the maturation of secondary sexual characteristics. Tanner published standards of the most useful signs of sexual maturation that have been widely used throughout the world (Fig. 24-3). Self-assessment scales of adolescent maturation are available and are used in some studies to avoid the embarrassment of a secondary sexual examination in normal children and adolescents. However, the answers to self-assessments may be influenced by the subjects’ views of what is considered normal or by wishes to conform with normal development and may be less accurate in some ethnic groups than others.

Female

Two distinct phenomena occur in the female. The development of the breast and its modified apocrine glands is primarily under the control of estrogens secreted by the ovaries (see Fig. 24-3). The growth of pubic and axillary hair (see Fig. 24-4) is mainly under the influence of androgens secreted by the adrenal cortex and the ovary. The glandular and connective tissue of the mammary gland begins to develop at the onset of pubertal maturation. Thus, lobules composed of small ductules and cellular connective tissue develop to a more pronounced degree in the female at puberty. Proliferation of fatty and connective tissue accounts for 80% of the volume of the adult, nonlactating female breast.

The classification of the stages of breast development depends on specific characteristics common to the female breast but does not include size or inherent shape of the breasts, which are determined by genetic and nutritional factors (see Fig. 24-3). Four stages were described by Stratz, and modifications were made to the schema by Tanner, who produced the most widely utilized staging. The initial breast development may be unilateral for several months and may be cause for unfounded concern by girls or parents. Indeed, surgical biopsies have been performed inappropriately in girls in whom it was not appreciated that asymmetrical development is normal. There are unusual cases of agenesis of the breast in which no glandular or fat enlargement occurs regardless of the level of estrogen stimulation. On the other hand, virginal breast hypertrophy, extreme and rapid increase in breast size at the onset of puberty, is rare. It has been attributed, at least in part, to increased sensitivity to estrogen action or to increased local estrogen synthesis and growth factors.

Changes in the diameter of the papilla of the nipple are sequential and linked to stages of pubertal development. Nipple papilla diameter does not increase much during pubic hair stage 1 to 3 or breast stage 1 to 3 (diameter is 3 to 4 mm) but does increase after breast stage 3, providing an objective method of differentiating stage 4 from stage 5 (final diameter is approximately 9 mm) (Table 24-1).

The stage of breast development is usually comparable to the stage of pubic hair development in normal girls, but as different endocrine organs control these two processes, these features mature at different ages, and discordance can occur in disease states, the stages should be classified separately (Table 24-2 and Table 24-3).

Areolar diameter also increases in boys at puberty, and most boys have palpable glandular enlargement of the breast, transient gynecomastia (see later in this chapter).

Although rarely evident clinically in individual girls because of its subtle nature, increase in height velocity (rather than
breast development) is actually the first sign of puberty in girls; however, breast budding is what is first noted by most lay or medical observers. There are changes in the appearance of the vaginal opening at puberty. Dullling and thickening of the vaginal mucosa from the prepubertal reddish glistening appearance are due.

The growth and maturation of the penis usually correlate closely with pubic hair development because both features are under androgen control. However, for the most accurate assessment the stages of pubic hair development and genital development should be determined independently and recorded separately because discordant stages are a clue to potential disease states of the adrenal gland or testes. Partially to the development of the thigh but not up the linea alba or elsewhere above the base of the inverse triangle. Most men will have further spread of the pubic hair. </table>
testis is normally larger than the left, and the left testis is located lower in the scrotum than the right testis.

The phallus is most accurately measured stretched while in the flaccid state as there is much variation between individuals in the length of the unstretched penis. The length of the erectile tissue (excluding the foreskin) increases from an average of 6.2 cm in the prepubertal state to 12.4 ± 2.7 cm in the white adult. Ethnic differences have been noted; the mean value in black men is 14.6 cm and in Asians 10.6 cm.  

As in girls, the areolar diameter increases in boys during puberty; a distinct separation between the sexes occurs in stage 4, when female areolar diameter increases much more than male values. In addition, in gynecomastia the areolar diameter increases above normal.
Limits of Normal Pubertal Development

Data on the normal variation in pubertal development in the United States are becoming more plentiful, but guidelines remain controversial. A prior survey of the age of attainment of various stages of puberty in the United States began with subjects 12 years of age and, although useful in defining the upper limits of normal pubertal development, the survey is uninformative about the lower limits of the age of onset of puberty.\(^9\)\(^8\)\(^7\)\(^6\) A later longitudinal study (see Table 24-3) of white boys and girls started at 9.5 years of age and adds much to the determination of the mean age of attainment of stages of puberty\(^8\)\(^9\)\(^7\); nonetheless, it starts too late to include normal children who enter puberty at an earlier age (see Table 24-3). A large cross-sectional study sponsored by the American Academy of Pediatrics in which 17,070 girls visited the offices of 225 specially trained pediatricians across the United States started at 3 years of age but ended at 12 years of age and so excludes a proportion of normal children who enter puberty at a later age.\(^8\) The standard deviation (SD) of the longitudinal study\(^9\) was low, 1.0 years or less in most cases, whereas the cross-sectional study had a larger SD of approximately 2 years.\(^9\) This difference may be due to the difference in the study design, but it may reflect a limit in the spread of the upper end of the normal pubertal curve (rarely does even the subject with the most severe constitutional-delay spontaneously enter puberty after 18 years of age), where there may be a skewing of the normal age of onset of puberty to an earlier spread of ages.

The latest and largest multiracial and ethnic study of the age of onset of puberty in 2114 American boys aged 8 through 19 years suggests that a decrease has occurred over the last decades, but the observations are controversial.\(^8\)\(^9\)\(^7\)\(^6\) as is the report of the data for girls presented before. Using the National Health and Nutrition Examination Survey (NHANES) III database, the authors determined that the onset of pubic hair occurs earlier in black boys than in white boys, with a tendency to later onset in Mexican American boys. Between the ages of 8 and 9 no white boys had pubic hair, whereas 5.3% of black boys were at least at Tanner stage 2.\(^7\) The age of genital development was based on the visual change in scrotal skin and enlargement of the testes (an unsatisfactory method of assessing the size of the testes compared with direct examination); by the beginning of age 8, the earliest age studied, 29.35% of white boys, 37.8% of black boys, and 27.3% of Mexican American boys purportedly had genital development. These observations suggest an earlier onset of puberty in a substantial number of boys before the previously accepted lower age limit of 9 years. Further, the height and weight of these boys reaching the earlier stages of puberty were greater than reported in the past, although the heights and weights of boys reaching adult ages were equivalent to the past data. (The

\*African-American girls enter puberty approximately 1 to 1½ years earlier than white girls and begin menses 8½ months earlier.

</table>
new growth charts from the National Center for Health Statistics, found at www.dcd.gov, are virtually superimposable on the charts developed in the 1970s, indicating no change in growth rate in the overall population. The earlier onset of puberty occurred in only a subset of boys.)

A number of aspects of this study have been questioned. For example, the observers for NHANES III did not measure testicular volume, an important factor in the assessment of pubertal development, and a one-stage variance was allowed between the observers’ finding and the quality control, a variance that is quite significant between stage 1 and stage 2 of pubertal development in boys. Thus, just as there is difficulty in determining the difference between stages 1 and 2 of breast development, there is substantial difficulty in determining the difference between stages 1 and 2 of genital development without a direct assessment of testicular size. Clearly, the United States is lacking a comprehensive large, preferably longitudinal, study that would start early enough to include the youngest normal pubertal subjects and continue long enough to include the oldest. Failing such a study, we define the normal onset of puberty as 2.5 SD from the mean (percentile 99.4) and use a combination of the studies just discussed to establish reasonable guidelines for such boundaries.

The mean age for a white boy to reach genital stage 2 or pubic hair stage 2 in the longitudinal study is 11.2 years with an SD of 0.7 years; a 2.5 SD range from 8.9 to 13.3, and for simplicity we say the mean age of onset of puberty in boys is 11 years with the limits of 2.5 SD at 9 to 13.5 years of age (these are similar to the limits invoked in the past), although it is quite possible that some normal boys, especially black boys, enter puberty between 8 and 9 years of age.

In the evaluation of girls, it may be difficult for the physician to detect the onset of stage 2 breast development during an office visit, whereas assessment of stage 3 is generally obvious. Using the longitudinal data of a mean age of 11.2 and an SD of 0.7 years, the normal range is defined as 8.9 to 13.3. This correlates well with the U.S. Health Examination Survey of 1977. Using the large number of white and black girls in the cross-sectional study and the average ages of stage 2 and stage 3 from that study, the mean age of breast development for white girls is 10.6 years with 2.5 SD encompassing 8.7 to 14.5 years. However, in the cross-sectional study 3.0% of white girls had stage 2 breast development by 6 years and 5.0% by 7 years, whereas 6.4% of blacks had stage 2 breast development by 6 years and 15.4% by 7 years. It seems best to combine these findings, deviate from the ± 2.5 SD limits in this case, and set the mean at 10.6 years and the range between 6.7 and 13 years for whites and accept 8.9 years as the mean age for black girls with -2.5 SD at 6 years and the upper age range at 13 years. Black girls have an earlier onset of pubertal development of about 1 year even though their average age of menarche in the cross-sectional study was only 8½ months different (12.2 years for blacks and 12.9 for whites).

These data provide guidelines for choosing which candidates with early onset of puberty need expensive diagnostic tests and long-term therapy; many of the children who previously appeared to have mild sexual precocity may now be considered to represent normal variation. It would be inappropriate to include the youngest normal pubertal subjects and continue long enough to include the oldest. Failing such a study, we define the normal onset of puberty as 2.5 SD from the mean (percentile 99.4) and use a combination of the studies just discussed to establish reasonable guidelines for such boundaries.

The sequence of events at puberty in females. The design of the figure is described in the legend of Figure 24-6. (From Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. Arch Dis Child 1970; 45:1323.)

The sequence of events at puberty in males. An average is represented in relation to the scale of ages; the range of ages within which some of the changes occur is indicated by the figures below. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. Arch Dis Child 1970; 45:1323.)
study extensively all normal girls found in these lower limits of normal. We emphasize that family history, the rapidity of development of secondary sexual characteristics, the rate of growth, and the presence or absence of central nervous system (CNS) or other types of disease must enter into the decision of whether to evaluate a child. As we recommended in the previous edition, the Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society support such a revision of the lower limits of the normal age of onset of puberty. Thus, the limits of normal puberty might be set at 9 to 14 years for boys (rounding 13.5 years to 14 years for simplicity), at 7 to 13 years for white girls and 6 to 13 years for black girls.

On the basis of the Herman-Giddens study, it seems likely that the onset of puberty is earlier today than before 1950 to 1960, and that the age of menarche in white girls has changed little if at all over the past four to five decades. Marti-Henneberg

and Vizmanos showed that the earlier normal girls entered puberty, the longer the duration of puberty before menarche. Thus, girls who started puberty at 9, 10, 11, and 12 years of age experienced menarche 2.77, 2.27, 1.78, 1.44, and 0.65 years later, respectively. Interpretations of the age of onset of puberty in white American girls are tentative as there are no previous comparably large data sets and none that analyzes white and black girls separately.

There is a disturbing trend in the United States and elsewhere to an increasing prevalence of overweight (often defined as BMI > 85th percentile for age) and obesity (BMI > 95th percentile for age) in childhood. An analysis of the same pediatric office study data used for the updated statistics on the age of puberty for girls in the United States noted earlier yielded a relationship between BMI corrected for age and an earlier onset of puberty and of reaching various stages of puberty for black girls but less so for white girls. Further, the study of the age of onset for boys of various ethnic groups in the United States, although controversial, indicates a direct relationship of BMI to age of onset of puberty in boys. If the trend to increased BMI in U.S. children continues, we may anticipate a noncontroversial decrease in the age of attainment of puberty in the future.

International data are available for the age of pubertal stages

International data are available for the age of pubertal stages

collected in cross-sectional and longitudinal studies (see Table 24-2 and Table 24-4). The results show similarities to United States data in boys (see Table 24-4), but the data differ for girls (see Table 24-2). The effect of increased BMI on age of onset has been studied in Sweden, where a greater gain in BMI between 2 and 8 years was related to an earlier onset of puberty and each BMI unit gained decreased the age of onset of puberty 0.6 years in boys and 0.7 years in girls. Further, each increased unit of BMI gain in childhood also reduced the height gain in adolescence, 0.88 cm for boys and 0.51 cm for girls, and there was no effect of BMI on final height.

Usually, growth patterns for black and white children are plotted on the standard North American growth charts, but ethnic group-specific growth velocity charts are available for some groups.
Other Dimorphic Physical Changes

Other physical changes show sexual dimorphism. In boys, both the membranous and cartilaginous components of the vocal cords lengthen during puberty. In the peripubertal period the length of the vocal cords in both boys and girls is about 12 to 15 mm, of which the membranous portion is 7 to 8 mm. In adult men the vocal cords attain a length of 18 to 23 mm (membranous portion 12 to 16 mm), whereas in women the cords enlarge only slightly (13 to 18 mm). In the castrati, whose vocal brilliance had a great influence on the lyrical Italian operas, the membranous component of the vocal cords was the same length as in prepubertal boys and even shorter than in women.\[108\] During puberty, the male larynx, cricothyroid cartilage, and laryngeal muscles enlarge. The relatively largest change in singing and speaking frequencies occurs between Tanner genital stages 3 and 4,\[109\]\[110\] breaking of the voice occurs at approximately 13 years, and the adult voice is achieved by about 15 years.\[111\] The singing voice changes after the deepening of the speaking voice by one octave.\[112\]

Facial hair in boys is first apparent on the corners of the upper lip and the upper cheeks; it then spreads to the midline of the lower lip and finally to the sides and the lower border of the chin. The first stage of facial hair development usually occurs during public hair stage 3 (average age of 14.9 in the United States), and the last stage occurs after public hair stage 5 and genital stage 5.

Axillary hair appears at approximately 14 years in boys. Ninety-three percent of black American girls have axillary hair by age 12, in contrast to 68% of white girls.\[113\] Axillary sweat glands begin to function as the hair appears. The appearance of circumanal hair slightly precedes that of axillary hair in boys.

Comedones, acne, and seborrhea of the scalp appear as a result of the increased secretion of gonadal and adrenal sex steroids.\[114\] Early-onset acne correlates with the development of severe acne later in puberty. The most serious variety, acne fulminans, occurs mainly in pubertal males.\[115\] Acne vulgaris, the most prevalent skin disorder in adolescence, occurs at a mean age of 12.2 years ± 1.4 years (SD; range 9 to 15 years) in boys and progresses with advancement through puberty. However, acne vulgaris can be the first notable sign of puberty in a girl, preceding public hair and breast development.\[116\] At late prepuberty comedones are present in many boys, and 100% of boys have comedones by genital stage 5.

Dental hygiene is often worse in boys than girls after the onset of puberty; unfortunately, this is also the age when gingivitis begins to appear along with the formation of pockets at the gum line.\[117\] There is a positive correlation between sex steroid concentrations and the presence of the bacteria most responsible for the inflammation of gingivitis in boys and girls.\[118\]
Gonadal Development and Function

Female

Ovarian Development in Puberty

The peak number of germ cells in the fetal ovary is attained at 16 to 20 weeks of gestation (also see Chapter 2). Primordial follicles appear beginning at 20 weeks of fetal life, soon followed by the appearance of primary follicles; they constitute the lifelong store of follicles for the individual because no more arise. Follicle-stimulating hormone (FSH) receptors have not been detected in midtrimester human fetal ovaries; fetal pituitary FSH is not required for proliferation of oogonia, oocyte differentiation, or formation of primordial follicles. During fetal life and childhood, follicular growth to the large antral stage occurs, but before menarche all developing follicles are destined to undergo atresia (Fig. 24-8). Thus, large preovulatory follicles are rarely present before puberty. During follicular growth, the oocyte enlarges and granulosa cells are transformed from spindle-shaped to cuboidal cells that, along with the ovum, secrete the zona pellucida.

Our understanding of the mechanism of FSH and luteinizing hormone (LH) action through plasma membrane-associated receptors has advanced considerably. The granulosa cells multiply with a substantial increase in volume of the follicle, and ultimately a plasma transudate, the follicular fluid, forms in response to FSH and fills the antrum. The theca develops during the time of antrum formation. During reproductive life the follicle progresses further to luteinization or terminal differentiation into a corpus luteum, which is the major source of gonadal steroids after ovulation. After 8 days of gonadal steroid secretion in the absence of fertilization, the follicle undergoes programmed cell death or apoptosis and cytolysis results in an avascular scar. If fertilization occurs, fetal tissue, through the secretion of human chorionic gonadotropin (hCG), supports the maternal corpus luteum throughout pregnancy.

Ultrasoundographic studies (Fig. 24-9) show that the corpus of the uterus increases during pubertal progression from an initial tubular shape to a bulbous structure and that the length of the uterus increases from 2 to 3 cm to 5 to 8 cm and the volume from 0.4 to 1.6 mL to 3 to 15 mL. During prepuberty the ovarian volume is 0.2 to 1.6 mL on ultrasound scans, and after the onset of puberty the volume increases to 2.8 to 15 mL. Tall girls have a greater ovarian volume than girls of average size. An increase in the multicystic appearance of the ovaries on ultrasonography occurs with the progression through puberty and should not be considered a sign of disease.

Menarche

Menarche (see Chapter 16) usually occurs in the 6-month period preceding or following the fusion of the second and first distal phalanges and the appearance of the sesamoid bone; this corresponds to Tanner stage 4 in most cases. The 95th percentile for menarche is 14.5 years, although many textbooks define primary amenorrhea as absence of menses at 16 years of age; the reconsideration of the age of onset of female puberty should lead to a reconsideration of the age of definition of primary amenorrhea. Anovulatory cycles are common in the first years after menarche. There is a reported prevalence of 85% anovulation in the first 2 years after menarche that decreases to 20% anovulatory cycles by the fifth year; others have observed a lower number of ovulatory events shortly after menarche as well as 5 years after the event. Whereas the majority of pubertal females are infertile in terms of risk of pregnancy, a substantial number are fertile as evidenced by the prevalence of teenage pregnancy. Although the number of early teenage pregnancies is decreasing, in 2000 there were 8519 births to mothers 10 to 14 years of age.

Male

Testicular Development in Puberty

The testes are active during the prepubertal period, albeit at a lower level than during pubertal development. During pubertal development the testes increase in size, principally because of the growth of the seminiferous tubules associated with the onset of spermatogenetic activity, and mitosis of Sertoli cells and testosterone production increase (Fig. 24-10 and Table 24-8). The Sertoli cells are the major cell type in the seminiferous cords in prepuberty and early puberty, but in the adult, germ cells predominate. During progression through puberty, the Sertoli cells cease to undergo mitosis, differentiate into adult-type Sertoli cells, and form clumps replete with the testis blood vessel barrier.

Although Leydig cells can be detected in early gestation and again during the neonatal period of increased testosterone secretion, during childhood the interstitial tissue is composed principally of undifferentiated mesenchyme-type cells. With pubertal development and rising serum LH levels, adult-type Leydig cells appear. It is suggested that three phases of Leydig cell maturation associated with ages of increased testosterone production be recognized: 14 to 18 weeks of fetal life, 2 to 3 months after birth, and from puberty through adulthood. The seminal vesicle enlarges through childhood to puberty to hold 3.4 to 4.5 mL or 70% of the seminal fluid. The mean blood flow in the testes increases to adult values, as measured by Doppler sonography, in boys with a testicular volume greater than 4 cm.

Spermatogenesis

The first histologic evidence of spermatogenesis appears between ages 11 and 15 years; sperm can be detected in the first morning urine specimen at a mean chronicologic age of 13.3 years, although other studies extend this milestone up to 16 years depending on the population studied. There is a higher incidence of spermatogonia in early puberty than in late puberty, suggesting that there may be a continuous flow of sperm through the urethra in early puberty but that ejaculation is necessary for sperm to appear in the urine in late puberty. Spermatogonia probably reflects the maturation of spermatogenesis, but normospermia (sperm concentration, morphology, motility) is not present until a bone age of 17 years. Nonetheless, potential for fertility is reached before an adult phenotype is attained; spermatogonia was detected in 2 of 28 normal boys with bilateral testicular volumes of 3 mL and no other signs of puberty. Hence, spermarche (the onset of spermatogenesis) is a relatively early pubertal event that occurs.
at a mean pubic hair stage of 2.5, before the attainment of adult plasma testosterone concentrations and before peak height velocity is reached. The first conscious ejaculation occurs at a mean chronologic age of 13 ½ in normal boys and at a mean bone age of 13 ½ in boys with delayed puberty.
Adolescent Growth

Pubertal Growth Spurt

Prepubertal height and growth velocity are similar in boys and girls. The greatest growth occurs in infancy, and growth decreases to the nadir known as the minimal prespurt velocity just before the pubertal growth spurt. During puberty boys and girls experience a growth velocity greater than at any postnatal age since infancy. The pubertal growth spurt may be divided for purposes of comparison into three stages: the time of minimal growth velocity in peripuberty just before the spurt (takeoff velocity), the time of most rapid growth or peak height velocity, and the stage of decreased velocity and cessation of growth at epiphyseal fusion. Boys reach peak height velocity approximately 2 years later than girls and are taller at takeoff (Fig. 24-11 and Table 24-9); peak height velocity occurs during stage 3 to 4 of puberty in most boys (see Table 24-4, Table 24-5, and Table 24-7 and Fig. 24-6) and is completed by stage 5 in more than 95% of boys. 90,91 The pubertal growth spurt in girls occurs between stages 2 and 3 (see Table 24-2 and Fig. 24-8). 92 Boys grow a mean of 28 cm and girls grew 25 cm between takeoff and cessation of growth in a study in the United Kingdom. 93 The mean height difference of 12.5 cm between adult men and women in the Zurich growth study resulted partly from the greater prespurt growth of boys (+1.5 cm); partly from the height difference at age of takeoff, with boys being taller at their later age of takeoff than girls (+6.5 cm); partly from the greater gain in height of boys during the pubertal growth spurt (+6 cm); and partly from the greater postspurt growth in girls (-1.5 cm). 94

A mathematical model of growth, based on longitudinal data, separates the infancy, childhood, and pubertal phases of growth and allows evaluation of growth in spite of the variation in the age of the onset of puberty. A slowly decelerating childhood component is the base, with a sigmoidal pubertal component added during secondary sexual development (Fig. 24-12). This model provides a new means of predicting adult height, the height adjusted for pubertal onset (HAPO). 95 Variations on this technique of height prediction use the infancy-childhood-pubertry growth curve either (1) without bone age or (2) without bone age but with the use of parental height information when available. 96,97 Tanner and Davies 98,99 have constructed growth curves for American children using longitudinal data from the National Center for Health Statistics and calculated data from theoretical growth curves thereafter (see Chapter 23); these curves can be adjusted for time of peak height velocity and appear to have greater validity for evaluation of growth of individual children during adolescence than the standard cross-sectional charts.

A host of other physiologic and biochemical measurements change with the onset of puberty and must be interpreted in terms of the stage of pubertal development. The mean heart rate and maximal oxygen uptake do not change in boys with the passage of peak height velocity, but respiratory quotient increases at the time of peak height velocity; 100 Serum inorganic phosphate, alkaline phosphatase, serum osteocalcin (Gla protein level) and urinary pyridinoline, deoxypyridinoline, and galactosyl-hydroxylysine excretion reflect the increased osteoblastic activity and growth rate at that time in both sexes. 101,102,103,104,105,106 Serum urate rises at the end of pubertal development in average boys but obese boys experience a rise earlier in puberty. 107

Because girls reach peak height velocity about 1.3 years before menarche, there is limited growth potential after menarche; most girls grow only about 2.5 cm in height after menarche. 108

although there is a variation from 1 to as much as 7 cm. Boys have no event comparable to menarche during pubertal development to mark the amount of remaining growth; all that can be deduced by physical examination is that a boy in early puberty is likely to have significant growth left, whereas in late puberty limited growth is likely. The ages at menarche, takeoff, and peak height velocity are not good predictors of adult height because the duration of pubertal growth is the more important determinant of final height; later onset of pubertal and consequent increase in height at takeoff of the pubertal growth spurt can be balanced by a decrease in actual height achieved during peak height velocity and result in no net change in adult height. Nonetheless, extremely early onset of puberty can diminish ultimate adult stature, 109 and prolonged delay of puberty 110 can increase stature.

The age at peak height velocity and the age at initiation of puberty correlate well with the rate of passage through the stages of pubertal development in normal children. 111 Both stature and the upper/lower segment ratio, defined as the length from the top of the pubic ramus to the sole of the foot, change markedly during the peripubertal and early pubertal periods because of the elongation of the extremities. 112 As a rule, at birth the upper/lower segment ratio is 1.7, at 1 year the ratio is 1.4, and at 10 years the ratio is 1.0 in a normal healthy individual. The legs begin to grow before the trunk, although late in puberty, during the growth spurt, growth of the legs is similar to growth of the upper torso. 113 The mean upper/lower segment ratio of

| **Peak height velocity is not achieved until a late stage of sexual maturation (stage III-IV).** |

ratio of sitting height to standing height is higher in pubertal and adult females than in males.

In general, hypogonadal patients have delayed epiphyseal fusion and lack a pubertal growth spurt; therefore, their extremities grow for a prolonged period, leading to a decreased upper/lower segment ratio and an increased span for height, a condition known as eunuchoid proportions. Eunuchoid proportions are found in subjects with defects in estrogen synthesis and estrogen receptor deficiency, but normal proportions occur in complete androgen insensitivity syndrome, demonstrating the primary role of estrogen in mitigating or establishing these proportions.

Further, the distal parts of the extremities, the hands and feet, grow before the proximal parts; a rapid increase in shoe size is a harbinger of the pubertal growth spurt. Note that boys with Klinefelter’s syndrome have long legs, but not long arms, as a physical feature found even before the onset of puberty.

The shoulders become wider in boys, whereas the hips enlarge more in girls; the ratio of bicipital (shoulder) breadth to bicipital (hip) breadth remains constant in boys at about 1.37 but decreases in girls from 1.35 to 1.27.

The female pelvic inlet widens, mainly because of the growth of the os acetabuli. The size of the brain reaches 95% of adult size by the onset of puberty (see more about brain development later).

The size of the head approaches the adult size by age 10, but changes in relationships of the parts of the face are apparent during puberty. Thus, the mandible and nose enlarge more in boys, but they and the maxilla, brow, frontal sinuses, and middle and posterior fossae enlarge in both sexes, mainly during the pubertal growth spurt. Children with isosexual precocity have the facial appearance of older children, and individuals with delayed puberty have faces of younger children. The pituitary gland enlarges more in the female, in a magnetic resonance imaging (MRI) study the height of the pituitary gland was no greater than 6 mm before puberty, was 8 to 10 mm in teen-age females and had a spherical appearance in some, was no more than 7 mm in teen-age males, and decreased in young adults of both sexes.

Hormonal Control of the Pubertal Growth Spurt

Hormonal control of the pubertal growth spurt is complex (Fig. 24-13 and Fig. 24-14). Growth hormone (GH) is clearly involved in increasing growth at puberty through the stimulation of insulin-like growth factor I (IGF-I, previously called somatomedin-C) production. Gonadal steroids have two effects on pubertal growth: (1) induction of an increase in GH secretion and thus the consequent increase in IGF-I production, thereby indirectly stimulating pubertal growth, and (2) a direct effect on cartilage and bone by stimulating local production of IGF-I, among other local factors.

In the developing human skeleton, gonadal steroids have growth-promoting and maturational actions on chondrocytes and osteoblasts among other bone constituents, the latter action, which eventually leads to epiphyseal fusion and the cessation of longitudinal growth in both boys and girls, is mediated mainly by estrogen either directly secreted (in girls) or arising from the conversion of testosterone and androstenedione to estrogen in peripheral tissues by aromatase. Individuals with a mutation in the estrogen receptor gene or the CYP19 gene encoding aromatase continue to grow, lack a pubertal growth spurt, and have open epiphyses and osteopenia. Further, estrogen treatment of men with aromatase deficiency leads to epiphyseal closure, cessation of growth, and a striking increase in bone mass. On the other hand, patients with aromatase excess, who produce excess estrogen, have advanced skeletal maturation and rapid growth and may ultimately reach short adult stature (see later).

Although estradiol secreted by the ovary has been recognized for over two decades as the major sex steroid responsible for the pubertal growth spurt, skeletal maturation, and bone mineral accrual in the female, until the detection of the rare human genetic defects in estrogen synthesis or action, conventional wisdom dictated that in the male testosterone mediated these maturational changes during puberty. In the male as well as the female, estrogen (not androgen) is the critical sex hormone in the pubertal growth spurt, skeletal maturation, the accrual of peak bone mass, and the maintenance of bone mass in the adult. Estrogen stimulates chondrogenesis in the epiphyseal growth plate, increasing pubertal linear growth. At puberty, estrogen promotes skeletal maturation and the gradual progressive closure of the epiphyseal growth plate.

Surprisingly little is known about the mechanism of action of estrogen on the skeletal growth plates (Table 24-10). During puberty and into the third decade, estrogen has an anabolic effect on the osteoblast and an apoptotic effect on the osteoclast, increasing bone mineral acquisition in the axial and appendicular skeleton. Further, in the adult, estrogen is important in maintaining the constancy of bone mass through its effect on bone remodeling and bone turnover (see Table 24-10). The evidence establishing a primary role for estrogen in the developing skeleton by no means excludes a direct action of testosterone on bone in the human male, but this action is less well characterized and quantified than thought in the past. The greater increase in periosteal bone deposition, with resultant thickening of cortical bone and greater bone density in boys, is probably related to a direct effect of testosterone. In a carefully studied group of individuals with complete androgen insensitivity (and reportedly appropriate estrogen replacement therapy), a modest decrease in bone mineral density (BMD) Z scores was noted at the spine but not hip using age-specific female standard values, but the reductions were greater against male standards and when apparent BMD (a measure of volumetric BMD) was used. These findings support the concept that lack of a direct effect of testosterone on the skeleton, especially the spine, has a part in the defects in bone mineralization in women with complete androgen insensitivity (Table 24-11)
Growth Hormone

GH and IGF-I are major hormonal and growth factors in the pubertal growth spurt. The secretion of GH approximately doubles during puberty in both boys and girls.

Increased GH pulse amplitude and the amount of GH secreted per pulse (not frequency or metabolic clearance rate) in the basal state are mainly responsible for the augmented GH levels. Pulsatile GH secretion rose through pubertal development, although the frequency of the GH pulses did not change with pubertal development, nor did the intersecretory burst interval and half-life of GH.

The increase in GH secretion occurs earlier in girls, coincident with the onset of breast development (Tanner stage 2), and is maximal at Tanner stage 3 to 4 breast development; in boys, in contrast, the increase occurs later and peaks at stage 4 genital development. GH secretion and IGF-I levels decrease from the higher pubertal values to adult values after late puberty in both sexes. Stimulated GH secretion also increases at puberty; indeed, a study of 88 subjects of normal height found that 61% of prepubertal children did not have a GH peak above 7 ng/mL after exercise, arginine, or -dopa, but by stage two of puberty 44% met the 7 ng/mL threshold.

ng/mL level, by stage three 11% met the level, and at stage four and five 100% did so. Hexarelin, a six-amino-acid GH-releasing peptide, stimulated as much GH secretion in prepuberty as it did in puberty, in contrast to the responses to other secretagogues, which changed with puberty.

The increase in estradiol at puberty, arising in boys from both testicular secretion and extraglandular synthesis from testosterone and androstenedione and in girls from secretion by the ovaries, is the principal mediator of the increase in pulse amplitude and the amount of GH secreted per pulse. The effect of testosterone, however, is mediated mainly through its conversion to estradiol as estrogen blockade with tamoxifen decreases GH secretion in boys. The administration of androgens that cannot be aromatized to estrogen (e.g., oxandrolone and dihydrotestosterone) had less effect upon GH secretion, but androgen blockade with flutamide increased GH secretion.

Dihydrotestosterone, which is not aromatized to estrogen, does not increase GH secretion or the plasma concentration of IGF-I and may even decrease the integrated GH secretion, but it still stimulates an increased rate of growth, suggesting a possible direct effect of androgen on pubertal growth independent of GH or estradiol. This priming effect of estrogen on GH secretion is used in clinical practice, as estrogen administered before a provocative test in pubertal subjects increases the GH response. Increased GH secretion also occurs in sexual precocity. GH secretion decreases with the fall in gonadal steroid levels after treatment of children with true precocious puberty with potent luteinizing hormone releasing hormone (LHRH) agonists.

Patients with isolated GH deficiency or GH resistance have an attenuated pubertal growth spurt, indicating the importance of GH and IGF-I in this time of rapid growth. In a series of 26 women with apparently isolated GH deficiency who had spontaneous puberty, 39% had menarche after 16 years of age and almost 50% continued to have menstrual disorders. Individuals with severe primary or secondary hypogonadism have a minimal growth spurt or no pubertal growth spurt, demonstrating the primary role of gonadal steroids in pubertal growth. Hypopituitary patients deficient in both GH and gonadotropins do not have an adolescent growth spurt when GH alone is replaced; gonadal steroids must also be given, substantiating the interaction of GH and gonadal steroids in the pubertal growth spurt.

However, in normal puberty, neither the magnitude of the increase in GH secretion nor the concentration of plasma IGF-I correlates with peak height velocity of the pubertal growth spurt. This suggests that although a threshold level of GH secretion is a necessary component, the extent of the growth spurt correlates with gonadal sex steroid secretion. Individuals with both true precocious puberty and GH deficiency (usually a consequence of cranial radiation for a brain tumor) can exhibit a growth spurt similar to and clinically indistinguishable from that of children with true precocious puberty and normal GH secretion. After treatment with an LHRH agonist for sexual precocity, patients with GH deficiency and true precocious puberty have a significant decrease in growth velocity along with the suppression of their pubertal progression, illustrating the direct effect of gonadal steroids, principally estradiol, on the pubertal growth spurt in both males and females.
The concentration of plasma IGF-I increases during puberty to reach an earlier peak in girls than in boys and then decreases to adult levels (Fig. 24-15). Increased GH secretion at puberty induces the rise in IGF-I level, and the increase in both hormones is associated temporally with the pubertal growth spurt. The concentration of plasma IGF-I is high for chronologic age in sexual precocity and low in delayed puberty. Although the precise role of gonadal steroids in the pubertal increase in IGF-I concentration is uncertain, the major effect appears to be mediated through increased secretion of GH and circulating IGF-I with an additional effect through the gonadal steroid-induced local generation of IGF-I in cartilage and bone. Bone contains both estrogen and androgen receptors as well as the enzyme aromatase. Studies of patients with true precocious puberty before and after therapy with an LHRH agonist show elevated serum GH concentrations in the untreated state and suppressed GH concentrations for age and a decrease of plasma IGF-I concentration after therapy but values do not decrease to prepubertal values, further supporting the concept that GH is the major factor that raises circulating IGF-I levels in puberty.

A confounding factor is the relative role of hepatic-generated circulating IGF-I (endocrine role) and of locally produced IGF-I (paracrine-autocrine role) in linear growth. For example, mice with a selectively and totally deleted hepatic IGF-I gene had strikingly reduced circulating levels of IGF-I but normal postnatal body and bone growth.

**Gonadal Sex Steroids**

The adolescent growth spurt in normal girls and boys depends on both estradiol and GH. A pubertal growth spurt, which leads to a final height close to that of normal men, occurs in individuals with the complete form of androgen resistance (androgen insensitivity syndrome), a finding that supports the critical role of estrogen rather than androgen in the adolescent growth spurt in boys. In a study of 18 adult XY women with the complete androgen insensitivity syndrome, 7 (38.8%) exceeded 180.00 cm in height. The detection of estrogen resistance related to a null mutation in the gene encoding the estrogen receptor and of derangements in the CYP19 gene leading to severe cytochrome P450 aromatase deficiency has highlighted the cardinal role of estradiol but not testosterone in both boys and girls in the pubertal growth spurt, complete epiphyseal maturation, and normal skeletal proportions and mineralization. Further, a supersensitive assay for plasma estradiol in prepubertal and pubertal boys showed a high positive correlation for estradiol and growth in prepubertal boys and a positive relationship between serum estrogen concentrations and peak growth velocity, which occurred about 3 years after the onset of puberty. The concentration of serum estradiol did not correlate with that of serum GH, further implicating estrogen in the pubertal growth spurt and skeletal maturation of boys as well as girls.

Children with chronic adrenal insufficiency who are given appropriate replacement therapy have a normal pubertal growth spurt despite deficient adrenal androgen secretion, indicating a minimal impact of these adrenal androgens on normal growth at puberty. Thyroid hormone has a permissive role in the pubertal growth spurt but is a requisite for normal growth. Patients with primary hypothyroidism may not have a growth spurt even when the disorder is accompanied by sexual precocity (see "Juvenile Hypothyroidism").
Bone Age

Skeletal maturation is assessed by comparing radiographs of the hand, the knee, or the elbow with standards of maturation in a normal population. Ossification centers appear in early life, the bones mature in shape and size and develop articulation of surfaces, and ultimately the epiphyses or growth plates fuse with their shafts. Bone age, an index of physiologic maturation, does not have a well-defined relationship in normal children to the onset of puberty; it is just as variable as chronologic age. However, bone age is useful for predicting the age of menarche and in delayed puberty correlates better with the onset of secondary sexual development than does chronologic age.

There is controversy concerning the relationship between the initiation of the pubertal growth spurt and the rate of maturation of bone age. Some studies suggest that there is a strong relationship between the timing of the pubertal growth spurt and rate of skeletal maturation and that the timing and rate of growth in stature and rate of skeletal maturation are highly integrated genetic processes. Another view is that whereas peak height velocity occurs at a limited range of bone ages, the takeoff of the pubertal spurt occurs at a wider range of bone ages. In addition, bone age, height, and chronologic age can be used for the prediction of final adult height from the Bayley-Pinneau tables or by use of the Roche-Wainer-Thissen, Tanner-Whitehouse, or Walker technique.

Separate standards are used for boys and girls; skeletal maturation is more advanced in girls than in boys of the same chronologic age. For example, the bone ages of 11 years in girls and 13 years in boys (bone ages of early puberty in each sex) are equivalent stages of bone maturation by the hand-wrist method. Although there are no separate standards of bone age, black children have slightly more advanced bone ages than white children of the same chronologic age. Differences between bone age and chronologic age must exceed 2 SD (according to tables available in the respective bone age atlases) to be of biologic significance.

As commonly estimated, bone age is imprecise and a qualitative rather than a quantitative measure. The development of techniques for scanning radiographs coupled with computer analysis should increase the precision of the procedure. The estimation of skeletal age may be confounded by asymmetrical conditions. For example, patients with hemiplegia related to cerebral palsy have a less advanced bone age on the affected side than the normal side. This difference (mean of 7.3 months) is greater than the difference noted between left and right sides in normal children (less than 6 months).

Skeletal Density

Areal BMD (two-dimensional image), a function of the size of bone, increases throughout childhood but volumetric bone density (the amount of bone within the periosteal envelope) does not. During growth, the increase in bone mass is attributable to the increase in both length and diameter. The increase in BMD during the prepubertal and pubertal years is due to the increase in the size of the long bones.

Bone density increases at the spine in both sexes. The BMD at the beginning of puberty in 40 white children studied longitudinally predicted the peak bone mass at sexual maturity and appeared to predict the likelihood of osteoporosis as an adult; such data should allow identification of the girls most in need of intervention.

BMD of the total body, lumbar spine, and femoral neck measured by dual-energy x-ray absorptiometry (DXA) increased at a mean annualized rate of 0.047 g/cm² for boys and 0.039 g/cm² for girls. Data from a longitudinal total-body DXA study suggest that boys accumulate mineral at 407 g/year and girls at 322 g/year or 359 mg/day for boys and 284 mg/day for girls; thus, 26% of adult calcium is laid down during the two adolescent years of peak calcium accretion of 14 years (mean) for boys and 12.5 years for girls.

BMD approaches a peak in girls by the age of 16 years and in boys by about 17 years; the rate then decreases, reaching a plateau in the third decade of life. The difference in the timing of the peak of BMD is related to the difference in the time of peak height velocity. There is a different tempo of growth of the axial and appendicular skeleton. Before puberty the legs grow more rapidly than the trunk, but during puberty there is more trunical growth in girls. Thus, different times of exposure to disease make different portions of the skeleton subject to different pathologic conditions; limb dimensions may suffer in prepuberty, spine dimensions may be affected in early puberty, and volumetric bone mineral content may change in late pubertal conditions.

There are specific differences in BMD acquisition related to ethnicity, and standards for black, white, Asian, and Hispanic youth are being developed (Fig. 24-16). Other DXA manufacturers have provided standards for BMD by young adults but not for children and adolescents (see standard values in clinical situations. Patients may be referred for osteoporosis if their DXA results are compared with young adult values when they have not yet reached maximal bone density. In fact, bone size reaches its adult value and peak height velocity occurs before maximal bone mineral content is reached; these factors may result in a period of increased fragility and susceptibility to trauma. Although quantitative computed tomographic (CT) scanning demonstrates an increase in the cortical bone density of the lumbar spine with age, less relationship is noted between cancellous bone density and age until the later stages of puberty. The increase in BMD correlates well with height, weight, age, pubertal development, and BMI but has less relationship with serum IGF-I. Weight is a main determinant of bone density in postpubertal females.

The strength of the femoral head increases markedly during puberty, and the femoral neck increases in density even more with participation in impact loading sports such as running (compared with active load sports such as swimming) (Table 24-12). The latter table contains bone volumetric density BMD (gm/cm³), which corrects, in part, for variations in bone size. Increased weight-bearing sports or gymnastic activities increase BMD before menarche in boys and girls. Bone hip density at 18 years was increased in women who participated in daily sports between 12 and 18 years. However, in one study, bone density and geometry were not related to physical activity and calcium intake in European girls.

The expense and complexity of DXA and CT scanning led to the investigation of other methods of assessment of bone growth. Quantitative ultrasound standards are being developed that may simplify the process. In sum, bone densitometry is useful in assessing the attainment of bone mass and the risk of osteoporosis and fracture. Calcium is a critical nutrient for skeletal health throughout the life cycle, with the intake of calcium during the years of puberty having a major effect on bone density later in life in most but not all studies. and is probably dependent upon other aspects of nutrition, although there are many gaps in our knowledge in this area. Extra calcium administration may increase bone accretion and may be accomplished safely by increased dairy product intake, but the effect of increased ingestion of calcium may last only as long as the calcium is administered. Girls who drink more milk during adolescence are likely to have greater BMD as adults. Increased sodium intake at the expense of calcium intake adversely affects bone accretion, although increased calcium intake does not disturb the magnesium balance of the individual.

Black children retain more calcium than whites and the bone structure is thicker in black children: the difference in vertebral bone density appears to develop by late puberty because in prepuberty there is no difference between the groups.

Boys tend to add bone mostly on the periosteal surface, which increases bone strength, whereas girls add bone on the endocortical surface, which, rather than
increasing strength, is postulated to serve as a reservoir for calcium perhaps for later lactation and pregnancy. Testosterone administration to normal prepubertal boys increased calcium retention and bone growth, an effect mediated mainly by peripheral aromatization to estradiol, including skeletal tissue. Although bone mineral content may normally be higher in boys than girls, when corrected for the increased volumetric bone density, boys and girls have identical values for bone mineral content; bone mineral content increases with pubertal development in boys and girls.

Abnormalities of puberty impair bone accretion in both sexes, mainly as a consequence of estrogen deficiency related to either decreased secretion or peripheral aromatization of androgens. Boys with constitutional delay in adolescence were reported to have decreased areal bone density as adults; however, normal volumetric bone density was found in adults previously affected by constitutional delay or primary hypogonadism. Treatment of hypogonadotropic hypogonadism in males with testosterone raised serum osteocalcin and increased bone density, and, at least in a 6-month period, testosterone increased bone density in adolescents with constitutional delay. Individuals with Klinefelter's syndrome and decreased testosterone concentrations have decreased bone density; for selected patients, testosterone replacement has been recommended in puberty to avoid this outcome. Further, loss of bone density occurs in girls with anorexia nervosa, hypothalamic amenorrhea, or ovarian failure. Children with true precocious puberty have increased bone density, but successful treatment with an LHRH agonist decreases bone density.

There is a correlation between the bone density of children and parents with osteoporosis, demonstrating the importance of genetics in the pubertal period of bone accretion; indeed, there is a relationship of bone density between generations if the effects of age and puberty are eliminated. In fact 60% to 80% of variance in peak bone mass has been attributed to genetic factors.

Bone turnover is reflected by changes in biochemical markers. The most significant indicators of bone turnover are bone-specific alkaline phosphatase, osteocalcin, and urinary deoxypyridinoline, which reach a peak at midpuberty and decrease thereafter. Lesser changes are reflected in concentrations of carboxy-terminal pyridinoline cross-linked telopeptide, immunoreactive urinary pyridinolines, and urinary galactosyl hydroxylysine. Estrogen was negatively correlated with bone turnover, suggesting that estrogen is responsible for the decrease in bone turnover in late puberty.
Body Composition

Striking changes in body composition and energy requirement occur during puberty along with the increase in gonadal hormone levels and maturation of secondary sexual characteristics. Lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men. The increase in lean body mass starts at 6 years in girls and 9.5 years in boys and is the earliest change in body composition at puberty. A "strength spurt" occurs during puberty after the pubertal growth spurt. The discrepancy in adult strength between men and women is due partly to the fact that men have more muscle cells and partly to the greater size of individual muscle cells; the muscle mass is 54% of body weight in adolescent boys and 42% of body weight in adolescent girls.

Weight is not necessarily a reflection of body fat; the BMI (calculated as weight in kilograms/height in square meters) is often invoked in describing the shape of the body in age-adjusted terms BMI changes with age, and there is no specific number indicating normal or abnormal BMI at all stages of development. Charts of BMI versus age between the 3rd and 97th percentiles are available at www.CDC.gov. Indeed, BMI is not as useful a reflection of body fat in growing children as in adults, but for consistency BMI is used at all ages. The use of weight/height or BMI was proposed as an index of obesity unrelated to age or height, which simplifies the assessment of adiposity; values of 12.74 in boys and 12.45 in girls before stage 4 pubertal development are said to be the mean values for normal individuals but this method is not in general use. Another quantitative measure of body fat is triceps skinfold.

Figure 24-16b. 5. Spine BMD for males by age. The curve for black males was significantly greater than the mean levels of all nonblacks; Asian and white males had greater mean spine BMD than Hispanics. Mean and SD curves are shown. (A and B, From Bachrach UK, Hastle T, Wang R, et al. Bone mineral acquisition in healthy Asian, Hispanic, black and caucasian youth: A longitudinal study. J Clin Endocrinol Metab 1999; 84:4707.)
which requires specialized training to achieve accuracy. DXA is used to determine the percentage of body fat, water, and bone with great accuracy but cannot differentiate visceral from subcutaneous or other adipose tissue. CT scanning was necessary to determine the distribution of fat in different body locations until the validation of MRI as a method to determine the subcutaneous and subcutaneous fat distribution without the use of radiation. Equations were developed to utilize anthropomorphic techniques to determine intra-abdominal adipose tissue (IAAT) and subcutaneous abdominal adipose tissue (SAAT). Studies of populations aiming to relate body fat to adverse outcomes may use BMI, but the results may not be comparable with the outcome if a direct measurement of IAAT or calculations directly reflecting IAAT are employed. Thus, a clear statement of methods is needed in any study before conclusions are validated.

It is the visceral adipose tissue that predisposes to metabolic complications of obesity, and the subcutaneous adipose tissue that leads to these different body forms is only an imperfect reflection of this internal distribution of fat cells. The IAAT is the most metabolically active fat, which can quickly undergo lipolysis. IAAT comprises visceral adipose tissue (metabolic products drain immediately into the portal system and into the liver) and retroperitoneal adipose tissue, whereas subcutaneous fat, the visible fat on physical examination, is spread throughout the body. Increased visceral fat is associated with hypertension, insulin resistance, increased high-density lipoprotein (HDL) cholesterol, and small very-low-density lipoprotein (VLDL) particles that are cholesterol laden and most likely to be converted to low-density lipoprotein (LDL); subcutaneous fat is associated with large, lipid-laden VLDL particles that are removed directly from the circulation and pose less risk. Thus, it is the visceral fat that has been implicated in metabolic derangements in adults, for example, dyslipidemia, hyperinsulinemia, and cardiovascular risk factors. Studies support the role of increased intra-abdominal fat in children as a cause of insulin resistance and dyslipidemia. Whereas waist/hip ratios are used as a substitute for the direct measurement of visceral adipose tissue in adults, waist/hip ratios do not reflect intra-abdominal adipose tissue in children and adolescents. Further, increased IAAT may cause these metabolic derangements without increased total body fat.

Hips enlarge with pubertal development in girls, but there is no change in waist circumference and the waist/hip ratio normally drops; the waist/hip ratios of various ethnic groups develop differently. Further, girls at breast stage 2 with predominant fat on the hips had higher gonadal steroid and gonadotropin concentrations, and girls with predominant fat in the abdomen had lower androgen/testosterone ratios, probably because of increased aromatization of androgens to estrogens in adipose tissue.

The generalized distribution of fat in males (central fat or apple shaped; android) is different from that in females (lower body fat predominance or pear shaped; gynecoid). Some evidence suggests a relationship between fat distribution and testosterone-binding globulin (TeBG; sex hormone-binding globulin).

With the change in fat composition there is also a change in body water; body water increases 5% in men and decreases 5% in women. Whereas extracellular water is about 25% of body weight in boys and girls, intracellular water increases at puberty in boys from 36% to 39% and decreases in girls from 36% to 29%.

Frisch and Revelle pointed out that late-maturing girls gain fat more slowly; they related menarche and the maintenance of menstrual function to the percentage and absolute amount of body fat. By 9 to 10 years of age, black females tend to have a higher caloric intake with more fat ingested and less physical activity than white girls; by 9 to 10 years there is a higher percentage of obesity in black girls than in white girls. Black and white girls have an equal prevalence of dieting, but black girls more frequently attempt to gain weight, usually under parental influence, possibly related to the average 20 pounds greater weight of their mothers. Black girls have lower resting energy expenditure and total energy expenditure than white girls. This relationship does not change with pubertal development if the data are normalized for body composition. These data imply that lower caloric intake or increased activity is necessary for age- and pubertal stagedmatched black girls compared with white girls if weight is to remain stable.

The surgeon general has stated that there is an epidemic of obesity in children and adults in the United States. Between the last two NHANES studies (II to III), roughly in the last 20 years, there was a doubling of the prevalence of individuals over the 95th percentile in childhood and adolescence and a 50% increase in those above the 85th percentile. Excessive body fat has significant medical effects during childhood as well as later in life as the individual matures. However, medical complications occur with excessive body weight as well as can occur with inadequate dietary intake.

Dieting, defined as limiting caloric intake in order to lose weight, is not limited to adults or teenagers. In the third to the fifth grade, girls are already expressing dissatisfaction with their weight. At 10 years of age there is already a demonstrable difference in concern about eating and weight gain in girls compared with lack of such concern in boys. By fifth grade, 31% of girls are dieting, and by sixth grade, 62% are dieting. There is either no difference in the prevalence of dieting between white and black girls or an increased prevalence in whites, depending on the study, although there is evidence that black girls more often try to gain weight, apparently because of parental suggestion that they are too thin.

In Holland, a 40-year follow-up demonstrated increased mortality from ischemic heart disease of 2.3-fold increase in cardiovascular mortality. A study extending up to 52 years of children between 5 and 15 years in Maryland demonstrated a positive relationship between increasing relative weight and adult mortality for prepubertal boys and girls and postpubertal girls. In Sweden, a 40-year follow-up of hospitalized adolescents revealed a higher than expected mortality.

Countries that obesity in childhood is associated with increased risk factors for cardiac disease. Many workers recommend prevention of obesity as a method of improving cardiac risk factors or decrease in body fat if prevention has failed. A BMI above the 85th percentile was associated with one cardiac risk factor (dyslipidemia, hypertension, or elevated insulin) in 58% of the 813 overweight 5- to 17-year-olds surveyed in the Bogalusa Heart Study. Odds ratios for other associated with 2.4 (diastolic blood pressure), 3.0 (LDL cholesterol), 3.4 (HDL cholesterol), 4.5 (systolic blood pressure), 7.1 (triglycerides), and 12.6 (fasting insulin) for those with elevated BMI.

Countries that obesity in childhood is associated with increased risk factors for cardiac disease. Many workers recommend prevention of obesity as a method of improving cardiac risk factors or decrease in body fat if prevention has failed. A BMI above the 85th percentile was associated with one cardiac risk factor (dyslipidemia, hypertension, or elevated insulin) in 58% of the 813 overweight 5- to 17-year-olds surveyed in the Bogalusa Heart Study. Odds ratios for other associated with 2.4 (diastolic blood pressure), 3.0 (LDL cholesterol), 3.4 (HDL cholesterol), 4.5 (systolic blood pressure), 7.1 (triglycerides), and 12.6 (fasting insulin) for those with elevated BMI.
other studies in Finland, serum insulin correlated positively with BMI, concentrations of serum triglycerides, and blood pressure and inversely with the concentration of HDL cholesterol in 3- to 18-year-olds. High triglycerides, high systolic blood pressure, and low level of HDL cholesterol clustered among subjects within the highest insulin values. The hemostatic risk factors for adults, factor VIIc, von Willebrand factor antigen, and tissue-type plasminogen activator antigen, are related to plasma insulin and triglyceride concentrations in obese teenagers; plasminogen activator inhibitor-1 antigen correlated with fat mass in boys and girls; and factor VIIc correlated with fat mass in girls in an initial study.

Macro or micro evidence of arteriosclerosis is already found in youth and the tendency is increased by obesity. By 15 to 19 years of age, 2% of autopsied males in one study had advanced (American Heart Association grade 4 or 5) atherosclerotic coronary artery lesions associated with increased serum cholesterol, obesity, and hypertension. Thus, lesions with a vulnerability to rupture are present at a young age and related to coronary risk factors.

In several longitudinal studies, unfavorable lipid levels were tracked from childhood to adulthood; elevated cholesterol in adolescents was related to obesity, and adult values followed the values found in teenagers. Individuals tested during childhood or adolescence for the Muscatine Heart Study were retested later in adulthood in a longitudinal manner. On average, of children found to have cholesterol levels greater than or equal to the 90th percentile for their age and gender, on a single measurement 43% remained above the 90th percentile, 62% remained above the 75th percentile, and 81% remained in later adult life. Those between 5 and 23 years from the Bogalusa Heart Study who demonstrated elevated insulin values also had higher BMI, serum triglycerides, LDL cholesterol, VLDL cholesterol, and glucose and lower HDL cholesterol but higher systolic and diastolic blood pressure. There was a clustering of various components of syndrome X (dyslipidemia and hyperinsulinemia) that intensified as BMI increased in a subset of children studied longitudinally in the population. Of obese children, 39% had no risk factors, 34% had one, 16% had two, and 11% had three or more. A longitudinal study of black young adults found that BMI after birth and at age 7 years was correlated with later increased BMI and insulin resistance.
Blood Pressure

Although increased blood pressure may be demonstrated with pubertal maturation, this effect seems most related to the increase in BMI with development. Blood pressure is dependent upon BMI as well as height, factors that are interrelated. As teenagers are becoming more obese, there is an increasing prevalence of elevated blood pressure in adolescence. Blood pressure is higher at certain chronologic ages in black adolescents than in white subjects, and this difference has been attributed to the earlier pubertal maturation in black children. However, blood pressure rises in black children at lower BMI values than in white children, making the problem of hypertension worse in the black population. In sexual precocity, blood pressure rises above prepubertal levels to values commensurate with body size and BMI.

Blood pressure is elevated more frequently in obese than in lean children, and the effect is more severe if there is an abdominal distribution of fat. Of children with elevated blood pressure, 60% had 120% of the ideal body weight. Conversely, 20% to 30% of obese children have elevated blood pressure, and obese children have an 8.5- to 10-fold increased risk of hypertension as adults.

Blood pressure in adolescence is quite responsive to stress, and this lability may make it difficult to determine a true resting blood pressure in a brief clinic visit. Thus, multiple determinations are needed while the individual is quietly resting for optimal accuracy. With the increase in obesity in the population, determinations of blood pressure must be made with appropriately large cuffs; many obese teenagers must have blood pressure measured with a thigh cuff rather than the standard adult cuff. The bladder of the blood pressure cuff must be equal to or greater than the circumference of the arm midway between the olecranon and the acromial process. Blood pressure must be related to the height of the child using appropriate standards (found, for example, in the Harriet Lane Handbook of Pediatrics and Voors and colleagues). There may be a change in the blood pressure values throughout the day with puberty. A circadian rhythm of blood pressure with values lowest at 11 PM to 5:30 AM was present more often in mid-pubertal individuals (80% to 90%) than in early or prepubertal subjects (50%), suggesting the development of a circadian pacemaker during puberty.

Blood pressure in childhood and adolescence is predictive of adult blood pressure. Indeed, blood pressure tends to track with age so that a moderate elevation of blood pressure in puberty may lead to significant elevations as the individual grows older.

Other cardiovascular complications of obesity in adolescence include increased heart rate and cardiac output, possible risk for sudden death related to ventricular arrhythmias, sequelae of severe obstructive sleep apnea or prolonged QTc interval, slipped capital femoral epiphysis, Blount’s disease and flat feet, obstructive sleep apnea, CO₂ retention, hypoxia, right ventricular hypertrophy and failure associated with prolongation of the QT interval, and the obesity hypoventilation syndrome or pickwickian syndrome (characterized by hypoventilation, somnolence, CO₂ retention, hypoxia, polycythemia, right ventricular hypertrophy and failure, pulmonary embolism, and even sudden death). Although the heart enlarges in lean children during puberty, it does so to a lesser extent; during adolescence in the absence of obesity, fat-free mass is an important determinant of heart size, including left ventricular mass, and heart growth.
Brain anatomy and function change substantially during late childhood and adolescence. A reduction in cortical synaptic density and neuronal density, analogous to programmed cell death, occurs between 2 and 16 years. There is an increase in cortical metabolic rate that is higher in infancy but in late childhood declines to adult levels; this decline ceases by the end of the second decade. Examples of the reduction in brain plasticity during puberty are the inability to learn to speak a foreign language without an accent after puberty and the ability of a child to recover completely from a CNS injury that in the adult might lead to aphasia. Puberty is also the time of appearance of the ability to solve complex problems in a mature manner. Mania, depression, and schizophrenia are more common after puberty, possibly because of defects in these normal changes in brain architecture and function of puberty.

An increasing complexity of brain function during puberty is reflected in changes in electroencephalographic patterns. An increase in delta waves per minute and an increase in the amplitude of delta waves (0 to 3 Hz electroencephalogram waves) are found during deep sleep. The function of deep sleep (slow wave or nonrapid eye movement sleep) is thought to be restorative of the functions during the awake stage, such as learning, and the most restorative portion is high-amplitude delta wave sleep. During adolescence the time spent in deep (stage 4) sleep declines by 50%. Further, there is a 50% to 75% decrease in the amplitude of delta waves during sleep across childhood and adolescence.

Primary reading epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, and epilepsy with grand mal on awakening increase in prevalence during puberty. On the other hand, benign epilepsy with centrotemporal (rolandic) spikes, the most common idiopathic epilepsy, often goes into remission at puberty. Aminobutyric acid (GABA) is an inhibitory neurotransmitter thought to withhold the onset of puberty by decreasing gonadotropin-releasing hormone (GnRH) secretion. However, the use of GABAergic drugs in clinical treatment of epilepsy in children does not appear to cause a delay of the onset or progression of puberty; this may simply be a result of inadequate data or may be an indication that disruption of GABA by the oral route cannot interfere with the onset or progression of puberty. In spite of the lack of association of a change in pubertal development with exogenous GABAergic agents, a shift in endogenous GABA at this stage may be part of the explanation for the change in incidence of epilepsy at puberty.

A longitudinal study of the biologic aspects of childhood-onset schizophrenia reported changes in affected children's MRI and positron emission tomographic scans of the CNS. The increased onset of schizophrenia at the age of puberty may have an anatomic explanation related to the prefrontal cortex, an area implicated in the etiology of schizophrenia. Studies of changes in the dorsolateral prefrontal cortex in monkeys during puberty suggest a (speculative) relationship with the histologic study of the brains of human beings with schizophrenia. It is postulated that the remodeling of this area is particularly vulnerable to adverse influence at the time of puberty and that these influences may be implicated in the pathophysiology of schizophrenia.
NORMAL PUBERTAL BEHAVIOR AND PATHOLOGY IN PUBERTY

Although the attainment of an adult role in society occurs within a few years of achievement of reproductive maturity in non-westernized societies, the more technologically advanced society, the more protracted the time society allows for adolescent psychosocial development. The prolonged current period of the adolescent role in society, ranging from the age of 11 years to 20 years in America, arose recently in human history, dating to no more than the last 100 years in Western society.

The most important psychological and psychosocial changes in adolescence are the emergence of abstract thinking, the growing ability of absorbing the perspectives or viewpoints of others, an increased ability of introspection, the development of personal and sexual identity, the establishment of a system of values increasing autonomy from family and personal independence, greater importance of peer relationships of sometimes sub cultural quality, and the emergence of skills and coping strategies to overcome problems and crises. Adolescence may normally be divided into three periods by chronologic age: early, middle, and late adolescence. However, these periods may be reached at different chronological ages because rates of physiologic maturation differ in individuals within these age groups. Early adolescence, ages 11 to 15 years, is the period encompassing most of the biologic changes of puberty outlined earlier. Early adolescence includes a profound social change from the sheltered, single-classroom environment of elementary school to the multiple classrooms and multiple teachers of junior high school. There is exposure to new peers, often with different life experiences and behavior patterns. In contrast to the concrete reasoning of childhood, the individual develops maturing, but not mature, abstract thought and decision-making processes.

Middle adolescence, ages 15 to 17 years, the period of the high school years, is a calmer period than early adolescence; the school experience does not undergo a striking change, and many of the most prominent biologic and physical changes of puberty are past. This is a period of partial independence. There is acceptance of some increased autonomy (as reflected in society's acceptance of drivers' permits and licenses at these ages), but the individual still lives at home. The individual moves away from the family emotionally and is less influenced by his or her peer group than are early adolescent individuals; friendships play an increasingly important role.

Late adolescence starts at the senior year of high school and is the age of acceptance of adult roles in work, family, and community. If the individual attends college, this stage is prolonged.

Behavior and Normal Puberty

Almost 100 years ago, Hall, without using what would be considered contemporary research techniques, characterized the maturing child as experiencing "Sturm und Drang" (storm and stress), which is normally restrained by cultural influences. Many depictions of adolescent turmoil followed, continuing to this day in the popular media as well as in clinical treatises. Contrary to this view, most later empirical studies describe adolescent development as a continuous, adaptive phase of emotional growth characterized more by stability than disorder and by harmonious relationships between generations rather than conflict. Although mood changes are normally more rapid and marked in the teenage years than in adults (occurring over hours or days), these shifts must be differentiated from long-standing mood and behavioral changes of serious psychopathology. Thus, turmoil or truly tumultuous behavior in adolescence is not a normal phase but may reflect actual psychopathology that requires diagnosis and treatment.

In a longitudinal study of 320 normal first-year U.S. high school students observed for 4 years and of 64 observed for 8 years, 25% experienced "continuous growth" characterized by smooth, well-adjusted functioning in spite of stressful situations; 34% experienced "surgent growth" demonstrating good adaptation in general and short periods of difficulty and distress after some stressful situations; and 21% were judged to be in "turmoil" characterized by mood swings, anxiety, and depression. Thus, 79% had successful adaptive development and 21% did not, and the latter mainly came from homes characterized by conflict, familial mental illness, and socioeconomic distress. Another study of adolescent psychopathology demonstrated that many with adolescent turmoil "did not grow out of it" when studied 5 years later as they had eventual diagnoses of unipolar and bipolar depressive disorders. It may be concluded that 80% to 90% of adolescents do well psychologically during puberty and are happy individuals, but 10% to 20% have significant difficulties.
Mood and Self-Image in Puberty

Young girls at the beginning of puberty frequently exhibit a negative self-image. Body Image and Adolescent Adjustment questionnaire scores rise and positive body image, positive peer relationships, and superior adjustment improvement are noted with breast development. Mood in adolescence is not closely related to stage of puberty; for example, one study found no significant mood or behavioral changes as a function of pubertal stages in girls aged 10.6 to 13.3 years, controlling for age effects, except for a decrease in interest in sports with progression of stage. However, a significant curvilinear trend for depressive affect (increase, then decrease; \( P < .01 \)), impulse control (decrease, then increase; \( P < .04 \)), and psychopathology (increase, then decrease; \( P < .03 \)) scales emerged after grouping the questionnaire results by four levels of serum estradiol, indicating that these measures of psychological status undergo significant changes during times of rapid increases in hormone levels. Such data suggest that hormonal changes may be more important than physical changes as determinants of certain mood and behavior patterns at adolescence.

Change in mood during the menstrual cycle is frequently described but rarely exhaustively studied. Anecdotal evidence noted during a study of urinary hormone changes during the menstrual period indicated that mothers felt that their daughters changed from being "irrational and difficult" to "more reasonable and responsible adults" with the change from anovulatory cycles to ovulatory cycles.

Depression in Puberty

Reports of attempted suicide increase sharply during puberty, and suicide now ranks fourth as a cause of death among 15- to 19-year-olds. A retrospective analysis showed that adolescents who actually committed suicide during puberty had the onset of their depression in childhood or early puberty, even though the act of suicide occurred later in puberty.

Prepubertal boys and girls demonstrate an equal frequency of depression, although there is a more frequent occurrence in girls by midpuberty with a sharp demarcation at stage 3. This change in the prevalence of depression appears more related to serum sex steroid concentrations than to LH or FSH values or the physical changes of puberty.

Changes in the stress response with pubertal development (characterized by increased corticotropin-releasing factor leading to increased corticotropin, causing elevated cortisol secretion) are implicated in the development of various psychopathologic conditions in childhood depression. It is postulated that periods of biologic transition, such as puberty, are times of increased psychological vulnerability in which depression is manifest because of a malfunction of the stress response.

An estimated 1.7% to 5.5% of adolescents have seasonal affective disorders. Children with seasonal affective disorders displayed dysregulated circadian activity rhythms comparable to those reported in depressed children not related to seasonal depression but different from those observed in adults.

Schizophrenia in Puberty

Childhood-onset schizophrenia is rare, but the prevalence rises with the onset of puberty. More boys than girls are diagnosed with isolated (but not familial) schizophrenia that begins in the pubertal years; in contrast, adult-onset schizophrenia is more common in women than men. It was suggested that a protective effect of estrogen raises the threshold for schizophrenia in women until the age of menopause, at which time more severe cases occur in women than in men of the same age.

There are other psychological conditions that usually appear first during puberty, such as panic attack and migraine headaches.

Risk-Taking Behavior

Adolescents who function at lower levels of cognitive complexity or concrete thinking and have an early onset of puberty demonstrate an increase in risk-taking behavior. The age of onset of cigarette smoking and alcohol use is proportional to the age of onset of puberty in girls; earlier maturing girls partake earlier, and boys may follow the same pattern.
Sleep Patterns in Puberty

Without the pressure of work, school, and so forth, adolescents would stay up later and awaken hours later than a normal weekday schedule would dictate or than occurred in the schedule they followed at a younger age. Daytime sleepiness is prevalent in puberty. Older people have earlier waking times and rate themselves as more morning-like than young adults. This change to eveningness from morningness appears related to biologic in contrast to social factors, which were previously thought to be more important. However, there are confounding effects in the study of circadian rhythms in teenagers.

Many factors affect sleep schedules, such as parental involvement, obligations of peers and work, and the frequent occurrence of insufficient sleep. Thus, conclusions of studies in sleep laboratories are difficult to interpret. An initial attempt to study this phenomenon demonstrated a significant relationship between the morning rise in melatonin (offset phase of melatonin secretion) and advancing sexual maturation stage and a tendency to a later midpoint phase of melatonin secretion (between the nocturnal rise and morning fall in melatonin values) with advancing sexual maturation stage. These data support a biologic process to explain the shift in sleep patterns rather than a social process.
Sexuality in Puberty

Early and middle adolescence is the period of introduction to sexuality for many but not for a majority of teenagers. There was an increase in sexual intercourse in urban teenage girls between 1971 and 1981 of over 50% in white girls, with 17.3% of white 15-year-olds and 23.2% of black girls reporting sexual intercourse at 15 years and 39.5% of white and 46.7% of black girls reporting sexual intercourse by 17 years of age. The mean age of first intercourse was 17.5 years for white males, 15.5 years for black males, 17 years for Hispanic males, 18.5 years for white females, 17.5 years for black females, and 18.5 years for Hispanic females in the last decade. Twenty-four percent of U.S. boys and 27% of U.S. girls reported sexual activity by 15 years of age in 1996 according to the Alan Guttmacher Institute (http://www.agiusa.org/), with a rise to 39% of 16-year-old girls and 45% of 16-year-old boys. By 17 years, the totals rise above 50% with 52% of girls and 59% of boys reporting intercourse.

Fertility is reached before the adult phenotype is acquired. One million adolescents become pregnant in the United States each year, a rate of 110 per 100,000. However, there has been a decrease in pregnancies during the last 20 years in adolescents: a 27% decrease in pregnancies in black 15- to 17-year-olds (99.5 to 72.9 per 1000) and a 6% decrease in whites (25.7 to 24.1 per 1000). There is a continuing decline in teenage pregnancies, although the problem is still substantial. In 2000 there were 8519 births to mothers aged 10 to 14 years, the lowest value since 1966, a rate of 0.6 per 1000. There has been an increase in abortions among teenagers during the last decade.

Testosterone is commonly thought to be a stimulator of sexuality, and in laboratory animals this may be proved experimentally. Results of the study of pubertal human subjects, however, are more complex. Sexuality appears to be correlated with testosterone production in boys in some studies, but in others it appears to be modified by the social effects of pubertal maturation. Correlation of salivary testosterone determinations every month over 3 years with sexual activity revealed that rising testosterone is associated with sexual activity (coital and noncoital). In addition, rising testosterone was related to sexuality and falling salivary testosterone to decreased sexual activity when pubertal status was controlled. The hormonal influences on female sexual behavior remain elusive; the striking increase in testosterone at puberty in boys stimulates their sexual interest more than the modest increase in testosterone in females. Also, social pressures are more mixed in their messages to girls, both encouraging sexuality and restricting it in a way more disparate than encountered by boys. Surely, the earlier onset of puberty today compared with previous centuries has had a profound effect on societal norms of sexual behavior.

Longitudinal and cross-sectional studies demonstrate an effect of religious activity on the onset of coitus regardless of pubertal development or endocrine status; boys who attended religious services regularly had a lower likelihood of progression to coitus or even to more substantial sexual ideation than those who did not attend regularly. Boys with higher free testosterone levels at study entry who never or infrequently attended religious services were the most sexually active and had the most permissive attitudes. The conclusion of the study was that endogenous testosterone production is directly related to sexual behavior in boys but this relationship may be modified by religious exposure.

A study of normal puberty in girls in the 8th to 10th grades demonstrated that follicular phase levels of testosterone were associated with increased frequency of thinking about sex and masturbation. Although this study demonstrated a relationship between hormones and female sexuality, peer influences exerted a strong effect on masturbation and the progression of sexuality and transition to first coitus. Seventh and eighth grade girls were observed over 2 years to determine the relationship between pubertal hormone levels and the first intercourse in a longitudinal study. The expected relationship between testosterone and pubertal development was found, and there was a relationship between a rise in testosterone and transition to coitus and between a fall in testosterone and less likelihood of transition to coitus (similar to the results described in boys). Further, when white girls who attended religious services regularly were considered, the relationship with testosterone became nonsignificant; the relationship remained significant among girls who didn’t regularly attend religious services were considered. Thus, it appeared that rising testosterone increased the likelihood of transition to first coitus but this tendency could be opposed by religious exposure as a reflection of social pressure in white girls. Pubertal developmental stage itself did not predict coitus, suggesting that physical maturity was not the motivating feature.

Administration of exogenous sex steroids was related to sexual behavior and mood. A randomized, double-blind, placebo-controlled, crossover clinical trial involving 39 boys and 16 girls with delayed puberty evaluated the effects of administration of oral conjugated estrogen to girls and testosterone enanthate to boys at three dose levels that were intended to simulate early, middle, and late pubertal levels. A significant effect of the administration of testosterone to boys was reflected in increased nocturnal emission and touching behaviors at the middle and high doses. However, no other treatment effects on sexual behaviors or responses were seen in boys. Girls demonstrated a significant increase in “necking” related to the administration of estrogen only at the late pubertal dose. No other treatment effects on sexual behaviors or responses were seen in girls. Thus, the administration of physiologic (rather than higher) doses of sex steroids to boys or girls with delayed puberty had few effects on sexual behaviors and responses (it is likely to be more difficult to find progression to sexual activity in delayed puberty). Because the subjects included patients with Turner’s syndrome, gonadotropin deficiency, and constitutional delay in puberty, the results cannot be directed to a single clinical disorder. Further, a 3-month period may be considered too short to allow the study of the evolution of sexuality. Nonetheless, this model is a promising method of determining the effects of hormones on behavior in a prospective, intervention, and ethical manner and may be expected to yield further interesting results in the future. It may be concluded that exogenous testosterone administered in the short term to reflect physiologic levels has no significant effects on boys and girls.

A relationship between intelligence and sexuality emerged from the analysis of data from the National Longitudinal Study of Adolescent Health (Add Health), which includes approximately 12,000 adolescents enrolled in the 7th to 12th grades. The Biosocial Factors in Adolescent Development projects observed approximately 100 white males and 200 black and white females from this larger data bank over 3- and 2-year periods, respectively. On the basis of the Peabody Picture Vocabulary Test as a measure of intelligence and confidential self-reports of sexual activity, logistic regression models were used to determine relationships between the two measures and proportional hazard models were used to examine the timing of initiation of noncoital and coital activities as a function of intelligence. After controlling for age, physical maturity, and mother’s education, a significant curvilinear relationship was found between intelligence and coital status; adolescents at the upper and lower ends of the intelligence distribution were less likely to have sex. Higher intelligence was also associated with postponement of the initiation of the full range of partnered sexual activities.
Behavior in Variations of the Normal Age of Onset of Puberty

The timing of the onset of puberty may have an effect on psychosocial development and function in puberty. With regard to children who progress through puberty at the normal limits of pubertal development described earlier, early maturing girls and late maturing boys have the greatest prevalence of adjustment reactions in puberty and thereafter.\[454\]

In general, early developing boys are perceived to be more mature, are given more leadership roles, and are accepted as more attractive and smart by their peers. Late developing boys are more insecure, more susceptible to lower levels of self-esteem and body image, \[455\] and more vulnerable to peer pressure, especially in working class and minority groups. Much of the problem of late maturation is said to focus on the decreased height of the individual rather than the lack of sexual development.\[456\] Social maturation is said to lag even after androgen treatment in severe constitutional delay in puberty according to an older study.\[457\]

In contrast to early maturing boys, early maturing girls tend to experience more difficulty, especially in the junior high school setting, where they may attract the attention of older, more mature boys. Girls with early puberty had a higher prevalence of internalizing symptoms and even internalizing disorders.\[458\] Early puberty may lead to a negative body image in girls, whereas in boys the effect is positive. Early pubertal maturation in girls may be related to a small IQ advantage over late maturing girls, but there is no support for differences in specific areas of cognitive abilities.\[459\] Late maturing girls are often more comfortable, remain with the support of their families longer, and are less often brought to medical attention than late maturing boys.\[460\]

Delay in menarche related to stress or decreased weight may be further analyzed with respect to dating behavior. Menarche was delayed in lean ballet dancers compared with a control group of adolescent girls of the same age and compared with their own mothers.\[461\] The dancers studied were less likely to date than age-matched peers, and whereas menarcheal status had no effect on dating behavior in nondance control subjects, the dancers who did achieve menarche were more likely to date.\[462\]
HORMONAL AND METABOLIC CHANGES IN PUBERTY

Puberty is a stage in a continuum extending from sexual differentiation and the ontogeny of the hypothalamic-pituitary-gonadal apparatus in the fetus to the completion of sexual maturation. This process involves changes in the CNS and increased frequency and amplitude of LHRH secretion at puberty, which initiates and regulates the sequential increases in the secretion of pituitary gonadotropins and gonadal steroids that culminate in sexual maturity and fertility.

Gonadotropins

Because of the pulsatile secretion of LHRH, gonadotropin secretion is also episodic. Plasma levels of LH and FSH in the fetus rise after the establishment of the hypothalamic-pituitary portal system, with midmorning LH peaks being the most consistent. In the neonate, episodic LH release as a consequence of pulsatile LHRH secretion is the basis for the pulsatile 24-hour pattern of LH release in the neonate. Plasma levels of LH tend to remain high throughout childhood until puberty, when there is a gradual rise in LH levels, with an additional increase during sleep. The frequency and amplitude of LH pulses increase during sleep through puberty. The gonadal steroid values, however, are useful in determining the stage of pubertal development. To that end, the mean plasma estradiol, FSH, and LH concentrations in prepubertal and pubertal females by pubertal stage of maturation (1 = prepubertal; 5 = menstruating adolescents) and the mean bone age for each stage are shown in Table 24-13-

TABLE 24-13 -- Cardinal Hormonal Characteristics of Puberty

Remarkably, in the normal or the normal male monkey, there is relatively small change in LHRH messenger ribonucleic acid (mRNA) in the hypothalamus with the onset of pubertal development, suggesting that other factors repress LHRH secretion during the juvenile pause.

The peripubertal period is the time that immediately precedes signs of sexual maturation. In the prepubertal period, ultrasensitive LH assays provide indirect evidence of a diurnal variation of LHRH secretion with a preponderance at night; the frequency is similar to that of the early pubertal period, although the amplitude of LH does not increase until the peripubertal period. During the prepubertal period, enhanced release of LH can first be shown in response to intravenous LHRH, and the augmented release of pulsatile LH during sleep is prominent. During puberty, the episodic secretion of FSH and LH becomes more clear-cut as the amplitudes of the gonadotropin pulses increase. An increased amplitude of LH and FSH secretion occurs at night in prepubertal boys and girls; there is a temporal concordance of LH pulses with FSH pulses of 43%. Primary testicular failure is associated with enhanced amplitude and frequency of both FSH and LH pulses.

In the past, single daytime serum samples did not reliably indicate the stage of puberty because of the insensitivity of the assays. Nonetheless, studies of a large number of individuals using single daytime samples documented changes in the mean serum gonadotropin levels between prepuberty and puberty. In girls, FSH levels rise during the early stages of puberty and LH levels tend to rise in the later stages, from beginning to late puberty, the LH concentration rises over 100-fold. In boys, FSH levels rise progressively through puberty and LH levels rise and reach an early plateau.

Ultrasensitive LH and FSH assays now allow the accurate determination of basal levels of serum LH and FSH, and the results are lower than previous assays could detect. The basal values of serum LH and FSH are reported to predict the onset of pubertal development as well as can LHRH testing, a value of serum LH greater than 4 mIU/mL measured by immunochromatimometric assay is consistent with the onset of puberty. There is a more striking rise in serum LH amplitude by at least 1 year before the onset of puberty (the latter indicated by a testicular volume of at least 3 mL), whereas FSH rises more consistently through male pubertal increase with increased pulse amplitude. Moreover, the use of these ultrasensitive assays to determine concentrations of LH and FSH in urine reveals a pattern of a 5-fold rise in urinary FSH in boys and girls and a 52-fold rise in urinary LH in boys and a 100-fold rise in girls during puberty.

Doses of exogenous LHRH that are relatively ineffective in stimulating gonadotropin or gonadal steroid secretion before puberty become effective with the onset of puberty; thus, an amplification occurs in the hypothalamic-pituitary-gonadal axis with progression of puberty. Whereas the LHRH test usually requires multiple sampling after the administration of LHRH, a single determination at 30, 45, or 60 minutes may suffice with the new, sensitive immunoradiometric assay, but only if a positive result is obtained. Further, the use of an LHRH agonist (e.g., goserelin) in a single dose with determination of serum gonadotropins and sex steroids can help to differentiate the pubertal from the prepubertal state.

The pattern of release of gonadotropins and testosterone was determined in boys at every stage of pubertal development by sampling serum every 20 minutes for 24 hours. Disorderly patterns of secretion of LH but not FSH were noted just before the onset of puberty, followed by increased orderliness in early puberty and then...
increased disorderliness again in later puberty. This suggests that a more integrated feedback system operates in early puberty, which is followed by less stability.

Levels of biologically active LH as determined by rat or mouse interstitial cell assays and of biologically active FSH as assessed by rat Sertoli or granulosa cell assays have been compared with immunoreactive LH and FSH levels estimated by radioimmunoassay. Although discrepancies between serum bioactivity and immunoactivity of LH were reported earlier, more recent data indicate that a change in the bioactive/immunoactive ratio does not occur during puberty in boys or girls.

Qualitative as well as the well-defined quantitative changes occur in the pattern of FSH and LH in the pituitary gland, serum, and urine during development. The pattern of glycosylation of the a and b subunits of the gonadotropins is influenced by maturation, LHRH secretion, and the action of gonadal steroids on the pituitary gonadotrophs. Variation in glycosylation that affects the size and charge of the hormone is the principal cause of the heterogeneity of FSH and LH and the large number of isoforms, which vary according to the more acidic or more basic charge. This pleomorphism has an important effect on biologic half-life and biologic activity and provides an additional mechanism of regulating the biologic activity of the gonadotropins.

Although it has been difficult to characterize a diurnal variation of immunoreactive FSH secretion, secretion of bioactive FSH increases at night during sleep and is more resistant to testosterone-induced suppression than is immunoreactive LH.
Gonadal Steroids

Estrogen exerts different effects than testosterone, but only lately has it been appreciated that many actions on linear skeletal growth, skeletal maturation, and accretion of bone mass thought to be due to testosterone in the male are mainly attributable to its peripheral aromatization to estrogen.
Testosterone

The Leydig cells of the testes produce testosterone and, in lesser amounts, androstenedione, 5-androstenediol, dihydrotestosterone, and estradiol. In addition to direct secretion, a small amount of testosterone is derived from extraglandular conversion of androstenedione secreted by the testes and the adrenal. Although testosterone induces development of a male body habitus and voice change, dihydrotestosterone derived by 5-reduction in the target cell is the major mediator of the development of the phallus and the prostate, temporal hair recession, and beard growth. In the female, extraglandular conversion of ovarian and adrenal androstenedione accounts for almost all of the circulating testosterone.

Prepubertal boys and girls have plasma testosterone concentrations less than 0.3 nmol/L (0.1 ng/mL) except during the first 3 to 5 months of infancy in the male, when pubertal levels are found. Nighttime elevations of serum testosterone levels are detectable in the male by 5 years of age, before the onset of physical signs of puberty, and increase during early puberty after the appearance of sleep-entrained secretion of LH and increased pituitary sensitivity to LHRH. There is a lag of about 60 minutes between the peak of LH and the increase in testosterone, presumably related to synthesis and secretion of the steroid. In the daytime, increases in testosterone levels are detectable at approximately 11 years in boys when the testis volume is at least 4 mL, with a consistent increase throughout puberty. The steepest increment in testosterone occurs between pubertal stages 2 and 3 in males; testosterone concentrations can rise from 0.7 to 8 nmol/L (0.2 to 2.4 ng/mL) within 10 months.

Normal values for testosterone and other androgen metabolites are described; measurements of the ratio of testosterone to its metabolites can be used to identify athletes using illicit androgen preparations. Unfortunately, the ratio of testosterone to epitestosterone in the urine, which is used in this manner to evaluate "doping," may be elevated normally during the progression through puberty, casting doubts upon this testing procedure during puberty.

Free testosterone values are low or nondetectable until the age of normal pubertal development, at which time they rise in boys and girls. A sensitive mammalian cell recombinant bioassay for androgen bioactivity strongly correlated with serum immunoreactive testosterone concentration but not with 5-dihydrotestosterone, dehydroepiandrosterone, or androstenedione.

Sex steroids can be measured in saliva (as can many other types of steroids) for screening purposes or for monitoring.
Estrogens

In the female, the major estrogen, estradiol, is principally secreted (90%) by the ovary; a small fraction of circulating estradiol arises from the extraglandular conversion of testosterone and androstenedione. In the male, approximately 75% of estradiol is derived from extraglandular aromatization of testosterone and (indirectly) androstenedione and 25% from testicular secretion. Aromatase is absent or present in barely detectable amounts in prepubertal testes but maximal amounts appear in late puberty. In normal testes aromatase is predominantly present in the Leydig cells, but in testicular tumors of either Sertoli or Leydig cells, for example, associated with the Peutz-Jeghers syndrome, the Sertoli cells of the tumor express aromatase.

In the fetus and at term, levels of estrogens are high because of the conversion of fetal and maternal adrenal C19 steroids to estrogen by the placenta. Plasma levels of estrogen drop precipitously in the first few days of life. Estrogen levels are so low in prepuberty that detection has been difficult with standard techniques, but a highly sensitive bioassay demonstrated measurable serum concentrations of estradiol in both boys and girls before puberty with higher estradiol concentrations in girls than boys.

The mean concentration of serum estradiol equivalents in 21 prepubertal girls (7.7 ± 1.9 years) was 0.6 ± 0.6 (SD) pg/mL, significantly greater than the concentration (0.08 ± 0.2 pg/mL) found in 23 prepubertal boys (9.4 ± 2.0 years). The higher estrogen levels in girls may be an important factor in the more advanced levels of skeletal maturation in girls and play a part in their earlier onset of sexual maturation. Subsequently, the plasma estradiol level rises steadily through the stages of puberty until maturity and exhibits a diurnal rhythm (see Fig. 24-17), when concentrations of about 500 pg/mL are reached in the follicular stage and about 200 pg/mL in the luteal phase; estrone levels rise early and reach a plateau by midpuberty. The daily peak of estradiol in early pubertal girls occurs about 6 to 9 hours after the peak of serum LH detected during the night, apparently related to the time necessary for ovarian synthesis of estradiol.

### TABLE 24-14 -- Differences in the Timing of the Onset of Estrogen Synthesis in Girls and Boys

<table>
<thead>
<tr>
<th>Girls</th>
<th>Follicle-stimulating hormone (FSH) from late fetal life through puberty stimulates aromatase and estrogen synthesis by the ovary.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Boys</td>
<td>FSH leads to enlargement of the testes, the earliest sign of puberty in the male; spermarche occurs early in puberty and spermaturia at a mean age of 13.3 years before the sharp rise in testosterone levels and peak height velocity. Estradiol synthesis is not detectable in fetal or prepubertal Leydig cells and is at a very low level, until luteinizing hormone stimulates Leydig cell aromatase at late stage II to stage III of male secondary sexual maturation. Estradiol does not reach the level found in girls in early puberty who exhibit a pubertal growth spurt until at least midpuberty.</td>
</tr>
</tbody>
</table>

In all stages of puberty, boys have higher concentrations of estrone than estradiol, and levels of both estrogens are lower than those in girls at comparable stages. Boys have higher levels of estrone and estradiol in pubertal stage 5 than in stage 1. A new ultrasensitive estradiol assay demonstrated measurable serum estradiol equivalents in prepubertal boys with a rise through puberty until the pubertal growth spurt and a decrease thereafter. Klein and co-workers found a high correlation with peak growth velocity and the rise in estradiol concentration, which in boys occurred about 3 years after the onset of puberty. The mean estradiol level at peak growth velocity was similar in boys and girls at about 3 to 4 pg/mL. (Table 24-14)
Adrenal Androgens

There is a progressive increase in plasma levels of 5-steroids, dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS), in both boys and girls beginning before age 8 (skeletal age of 6 to 8) and continuing through early adulthood (Table 24-15). The increase in the secretion of adrenal androgen and its precursors is known as adrenarche. Plasma DHEA has a diurnal rhythm similar to that of cortisol, but plasma DHEAS shows less variation and is a useful biochemical marker of adrenarche. The role of adrenarche in puberty is discussed later (see "Adrenal Androgens and Adrenarche").
Testosterone-Binding Globulin (Sex Steroid-Binding Globulin)

Between 97% and 99% of circulating testosterone and estradiol is reversibly bound to TeBG; only the free steroid is physiologically active. TeBG is a glycoprotein of 90 to 100 kd, consists of heterogeneous monomers, and has one steroid binding site per dimeric molecule. Prepubertal levels of TeBG are approximately equal in boys and girls, and a decrease in TeBG level occurs with advancing prepubertal age and the concomitant increase in the plasma gonadal steroid levels; at puberty there is a small decrease in TeBG levels in girls and, as a consequence of testosterone, a greater decrease in boys. The rise in adrenal androgen levels at adrenarche may explain the early drop in TeBG levels, which allows more circulating free hormone at a given concentration of testosterone. Although the plasma concentration of testosterone is 20 times greater in men than in women, the concentration of free testosterone is 40 times greater. Boys with hypogonadotropic hypogonadism and patients with the androgen resistance syndrome show the same characteristic fall in TeBG levels at puberty, but values are intermediate between normal adult males and females. TeBG production is regulated by a number of factors. For example, it is down-regulated by GH administration in prepubertal children, perhaps by the action of IGF-I. TeBG is decreased in prepubertal children with diabetes mellitus.

| TABLE 24-15 -- Mean Serum Concentrations of Dehydroepiandrosterone Sulfate During Childhood |
|-----------------------------------------------|---------------|---------------|---------------|---------------|---------------|
| Concentration, µmol/L (ng/mL), at Chronologic Age | 68 yr | 810 yr | 1012 yr | 1214 yr | 1416 yr |
| Boys | 0.5 (188) | 1.6 (586) | 3.4 (1260) | 3.6 (1330) | 7.2 (2640) | 7.2 (2640) |
| Girls | 0.8 (306) | 3.2 (1170) | 3.1 (1130) | 4.6 (1690) | 6.9 (2540) | 6.3 (2320) |

| Concentration, µmol/L (ng/mL), at Bone Age |
|-----------------------------------------------|---------------|---------------|---------------|---------------|
| Boys | 0.98 (360) | 1.6 (574) | 3.4 (1250) | 5.8 (2150) | 10.9 (4030) |
| Girls | 0.73 (276) | 3.1 (1130) | 4.33 (1560) | 7.1 (2610) | 3.9 (1450) |

Prolactin levels rise in girls during puberty. Prepubertal mean (± standard error) plasma prolactin concentrations are 4.0 ± 0.5 µg/L in boys and 4.5 ± 0.6 µg/L in girls. Late pubertal girls and adult women have higher concentrations of prolactin (7.5 ± 0.7 and 8.3 ± 0.7 µg/L), whereas the mean concentration in adult men is 5.2 ± 0.4 µg/L. This sex difference is likely to be a consequence of the higher estradiol levels during puberty in girls and in women.
Inhibin, Activin, Follistatin

Inhibin, activin, and follistatin were discovered by their effect on FSH secretion. Inhibin and follistatin inhibit and activin stimulates FSH subunit expression and hence FSH biosynthesis and secretion. It is now recognized that they are synthesized in a variety of tissues in addition to the gonads and have diverse activities apart from those on the reproductive apparatus. Two distinct binding proteins for inhibin and activin have been described that are present in the circulation, the gonads, and other tissues: a 2-macroalbumin, a high-capacity, low-affinity binding protein, and follistatin, a glycosylated single peptide chain that functions not only as a high-affinity binding protein but also as a regulator of activin bioactivity (e.g., in the pituitary gland, a site of synthesis of both activin and follistatin). 1414

Inhibin, a heterodimeric glycoprotein product of the Sertoli cell of the testes and the ovarian granulosa cell (as well as the placenta and other tissues), exerts a negative feedback action on the secretion of FSH from the pituitary. Inhibin is composed of a subunit and one of two subunits, A or B, which form inhibin A or inhibin B, respectively, dimers with apparently identical function. Inhibin is a member of the transforming growth factor (TGF-) superfamily, which includes antimüllerian hormone (AMH, also called müllerian-inhibiting factor) and the dimers of two inhibin subunits, activin A and activin B, that stimulate the release of FSH from pituitary cells. 5 FSH induces synthesis and secretion of gonadal inhibin. Inhibin plays a role in the feedback regulation of FSH secretion during puberty in males and females. 1415 In men, inhibin B is a major feedback regulator of FSH release. 1416 (Inhibin B and inhibin A exhibit specific patterns of secretion during the menstrual cycle. 1417)

The assay for plasma inhibin is confounded by the fact that the dimeric inhibins occur in a wide range of molecular weights, including combinations of precursor forms of each of the subunits as well as a precursor of the subunit of inhibin, pro-C. The Monash radioimmunoassay detects the dimeric inhibins, inhibins A and B, as well as pro-C and related peptides and is essentially a nondiscriminatory total inhibin assay. 1418 Since the development of highly specific enzyme-linked immunosorbent assays for the mature 31-kd inhibin A and inhibin B dimers and for inhibin pro-C, 1419 1420 the detection of sex-specific differences in the pattern of inhibin secretion has advanced our knowledge of the biologic action of inhibin and the clinical usefulness of inhibin determinations. 1419 1420

During pregnancy, the placenta secretes inhibin A and the fetal membranes secrete both inhibin A and inhibin B, whereas, at least for the first 20 weeks of gestation, only inhibin A was detected in maternal serum. 1421 In umbilical cord serum from term female newborn infants, no inhibin was detected, whereas cord serum from male newborns contained inhibin B, the only inhibin detected in adult males; the median value was 167 pg/mL. 1422 In the human fetal testis -and B (but not A) subunits are present in both Sertoli and Leydig cells at 16 weeks of gestation; by 24 weeks of gestation immunoperoxidase of both subunits was greater in the Sertoli cells. Postnatally, the expression of both subunits was decreased by 4 months of age. Inhibin subunits were not detected in the fetal ovary, nor was immunoreactive follistatin present in fetal or neonatal gonads. 1423 These findings are consistent with inhibin A and inhibin B values in midgestation and term fetuses. 1424

Immunoreactive inhibin-like activity measured by the Monash assay increases in both boys and girls during puberty, with mean plasma levels increasing in boys from 161 to 442 U/L and in girls from 97 to 231 U/L between stage 1 and stage 5. 1425 In boys, the rise in serum immunoreactive inhibin was relatively constant during puberty, increasing 1.5-fold between a testis volume of 1 and 10 mL. 1426 However, as discussed before, the early inhibin immunosays cross-react with inactive monomeric inhibin precursors. There is a striking sex dimorphism in the pattern of circulating inhibin B and A from fetal life through full sexual maturation. 1427 In large cross-sectional studies 1428 1429 using highly specific inhibin B and inhibin A immunosays that correlate with the bioactivity of inhibin and distinguish inhibin B from inhibin A, the mean concentration of serum inhibin B increased between prepuberty (a stage when it is higher than the undetectable levels in castrate men) 1428 and the first stage of puberty; when the strong correlation with chronologic age was taken into account, a correlation with LH and testosterone values remained. From genital stage 2 puberty on, inhibin B levels were relatively constant despite a rise in the mean concentration of serum FSH between stages 2 and 3, after which the FSH value was relatively unchanged. By genital stage 3 a negative partial correlation between inhibin B and FSH was found that persisted as puberty advanced. 1428 1429 and by genital stage 4 there was a clear negative correlation of inhibin with serum FSH. 1428 Crofton and colleagues found that dimeric inhibin B rose twice in development, reflecting the two periods of Sertoli cell proliferation during infancy and early puberty, whereas an inverse relationship between inhibin and FSH was seen at midpuberty and thereafter, indicating the development of the negative feedback inhibition. 1428

Serum inhibin A and inhibin B increase early in puberty in girls, although there are individual increases in the prepubertal period directly related to FSH levels demonstrating sporadic follicular development in the infant and child related to FSH stimulation. 1428 Inhibin B is predominant in the follicular phase and inhibin A during the luteal phase. 1428 More specifically, inhibin A and inhibin B peaked in midpuberty and inhibin B decreased thereafter. 1428 Although there is no significant change in activin during female puberty, follistatin decreases from a midpuberty peak to later values that fall below prepubertal values.

Serum inhibins and FSH are markedly elevated in chronic renal failure but are reduced after renal transplantation. 1430 A low concentration of inhibin B in men and pubertal boys is an indicator of impaired seminiferous tubule function. 1431

Early pubertal boys with testicular defects have higher FSH concentrations and low inhibin levels. 1432 Inhibin B is the form most closely related to testicular function and is absent in orchidectomized men. 1432 Inhibin B is related to Sertoli cell function in prepuberty, but a developmental change occurs during puberty so that later in life inhibin B is related to spermatogenesis. Prepubertal boys with the Sertoli cellonly syndrome had normal inhibin B levels; postpubertal boys and men with Sertoli cell-only syndrome and early stage spermatogenic arrest had undetectable or low levels of inhibin B, whereas those with late stage spermatogenic arrest or obstructive azoospermia had normal or near-normal levels of serum inhibin B. 1433 1434 It is suggested that in prepuberty both the inhibin B and subunits are expressed in Sertoli cells, but during puberty and in men fully differentiated Sertoli cells express only the subunit and the subunit is expressed in germ cells; inhibin B in the adult appears to be a product of both germ and Sertoli cells. In prepubertal boys, basal plasma inhibin B concentrations have a high correlation with the incremental testosterone response to the administration of hCG and provide a useful assessment of both the presence of testes and its function. 1435
Antimüllerian Hormone

AMH (or müllerian inhibitory substance), a 14-kd glycoprotein dimer structurally related to the subunit of inhibin and TGF-, is produced by the Sertoli cell of the fetal testis and later in gestation by granulosa cells of the fetal ovary. Immunoassayable concentrations of AMH rise from birth to relatively high levels in the first year in newborn males, decrease by age 10, and decrease further during puberty. Newborn females have low or nondetectable serum levels of AMH, which rise only slightly thereafter; serum AMH concentrations are virtually nondetectable in most girls just before puberty.

There is an inverse relationship between serum AMH and androgen concentrations in pubertal boys and in boys with true precocious puberty, in whom values were appropriate for pubertal stage rather than chronologic age; in addition, patients with androgen resistance have elevated serum AMH concentrations in the newborn period and again at puberty and thereafter. Values are elevated in males with primitive Sertoli-like tumors and in girls and women with granulosa cell tumors; AMH is a useful gonadal tumor marker. Concentrations of AMH are slightly higher in individuals with delayed puberty than in pubertal age-matched control subjects and lower in those with testicular dysgenesis associated with impaired virilization than in normal boys. However, boys with isolated cryptorchidism have normal values of AMH. The serum concentration of AMH is useful in determining the presence of testicular tissue in differentiating anorchia from bilateral cryptorchidism in prepubertal boys; in the former AMH is absent, and in the latter AMH is in the normal range. Patients with dysgenetic testes often have low serum levels of AMH, and measuring the testosterone response to hCG is indicated to assess the presence of testicular tissue.
Prostate Specific Antigen

Prostate specific antigen (PSA) is detectable in both male and female cord blood and in the serum of infants, but PSA concentrations decrease to undetectable levels during childhood. PSA concentrations rise to the measurable range with the onset of puberty in the male and correlate with the progression of pubertal stage, the size of the testes and presumably the prostate, and serum LH and testosterone concentrations. PSA values were increased into the pubertal range in boys with idiopathic true precocious puberty and showed a significant decrease with GnRH agonist treatment.
Growth Hormone

As discussed earlier, serum GH concentrations rise during pubertal development in relation to increased gonadal sex steroid secretion. The secretion of GH increases twofold to threefold during puberty. In individuals with delayed puberty, increased GH secretion can be induced by the administration of exogenous androgens. GH rises in both boys and girls of normal stature during puberty but secretion decreases after the end of pubertal development; there is a relatively greater rise in girls, which starts at an earlier chronologic age than in boys because of the earlier onset of puberty in girls and occurs at an earlier pubertal stage in girls than in boys. During puberty in adolescents of normal height, there is an inverse relationship between weight and GH levels. Even though the frequency of GH secretory episodes is not altered by puberty or androgen administration, the amplitude and mass of the pulses increase. After pubertal development, GH secretion decreases with advancing age. Although it would appear that the rise in testosterone in boys mediates the rise in GH, it is mainly the aromatization of testosterone to estradiol that induces the effect on GH secretion (see earlier).

Treatment of late pubertal boys with the estrogen receptor blocker tamoxifen led to smaller GH secretory peaks and, to a lesser degree, fewer GH secretory episodes, supporting the critical role of estrogen. Further, the administration of exogenous estrogen increased the peak GH reached after insulin-induced hypoglycemia, exercise, and arginine. GH release is stimulated by hypothalamic GH-releasing hormone (GHRH), but another class of six- and seven-amino-acid peptides (growth hormonereleasing peptide or GHRP) also stimulate GH release independently and in a manner additive to GHRH. GHRP stimulates the release of GH in the absence of GHRH as well as in its presence. GH secretion is increased in puberty compared with prepuberty both in the basal state and after GHRH or GHRP stimulation. Urinary GH excretion reflects serum levels and changes with pubertal development as a peak was reached at pubertal stage 3 to 4 in studies with sensitive enough assays; higher values of urinary GH content were reached in boys than in girls.

Urinary GH determinations after intravenous administration of arginine correlate inversely with BMI and GH excretion in pubertal but not in prepubertal short normal children or in patients with Turner's syndrome.

Growth hormonebinding protein (GH-BP) has the same amino acid sequence as the extracellular component of the GH receptor and is directly related to the amount of cellular GH receptors; in normal children, plasma GH-BP is inversely related to 24-hour GH secretion. There is disagreement over the changes in GH-BP with maturation. Serum GH-BP rises early in childhood and rises through puberty in some cross-sectional studies but not in others or in longitudinal studies. In the longitudinal study in which plasma GH-BP did not change appreciably with the onset of puberty, it was suggested that at the time of the pubertal growth spurt there is a relative increase in unbound (free) GH in relation to GH bound to GH-BP. GH-BP is related to adiposity, and it may be this factor that accounts for the increased levels of GH-BP in girls compared with boys and for the rise in GH-BP in girls with precocious puberty as well as the negative influence of testosterone on GH-BP levels.
Insulin-Like Growth Factor I

A cross-sectional study of free IGF-I concentrations in 1030 subjects confirmed the pattern of a slow rise in serum free IGF-I in prepuberty followed by a steeper rise during puberty. The concentration of IGF-I rises during puberty to levels higher than those of prepubertal or adult subjects, remains elevated past the time of peak height velocity with a peak attained 1 or 2 years after the pubertal growth spurt, thus later in boys than in girls, and then falls to normal adult levels. The pattern of the GH-dependent serum insulin-like growth factorbinding protein 3 (IGF-BP-3) in pubertal development is similar to that of serum IGF-I. However, serum IGF-BP-3 concentrations correlate with BMI even though IGF-I does not.

Measurement of free IGF-I shows the same pattern of change with development as the measurement of total IGF-I, but the magnitude of the change in puberty differs between the two. A decrease of free IGF-I is described with age in the later stages of puberty. The increase in the serum ratio of IGF-I to IGF-BP-3 at the time of the pubertal growth spurt appears to be due to production because proteolysis of IGF-BP-3 does not change in puberty in normal children. The testosterone level in boys and the estradiol level in girls correlate with the rise in IGF-I concentration, but gonadal steroids are not the direct cause of the increase in circulating IGF-I levels. Secretion of GH approximately doubles during puberty; the major effect of estrogen and testosterone on IGF-I generation is mediated indirectly through augmented release of GH (see earlier). Children with true precocious puberty have plasma IGF-I values characteristic of children in the same stage of normal puberty rather than children of the same chronologic age. After treatment of children with true precocious puberty with LHRH agonists to lower plasma gonadotropin and sex steroid levels, IGF-I values slowly decrease along with the secretion of GH. In sexual precocity, as in normal puberty, gonadal steroid secretion appears to stimulate GH secretion, which in turn increases IGF-I generation.

Serum IGF-II shows no pubertal peak and falls during adulthood in boys.
Insulin

Insulin sensitivity decreases normally during puberty. Serum fasting insulin concentration increases twofold to threefold with peak height velocity, and insulin secretion after a glucose load increases over prepubertal levels, suggesting a degree of insulin resistance during normal puberty. *This impairment of insulin-stimulated insulin metabolism can be demonstrated by the euglycemic insulin clamp technique* in normal subjects and is more striking in adolescents with diabetes mellitus. Further, insulin-mediated glucose disposal in oxidative and nonoxidative pathways of cellular glucose utilization in peripheral tissues is about 30% lower during Tanner stages 2 and 4 than in prepuberty and the young adult stage as determined by using the hyperinsulinemic euglycemic clamp technique or the minimal model, frequently sampled intravenous glucose tolerance test. *Hyperglycemic clamp studies also indicate that pubertal individuals compensate for this defect by increasing insulin secretion and suggest that the insulin resistance does not involve the effect of insulin on amino acid metabolism* in normal pubertal individuals. *Thus the enhanced insulin response to glucose in puberty related to the relative insulin resistance may increase the anabolic effects of insulin with regard to protein metabolism.*

This normal phase of insulin resistance appears temporarily and possibly causally related to the rise in GH, a hormone that opposes the action of insulin. A normal individual adapts to these changes, but an individual at risk for type 2 diabetes may not adapt to the insulin resistance and with the accompanying defect in pancreatic action characteristic of type 2 diabetes often develops clinical type 2 diabetes during the pubertal years. Indeed, with the increasing prevalence of obesity in the young, there is a secondary peak in the onset of type 2 diabetes at 13.5, although it is encountered in younger children as well.

Insulin resistance is related to many cardiovascular risk factors. Further, insulin resistance is characteristic of the state of functional ovarian hyperandrogenism seen after a history of premature puberty; this constellation is more frequent in children with a history of low birth weight. Insulin resistance in childhood appears to decrease the likelihood of tracking of obesity into adult age. The response of insulin to an oral glucose tolerance test is greater in black subjects than in white subjects at all stages of pubertal development; this ethnic difference in insulin resistance is suggested as a cause for the increased incidence of type 2 or non-insulin-dependent diabetes mellitus in black adults compared to white adults.

Patients with type 1 (insulin-dependent) diabetes mellitus usually require an increase in the dose of insulin for euglycemic control at puberty. The insulin resistance has been attributed, at least in part, to increased fat oxidation at puberty, which correlates with rising serum IGF-I and may be linked to increased GH secretion. Insulin sensitivity is related to pubertal stage and BMI; in a longitudinal study, insulin sensitivity inversely correlated with BMI, decreased with progression from pubertal stage 2 to stage 3, and was lower in girls than boys at either stage 2 or 3. Insulin resistance is present early in the course of Turner’s syndrome and thalassemia major. In children with well-managed type 1 or insulin-dependent diabetes mellitus, the growth rate may decrease mildly and transiently in the 10 years after diagnosis; bone age advancement slows during this period, leading to a transient slowing of development. However, the effect of diabetes on growth is smaller than the genetic influence of parental height. Although growth velocity increases again, mainly during puberty, weight gain increases even more in affected children during puberty, leading to a higher incidence of obesity in children with type 1 diabetes mellitus than expected from family patterns.

Unfortunately, some adolescents with type 1 diabetes mellitus, predominantly girls, reduce their insulin use in order to lose weight, with dire consequences. A retrospective study found a decrease in final height if the diagnosis of type 1 diabetes mellitus was made prior to 5 years of age but not if the diagnosis of type 1 diabetes mellitus was made later; the pubertal growth rate was reduced in all patients, but girls were more affected than boys. Adolescents with type 1 diabetes mellitus have a lower serum concentration of IGF-I than control subjects. The elevated GH levels are associated with low serum IGF-I and low serum GH-BP concentrations, and there is no longer the usual reciprocal relationship between serum GH and GH-BP.

Obese teenage girls with predominant abdominal adiposity have insulin resistance and are at higher risk for the development of breast cancer; abdominal adiposity may be recognized in the prepubertal state and is associated with early puberty, early menarche, and, later exposure to an endocrine profile predisposing to breast cancer. Plasma insulin in obese adolescent boys correlates with fasting plasma glucose, plasma triglycerides, uric acid, and systolic blood pressure, whereas in obese adolescent girls it correlates with plasma triglycerides and systolic and diastolic blood pressure; plasma insulin correlated negatively with HDL cholesterol in both boys and girls. Retinopathy related to type 1 diabetes mellitus characteristically appears in the teenage years or later, but the duration and control of diabetes in the pubertal years are contributing factors; there is an increased appreciation of the prevalence of retinopathy in the prepubertal years.

The fluoroscopic photometry ratio increases at the time of puberty, indicating a decrease in the blood-retina barrier during this period. The American Diabetes Association recommends screening for microalbuminuria, an indicator of the development of diabetic nephropathy; microalbuminuria may develop quite early in puberty rather than at the later stages as previously suggested. With the increased prevalence in type 2 diabetes, screening criteria have been proposed but are under evaluation. At present, a child with BMI-SC more than the 85th percentile should be screened if one of the following criteria is present: (1) a family history of type 1 diabetes mellitus, (2) signs of insulin resistance (acanthosis nigricans, FOH, hypertension, or dyslipidemia), or (3) membership in certain ethnic groups (black, Native American, Hispanic American, and Asian American). If a fasting plasma glucose level is greater than 126 mg/dL, a 2-hour postprandial value is over 200 mg/dL, or there are symptoms such as weight loss, polyuria, or polydipsia and a casual plasma glucose is over 200 mg/dL, the diagnosis of diabetes mellitus is likely and determination of the type of diabetes is appropriate.

Type 2 diabetes mellitus has been recognized in children and adolescents in the past, but the incidence is increasing, probably because of the increase in obesity in these age groups. Type 2 diabetes mellitus appears most often among children and adolescents of ethnic minority populations (African American, Native American, Hispanic American, and, more recently appreciated, Asian American) and should be considered in subjects manifesting acanthosis nigricans as a marker for insulin resistance; girls with hyperandrogenism not otherwise explained are also concerned of Type 2 diabetes mellitus in the young is a heterogeneous disorder and obesity, although common, is a variable feature.

This remarkable increase in type 2 diabetes mellitus should not be confused with maturity-onset diabetes of the young (MODY) syndromes. Six variations of MODY have been defined, all with slowly progressive loss of pancreatic beta cell function and inherited as an autosomal dominant trait in individuals who need not be obese. Type 2 MODY appears to be linked to a mitochondrial defect in glucokinase. Patients with MODY may ultimately require insulin therapy.

Several syndromes of insulin resistance combine hyperglycemia and virilization. The Kahn type A syndrome features include a lean, muscular adolescent female phenotype with acanthosis nigricans, hirsutism, oligomenorrhea or amenorrhea, and ovarian hyperthecosis with stromal hyperplasia associated with abnormalities of the insulin receptor gene. Hyperandrogenism, acanthosis nigricans (HAIR-AN) syndrome and polyolcystic ovary syndrome (PCOS) are less severe than Kahn type A and are usually manifest in adolescent females. Rabson-Mendenhall is a syndrome of severe insulin resistance (possibly leading to diabetic ketoacidosis), dysmorphic facies, acanthosis nigricans, thickened nails, hirsutism, dental dysplasia, abdominal distention, and phallic or clitoral enlargement. The Rabson-Mendenhall syndrome, like the Donohue leprechaunism syndrome, which shares some features, is due to homozgyous or compound heterozygote defects in the insulin receptor gene. Kahn type B syndrome is due to inhibitory or stimulatory antibodies to the insulin receptor, sometimes with acanthosis nigricans and ovarian hyperandrogenism; this syndrome can occur in ataxia-telangiectasia syndrome or in otherwise normal adolescents. Individuals with the Seip-Berardinelli syndrome combine lipodystrophy and severe insulin resistance and complete or partial absence of subcutaneous fat with increased growth and skeletal maturation, muscle hypotrophy, acanthosis nigricans, hypertrichosis, organomegaly, and mild hypertrophy of the external genitalia. Most of these type 2 diabetes mellitus syndromes can be treated with oral hypoglycemic agents initially; progression of the disorder may require the use of insulin.
Serum Lipids

Testosterone increases serum LDL cholesterol and decreases HDL cholesterol concentrations and thereby accounts for the adverse LDL/HDL ratio in adult males compared with adult females. Postheparin hepatic lipase activity is increased by exogenous androgens (and decreased by estrogens), accounting for the decrease in HDL after androgen treatment or after a rise in endogenous androgen secretion. Serum lipoprotein A is not related to pubertal stage in normal subjects but rather appears related to genetic influences. Even though there is an increased risk of coronary heart disease in patients with type 1 diabetes mellitus and lipoprotein A is related to coronary heart disease, lipoprotein A concentrations are not different in children with type 1 diabetes mellitus compared with control subjects. However, lipids tracked over the pubertal period in a longitudinal study showed that 9-year-old girls with high LDL cholesterol retained high LDL concentrations 12 years later and those starting with lower LDL continued to have lower LDL. In an Australian study of prepubertal and early pubertal children, obesity was related to elevation of apolipoprotein B and the ratio of apolipoprotein B to apolipoprotein A-1; these measures are correlated with the development of atherosclerosis. In an American study, the waist circumference and the waist-to-hip ratio correlated inversely with serum HDL and directly with serum triglycerides and the BMI correlated positively with serum triglycerides and diastolic blood pressure; waist circumference was correlated with apolipoprotein B and the apolipoprotein B/apolipoprotein A-1 ratio.

Patients with familial hypercholesterolemia already have carotid intimal plaques by the age of puberty demonstrable by B-mode ultrasonography. Further, intra-abdominal adipose tissue indicated by MRI is positively related to serum total and LDL cholesterol and triglycerides in obese adolescents 10 to 15 years of age, an indicator of cardiovascular risk factors at these early ages. A 40-year longitudinal study of obese children and adolescence found continuing obesity into adulthood; the heaviest subjects and those who gained the most weight during the study had a greater risk of death or cardiovascular disease as well as diabetes.
Cortisol

Although no change occurs in the secretory rate of cortisol, salivary cortisol values increase slightly and correlate with pubertal stage without a sex difference.
The onset of puberty is a consequence of maturational changes that are incompletely understood. The development of secondary sexual characteristics, the adolescent growth spurt, the attainment of fertility, and the psychosocial changes entain from the maturation of the gonads and the increase in gonadal steroid secretion. The events characterizing the development of gonadal function can be viewed as a continuum extending from sexual differentiation and the ontogenesis of the hypothalamic-pituitary-gonadal system through a juvenile pause (in which the system is largely quiescent) to the attainment of full sexual maturation and fertility during puberty. These developmental and maturational events have as their end point procreation.

Two independent, but associated processes (controlled by different mechanisms but closely linked temporally) are involved in the increased secretion of gonadal steroids in the peripubertal and pubertal period. The first, adrenarche, the increase in adrenal androgen secretion, precedes by 2 years or so the second, gonadarche, the consequence of the pubertal reactivation of the hypothalamic-pituitary-gonadal system

---

**TABLE 24-16** — Hypothesis of the Control of the Onset of Human Puberty

| 1. Central Dogma: The CNS exercises the only major restraint on the onset of puberty. The neuroendocrine control of puberty is mediated by the hypothalamic LHRH-secreting neurosecretory neurons in the mediobasal hypothalamus, which act as an endogenous pulse generator (oscillator). |
| 2. The development of reproductive function is a continuum extending from sexual differentiation and the ontogenesis of the hypothalamic-pituitary-gonadal system in the fetus to the attainment of full sexual maturation and fertility. |
| 3. In the prepubertal child the LHRH pulse generator, operative in the fetus and infant, functions at a low level of activity (the juvenile pause) because of steroid-independent and steroid-dependent inhibitory mechanisms. |
| 4. Puberty represents the reactivation (disinhibition) of the CNS suppressed LHRH pulse generator characteristic of late infancy and childhood, leading to increased amplitude and frequency of LHRH pulsatile discharges, to increased stimulation of the pituitary gonadotropes, and finally to gonadal maturation. Hormonally, puberty is initiated by the recurrence of augmented pulsatile LHRH and gonadotropin secretion, mainly at night. |

CNS, central nervous system; LHRH, luteinizing hormone-releasing hormone.

---

intercellular as well as intracellular messenger. Further, LHRH acting as an autocrine factor may play a role in the synchronization mechanism. LHRH is synthesized in these neurons and released episodically from axon terminals at the median eminence into the primary plexus of the hypothalamic-hypophyseal portal circulation. The hormone is then transported by the portal vessels to the anterior pituitary gland. LHRH is essential for the release of both FSH and LH. In some species, notably rodents, extrahypothalamic CNS structures, including the limbic system (hippocampus and amygdala), influence gonadotropin secretion. Further, the amplitude and frequency of the pulsatile LHRH signal are modified by catecholaminergic and serotoninergic neurons, through their effect on hypothalamic norepinephrine, dopamine, and serotonin, and by opioid peptide, neuropeptide Y (NPY), leptin, galanin, corticotropin-releasing hormone, GABA, and excitatory amino acid neuronal networks. Whether the influence of extrahypothalamic factors on episodic LHRH release in humans is mediated by these pathways remains to be established; among these factors in humans and nonhuman primates, the inhibitory effects of GABA, opioid peptides, and corticotropin-releasing hormone on the LHRH pulse generator and the stimulatory effects of excitatory amino acids and adrenergic pathways are the most firmly established. Thus, the hypothalamic-pituitary gonadotropin unit is influenced by gonadal steroids, inhibin, activin, and follistatin and by complex neural influences that integrate a variety of intrinsic and extrinsic stimuli and functional factors and cues. In vitro studies suggest that the generation of the LHRH pulse is an intrinsic property of the LHRH neurosecretory neuronal network and that other factors modulate the fundamental autoregulation of the LHRH neuron. Several factors

2. The pulsatile gonadotrophs, which contain the seven-transmembrane-domain Gs protein-coupled LH/FSH receptors, are in response to the LHRH rhythmic signal, release LH and FSH in a pulsatile manner. Each LH (and FSH) pulse is induced by a pulse of LHRH.

3. The gonads, which are modulated primarily by the amplitude of the gonadotropin pulse, transmit the episodic gonadotropin signal into pulsatile secretion of gonadal steroids. This control mechanism, with its three principal components (medial basal hypothalamic LHRH neurosecretory neurons, pituitary gonadotrophs, and gonadotropin-responsive elements of the gonad), is common to all mammalian species.

Pattern of Gonadotropin Secretion

There are two pulsatile secretory patterns of gonadotropins: tonic and cyclic. Tonic, or basal, secretion is regulated by a negative, or inhibitory, feedback mechanism in which changes in the concentration of circulating gonadal steroids and inhibin result in reciprocal changes in the secretion of pituitary gonadotropins. This is the pattern of secretion in the male and one of the control mechanisms in the female. Cyclic secretion involves a positive, or stimulatory, feedback mechanism in which an increase in circulating estrogens, to a critical level and of sufficient duration, initiates the synchronous release of LH and FSH (the preovulatory LH surge) that is characteristic of the normal adult woman before menopause. The secretion of FSH and LH is probably always pulsatile or episodic, whether the pattern is tonic or cyclic and regardless of age (i.e., in the fetus, infant, or child, during puberty, or in the adult). However, it is difficult to detect small pulses when the plasma gonadotropin concentration is low (as in prepubertal individuals) because of methodologic limitations. In women, the overall pattern of LH pulse frequency and amplitude varies widely during the menstrual cycle from about one pulse per hour in the midfollicular phase to one pulse per 5 hours in the late luteal phase. Striking changes in the pattern of the pulsatile gonadotropin spikes and their circadian rhythm occur in the peripubertal period and during puberty. Even though LHRH stimulates the release of both FSH and LH, the pulsatile secretion of immunoreactive FSH in normal adult women is prominent; this discordance in FSH and LH pulses is attributed in part to the longer half-life of FSH than LH, to differences in the factors that modulate the action of LHRH on FSH and LH release by the gonadotrophs (especially gonadal steroids, inhibin, and possibly activin and follistatin), and to intrinsic differences in the secretory pattern of the two gonadotrophs. For example, a change in the frequency of LHRH pulses can modify the ratio of FSH to LH released; midfollicular phase concentrations of estradiol and adult male concentrations of plasma testosterone have a greater inhibitory effect on the response of FSH than on that of LH to pulsatile injections of LHRH.

The inherent oscillatory characteristic of gonadotropin secretion is a consequence of the pulsatile release of LHRH. However, the physiologic significance of the episodic, rhythmic pattern of gonadotropin secretion was unclear until studies of the rhesus monkey by Knobil and associates and revealed the essential nature of a periodic, oscillatory LHRH signal for the regulation of gonadotropin secretion. Inhibition of gonadotropin secretion results from the continuous infusion of LHRH because of desensitization of LHRH receptors on the gonadotroph. Intermittent, or pulsatile, administration (e.g., LHRH 1 µg/minute for 6 minutes every hour) restored pulsatile release of LH and FSH in adult monkeys in which hypophysectomy lesions obliterated the arcuate nucleus region and thus eliminated endogenous LH secretion. Further, pulsatile LHRH administration reestablished gonadotropin secretion in animals in which gonadotropin secretion had been suppressed by the continuous infusion of LHRH. These classical studies provided evidence that the LHRH signal to the pituitary gonadotrophs of the adult is frequency as well as amplitude coded. Therapeutic pulsatile administration of natural LHRH has made possible the induction of ovarian or testicular maturation, including fertility, in patients with hypothalamic hypogonadism and the suppression of gonadotropin secretion by long-acting potent LHRH analogues, for example, in boys and girls with true precocious puberty (see later).
Ontogeny

Studies in the mouse, rhesus monkey, human, and all vertebrates examined indicate that LHRH neurons do not originate in the CNS. Instead, they arise in the embryo from the epithelium of the olfactory placode and migrate by an ordered spatiotemporal course along the pathway of the nervous terminals-vernamental complex to the forebrain; the latter also originates in the olfactory placode and forms a connection between the nasal septum and the forebrain (Fig. 24-22). In the mouse embryo (studied in detail by Schwanzel-Fukuda and Pfaff) and by Wray and associates by immunocytochemistry, [H]thymidine autoradiography, and in situ hybridization histochemistry, the LHRH cells arise by embryonic day 9.5 (gestation days 18 and 19), exhibit a sharp peak of mitosis between days 10 and 11, and express LHRH mRNA and immunoreactive LHRH by day 10.5; by day 12.5 all cells that make up the postnatal population of LHRH neurosecretory neurons are present. The cells migrate in a rostralcaudal direction through the nasal septum into the forebrain from day 12.5 to 15.5 along with the terminalis nerve. By day 16.5 the LHRH neurosecretory neurons have a postnatal distribution in the hypothalamus (see Fig. 24-22). LHRH cells were limited to the nasal region in the 36-day monkey embryo.

LHRH neurons in the mouse. The route of migration of the LHRH neurosecretory neurons (black dots) in the mouse embryo is shown from their origin in the medial olfactory placode (a plate-like thickening of embryonic ectoderm) in the nasal region through the forebrain into the hypothalamus and preoptic areas. At embryonic (E) day 11 to 11.5 LHRH cells are in the anlage of the vomeronasal organ and medial wall of the olfactory placode. By E day 13 the number of LHRH neurons has increased, and most are in the nasal septum with the nerves terminals and the vomeronasal nerves; only a few cells are in the brain. By E day 14 the majority of LHRH cells are in the ganglion terminale and the central root of the nerves terminals and arch through the forebrain to the hypothalamus. By E day 16 most of the LHRH neurons are in the hypothalamus and preoptic areas, and the migration is almost complete. GT, ganglion terminalis; OB, olfactory bulb; POA, preoptic area, VNO, vomeronasal organ. (Adapted from Schwanzel-Fukuda M, Pfaff DW. Origin of luteinizing hormone-releasing hormone neurons. The Human Fetus

Schwanzel-Fukuda and co-workers studied a 19-week gestational male human fetus with Kallmann’s syndrome (see later). No LHRH neurosecretory neurons were detected in the brain, including the hypothalamus. However, dense clusters of LHRH cells and fibers were present in the nose, including the nasal septum and cribriform plate, and within the dural layers of the meninges under the forebrain. The olfactory bulbs were absent. In contrast, normal male fetuses at 19 weeks of gestation had the expected distribution of LHRH neurons in the hypothalamus. In subsequent studies, LHRH immunoreactivity was observed in the epithelium of the medial aspect of the olfactory placode by 42 days of gestation but not at 28 to 32 days. These findings in the human are consistent with the migration of LHRH neurosecretory neurons from the olfactory placode to the hypothalamus in other mammals. Adults have about 1500 to 2000 hypothalamic LHRH neurons. In the mouse, the number of LHRH neurons in the adult is similar to that in late fetal life.

LHRH has been detected in human embryonic brain extracts by 4.5 weeks and in the fetal hypothalamus early in gestation. Further, the fetal pituitary gonadotrophs are responsive to LHRH. The hypotalamic-hypophyseal portal system is functional by 11.5 weeks of gestation. By 9 weeks, LHRH neurons are detectable in the fetal hypothalamus, and by 16 weeks axon fibers that contain LHRH are present in the median eminence and terminate in contact with capillaries of the portal system. In fetal sheep the hypothalamus secretes LHRH in a pulsatile manner. Thus, the available data are consistent with the development of a human fetal hypothalamic LHRH pulse generator by at least the end of the first trimester.

In the previous discussion of hormonal changes, the changing pattern of gonadotropin and gonadal steroid secretion was considered in relation to age. The human fetal gonad is affected by placental gonadotropins and by fetal pituitary FSH and LH. Early in gestation, the placental gonadotropin hCG may play an important role in the secretion of testosterone by the Leydig cells of the fetal testes during the masculinization of the Wolffian ducts and the external genitalia. However, it is uncertain whether functional hCG/LH and FSH receptors are present in the fetal testes by 12 weeks of gestation and whether the early fetal testes responds to hCG. Fetal Leydig cells are a unique population of Leydig cells limited to the fetus and infant, which regress to be followed by the differentiation of adult-type Leydig cells in the peripheral period. In comparison with the adult type, fetal Leydig cells form tightly opposed clusters joined by gap junctions and lack Reinke crystals, are resistant to hCG/LH-induced desensitization (indeed, hCG/LH produces up-regulation of LH/hCG receptors), and contain little aromatase activity and few estradiol receptors.

In contrast to the fetal testis, the fetal ovary apparently does not have to have FSH receptors early in gestation. It is only late in the second trimester, after completion of male phenotypic differentiation, that fetal FSH and LH have been documented to have an effect on the growth and maturation of the fetal testis and ovaries. There is an apparent sex difference in the stage of gestation at which fetal pituitary gonadotropins have an important effect on the development of the fetal gonad. In the anencephalic fetus (which as a consequence of the severe CNS defect is deficient in hypothalamic LHRH, resulting in deficiency of pituitary gonadotropins) the testes appear hypoplastic by early in the third trimester; however, the ovaries in this disorder are normal until at least 32 weeks of gestation.

FSH and LH are detectable in the human fetal pituitary gland by 10 weeks of gestation, and the content increases until approximately 25 to 29 weeks of gestation. The fetal pituitary gland not only can synthesize and store FSH and LH but also can secrete these hormones by 11 to 12 weeks. The fetal serum LH and FSH concentrations rise to peak levels by midgestation and then decrease; the values in umbilical venous blood at term are low (see Fig. 24-24 and Fig. 24-25). Subsequent studies, using fetal blood obtained by cordocentesis and highly sensitive gonadotropin immunoassays, while largely confirming earlier studies have provided new information on the pattern of change in both immunoreactive and bioactive gonadotropins and sex steroids between 17 weeks and term. The serum concentrations of FSH and LH and of bioactive FSH at 17 to 24 weeks of gestation were strikingly higher in female than male fetuses and in both sexes decreased remarkably between 25 and 40 weeks of gestation. Again using highly specific immunoassays of serum FSH and LH in umbilical cord blood from fetuses at 26 to 40 weeks of gestation, the mean FSH and LH concentrations were elevated at the beginning of the third trimester and decreased with
advancing gestational age to undetectable values in term fetuses. The mean FSH value was higher in female fetuses between 26 and 38 weeks, whereas the mean LH level was higher in males. These findings give additional support for the continued secretion of FSH and LH during late gestation but at gradually decreasing amounts.

In the ovine fetus, LH and FSH are secreted in a pulsatile manner in response to the episodic secretion of fetal hypophysial LHRH (Fig. 24-26); human fetal pituitary gonadotropins are probably released in the same mode. The mean FSH and LH content of fetal pituitary glands and the concentration of fetal serum FSH are greater in female than in male fetuses at midgestation. This difference has been ascribed to the higher concentration of plasma testosterone between 11 and 24 weeks in the male fetus (the only major difference in gonadal steroids between the male and female fetus and fetal testicular inhibin), and the decrease in both serum FSH and LH concentrations toward term during late gestation has been attributed to the maturation of the negative feedback mechanism.

the development of gonadal steroid receptors in the hypothalamic-pituitary unit, and the effect of inhibin.

Consistent with this sequence of events, in vitro studies indicate that the human fetal pituitary gland is responsive to LHRH as early as 10 weeks of gestation; the LHRH-stimulated release of LH is greater in second-trimester fetal pituitary cells cultured from females than males and is augmented by estradiol in both sexes. In vivo studies during middle and late gestation demonstrate the stimulating action of exogenous LHRH on fetal FSH and LH release by 16 weeks of gestation with a striking sex difference in the FSH response and a fall in responsivity to LHRH in late gestation (see Fig. 24-24 and Fig. 24-26). The anencephalic infant and some infants with neonatal hypothyroid hypopituitarism have an absent or diminished gonadotropin response to LHRH; in contrast to the brisk increase in gonadotropins elicited by LHRH in the normal infant.

The pattern of changes in FSH and LH concentration in the fetal pituitary glands and serum is consistent with a sequence of increasing synthesis and secretion in which peak serum concentrations reach castrate levels, followed by a decline after midgestation that persists to term. The high serum concentrations of FSH and LH in the female and LH in the male in early and midgestation are probably the result of relatively autonomous, unrestrained activity of the fetal hypothalamic LHRH pulse generator and subsequent stimulation of the fetal gonadotrophs by LHRH. As a consequence of the pulsatile secretion of LHRH, the release of fetal LH and FSH is episodic (see Fig. 24-24 and Fig. 24-26).

advances, the negative feedback mechanism matures and the hypothalamus secretes less LH, which in turn leads to decreased secretion of FSH and LH. This inhibition of hypothalamic LHRH release and pituitary gonadotropin secretion appears to be a consequence of the increasing sensitivity of the hypothalamus and its LH pulse generator to the inhibitory effects of high concentrations of sex steroids (estrogens and progesterone from the placenta and, in the male, testosterone from the fetal testes) in the fetal circulation and in the male fetus to a contributory effect to the decrease in FSH by luteinizing inhibin in late gestation. The increasing CNS control of gonadotropin secretion seems to require the maturation of gonad steroid receptors (intracellular or on the cell surface or both) in the fetal hypothalamus and in the pituitary gonadotrophs.

The Sheep Fetus

Studies in the human fetus did not provide insight into the mechanisms of maturation or regulation of the hypothalamic LHRH-pituitary gonadotropin gonadal apparatus. The fetal sheep model in which indwelling vascular catheters are placed in the fetus and pregnant ewe affords an opportunity for mechanistic studies. The length of gestation in the sheep is about 145 days. The ontogeny of fetal gonadotropins, hypothalamic LHRH, and gonadal steroids is similar to that in the human fetus (see Fig. 24-26).

Figure 24-23 Ontogeny of the luteinizing hormone-releasing hormone (LHRH) neurons in the rhesus monkey. In the 36-day embryo the LHRH cells (black dots) are located deep in the nasal septum along the path of the nerves to the brain. By day 38 LHRH cells are clustered along the dorsal region of the olfactory bulbs and nerves terminating with a few cells arching back along the ventral surface of the forebrain. By 55 days the LHRH neurons are in the process of migration, but clusters of LHRH cells have entered the central nervous system and reached the basal hypothalamus. Figure 24-24 Ontogeny of the hypothalamic-pituitary portal circulation. Fig. 24-25 Functional hypothalamic-pituitary portal system.
Fetal FSH and LH secretion in the ovine fetus is not autonomous. By midgestation, the secretion of fetal LH and FSH is pulsatile and mediated by the hypothalamic LH-RH pulse generator. The ovine fetal hypothalamic-pituitary gonadotropin unit has the capacity to respond to gonadal steroid negative feedback by 0.6 gestation. A sex difference in gonadotropin secretion occurs in both the ovine and the human fetus as demonstrated by the fact that orchiectomy (but not oophorectomy) in the ovine fetus leads to an increase in pulsatile secretion of LH (and to a lesser degree FSH). Opioidergic neurons have a tonic suppressive effect on the pulsatile release of LH-RH in the fetus. The excitatory amino acid analogue N-methyl-D-aspartate (NMDA) evokes an LH pulse mediated by LH-RH, which provides additional evidence for the functional integrity of the fetal LH-RH neurosecretory neurons and the capacity of the excitatory amino acids, glutamate and aspartate, to stimulate, directly as well as indirectly, the fetal LH-RH pulse generator (Fig. 24-27). Glutamate is present in abundance in the hypothalamus and is released from glutaminergic neurons by excocytosis in an adenosine triphosphate and calcium-dependent process. Furthermore, FSH stimulates inhibit synthesis by the ovine testis and ovary, and administration of an inhibit-rich extract inhibits fetal FSH but not LH secretion, evidence of the functional capacity of the FSH-fetal gonadal inhibin feedback system. These observations in the human and ovine fetus, including the pattern of change of FSH and LH, provide support for an operational hypothalamic LH-RH-pituitary gonadotropin unit by at least 0.3 gestation in the human fetus and 0.4 gestation in the ovine fetus and for the central role of the CNS in this process.

The Human Neonate and Infant

In both sexes, the concentration of plasma FSH and LH is low in cord blood as a consequence of the inhibitory effect of the high levels of placenta-derived estrogens. The hypothalamic regulatory mechanisms for pituitary gonadotropins, as for other pituitary hormones, are not fully developed at birth. Within a few minutes after birth in the male neonate, the concentration of LH increases abruptly in peripheral blood (about 10-fold) compared with that in cord blood. This short-lived surge in LH release is followed by an increase in serum testosterone concentration during the first 3 hours that persists for 12 hours or more. In the female neonate this increase in LH release does not occur; FSH levels during the first neonatal days are low in both sexes. After the fall in circulating levels of steroids of placental origin (especially estrogens) during the first few days after birth, the concentration of serum FSH and LH increases and exhibits a pulsatile pattern with wide perturbations during the first few months.

![Image 1](https://example.com/image1.png)

**Figure 24-24** Comparison of the pattern of change of serum testosterone, human chorionic gonadotropin (hCG), and serum and pituitary luteinizing hormone (LH) (LER-869) and follicle-stimulating hormone (FSH) levels in the human male fetus during gestation in relation to the morphologic changes in fetal testis. The top graph illustrates the regression curve for the increment (between baseline plasma LH and FSH level and the 15-minute response to administration of LH-RH) to the male fetus plotted as a function of gestational age. The scale marks the slight increase in plasma FSH. Data were recalculated from Takagai and colleagues. The evidence supports the hypothesis that the hypothalamic LH-RH pulse generator is functional early in gestation and mediates the rise in serum concentration of fetal pituitary gonadotrophins. To convert plasma hCG to international units per liter, multiply by 1.7. Other conversions are in the legends of Figure 24-17 and Figure 24-18. Modified from Kaplan SL, Grumbach MM. Pituitary and placental gonadotropins and sex steroids in the human and subhuman primate fetus. Clin Endocrinol Metab 1978; 7:487511; and Gluckman PD, Grumbach MM, Kaplan SL. The human fetal hypothalamus and pituitary gland. In Tulchinsky D, Ryan KJ [eds]. Maternal-Fetal Endocrinology. Philadelphia, WB Saunders, 1980, pp 196232.

FSH pulse amplitude is much greater in the female infant and is associated with a larger FSH response to LH-RH throughout childhood. LH pulses are of greater magnitude in the male (Fig. 24-28). This striking sex difference is also present in agonal infant and male infants and in the infant rhesus monkey. It is postulated that this difference in the pattern of pulsatile gonadotropin secretion in infancy is related, among other possibilities, to the effect of testosterone in the male fetus on the development and function of the hypothalamic-pituitary apparatus. The high gonadotropin concentrations (postnatal gonadotropin surge) are associated with (1) a proliferation of Sertoli cells and gonocytes (and their transformation into spermatogonia), (2) a transient second wave of differentiation of fetal-type Leydig cells, and (3) increased serum testosterone levels in male infants during the first few postnatal months and increased estradiol levels intermittently elevated during the first year of life and part of the second year in females. The mean FSH concentration is higher in females than in males during the first few years of life. By approximately 6 months of age in the male and 2 to 3 years of age in the female, the concentration of plasma gonadotropins decreases to the low levels that are present until the onset of puberty. Thus, the restraint of the hypothalamic LH-RH pulse generator is supported by at least 0.3 gestation in the human fetus and 0.4 gestation in the ovine fetus and for the central role of the CNS in this process.

![Image 2](https://example.com/image2.png)

and the suppression of pulsatile LH-RH secretion (and thus LH release) do not attain the prepubertal level of quiescence until late infancy or early childhood and earlier in boys than girls.

Although the rise in circulating gonadotropins, sex hormones, and inhibin in both sexes during infancy, the so-called postnatal surge, is quite well documented, the significance of this transitional state before the onset of the juvenile pause remains speculative. The increase in circulating testosterone derived in the normal male infant can be accompanied by facial comedones and even acneiform lesions and the increase in gonadotropins by a transient increase in testicular size, but there may be more subtle changes. For example, Sertoli cell

and germ cells proliferate for about 100 days after birth and then decline after about 6 months of age, coincident with the waning of gonadotropins and testosterone. The significance of this increase in Sertoli cells and spermatogonia in relation to adult fertility is not known. It has been speculated that the postnatal testosterone may have an imprinting effect on the CNS, but we are not aware of convincing evidence to support this conjecture.
Neural Control

The neural control of puberty involves two major factors: the timing of puberty and the mechanisms involved in control of the transition from the prepubertal or sexually infantile state through complete sexual maturation.

Timing and Onset of Puberty

The time of onset of puberty and its course are influenced by genetic factors and are modified by environmental factors operating through the CNS. The latter include socioeconomic factors, nutrition, general health, geography, and altitude. Although the action of multiple genes (quantitative or polygenic inheritance) on the time of onset of puberty (or, for example, on stature) has long been recognized, little is known about the gene loci involved in this complex quantitative trait or the effect of gene interactions (epistasis) on this paradigm of complex traits.

The specific mechanisms involved in the timing of puberty are complex. Frisch and Revelle have suggested that in healthy girls, despite different ages, there is an "invariant mean weight" (48 kg) for the initiation of the pubertal spurt in weight, the maximal rate of weight gain, and menarche and that this association is primarily related to fatness. The Frisch hypothesis has generated controversy and has been criticized by some authorities. In part because the empirical estimations and the equations used to determine fat mass have been challenged. The role of nutritional factors and body composition in the onset of menarche is supported by the earlier age of menarche in moderately obese girls; delayed menarche in states of malnutrition and chronic disease, in twins, and after early rigorous athletic or ballet training; and the relationship of weight and diminished body fat to changes in gonadotropin secretion and amenorrhea in girls with anorexia nervosa, voluntary weight loss, and strenuous physical conditioning. Long-term studies of girls who had had malnutrition in infancy suggest that no permanent delay in puberty persists after early treatment.

The proposed causal relationship of "critical body weight," "critical metabolic rate," and body fat to the time of onset of puberty in girls has not been substantiated by direct measurements. When increments in the excretion of urinary gonadotropins were correlated with changes in body composition at puberty, both developmental events occurred simultaneously rather than sequentially. Moreover, menarche is a late event in the pubertal process and is remote from the factors that initiate the hormonal events and the first signs of sexual maturation. Thus, the results of a longitudinal study relating the beginning of testicular and breast development to percentage of body fat are of particular interest; although puberty began at different chronologic ages in the 469 girls studied for 5 years, there was a similar percentage of body fat associated with the onset of puberty. Other studies reported no change in body fat or body composition at the time of menarche that accompany the change in hormone production; there are, however, substantial changes in early puberty and premenarche in girls.

It has long been postulated that some alteration of body metabolism linked to energy metabolism may affect the CNS restraints on pubertal onset and progression. The relationship of adipose tissue mass, fat metabolism, and energy balance to reproduction was illuminated by the discovery of the genes encoding leptin, an 167-amino-acid cytokine-like protein produced mainly, but not exclusively, by adipose tissue. Its receptor, a member of the gp family of cytokine receptors, occurs in several isoforms, of which in the hypothalamus and other areas of the brain only the leptin receptor splice variant with the long intracellular domain (Ob-Rb) contains the protein motifs that possess signaling properties. In the human, leptin circulates in both a free and a high-molecular-weight bound form. Leptin is secreted in a pulsatile fashion and exhibits a diurnal rhythm with a peak at night and a nadir in the morning. Leptin binding activity in serum is highest in childhood and decreases to relatively low levels during puberty. Considerable interest has focused on the potential role of leptin in the control of the onset of puberty from a proposal that it was an essential, if not a key, factor in triggering the onset of puberty to one in which it had a more subsidiary role.

Leptin is a highly conserved 167-amino-acid cytokine-like protein produced mainly, but not exclusively, by adipose tissue. Its receptor, a member of the gp family of cytokine receptors, occurs in several isoforms, of which in the hypothalamus and other areas of the brain only the leptin receptor splice variant with the long intracellular domain (Ob-Rb) contains the protein motifs that possess signaling properties. In the human, leptin circulates in both a free and a high-molecular-weight bound form. Leptin is secreted in a pulsatile fashion and exhibits a diurnal rhythm with a peak at night and a nadir in the morning. Leptin binding activity in serum is highest in childhood and decreases to relatively low levels during puberty. Considerable interest has focused on the potential role of leptin in the control of the onset of puberty from a proposal that it was an essential, if not a key, factor in triggering the onset of puberty to one in which it had a more subsidiary role.

Leptin is a well-established afferent saliety factor in the human that acts on the hypothalamus, including nuclear controlling appetite, to suppress appetite. In rodents it stimulates energy expenditure among a variety of other actions. A mutant gene was first isolated from the extremely obese ob/ob mouse by positional cloning; soon thereafter, the leptin receptor was cloned and the mutation identified in the obese db/db mouse.

Ob/ob and db/db mice have the same phenotype. They are not only obese but also fail to achieve puberty and fertility because of hypogonadotropic hypogonadism, providing evidence for an important role of leptin in

[Figure 24-29 Change in the pattern of pulsatile follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion in early infancy, childhood, and puberty. The data for early infancy are derived from Walther and colleagues. Note the pulsatile secretion in the infant and the striking difference in the amplitude of FSH and LH pulses between male and female infants. After infancy, the amplitude and frequency of gonadotropin pulses decrease greatly for almost a decade (juvenile pause) until the onset of puberty. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sosenko PC, Aubert ML, eds. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)]

[Figure 24-30 The pulsatile action of leptin secreted by adipocytes on the hypothalamic luteinizing hormone-releasing hormone (LHRH) pulse generator. Its indirect action through hypothalamic neural networks is illustrated as well as direct action. Leptin appears to function as a permissive factor, not a trigger, in the onset of human puberty. Although leptin is reported to advance puberty in rodents, its role in "triggering" puberty in humans has not been established and is speculative. FSH, follicle-stimulating hormone; mRNA, messenger ribonucleic acid. (See text.)]
reproduction. This association was strengthened by the collaboration of the infertility in ob/ob mice by the administration of recombinant leptin. The first reports on the effect of leptin administration to normal prepubertal mice described decreased appetite and body weight and the advancement of vaginal opening, but the concentration of serum leptin in normal mice did not increase with the onset of and during sexual maturation. Studies in the rat showed that pubertal delay associated with food restriction was partially reversed by the administration of leptin and suggested that a fall in circulating leptin below a critical level would occur with 30% to 75% food restriction. However, leptin administration to normal prepubertal rats did not advance the time of onset of puberty. Cheung and colleagues summarizing the studies in rodents, concluded that although a critical threshold level was necessary for puberty to begin and advance, leptin alone (as in leptin administration to normal rodents) was insufficient to promote puberty.

Among the various sites of action of leptin in the hypothalamus, one site seems to involve a direct action on hypothalamic LHRH neurons: in the rodent these neurosecretory neurons contain leptin receptors (including the Ob-Rb isoform) and release LHRH in response to leptin. Leptin may also act indirectly on the LHRH pulse generator (Fig. 24-30).

There are significant species differences in the role of leptin in reproductive function not only among rodents but also between human and nonhuman primates. In the male rhesus monkey, leptin levels were similar through the advancement of prepuberty to puberty. In the peripheral rhesus monkey 3 to 5 years old, fasted for 2 days, the administration of leptin prevented the decrease in plasma gonadotropins detected in the untreated animals. Continuous infusion of leptin into the lateral ventricle of gonadial male monkeys failed to evoke an increase in LHRH on gonadotropin secretion.

Cheung and colleagues have reassessed the role of leptin in the onset of puberty in the mouse and rat. In well-designed studies, they reported that leptin is not a metabolic trigger for onset of puberty in the rodent but is one among several permissive factors. This assessment is supported by the studies of Bronson and Risman in female mice. Does leptin in the human provide a peripheral, somatic trigger for the onset of puberty to the CNS, or does it have a permissive role, signaling the hypothalamus and the LHRH pulse generator that a critical energy store (obesity) has been attained? Leptin reflects body fat and hence energy stores and has an important role in the control of body weight and the regulation of metabolism. In 1997 the first longitudinal study of plasma leptin in normal boys before and during puberty suggested that there was a brief rise in circulating leptin that provided hormonal evidence of the onset of puberty. Later, two large cross-sectional studies and a longitudinal study of serum leptin levels in prepubertal and pubertal boys and girls showed that leptin increased gradually during the prepubertal years; the levels were similar in both sexes. However, during puberty, leptin continued to rise in girls, whereas in boys the leptin mean levels peaked at Tanner stage 2 and decreased to prepubertal concentrations by genital stage 5. The decrease was attributed to the effect of testosterone on leptin secretion.

Among other variables, adipose tissue mass, percentage body fat, and age were correlated with leptin levels. A correlation was not found between 24-hour serum estradiol and leptin concentrations in nonobese and obese prepubertal and early pubertal girls. People with a homozygous mutation in the leptin gene or the leptin receptor have not only morbid obesity but also a striking delay in puberty owing to hypogonadotropin hypogonadism. Two 19-year-old sisters with a mutation in the leptin receptor that resulted in a truncated leptin receptor were sexually infantile as a consequence of hypogonadotropic hypogonadism. Similarly, in a large Turkish pedigree affected by a stop codon mutation in the gene encoding leptin, a 23-year-old man had failed to attain puberty because of hypogonadotropic hypogonadism. The two affected women were prepubertal and amenorrheic until ages 29 years and 36 years, respectively, when the 23-year-old began to have irregular scant periods and the 36-year-old began to menstruate monthly. A 3-year-old girl with congenital leptin deficiency following treatment with recombinant leptin lost weight and had an early pubertal pattern of LH release to the administration of LHRH. The effects of the mutations indicate that the virtual absence of leptin or of a functional leptin receptor leads to sexual infantilism related to hypogonadotropic hypogonadism, similar to that in ob/ob and db/db mice. The extremely late signs of pubertal development in the two leptin-deficient women are unexplained.

These observations suggest that severe leptin deficiency causes hypogonadotropic hypogonadism and that a critical level of leptin and a leptin signal are required to achieve puberty. However, a rise in leptin is not required to trigger puberty. Boys with a constitutional delay in growth and puberty can enter puberty without an increase in circulating leptin; these boys have lower than expected mean levels of leptin and weight. Further, in two women with congenital lipodystrophic diabetes (Berardinelli-Seip syndrome), which is associated with absence of both subcutaneous and visceral adipose tissue, the severe hypoleptinemia did not lead to a delay in menarche. One of the women had three unaffected children.

In sum, accumulating evidence supports the function of leptin as a permissive factor (tonic mediator) and not a trigger (phasic mediator) in the onset of human puberty (Table 24-18). A major qualitative locus on human chromosome 2 is linked to serum leptin levels and fat mass (the structural gene that encodes leptin is located on chromosome 7), an additional indication that a variety of factors affect leptin. Further, in relation to puberty as an energy-dependent process, a group of 9- to 10-year-old boys observed for 18 months, during the months leading up to an increase in morning salivary testosterone concentrations, had a relatively constant basal metabolic rate (BMR)/lean body mass ratio and an increase in the ratio of BMR/total daily energy expenditure. It is suggested that a subtle energy-dependent process is in play, possibly related to an increase in brain BMR as a secondary phenomenon at the initiation of puberty, or that a central rise in BMR is a signal for the onset of puberty. The timing of puberty has been linked to the vagus, but generally accepted, concept of maturation of the CNS; the maturation is the outcome or consequence of the totality of environmental and genetic factors that retard or accelerate the onset of puberty. It is a provocative but unproven hypothesis that a metabolic signal related to body composition is an important factor in the maturation or activation of the hypothalamic LHRH pulse generator and not a result of the early hormonal and body composition changes in human puberty. In either event, clinical and experimental data support the contention that the factors influencing the timing of puberty are expressed finally through CNS regulation of the onset of puberty.

Mechanisms of Control

In some species, the neural control mechanism is exquisitely sensitive to the environment; for example, in the rat and the mouse, eurexcorporate factors and cues, including light, olfaction, and pheromones, have an important influence, by way of the CNS, on gonadotropin secretion. In seasonal breeding species,
such as sheep, the length of the light-dark cycle is critical and the pattern of gonadotropin secretion is different. In contrast, male and female primates exhibit an estrogen-provoked LH surge. In brief, diverse strategies and adaptive mechanisms have evolved to control puberty in different species.

In both the human and the subhuman primate, the increase in LH and FSH secretion in early infancy is followed by a...
presence of a CNS inhibitory mechanism that, independent of gonadal steroid secretion, restrains the hypothalamic LHRH pulse generator during this pause.

This mechanism suppresses LHRH and as a consequence gonadotropin synthesis and pulsatile secretion and restrains the onset of puberty. The fall in gonadotropin secretion in agonadal children cannot be explained by gonadal steroid feedback (because functional gonads are lacking) or by increased secretion of adrenal steroids (because concentrations are low and glucocorticoid suppression of the adrenal does not augment the concentration of circulating gonadotropins). Therefore, a steroid-independent inhibitory mechanism for suppression of the hypothalamic LHRH pulse generator, located within the CNS, seems to be the dominant factor in restraint of puberty between ages 4 and 11. Gradual loss of this intrinsic CNS inhibitory mechanism would lead to disinhibition or reactivation of the LHRH pulse generator at puberty.

Interaction of Negative Feedback Mechanism and Intrinsic Central Nervous System Inhibitory Mechanism

We believe that both of these mechanisms interact to restrain puberty (see Fig. 24-34). During the first 2 to 3 years of life, the gonadal steroid negative feedback mechanism seems dominant, as evidenced by the striking difference in gonadotropin secretion between the agonal and the intact infant and young child. Extrapolating from the changing pattern of plasma FSH and LH levels in agonal infants and children, beginning at about 3 years of age the intrinsic CNS inhibitory mechanism becomes dominant and remains so during the rest of the juvenile pause, as evidenced by the fall in FSH and LH levels between ages 3 and 10 despite the lack of functional gonads. During this segment of the juvenile pause, the negative feedback mechanism is operative; agonal patients in this age group have higher mean plasma FSH levels than normal prepubertal children and a greater FSH and LH response to the acute administration of LRH. However, the negative feedback mechanism probably plays a secondary role.

As puberty approaches, the CNS inhibitory mechanism gradually wanes, initially during nighttime sleep, and the hypothalamic LHRH pulse generator becomes less sensitive to gonadal steroid negative feedback (Fig. 24-35). After the onset of puberty, gonadal steroid negative feedback attains the setpoint characteristic of the adult and is again the dominant mechanism in restraining gonadotropin secretion (along with inhibin), as reflected in the increased gonadotropin concentrations characteristic of the adolescent with severe primary hypogonadism (see Fig. 24-34). A similar pattern has been described in the infant monkey. The postulated ontogeny of this dual mechanism of restraint of puberty is illustrated in Figure 24-35. Many neural, neurotransmitter-neuromodulator, hormonal, growth, and metabolic factors as well as exteroceptive influences and cues can influence the activity of the LHRH pulse generator, but the nature of the intrinsic CNS inhibitory mechanism remains uncertain.

Indirect evidence for an inhibitory neural network that arises or projects through the posterior hypothalamus and suppresses the LHRH pulse generator has been derived from studies of children with organic forms of true (or central) precocious puberty. For example, a suprasellar arachnoid cyst can cause true precocious puberty by compressing and distorting the hypothalamus. In some children with such cysts, the puberty is reversed with regression of the hormonal and physical features of puberty after decompression of the cyst (Fig. 24-36). We suggest that the disinhibition of the CNS inhibitory mechanism was reversed by treatment of the cyst. The LHRH-secreting hypothalamic hamartoma, a heterotopic mass of nervous tissue that contains LHRH neurosecretory neurons, attached to the tuber cinereum or the floor of the third ventricle, can cause true precocious puberty. In children with such cysts, the puberty is reversed with regression of the hormonal and physical features of puberty after decompression of the cyst. In the rhesus monkey, despite the damping of the LHRH pulse generator during the juvenile pause, the content of hypothalamic LHRH and the LHRH mRNA during this phase is similar to that in the infant and adult monkey. It should be emphasized that quiescence of the LHRH pulse generator during the juvenile pause is not absolute. Low-amplitude LH and FSH pulses are detectable by sensitive and specific immunoradiometric assays. The end of the juvenile pause is marked by an increase in LH pulse amplitude most evident during the early hours of sleep.

Potential Components of the Intrinsic Central Nervous System Inhibitory Mechanism

Indirect evidence for an inhibitory neural network that arises or projects through the posterior hypothalamus and suppresses the LHRH pulse generator has been derived from studies of children with organic forms of true (or central) precocious puberty and studies in the female and male monkey. Children with true precocious puberty associated with posterior hypothalamic neoplasms (usually a pilocytic astrocytoma), radiation of the CNS, midline CNS developmental abnormalities such as septo-optic dysplasia with deficiency of one or more pituitary hormones, or other CNS lesions provide indirect evidence for an inhibitory neural component located in or projecting through the posterior hypothalamus. As a consequence of these lesions, the neural pathway inhibiting the hypothalamic LHRH pulse generator is compromised, resulting in its disinhibition and activation. For example, a suprasellar arachnoid cyst can cause true precocious puberty by compressing and distorting the hypothalamus. In some children with such cysts, the puberty is reversed with regression of the hormonal and physical features of puberty after decompression of the cyst. We suggest that the disinhibition of the CNS inhibitory mechanism was reversed by treatment of the cyst. The LHRH-secreting hypothalamic hamartoma, a heterotopic mass of nervous tissue that contains LHRH neurosecretory neurons, attached to the tuber cinereum or the floor of the third ventricle, can cause true precocious puberty. The LHRH neurons within the hamartoma with their axon fibers projecting to the median eminence secrete LHRH in pulsatile fashion. We consider the hypothalamic hamartoma an "ectopic LHRH pulse generator" that functions independently of the CNS inhibitory mechanism that normally restrain the hypothalamic LHRH pulse generator. An analogy can be drawn between the LHRH-secreting hypothalamic hamartoma and the rescue of fertility in the LHRH-deficient hypogonadal mouse (hyp/hyp) by transplantation of fetal or neonatal hypothalamic tissue into the third ventricle. Some rare, large hypothalamic hamartomas that cause true precocious puberty contain few or no LHRH neurosecretory neuron but contain TGF-. It is postulated that the secretion of TGF-, an astroglia-derived growth factor, may interact directly or indirectly to stimulate LHRH release.

Moreover, the ontogeny of the fetal LHRH pulse generator suggests that its initial unrestrained function is followed by differentiation of inhibitory mechanisms in late gestation. Similarly, the immortalized LHRH neurosecretory neuronal cell line exhibits spontaneous, synchronized autorhythmicity in the release of LHRH. Taken together, these observations suggest that a stimulatory input is not required for pulsatile LHRH secretion. In addition, precocious sexual maturation can be induced in the juvenile female rhesus monkey by posterior hypothalamic lesions; such lesions advance the age at onset of a pubertal increase in LH secretion and the time of the first positive feedback effects of estrogen.

Table 24-19 lists some of the neural and neurotransmitter-neuromodulator factors that may play a role in the restraint of the LHRH pulse generator during the juvenile pause. Noradrenergic, dopaminergic, serotoninergic, and opioidergic pathways; inhibitory neurotransmitters (e.g., GABA); excitatory amino acids (e.g., glutamic and aspartic acids); nitrergic transmitters; other brain peptide, including neurotrophic and growth factors; and corticotropin-releasing hormone affect the hypothalamic LHRH pulse generator.

The studies of Plant and of others in the human exclude melatonin as a critical restraining factor in primates. Many studies have assessed the role of endogenous opioid peptides as possible mediators of the juvenile pause. None provide support for an important role of this family of neuro peptides in the juvenile pause. A critical and landmark advance in our understanding of the nature of the juvenile phase and central inhibition of the
The onset of puberty in rhesus monkeys is characterized by a decrease in GABAergic (and possibly NPY) inhibition of excitatory NMDA amino acid neurotransmitter receptors. These receptors are widely distributed throughout the CNS, including the hypothalamus. Among the facilitory neurotransmitters that affect the release of LHRH, norepinephrine, NPY, and galanin do not appear to have a critical role in the control of the developmental switch of GABAergic synaptic transmission from excitatory to inhibitory. The results suggested that there is a potent inhibition by GABA and GABAergic neurons of the LHRH pulse generator in prepuberty and that exogenous administration of GABA in prepuberty is ineffective because of the high local endogenous GABA levels. Glutamic acid decarboxylase (GAD) is the enzyme that catalyzes the conversion of glutamate to GABA. Two classes of GAD, GAD 65 and GAD 67, are present in mammalian brain. Both GAD mRNAs are detectable in the mediobasal hypothalamus, the site of the LHRH pulse generator. Moreover, antisense oligodeoxynucleotides for GAD 67 and GAD 65 mRNA s inhibited the stimulation of LHRH release whereas nonsense o-oligodeoxynucleotides did not.

The slowest maturation of the hypothalamic LHRH pulse generator is associated with the dominance of the intrinsic CNS inhibitory mechanism and results in true precocious puberty. Two possible mechanisms are proposed. The effect of GABA quite likely has a direct action on the LHRH pulse generator neuron as GABA acting through both GABA_A and GABA_B receptors affects LHRH secretion in the perfused mouse GT1 LHRH-releasing neuronal cell line, which contains GABA_A receptors. Conversely, the chronic repetitive administration of bicuculline into the base of the third ventricle of a prepubertal monkey at 15 months of age caused premature menarche and the onset of the first ovulation.

GABA is the principal inhibitory neurotransmitter in the juvenile and adult brain, but early in brain development extending (at least in the experimental animal) through the postnatal period, GABAergic synaptic transmission is excitatory and increases the intracellular

the hypothalamic LHRH pulse generator and increased release of glutamate, the major excitatory amino acid neurotransmitter in the hypothalamus. Plant and associates induced pubertal or adult-like patterns of episodic LHRH release in both the prepubertal and pubertal female rhesus, NMDA administered centrally and peripherally induced the release of LHRH. The sensitivity to the stimulatory glutaminergic input into the LHRH pulse generator increases strikingly after the onset of puberty, but it is the reduction in GABAergic inhibition that is the critical factor in disinhibition of the LHRH pulse generator. Parenthetically, NMDA administration acutely stimulated the LHRH pulse generator in the ovine fetus, providing additional evidence for the role of NMDA receptors in fetal LHRH neurons and the functional capacity of the fetal pulse generator. Immortalized LHRH neurons contain inotropic NMDA receptors that mediate the release of LHRH by NMDA.

In sum, with the onset of puberty, the disinhibition and reactivation of the LHRH pulse generator are associated with a fall in GABAergic inhibitory neurotransmission and a concomitant increase in the input of excitatory amino acid neurotransmitters (e.g., glutamate) as well as other neurotransmitters (e.g., norepinephrine and NPY). Ojeda and Ma have proposed that in addition to the transsynaptic mechanisms, astrocytes regulate LHRH neurosecretion through astroglia-derived growth factors (including transforming growth factors, IGF-I, basic fibroblast growth factor, neuregulins, and epidermal growth factorked peptides that act directly or indirectly to stimulate LHRH release and, accordingly, may contribute to the reactivation of the LHRH pulse generator at puberty. These observations provide additional evidence that the hypothalamic LHRH neurosecretory neuron is not a limiting factor in puberty. The LHRH pulse generator joins the anterior pituitary gland, gonads, and gonadal steroid end organs as elements that are functionally intact prepuber tally and in the fetus and can be fully activated before puberty as well as in the fetus by the appropriate stimulus. Hence, the CNS restraint of puberty lies above the level of the autorhythmic LHRH neurons or hypothalamus and extends to the area postrema, which contains LHRH neurons and regulates sleep. Sleep-Related Luteinizing Hormone Release and Onset of Puberty

Episodic, or pulsatile, secretion is the fundamental mode of release of pituitary LH and FSH and is evoked by the pulsatile LHRH signal originating from the hypothalamic LHRH oscillator. Discrete episodic bursts of LH release occur approximately once every 120 minutes (about 12 episodes over a 24-hour period) in adult men and about once every hour during the midfollicular phase in women. In sensitive radio-immunoassays, secretory pulses of LH are detectable in prepubertal children and are of lower amplitude than those in pubertal children or adults. The low concentrations of plasma LH and FSH make it difficult to demonstrate pulsatile secretion for methodologic and statistical reasons, but this problem has been overcome by the use of highly sensitive immunoassays.

In adult men and women during most phases of the menstrual cycle, little difference in the amplitude or frequency of these episodic pulses is apparent during a 24-hour period. In pubertal children, however, Boyar and colleagues described the mainly sleep-associated pulsatile release of LH in early puberty and midpuberty; only in late puberty were prominent LH secretory episodes detected during the day, although the absolute differences were small. In prepubertal, early, and midpubertal, and even prepubertal children, an increase in the amplitude of LH pulses occurs during sleep (Fig. 24-40); in late puberty, the daytime LH pulses increase in amplitude but are still less than during sleep until the adult pattern is finally achieved.

The infant exhibits episodic gonadotropin secretion with a striking sex difference: the amplitude of the pulses is large and correlates with the increased plasma gonadotropin levels during the first 6 months in boys and the first 1 to 2 years in girls. After this age, pulsatile secretion is more difficult to detect before the pubertal period but is demonstrable at low amplitude mainly at night; a diurnal rhythm of serum LH, FSH, and testosterone is already demonstrable in 5- to 6-year-old children and becomes more prominent in boys with advancing bone age. In boys, augmented LH release during sleep leads to increased excretion of urinary LH in pubertal children at night than during the day, although the absolute differences were small. In prepubertal, early and midpubertal, and even prepubertal children, an increase in the amplitude of LH pulses occurs during sleep (Fig. 24-40). This pattern of sleep-associated LH secretion occurs in agonalad patients during the pubertal age period, suggesting that it is not dependent on gonadal function. Furthermore, augmented sleep-related gonadotropin release is demonstrable in children with idiopathic true precocious puberty, and in glucocorticoid-treated children with congenital adrenal hyperplasia who have an advanced bone age and early onset of true puberty.

Sleep-enhanced LH secretion can be viewed as a maturational phenomenon related to changes in the CNS and in the hypothalamic restraint of LH release. However, the neural factors involved in the initiation of this circadian rhythm are unclear. Episodic release of gonadotropins is suppressed by anti-LHRH antibodies and by the administration of gonadal steroids or of certain catecholaminergic agonists and antagonists and is augmented by the opioid antagonist naloxone. Naloxone does not alter the testosterone-mediated suppression of LH, nor does it alter the testosterone effects on LH pulsatility in early to midpubertal boys. We have suggested that an increase in endogenous LHRH secretion at puberty has a priming effect on the gonadotroph and leads to increased sensitivity of the pituitary to LHRH (either endogenous or exogenous). In the monkey, a striking increase in the pulse amplitude and a lesser increase in pulse frequency occur between prepuberty and puberty. Sleep-associated LH release in the peripubertal period correlates with the increased sensitivity of the pituitary gonadotrophs to administration of LHRH in the peripubertal period and puberty.
The increased LH release at night in both sexes is evidence that the hypothalamic LHRH pulse generator is initially less inhibited during sleep even in prepubertal children. The much augmented LH pulse amplitude entrained during sleep is the neuroendocrine hallmark of the onset of puberty.

Puberty encompasses orderly maturational changes that involve, sequentially, the extramedial basal hypothalamus, the hypothalamic LHRH pulse generator, the pituitary, the gonads, and the gonadal steroid target organs. At each level these structures may exhibit differences in responsiveness to neural or trophic stimuli, depending on their sensitivity and on the particular hormonal milieu. If the increased secretion of gonadotropins at the beginning of puberty is a consequence of changes in both neural and hormonal restraints on the synthesis and pulsatile secretion of LHRH, disinhibition and reaugmentation of the LHRH pulse generator should lead to increased amplitude and frequency of pulses initially, followed by priming of the gonadotrophs, increased pulsatile gonadotropin secretion from the pituitary, and finally augmented output of steroids by the gonad.

LHRH release is not directly measurable in the human, but endogenous LHRH secretion can be estimated indirectly and qualitatively by determining the pulsatile pattern of LH and by the gonadotropin response to exogenous LHRH. The pituitary sensitivity to synthetic LHRH and the dynamic reserve or readily releasable pool of pituitary gonadotropins have been studied at different stages of the menstrual cycle, in various disorders of the hypothalamic-pituitary-gonadal system. The results support the concept that the prepubertal state is characterized by functional LHRH deficiency. The release of LH after administration of LHRH is minimal in prepubertal children before infancy, increases during the peripubertal period and puberty, and is still greater in adults (depending on the phase of the menstrual cycle in women). The change with maturation in the pattern of FSH release is different from that of LH and results in a striking reversal of the FSH/LH ratio after administration of LHRH to both males and females beyond infancy, increases during the peripubertal period and puberty, and is still greater in adults (Fig. 24-41), and is still greater in adults (see Fig. 24-41). Moreover, there is a sex difference in the FSH response, with pubertal and prepubertal females releasing more FSH than males at all stages of sexual maturation.

These observations suggest a striking change in pulsatile sensitivity in LHRH to prepubertal and pubertal individuals as well as a sex difference in the "dynamic reserve" of pituitary FSH. The sex difference in LH and FSH response to LHRH suggests that the pituitary gonadotrophs of prepubertal females are more sensitive to LHRH than those of prepubertal males, even though the concentration of circulating gonadal steroids is low in both sexes at this stage of maturation. Prepubertal girls have a larger readily releasable pool of pituitary FSH than prepubertal or pubertal males, possibly related in part to the higher concentration of inhibin B in pubertal boys (see Fig. 24-41). The sex difference in sensitivity to LHRH and releasable FSH and the low inhibin levels in the prepubertal female may be factors in the higher frequency of idiopathic true precocious puberty in girls and in the occurrence of premature thelarche. The available data are consistent with the hypothesis that less LHRH is required for FSH than for LH release. These findings also point out the difference between pulsatile sensitivity and the actual secretory rate of FSH and LH.

The responses to LHRH in peripubertal children who do not yet exhibit physical signs of sexual maturation provide evidence that the self-priming effect of endogenous LHRH augments pulsatile responsiveness to exogenous LHRH and is an important factor in the increased gonadotropin secretion at puberty. This change in responsiveness of the gonadotrophs is apparently mediated by increased pulsatile secretion of LHRH and the increased LH response to synthetic LHRH is one of the earliest hormonal markers of puberty onset.

The degree of previous exposure to gonadotropes to endogenous LHRH appears to affect both the magnitude and the quality of LH responses to a single intravenous dose of LHRH. Studies of the effects of acute and chronic administration of synthetic LHRH in hypergonadotropic hypogonadism, hypogonadotropic hypogonadism, constitutional delayed growth and adolescence, and idiopathic precocious puberty support this concept of self-priming. The prepubertal pituitary gland has a smaller pool of releasable LH and decreased responsiveness to the acute administration of synthetic LHRH. With the approach of puberty, the derepression of the hypothalamic LHRH pulse generator and the increased pulsatile secretion of LHRH augment pulsatile sensitivity to LHRH and enlarge the reserve of LH. The reason for the discordance in FSH and LH release prepubertally is not clear, but the frequency of LH pulses may be a

![Figure 24-40](image-url) Plasma luteinizing hormone (LH) and testosterone sampled every 20 minutes in a 14-year-old boy in pubertal stage 2. The histogram displaying sleep stage scores is depicted above the period of nocturnal sleep. Sleep stages are rapid eye movement (REM) stages I to IV shown by depth of line graph. Plasma LH is expressed as mIU/mL. Plasma testosterone is expressed as nanograms per 100 mL. To convert LH values to international units per liter, multiply by 1.0. To convert testosterone values to nanomoles per liter, multiply by 0.3467. (From Buxar RM, Rosendahl RD, Kaplan S, et al: Human puberty: simultaneous augmented secretion of luteinizing hormone and testosterone during sleep. Reproduced from the Journal of Clinical Investigation, 1974, vol. 54, pp. 609576 by copyright permission of the American Society for Clinical Investigation.)

![Figure 24-41](image-url) Changes in plasma luteinizing hormone (LH) (top) and follicle-stimulating hormone (FSH) (bottom) levels in prepubertal, pubertal, and adult individuals. Note the limited LH response in prepubertal children compared with that of pubertal and adult subjects. The FSH response to LH-releasing hormone (LHRH) is similar in prepubertal, pubertal, and adult males. In females, the FSH response is significantly greater than that of prepubertal, pubertal, or adult males. For conversion to SI units, see the legend of Figure 24-17. (Modified from Grumbach MM, Roth JC, Kaplan SL, et al: Hypothalamic-pituitary regulation of puberty in man: evidence and concepts derived from clinical research. In Grumbach MM, Gravh DD, Mayer FE [eds]: Control of the Oesest of Puberty. New York, John Wiley & Sons, 1974, pp. 115166.)
factor in the adult rhesus monkey with ablative hypothalamic lesions that eliminate endogenous LHRH secretion, reduction of the frequency of exogenous LHRH pulses from one per hour to one every 3 hours increased the FSH/LH ratio. Furthermore, inhibin and endogenous gonadal steroids may also affect this ratio through action on the hypothalamus, the pituitary gland, or both.

These observations and the previously discussed role of the intermittence of the LHRH signal to the gonadotrophs as an essential factor in the neural control of gonadotropin secretion have important implications for the induction of puberty. Pulsatile administration of LHRH to prepubertal monkeys promptly initiated puberty (and, in females, ovulatory menstrual cycles) and restored complete gonadal function in adult monkeys with hypothalamic lesions. Similar studies in the human yielded comparable results in prepubertal children and in adults with hypothalamic hypogonadotropic hypogonadism. These results provide further support for reactivation of the hypothalamic LHRH pulse generator as the first hormonal change in the onset of puberty.

Responsiveness of the gonads to gonadotropins also increases during puberty. For example, the augmented testosterone secretion in response to administration of hCG at puberty in boys is probably a consequence of the priming effect of the increase in endogenous secretion of LH (in the presence of FSH) on the Leydig cell.

Maturation of Positive Feedback Mechanism

In normal women, the midcycle surge in LH and FSH secretion is attributed to the positive feedback effect of an increased concentration of plasma estradiol for a sufficient length of time during the latter part of the follicular phase. Estradiol has both negative and positive feedback effects on the hypothalamic-pituitary system. Although the suppressive effect is probably operative from late fetal life on, the positive action of endogenous (or exogenous) estradiol on gonadotropin release has not been demonstrated in normal prepubertal and early pubertal children. Hence, acquisition of positive feedback, a requisite for ovulation, is a late maturational event in puberty and, from the present evidence, probably does not occur before midpuberty in normal girls.

Among the requirements for a positive feedback action of estradiol on gonadotropin release at puberty are (1) ovarian follicles primed by FSH to secrete sufficient estradiol to reach and maintain a critical level in the circulation, (2) a pituitary gland that is sensitized to LHRH and contains a large enough pool of releasable LH to support an LH surge, and (3) controversial in the human but not in lower animals, sufficient LHRH stores for the LHRH neurosecretory neurons to respond with an acute increase in LH secretion in addition to the usual adult pattern of pulsatile LH secretion.

The main site of action of estradiol is at the level of the anterior pituitary, but estrogen has dual sites of action including a negative as well as positive feedback action on the hypothalamus. Knobil and colleagues have shown in the rhesus monkey that positive as well as negative feedback can occur in adult ovariectomized females in whom the medial basal hypothalamus is surgically disconnected from the remainder of the CNS. In monkeys with hypothalamic lesions, unvarying, intermittent LHRH administration leads to sufficient estradiol release from the ovary to induce an ovulatory LH surge in the absence of an increase in the dose of the LHRH pulses. Estradiol has a positive feedback effect directly on the pituitary gland in normal women, and prolonged administration of estradiol is accompanied by an increased LH response to LHRH administration in women. The fact that the major positive feedback action on the pituitary gland is demonstrable in the absence of an increase in pulsatile LHRH secretion suggests that the failure to elicit a positive feedback action with administration of estradiol to prepubertal girls could be related to the inadequate LHRH pulses or insufficient LH reserve, respectively, or both components.

That gonadotropin cyclic and estradiol-induced positive feedback can be demonstrated by midpuberty and before menarche does not imply that the positive feedback loop is complete. Indeed, the modulating effect of the pubertal ovary and its output of estradiol on the hypothalamic-pituitary gonadotropin unit may be insufficient to induce an ovulatory LH surge even when there is an adequate pituitary store of readily releasable LH and FSH. The ovary, because of lack of sufficient gonadotropin stimulation, decreased responsivity, or other local factors, does not secrete estradiol at a high level or long enough to induce an ovulatory LH surge. We visualize the process leading to ovulation as a gradual one in which the ovary (the Zeitgeber for ovulation) and the hypothalamic-pituitary gonadotropin complex become progressively more integrated and synchronous until, finally, an ovary primed for ovulation secretes sufficient estradiol to induce an ovulatory LH surge.

Studies of basal body temperature and of plasma progesterone concentrations suggest that as many as 55% to 90% of cycles are anovulatory during the first 2 years after menarche and that the proportion decreases to less than 20% of cycles by 5 years after menarche. A cyclic surge of LH occurs during some anovulatory cycles in adolescence, but the mechanism of ovulation seems unstable and immature and does not appear to have attained the fine-tuning and synchronization requisite for maintenance of regular ovulatory cycles. There is a rise in BMI, waist circumference, hip circumference, serum LH, androstenedione, testosterone, and DHEAS in the few years following menarche.
Summary of Present Concept

Our present concept of the role of the hypothalamic-pituitary-gonadal system in the control of the onset of puberty is illustrated in Table 24-20. Clearly, the understanding of these complex maturational processes is incomplete. Puberty is not an immutable process; it can be arrested or even reversed. Environmental factors and certain disorders that affect the onset or progression of puberty mediate their effects by direct or indirect suppression of the hypothalamic LHRH pulse generator and its periodic oscillatory signal, LHRH. For example, strenuous physical conditioning in girls (but not boys) and anorexia nervosa can delay or arrest puberty or lead to the reversion of the hypothalamic-pituitary unit to a prepubertal state, depending on the magnitude of the functional LHRH insufficiency. With a decrease in physical activity in the former and with resumption of weight gain and attainment of sufficient body mass in the latter, the pubertal process is reactivated. In rare instances, true precocious puberty caused by an extrinsic mass lesion that impinges on the hypothalamus can be reversed by decompression or removal of the mass (a subarachnoid cyst, for example).
ADRENAL ANDROGENS AND ADRENARCHE

The adrenal component of pubertal maturation (the adrenarche) and the interactions between adrenal and gonadal hormones are poorly understood. Speculation has focused on the mechanism of adrenarche, the fact that adrenarche occurs earlier than gonadarche (the maturation of the hypothalamic-pituitary-gonadal system), and the interaction between adrenal and gonadal hormones at puberty.

Nature and Regulation of Adrenal Androgens

The major adrenal androgen precursors secreted by the adrenal cortex are DHEA, DHEAS, and androstenedione; apparently, none of these C_{19}-steroids directly activate the androgen receptor. By extraglandular metabolism, the so-called adrenal androgens contribute to physiologically active testosterone and estradiol. In normal adult women, only androstenedione is an important precursor; DHEA and DHEAS contribute little to circulating testosterone and estradiol but can be converted locally to these steroids in some peripheral tissues. However, scant information is available on the metabolism and kinetics of DHEA and DHEAS in prepubertal children. Androstenedione is the major androgen secreted by the ovary during and after puberty. It is more readily converted to potent androgens than DHEA or DHEAS. However, DHEA and especially DHEAS (which binds avidly to serum proteins, particularly albumin) are useful biochemical markers of adrenal androgen secretion and the onset of adrenarche.

Cross-sectional and longitudinal studies have demonstrated a progressive increase in the plasma concentration of DHEA and DHEAS in boys and girls by about the age of 6 (to 8 years skeletal age) that continues through puberty (age 13 to 15). Reaches a peak at ages 20 to 30, and then gradually decreases. These age-related and developmental (e.g., fetal) changes in DHEA are unique and not matched by other steroid hormones (Fig. 24-42). The 20-fold increase in the concentration of DHEAS between the onset of adrenarche and midpuberty, without a concomitant increase in plasma cortisol, is accompanied by increased excretion of urinary 17-ketosteroids, especially 11-deoxy C_{19}-steroids. This increase serves as a mark of the onset of adrenarche and begins approximately 2 years before the increase in gonadotropin and gonadal steroid secretion. The increase is not associated with increased sensitivity of the pituitary gonadotrophs to LHRH or with sleep-associated LH secretion and occurs at an age when the hypothalamic-pituitary-gonadal complex is functioning at a low level. Associated with the increase in the adrenal secretion of DHEA and DHEAS (and independent of a change in the secretion of cortisol or aldosterone) are the appearance and growth of the zona reticularis coincident with adrenarche (see Fig. 24-42). The zona reticularis, the innermost zone of the adrenal cortex, is the last step in zonation of the adrenal cortex and the sole source of DHEA and DHEAS. In contrast to the zona glomerulosa and zona fasciculata, four main features distinguish the zona reticularis:

1. An exceedingly low level of expression of 3-hydroxysteroid/4,5-isomerase type 2 and cytochrome P450 mRNAs and minimal enzyme activities.
2. Abundant dehydroepiandrosterone (hydroxysteroid) sulfotransferase activity. Unlike cortisol secretion, the secretion of DHEA and DHEAS in response to ACTH administration varies with age. Dissociation of adrenarche and gonadarche occurs in a variety of disorders of sexual maturation.

3. Relative increase in 17,20-lyase to 17-hydroxylase activity of P450c17, the enzyme that catalyzes both activities and cytochrome b5 synthesis. These characteristics are shared by the fetal zona of the fetal adrenal cortex.

4. Expression of major histocompatibility complex class II (human leucocyte antigen DR) antigens (these antigens are not expressed in the fetal zona of the fetal adrenal cortex).

The CYP17 gene encodes the microsomal enzyme P450c17, the single enzyme that catalyzes both adrenal 17-hydroxylase and 17,20-lyase activities. In contrast to the zona fasciculata, the zona reticularis has an increased 17,20-lyase/17-hydroxylase ratio. Tissue-specific regulation of the 17,20-lyase activity between the human adrenal and testis is well described. In the human Leydig cell (and quite likely the zona reticularis) the 5 pregnenolone substrate is 17-hydroxylated and the 17-hydroxyprogrenenolone is oxidized to DHEA, whereas in the zona fasciculata the 17-hydroxyprogrenolone is converted to 17-hydroxyprogesterone and 21-hydroxylated and the oxidation to DHEA is inhibited. In the rat, site-directed mutagenesis of arginine 346 to alanine in P450c17 led to retention of 80% of 17-hydroxylation activity but reduced to 7% the 17,20-lyase activity. Similarly, mutation of the corresponding residue in human P450c17 (arginine 347 to alanine) resulted in strikingly decreased 17,20-lyase activity but retention of 17-hydroxylase activity. Two X/Y phenotypic females with hypergonadotrophic hypergonadism and normal mineralocorticoid and glucocorticoid function had isolated 17,20-lyase deficiency because of homoygous mutations at either the arginine 347 residue or arginine 358 in P450c17.

In contrast to these observations of loss of 17,20-lyase activity with retention of 17-hydroxylase activity, Miller and colleagues showed that the ratio of human 17,20-lyase to 17-hydroxylase activities were increased by increased phosphorylation of serine and threonine residues on the P450c17 enzyme and b5 and by the increased abundance of the redox cytochrome P450 oxidoreductase and by cytochrome b5, which preferentially promotes 17,20-lyase activity by allosterically affecting the interaction between P450c17 and P450 oxidoreductase. These studies provide a provisional hypothesis for the mechanisms that appear to be involved in the relatively increased 17,20-lyase activity of the zona reticularis but not its regulation.

There are several hypotheses about the control of adrenal androgen secretion. Evidence, although incomplete and indirect, suggests that the regulation of androgen secretion in the zona reticularis is based on a dual control mechanism: (1) corticotropin (adrenocorticotropic hormone [ACTH]) is obligatory, as evidenced, for example, in the findings in ACTH deficiency or resistance, for (2) the action of an unidentified adrenal andrognstimulating factor, possibly pituitary in origin or from a nonadrenal source, or an intra-adrenal event. This concept is illustrated in Figure 24-44. Rejected alternatives to a unique adrenal androgen stimulating factor are the known pituitary hormones, such as an isolated increase in ACTH or endorphin, pro-opiomelanocortin (residues 79 to 96), and normal mineralocorticoid and glucocorticoid function had isolated 17,20-lyase deficiency because of homoygous mutations at either the arginine 347 residue or arginine 358 in P450c17.

A distinct adrenal androgen stimulating factor, whether of pituitary, intra-adrenal, or other origin, could explain the following observations.

1. The spurt in adrenal growth and the differentiation and growth of the zona reticularis at adrenarche occur independently of an increase in ACTH or cortisol secretion but correlate with the increase in plasma DHEAS (see Fig. 24-42).

2. Cortisol and adrenal androgen secretions vary independently with age, during normal as well as premature adrenarche, and in Cushing's disease, starvation, malnutrition, anorexia nervosa, and chronic disease.

3. Unlike cortisol secretion, the secretion of DHEA and DHEAS in response to ACTH administration varies with age.

4. Dissociation of adrenarche and gonadarche occurs in a variety of disorders of sexual maturation (see Fig. 24-44), including premature adrenarche (onset of pubic or axillary hair before age 6), chronic adrenal insufficiency, true precocious puberty (when the onset is before age 6), primary hypergonadism, isolated gonadotropin deficiency, and anorexia nervosa.

A longitudinal study of 42 children demonstrated that an increase in BMI (not the value itself at any age) is related to the rise in the urinary excretion of DHEAS, suggesting that a change in nutritional status is one physiologic regulator of adrenarche.
Adrenal Androgens and Puberty

The earlier onset of adrenarche than gonadarche and the contribution of adrenal androgens to the growth of public and axillary hair have led some to suggest that in normal children adrenal androgens are an important factor in the onset of puberty and the maturation of the hypothalamic-pituitary-gonadal complex. Although true precocious puberty may occur in circumstances in which the prepubertal child has previously been exposed to excessive levels of androgens from an endogenous or an exogenous source (e.g., after the initiation of glucocorticoid therapy in congenital virilizing adrenal hyperplasia or after removal of a sex steroid-secreting adrenal or gonadal neoplasm), there is little evidence that adrenal androgens play an important qualitative or rate-limiting role in the onset of puberty in normal children. Most patients with premature adrenarche, who secrete excessive amounts of adrenal androgens for their age, enter puberty and experience menarche within the normal age range. Moreover, prepubertal children who have congenital or acquired chronic adrenal insufficiency (Addison's disease) and, consequently, have deficient or absent adrenal androgen secretion usually have a normal onset of and progression through puberty when given appropriate glucocorticoid and mineralocorticoid replacement therapy.

Thus, early activation of adrenal androgen secretion does not commonly lead to sexual precocity, nor is deficient or absent adrenal androgen output usually associated with delayed puberty. Furthermore, growth studies in children with chronic adrenal insufficiency, isolated gonadotropin deficiency, hypergonadotropic hypogonadism, and androgen resistance suggest that in girls and boys adrenal androgens are not essential for the adolescent growth spurt, whereas gonadal steroids secreted by the testis and ovary are and act in concert with GH. A transient increase in height velocity (about 1.5 cm/year in both sexes) that occurs in middle childhood (6 to 7 years) and lasts about 2 years has been attributed by some to adrenarche. However, the middle childhood spurt, which terminates while serum DHEAS continues to increase, is related to the cyclic pattern of prepubertal growth and to genetic regulation of growth rather than an increase in either adrenal androgen or GH secretion. This hypothesis, which has been controversial, is supported by a longitudinal analysis of urinary excretion of DHEAS and total 17-ketosteroid sulfates with prepubertal growth.
In patients with constitutional delay in growth and puberty, bone age correlates better with the time of onset of and stage of puberty than does chronologic age. These patients have a retarded bone age at presentation but, on achieving a bone age of approximately 12 to 14 years for boys and 11 to 13 years for girls, they can be expected to show the earliest stages of sexual maturation. The U.S. Health Examination Survey showed that 5.7% of boys with a bone age of 14 years lacked pubic hair (stage 1) and 4% were in genital stage 1, whereas at age 15 years only 0.2% were still in pubic hair stage 1 and 0.8% were still in genital stage 1. Unfortunately, the study started at an age at which the same descriptive information could not be determined for girls. 

In summary, healthy individuals who spontaneously enter puberty after the age of 13 for girls and 14 for boys have constitutional delay in growth and adolescence. Affected individuals are usually short (2 SD below the mean value for height for age) at presentation but, on achieving a bone age of approximately 12 to 14 years for boys and 11 to 13 years for girls, they can be expected to show the earliest stages of sexual maturation. The U.S. Health Examination Survey showed that 5.7% of boys with a bone age of 14 years lacked pubic hair (stage 1) and 4% were in genital stage 1, whereas at age 15 years only 0.2% were still in pubic hair stage 1 and 0.8% were still in genital stage 1. Unfortunately, the study started at an age at which the same descriptive information could not be determined for girls.

Ovarian steroid biosynthetic defects

and these patients are the ones who most often seek medical advice. The combination of delayed pubertal maturation and decreased stature during adolescence, superimposed on a strong familial tendency toward short stature, leads to conspicuous shortness, especially in the peripubertal period, more often than with either condition alone. We emphasize that no one test distinguishes between constitutional delay in growth and puberty and hypogonadotropic hypogonadism.

Growth rate before the actual onset of puberty in these patients is often suboptimal for chronologic age, but growth velocity usually increases to normal levels after puberty begins. A theoretical model of growth in delayed puberty is proposed on the basis of the infancy-childhood-puberty growth chart. A transient decrease in GH secretion is present in some individuals with constitutional delay but is usually normal. GH release as well as GH secretagogues including the administration of GH-releasing hormone may be decreased in children with constitutional delay in puberty. The amplitude of GH secretion and the GH response to GH-releasing hormone increase after the administration of exogenous androgens or estrogens. Thus, constitutional delay in puberty may constitute a state of functional temporary GH insufficiency for chronologic age but not for bone age; this does not constitute a rationale for treatment of constitutional delay with GH. There is an interaction of IGF-I and gonadotropins in the ovary and testis, and the relatively low secretion of GH (and presumably intraglandular IGF-I) in constitutional delayed puberty may impair the gonadal secretion of gonadotropins. Affected boys seem to be more distrest by short stature than by the delay in sexual development. Occasionally, individuals with constitutional delay in puberty are of normal stature. In such instances, the genetic tendency for growth is greater than in cases characterized by short stature. In these patients, diagnostic and therapeutic decisions focus on the pubertal status alone. Patients with constitutional delay in adolescence and growth often do not reach their predicted height. This has been attributed in a retropective study to a lack of growth of the spine in relation to leg length and is said to result in eunuchoid proportions when the subject reaches adulthood (associated with a decreased upper to lower segment ratio); the greater this segmental disproportion is, the closer the patient is to reaching target height. An alternative explanation for reduced adult stature is that the patients most likely to be referred and reported are those who combine genetic short stature with constitutional delay in growth and puberty. The magnitude of the catch-up linear growth during puberty in boys is a major determinant of adult height.

Although the use of exogenous androgens may improve self-image and start the secondary sexual changes of puberty, low-dose androgens neither improve final height nor change the

eunuchoid proportions. Further, the use of GH therapy has not been shown to increase the final height in constitutional delay even if growth velocity does transiently increase with GH therapy. Girls with constitutional delay in growth and puberty present more rarely than boys, but as a group they also reach suboptimal height. They usually reach their predicted adult height but not their target height, whereas some boys may reach neither, and as a group patients with constitutional delay have a mean deficit of 2.4 cm below the mean predicted height. Individual differences in final height are striking, however, varying about 10 cm from predicted adult height. In counseling, the physician must be aware of the limitations in the accuracy of a prediction of final height in a patient with current methods. Some studies have combined LHRH agonist therapy with GH treatment to increase final height in children who are normal except for genetic short stature, but the preliminary results are either inconclusive or show increased predicted or near final height (which does not necessarily translate into increased adult height). This approach to treatment remains experimental and exceptionally expensive ($14,000 per centimeter gained by one estimate).

The discovery of the critical role of estradiol in skeletal maturation in boys as well as girls led to the suggestion that in boys with constitutional delayed growth and puberty, treatment with a potent aromatase inhibitor would improve adult height by inhibiting skeletal maturation. Preliminary evidence was obtained in a double-blind, randomized, placebo-controlled study involving boys with constitutional delay in puberty in which treatment with a course of monthly intramuscular repository testosterone and placebo was compared with testosterone and once-daily oral letrozole (a potent fourth-generation aromatase inhibitor). In the letrozole plus testosterone group, in which serum estradiol was strikingly suppressed during the 12-month period, the mean increase in predicted adult height was 5.1 cm while the predicted adult height was unchanged in the testosterone placebo group. These early observations suggest that adult height can be increased by inhibiting estradiol synthesis and dampening the rate of skeletal maturation without affecting the development of male secondary sex characteristics. Normal volumetric bone density has been described in young men previously affected by constitutional delay, in contrast to the decreased peak bone mass related to
Insufficient pulsatile secretion of LH RH and the resulting FSH and LH deficiency lead to delayed sexual maturation. The magnitude of the LH RH deficiency and hence the phenotype can vary from severe sexual infantilism to instances in which the separation from constitutional delay of puberty is difficult. LH RH deficiency may be secondary to a genetic or developmental defect present at birth but undetected until the age of expected puberty, or it may be due to a tumor, inflammatory process, vascular lesion, radiation, or trauma.

The deficiency of pulsatile LH RH may be quantitatively absolute or relative or qualitative, especially in females; it may involve abnormalities in the amplitude or frequency of LH RH or L H pulses or both. 

...comparatively, gonadotropin deficiency may arise from lesions or defects that involve the pituitary gland directly. When GH is affected as well as gonadotropins, impaired growth is...
Sexual infantilism may be caused by other extrasellar tumors that arise in or encroach on the hypothalamus. Germinomas (previously termed pinealomas, ectopic pinealomas, atypical teratomas, or dysgerminomas) or other germ cell tumors of the CNS are the extrasellar tumors that most commonly cause sexual infantilism, although, when all primary CNS tumors are considered, germinomas are rare. The diagnosis is usually made during the second decade of life. Polydipsia and polyuria are among the most common symptoms followed by visual difficulties and abnormalities of growth and puberty. The most common endocrine abnormalities are deficiencies of vasopressin and GH, but other anterior pituitary hormone deficiencies (including gonadotropin deficiency) and elevated serum prolactin levels are frequent. The concentrations of hCG, in spinal fluid especially and in serum, and of -fetoprotein are useful tumor markers in children and adolescents with a CNS germ cell tumor. Rather than delaying puberty, germ cell tumors in boys may cause gynecomastia precociously by secretion of hCG (see section on sexual precocity). A similar problem is seen in suprasellar teratomas that produced mild sexual precocity in a 6-year-old girl who had nondetectable serum concentrations of LH and FSH was reported. This pubertal development was thought to be possibly related to aromatase activity of the teratoma; with therapy and regression of the tumor, the breast budding disappeared.

A germ cell tumor may arise in the suprasellar hypothalamic region, in the pineal region, or in another area of the CNS. Subependymal spread along the lining of the third ventricle is common, and seeding may lead to involvement of the lower spinal cord and corda equina. MRI scans with contrast enhancement are useful in the diagnosis of tumors more than 0.5 cm in diameter and detection of isolated enlargement of the pituitary stalk, an early finding on MRI scans. Periodic MRI monitoring for further development of a tumor is indicated whenever thickening of the pituitary stalk is encountered. Hypothalamic-pituitary abnormalities on MRI are related to functional defects such as diabetes insipidus. Unlike the size of the pituitary gland, which increases 100% between years 1 and 15, the size of the pineal gland does not change after age 1 in normal individuals, and thus any enlargement after that time is suspicious of a mass lesion. Pure germ cell tumors are low in radioactivity, and therefore the preferred treatment; the clinical features and the response to radiation therapy are so characteristic that surgery is rarely indicated except for biopsy to establish a tissue diagnosis. When a mixed germ cell tumor is found, both radiation therapy and chemotherapy are recommended.

Hypothalamic and optic gliomas or astrocytomas occurring either as part of neurofibromatosis (von Recklinghausen's disease) or incidentally, can also cause sexual infantilism.

Pituitary Tumors

Pituitary adenomas are rare in childhood and adolescence as only 2% to 6% of all pituitary adenomas occur in this age group. In one study, 50% of pituitary adenomas occurring before adulthood were prolactinomas, 20% were GH-secreting adenomas, and 30% were chromophobe adenomas. Hyperprolactinemia related to microprolactinomas or macroprolactinomas of the pituitary is uncommon in childhood and adolescence and is a rare cause of delayed puberty in both boys and girls. Among our patients, only 2 of 29 had delayed onset of puberty, although primary amenorrhea was the presenting symptom in 13 of 20 prolactinomas. Galactorrhea may be absent by history but is often demonstrable by manual manipulation of the nipples (because serum prolactin may rise after manipulation of the nipples, samples should be obtained before examination or many hours later). Transphenoidal resection of microprolactinomas in children and adolescents was an effective treatment with an 89% cure rate. The dopamine agonist bromocriptine is used by some as a method of decreasing serum prolactin concentrations and decreasing the size of the tumors; we use this approach in children and adolescents in whom resection of the adenoma is incomplete and to reduce the size of large macroprolactinomas before attempted surgical removal.

Pupertal progression in affected boys and girls as well as normal menstrual function in girls usually follows the reduction in serum prolactin levels. In certain prolactinomas in children and adolescents, there was a preponderance of macroadenomas in girls and of macroadenomas in boys, and these larger tumors led to local symptoms related to their size.

Other Central Nervous System Disorders Leading to Delayed Puberty

Langerhan's Cell Histiocytosis (Hand-Schüller-Christian Disease, or Histiocytosis X)

This disorder, now thought to be a clonal proliferative disorder of Langerhan's histiocytes or their precursors, is characterized by the infiltration of lipid-laden histiocytic cells or foam cells in the skin, viscera, and bone. Diabetes insipidus, usually resulting from infiltration of the hypothalamus or the pituitary stalk or both, is the most common endocrine manifestation. However, GH deficiency and delayed puberty may occur. There may be visceral involvement including the lung, liver, and spleen. Other findings include cyst-like areas in flat bones of the skull, the ribs, the pelvis, and the scapula; in the long bones of the arms and legs, and in the dorsolumbar spine. Lesions of the mandible may lead to the radiographic impression of "floating teeth" within rarefied bone and the clinical finding of delayed closure of the fontanelles. Lesions of the mandible may lead to the radiographic impression of "floating teeth" within rarefied bone and the clinical finding of delayed closure of the fontanelles.

Postinfectious Inflammatory Lesions of the Central Nervous System, Vascular Abnormalities, and Head Trauma

These are unusual causes of hypogonadotropic hypogonadism. Rarely, tuberculous or sarcoid granulomas of the CNS are associated with delayed puberty. Radiotherapy to the head may be hypoplastic, presumably because of the lack of hypothalamic-pituitary factors, and in some patients the neurohypophysis may have an ectopic location.

In our series, the syndrome is associated with decreased maternal age. A mutation in the HESX1 gene is a rare cause of septo-optic dysplasia. Other developmental defects of the anterior pituitary gland associated with hypothalamic-hypogonadism and other pituitary hormone deficiencies are caused by autosomal recessive mutations in homeobox genes encoding transcription factors involved in the early aspects of pituitary development. These include, in addition to HESX1, mutations in LHX3 and PROP1.
Isolated Gonadotropin Deficiency

Isolated hypogonadal hypogonadism is characterized by selective deficiency of gonadotropins owing to a defect at the level of the hypothalamus involving the LHRH pulse generator or the gonadotrophs, or both, without an anatomic lesion (Table 24-23 and Table 24-24). As a consequence, signs of puberty fail to occur by age 14 years in boys and age 13 years in girls or the pubertal maturation is incomplete or transient. In boys, micropenis or undescended testes or both signs are evidence of a fetal testosterone deficiency. The heterogeneous disorders that lead to isolated hypogonadotropic hypogonadism are typically associated with a prepubertal concentration of gonadal sex steroid values (testosterone in boys; estradiol in girls) and low or normal gonadotropin levels. In the severe form, the concentration of gonadal sex steroids and gonadotropins is low, pulsatile secretion of LH is absent or virtually so, and the LH response to the administration of LHRH is deficient. The tests, if palpable, are small and the concentration of serum inhibin B and estimate of seminiferous tubule function are low.

Isolated gonadotropin deficiency may occur in families (about 20% to 30% of patients) or sporadically. The pattern of inheritance in affected families is that of an autosomal dominant, autosomal recessive, or X-linked recessive trait. In contrast to patients with CNS tumors, who usually have associated GH deficiency and growth failure, and to patients with constitutional delay in growth and adolescence, who are short for chronologic age, patients with isolated gonadotropin deficiency are usually of appropriate height for their age. Because their concentrations of gonadal steroids are too low for the epiphyses to fuse at the normal age, these patients develop increased arm span for height and decreased upper/lower ratios (eunuchoid body proportions) and, if untreated, usually become tall adults. An autosomal recessive form has been described in the mouse (hypf) in which there is a deletion of a part of the LHRH gene. The mutant RNA is incapable of generating functional LHRH.

Kallmann's Syndrome

This genetically heterogeneous syndrome (Table 24-25) is the most common form of isolated hypogonadotropic hypogonadism with delayed puberty in which anosmia or hyposmia resulting from agenesis or hypoplasia of the olfactory lobes or sulci, or both, is associated with LHRH deficiency. The prevalence in boys is about four times that in girls. Although the extent of the defect in olfaction usually seems to correlate with the degree of LHRH deficiency, even in patients with complete anosmia the LHRH deficiency may be partial (fetal eunuch syndrome). Rarely, affected men who had a severe delay in puberty may recover spontaneously, experience an increase in testicular size, and enter full puberty.

The magnitude of the LHRH deficiency correlates with the size of the testes. A variety of deletions and mutations of the KAL1 gene have been described, including large and small (exon) deletions, point mutations, and mirror movements of the upper extremities (synkinesia) (see Table 24-24). All of these structures and organs are sites of expression of the KAL1 gene in the human fetus. Associated defects inconsistently present are cleft lip, cleft palate, imperfect facial fusion, seizure disorders, short metacarpals, pes cavus, neurosensory hearing loss, mirror movements of the upper extremities (synkinesia), and growth failure, and to patients with constitutional delay in growth and adolescence, who are short for chronologic age, patients with isolated gonadotropin deficiency are typically associated with a prepubertal concentration of gonadal sex steroid values (testosterone in boys; estradiol in girls) and low or normal gonadotropin levels. In the severe form, the concentration of gonadal sex steroids and gonadotropins is low, pulsatile secretion of LH is absent or virtually so, and the LH response to the administration of LHRH is deficient. The tests, if palpable, are small and the concentration of serum inhibin B and estimate of seminiferous tubule function are low.

TABLE 24-24 — Isolated Gonadotropin Deficiency: Clinical Features in 20 Adolescent Boys

Males more commonly affected

Familial or sporadic

Height normal for age; tall adult height if untreated

Eunuchoid skeletal proportions

Delayed bone age

Small, often cryptorchid testes; Diameter <2.5 cm prepubertal size; phallus may be small

Normal adrenarche

Examine for anosmia or hyposmia (Kallmann's syndrome)

Look for associated malformations (facial, central nervous system, skeletal, renal)
deletions in this region of the X chromosome can lead to an association of Kallmann's syndrome with X-linked ichthyosis caused by steroid sulfatase deficiency, mental retardation, and chondroplasia punctata.

Autosomal dominant inheritance of the phenotype is supported by some early studies, and this pattern of inheritance is further suggested by a report of an affected male who fathered an affected son after treatment with hCG. Apparent autosomal recessive inheritance characterizes other kindreds. Thus, the various forms of Kallmann's syndrome are due to heterogeneous mutations in which the phenotype can vary. For example, a 20-year-old man with the complete picture of Kallmann's syndrome had an identical twin brother (proved by genetic fingerprinting) with anosmia but a normal adult phenotype and normal plasma testosterone and gonadotropin concentrations.

In classical, X-linked Kallmann's syndrome, fetal LHRH neurosecretory neurons fail to migrate from the olfactory placode, where they arise, to the medial basal hypothalamus, where they constitute the LHRH pulse generator (see earlier discussion). The defect may be absolute or relative. The fetal LHRH-containing cells and neurites are arrested in their migration to the brain and end in a tangle around the cribriform plate and in the dural layers adjacent to the meninges beneath the hypothalamus, where they constitute the LHRH pulse generator (see earlier discussion). The defect may be absolute or relative. The fetal LHRH-containing cells and neurites are arrested in their migration to the brain and end in a tangle around the cribriform plate and in the dural layers adjacent to the meninges beneath the hypothalamus, where they constitute the LHRH pulse generator (see earlier discussion).

As noted previously, in some patients this abnormality can be seen in cranial MRI scans. Hence, the MRI: aplasia or hypoplasia of olfactory bulbs and/or sulci

**TABLE 24-25 -- Features of Kallmann Syndrome**

**Clinical**

- LHRH deficiency: absent or arrested puberty
- Anosmia or hypop sia
- In infancy: microphallus; cryptorchidism
- Normal stature and growth in childhood
- Normal adrenarche
- Eunuchoid proportions
- Associated midline defects (e.g., cleft lip, cleft palate, midline cranial anomalies)
- MRI: aplasia or hypoplasia of olfactory bulbs and/or sulci

**Prevalence:** approximately 1 in 7500 males, 1 in 50,000 females; one-tenth prevalence of Klinefelter's syndrome

**Inheritance:** sporadic and familial cases; genetic heterogeneity

- **X linked**
- X-linked recessive (Kallmann et al.
- X chromosome deletion: Xp22.3 (Ballabio et al.

- **Autosomal**
- Dominant (sex limitation) (Santen and Paulsen
- Recessive (White et al.

- **Anatomy:** developmental field defect
- Aplasia or hypoplasia of olfactory bulb and sulcus
- Arrested migration of LHRH neurosecretory neurons from olfactory placode to medial basal hypothalamus
- LHRH, luteinizing hormonereleasing hormone.

Kallmann's syndrome can be considered a developmental malformation caused by a field defect.
Other Forms of Isolated Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism may be transmitted by autosomal recessive inheritance with none of the other features of Kallmann’s syndrome. Males with cerebellar ataxia and deficient gonadotropin production are reported in kindreds with X-linked inheritance (possibly a variant form of Kallmann’s syndrome), and hypogonadotropic hypogonadism may be associated with the multiple lentigines and basal cell nevus syndromes.

Luteinizing Hormone/Releasing Hormone Receptor Mutations

A mutation in the human LHRH gene itself has not been reported, in contrast to the mutation described in the hyp/hyp

mouse. However, familial and sporadic patients have been reported with mutations in the gene encoding the GnRH receptor, the G protein-coupled seven transmembrane segments, which lead to various degrees of hypogonadotropic hypogonadism with normosmia.

More than six families as well as sporadic patients have been described in this autosomal recessive disorder, with heterozygous or homozygous mutations in the LHRH receptor. Mutations are dispersed throughout the coding region of the gene. The clinical presentation is heterogeneous even within the same pedigree and especially in patients with compound heterozygous mutations. The patients may present with severe features of isolated hypogonadotropic hypogonadism, sexual infantilism, long-delayed puberty, relatively mild hypogonadism, and infertility. The clinical variants include the fertile euarch variant and reversal in adulthood.

The impairment of signal transmission by the mutant LHRH receptor is highly variable; in one affected woman, pulsatile LHRH treatment induced ovulation and made a successful pregnancy possible.

In all types of congenital gonadotropin deficiency, male patients are likely to manifest micropenis (penile length less than 2.5 cm at birth and in infancy) because of lack of fetal gonadotropin stimulation of fetal testes during the last half of gestation. Rarely, boys with congenital GH deficiency have micropenis even if gonadotropin levels are normal. Infants and children with microgenitalia related to hypothalamic deficiencies may be treated with one or two 3-month courses of testosterone enanthate, 25 mg per month given intramuscularly, to enlarge the size of the penis.

Although concern was raised that early testosterone therapy might not allow the attainment of a normal adult penile size, experience has proved otherwise. Further, the concern that the penis might not respond to androgens later in life if exposed to testosterone in childhood, a pattern noted in the rat, proved incorrect. Thus, it is appropriate to treat male infants and children with micropenis related to gonadotropin or GH deficiency with short courses of androgens to enlarge the penis into the normal childhood range. It is not appropriate to reverse the sex of a male infant because of microphallus owing to such causes as fetal testosterone deficiency.

X-Linked Congenital Adrenal Hypoplasia and Hypogonadotropic Hypogonadism

This uncommon X-linked recessive disorder of adrenocortical organogenesis is due to a deletion or mutation in the DAX1 gene (dosage-sensitive, sex reversal, adrenal hypoplasia congenita, X chromosome gene 1). The DAX1 gene, a member of the nuclear receptor superfamily, encodes an orphan receptor that is a putative transcriptional repressor. The DAX1 locus undergoes X inactivation. It maps to the DSS (dosage-sensitive sex reversal) locus (Xp21); a double dose of DAX1 is associated with a female phenotype or ambiguous genitalia in 46,XY males.

DAX1 protein has a novel domain in the amino terminus that contains two putative unique zinc finger motifs, and the carboxy terminus contains a conserved ligand-binding domain that binds deoxyribonucleic acid (DNA), localizes in the nucleus, and contains a transcriptional silencing domain that antagonizes the steriodogenic factor-1 (SF-1) trans-activation function. DAX1 has an SF-1 response element in the Sprotomer region.

Abnormalities of the DAX1 gene are characterized by severe glucocorticoid, mineralocorticoid, and, at puberty, androgen deficiency. A mature adrenal cortex is lacking and the abnormal structure of the adrenal cortex resembles that of the fetal zona made up of disorganized vacuolated cytoplasmic cells. The major effect of DAX1 deficiency is a severe primary adrenal insufficiency that with hyponatremia, hyperkalemia, acidosis, and hypocholesterolemia (failure to thrive, vomiting, poor feeding, dehydration, circulatory collapse, increased pigmentation) is lethal if untreated early in life. The concentration of plasma ACTH and plasma renin activity are high; plasma cortisol and aldosterone levels are low. Less commonly, the onset of symptomatic adrenal insufficiency is delayed into later childhood, an early sign of which is increased skin pigmentation.

In the infant male, salt wasting are usually the most prominent feature but cortisol deficiency is present and detectable, and the adrenal insufficiency includes deficient secretion of the zona reticularis steroids, DHEA and its sulfocoujugate. The testses are undescended in less than half of the patients; micropenis is rare, but urogenital abnormalities and hearing loss are occasionally present. Most commonly, because of hypogonadotropic hypogonadism, signs of sexual maturation at the age of puberty are lacking, including absence of pubic and axillary hair and testicular enlargement; the concentrations of serum FSH, LH, and testosterone are
There are exceptions to this typical presentation, related in part to the nature of the DAX1 mutation; for example, the adrenal dysfunction may be subtle and delayed puberty, owing to hypogonadotropic hypogonadism, the prominent clinical feature.

Boys who do not present with clinical evidence of adrenal insufficiency in infancy often have a more insidious onset during childhood. In rare instances, the adrenal insufficiency is not detected until adulthood and the hypogonadotropic hypogonadism is partial. In a pedigree in which two affected boys had a hemizygous DAX1 nonsense mutation and neonatal onset of adrenal insufficiency, a maternal aunt who was homozgyous for the mutation had sexual infantilism and primary amenorrhea but even after decades of follow-up maintained normal adrenal function. A maternal grandfather who carried the same mutation was asymptomatic. This pedigree again highlights the limitations and complexities of genotype and phenotype correlations. A survey of 106 individuals with variants of puberty delay or hypogonadotropic hypogonadism indicated that a mutation of DAX1 is rare and most unlikely to be the cause in such cases unless there is a history of adrenal insufficiency.

For many years, the nature of the hypogonadotropic hypogonadism in this condition has been uncertain. Two advances clarified this issue. First, as discussed subsequently, intragenic mutations in the DAX1 gene indicate that the hypogonadotropic hypogonadism is an intrinsic characteristic of the disorder, a manifestation of the single gene mutation and not related to the involvement of a contiguous gene. Second, the DAX1 gene is expressed not only in the adrenal cortex and testes (and weakly in the ovary) but also in the hypothalamus and pituitary. More commonly, there is evidence of both LHRH deficiency and an abnormality in the gonadotrophs, giving a mixed picture of both hypothalamic and intrinsic gonadotroph defects, but in some instances one or the other defect is primary, usually at the pituitary level. The pulsatile secretion of LH is absent or erratic; basal immunoreactive LH and FSH levels may be normal but the gonadotropins seem to lack bioactivity. Of interest, in affected male infants in whom hypotalamic/pituitary gonadotropin-pituitary function was assessed at birth and in infancy (as late as 140 days), the serum concentration of testosterone was normal (i.e., elevated to puberty levels), as was that of FSH and LH and there was the expected pubertal response to LHRH administration. In addition to the glucocorticoid and mineralocorticoid deficiencies, the serum DHEAS levels were low. These observations suggest that, at least in some affected boys, the LHRH pulse generator/pituitary gonadotropin apparatus is intact and functional in infancy and early childhood and that the LHRH-gonadotroph defects are not manifest until later in childhood or the peripubertal period.

A tall 2-year-old boy with a DAX1 mutation resulting in a frameshift and premature stop codon had as his first clinical manifestation penile enlargement and public hair that proved to be due to LHRH-independent sexual precocity. Serum testosterone values were in the early pubertal range; basal and LHRH-stimulated LH and FSH were prepubertal. The sexual precocity was not modified by LHRH agonist treatment; the LH receptor gene had a normal sequence. At age 3 years, he became progressively pigmented and cortisol and aldosterone deficiencies were documented as well as extremely high levels of plasma ACTH. On replacement therapy with cortisol acetate and 9-fluorocortisone, the size of his testes decreased and the concentration of serum testosterone fell into the prepubertal range. The observations suggested that the exceedingly high circulating ACTH levels, possibly acting through the human melanocortin 1 receptor present in human Leydig cells, were the underlying cause of the increased steroidogenesis and testosterone secretion, which was reversed by glucocorticoid treatment. In addition, as DAX1 inhibits the SF-1 trans-activation, a regulator of steroidogenic genes, the loss of DAX1 inhibition of SF-1 transcriptional activity may also have had a role.

Data on seminiferous tubule function are limited. Azoospermia unresponsive to gonadotropin treatment was detected in a few affected men. Delayed puberty is a manifestation in some female carriers of a DAX1 mutation. In addition to a deletion of DAX1, most mutations in the gene are nonsense mutations and frameshifts; missense mutations with a change in a single amino acid are relatively uncommon. In a review of 86 patients reported to have intragenic mutations in DAX1, the most common were frameshift mutations (49%); nonsense mutations were described in 28% and missense mutations in 20%, almost all of which were located in the ligand-binding domain.

Contiguous gene syndromes are not uncommon in association with X-linked congenital adrenal hypoplasia, the gene of which maps to Xp21, distal to the glycerol kinase (DMD) gene. Most mutations in the DMD gene are nonsense mutations and frameshifts; missense mutations with a change in a single amino acid are relatively uncommon. In a review of 86 patients reported to have intragenic mutations in DAX1, the most common were frameshift mutations (49%); nonsense mutations were described in 28% and missense mutations in 20%, almost all of which were located in the ligand-binding domain.

Isolated Luteinizing Hormone Deficiency

Isolated LH deficiency (the fertile eunuch syndrome) is associated with deficient testosterone production (which responds to administration of hCG) in the presence of variable spermatogenesis; in most instances, it is an incomplete form of isolated gonadotropin deficiency. The disorder may be idiopathic or secondary to a hypogonadotrophic pituitary neoplasm.

Isolated Bioactive Luteinizing Hormone

Rarely, isolated bioactive LH is due to a mutation in the gene encoding the LH subunit. The only known patient had a striking discrepancy between immunoreactive and bioactive LH. A 17-year-old male with a history of delayed puberty with increased immunoreactive serum LH levels but no LH bioactivity and normal serum FSH concentrations had a homozygous mutation in exon 3 of the LH subunit gene (glutamine 54 arginine). Biopsy of the testes showed absent Leydig cells and arrested spermatogenesis. Treatment with hCG increased testosterone secretion and spermatogenesis. The serum LH of the hypergonadotrophic mother exhibited only 55% of normal binding to the LH receptor. He had normal male sex differentiation, most likely because of the action of hCG during the second trimester and extending into the third trimester.

The patient had low testosterone concentrations; it is uncertain that he completely lacked LH bioactivity in late fetal life as he did not have micro-/485, a common finding in male infants with congenital LH deficiency.

Isolated Follicle-Stimulating Hormone Deficiency

Mutations in the FSH subunit, either homozgyous or compound heterozygous, have been reported in three females and two males. The three affected women presented with delayed puberty, lack of breast development or poorly developed secondary sex characteristics, and primary amenorrhea but normal adrenarche. Immunoreactive FSH was not detected in the serum; the LH concentration was elevated and serum estradiol was low. There are three female cases of disordered puberty with FSH subunit mutations. Two of three women had a homozygous nonsense mutation in the FSH subunit gene (Val 61 X) and the other was a compound heterozygote (Cys 51 Gly/Val 61 X).

Two affected men have been reported. Both had azoospermia; small, soft testes; and absence of serum FSH. In one man with normal puberty and LH and testosterone values, the missense mutation was a Cys 82 Arg substitution. The other man, with a nonsense mutation (Val 61 X), had delayed puberty, low testosterone and inhibited, and high LH.

Two males with this mutation had a normal (or only slightly delayed) onset and progression of puberty, but because of abnormal Serum development, the testes were small and soft and there was azoospermia. A woman with a mutation in the prohormone convertase 1 (PC1) gene had extreme childhood obesity, hypocortisolism, defects in conversion of proinsulin to insulin, and isolated hypogonadotropic hypogonadism.

Idiopathic Hypogonadotropic Dwarfism

Idiopathic hypopituitarism is usually caused by a deficiency of hypothalamic releasing factors. In the untreated state, patients with deficient LHRH with rare exceptions have delayed puberty. In contrast, patients with isolated GH deficiency ultimately undergo spontaneous pubertal development, without exogenous gonadal steroids, when the bone age reaches the pubertal stage of 11 to 13 years. Those who have associated gonadotropin deficiency do not
undergo spontaneous puberty, even when the bone age advances to the pubertal stage during GH therapy.

Common to many patients with idiopathic hypopituitarism is early onset of growth failure; late onset of diminished growth suggests the presence of a CNS tumor. There is an association between breech delivery, especially in males, perinatal distress, and idiopathic hypopituitarism, and malformations of the pituitary gland are demonstrable by MRI in common with such patients. The familial forms of multiple pituitary hormone deficiencies with either autosomal recessive or X-linked inheritance are less common.

The degree of hormone deficit and the age of onset of pituitary hormone deficiencies may vary within a single kindred with the same genetic defect.

The absence of GH and gonadotropins may allow long-term but slow growth to increase final height; the height at the onset of puberty and the height in relation to bone age determine the final height that is reached. One patient was reported to be taller than expected for the family after the diagnosis of panhypopituitarism was made at 25 years of age and treatment was given. Treatment with GH in prepubertal children with isolated GH deficiency can increase the rate of pubertal development. Alternatively, if GH treatment is instituted in children already in puberty who have a limited height potential, limitation of the amount of growth attained with GH treatment often results. In these instances, the use of LHRH agonists to suppress pubertal development in addition to the use of GH can increase final height.

The judicious use of low-dose testosterone in affected boys of pubertal age with associated gonadotropin deficiency does not seem to impair growth achieved by GH replacement.

Miscellaneous Conditions

Prader-Willi Syndrome

This autosomal dominant syndrome early-onset childhood hyperphagia; pathologic obesity and carbohydrate intolerance; infantile central hypotonia and lethargy; delayed onset and poor fetal activity, a tendency for intrauterine growth retardation; short stature by 15 years of age; small hands and feet; mild to moderate mental retardation; emotional instability including perseveration, obsessions, and compulsions; and characteristic facies with almond-shaped eyes, triangular mouth, and narrow bitemporal diameters associated with delayed puberty and hypogonadotropic hypogonadism caused by hypothalamic dysfunction. In spite of this, there is a tendency to early adrenarche.

Affected boys often have microgenia and cryptorchidism. Weight reduction may lead to menarche in some females. Hence, severe obesity may play a role in the impaired puberty in some patients. Plasma GH responses to provocative stimuli and to sleep are usually low but may be normal. The assessment of GH secretion has been confounded by the obesity; it is often decreased in nonGH-deficient obese individuals.

The role of relative GH deficiency in this disorder is uncertain and controversial (see Eiholzer and colleagues for a contrary view). In the past, GH deficiency has been advocated to support the treatment of Prader-Willi syndrome with recombinant human GH (rGH). This justification is no longer needed. In June 2000 the U.S. Food and Drug Administration (FDA) approved Prader-Willi syndrome as an indication for rGH treatment in affected children without a requirement for assessing GH secretion; genetic testing is required to confirm the clinical diagnosis.

The decision to approve rGH treatment was strongly influenced by long-term randomized control trials in Prader-Willi syndrome. GH treatment decreases body fat and increases fat utilization, lean body mass, linear growth, and energy expenditure and there are possible improvements in physical strength and motor development. The recommended dose is 1.0 to 1.5 mg/m²/day (0.03 to 0.05 mg/kg/day). The optimal dose, maintenance of positive clinical effects, optimal age for initiation of treatment, and frequency of adverse side effects including type 2 diabetes mellitus remain to be established.

A striking discovery is the discovery that patients with Prader-Willi syndrome have 4- to 5-fold higher fasting concentrations of plasma ghrelin (the "hunger hormone") than in equivalently obese controls. Ghrelin, a novel enteric hormone secreted among other tissues by the stomach, increases food intake (a powerful orexigen) and its body weight, and growth hormone secretion. This finding raises the possibility of new pharmacologic and surgical approaches to treatment.

The ghrelin gene is widely expressed in human tissues, the highest level is in the fundus of the stomach, where its novel acylated peptide ghrelin is localized to X/A cells, a distinctive endocrine cell population in the oxyntic mucosa.

This distinct genetic disorder with a frequency of about 1 in 20,000, rarely familial (the recurrence risk depends on the type of genetic defect), is caused by abnormalities involving the long arm of chromosome 15 in the region q11-q13. Approximately 70% of Prader-Willi cases are caused by a paternal deletion of 15q11-q13 (commonly about 3 to 5 megabase pairs in size); 20% to 25% of cases have maternal uniparental disomy (either isodisomy or heterodisomy) in which both chromosomes 15 are derived from the mother, possibly by nondisjunction during maternal meioisis, and represent a striking example of genomic imprinting. In 2% to 5%, an imprinting center defect has been detected. The lack of a functional paternal 15q11-q13 region, caused by any of a variety of genetic mechanisms, can result in the syndrome. One candidate imprinted gene, among several, that maps to this region, SNRPN (small nuclear ribonucleoprotein-associated polypeptide Smn), implicated in splicing pre-rRNA, is expressed in the brain including the hypothalamus and has been advanced as one explanation of the syndrome. Little is known about the fine structure of the brain in this syndrome. A study of the hypothalamic paraventricular nucleus described a decrease in the number of immunoreactive oxytocin-containing cells in both male and female. Its physiology and disorders. In Yen SSC, Jaffe RB (eds). Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1996, pp. 313384.)

Laurence-Moon and Bardet-Biedl Syndromes

The Laurence-Moon syndrome has frequently been incorrectly combined with the Bardet-Biedl syndrome although they are now regarded as distinct entities. Both are rare autosomal recessive traits and both combine retinitis pigmentosa and hypogonadism of various etiologies. Many of the Bardet-Biedl patients have developmental delay, as do all of the Laurence-Moon patients. The Laurence-Moon syndrome, however, is associated with spastic paraplegia, whereas the Bardet-Biedl syndrome involves postaxial polydactyly, onset of obesity usually in early infancy, renal dysplasia, and a relatively high prevalence of the Bedouin of the Middle East. Similar findings are present in the Biedou syndrome II with iris coloboma, hypogonadism, obesity, polydactyly, and developmental delay, but it too is a distinct entity. The genetically and phenotypically heterogeneous Bardet-Biedl syndrome is linked to six loci that map to chromosomes 2, 3, 11, 15, 16, and 20; in most cases three mutant genes are required for a phenotype.

Functional Gonadotropin Deficiencies

Severe systemic and chronic disorders and malnutrition are associated with delayed puberty or failure to progress through the stages of puberty. It is necessary to distinguish the effects of malnutrition, which can lead to functional hypogonadotropic hypogonadism, from the primary effects of the disease. For example, a group of malnourished rural children from Kenya had chronicologic delay in pubertal development and excreted less urinary FSH and LH than well-nourished urban children of the same age. When the two groups were matched by pubertal stage rather than chronologic age, there was no different a difference in gonadotropin excretion.

A study of girls who had previously suffered from kwashiorkor demonstrated no delay in breast development or peak height velocity but a delay in pubic hair growth.
Anorexia nervosa, a common cause of gonadotropin deficiency in adolescence, is a functional disorder, apparently increasing in prevalence in girls but rare in boys. Cushing's disease can be associated with delayed onset or arrest of gonadarche, which is usually corrected by trans-sphenoidal removal of an ACTH-secreting tumor. Hypothyroidism may delay the onset of puberty or menarche; treatment with levothyroxine reverses this pattern. There is likely to be a permanent loss of height if pubertal growth spurt that can result in a normal final height. Celiac disease decreases the growth rate in childhood and adolescence, but with appropriate dietary restrictions final adult height appears normal.

Further, boys with cystic fibrosis have an autoimmune to their sperm that appears at the time of puberty and the appearance of spermatogenesis. Boys with cystic fibrosis have antispermat immunoglobulin M (IgM) antibodies when prepubertal and IgA, IgM, and IgG antibodies during puberty; men with congenital absence of the vas deferens, for comparison, had IgM and IgG antisperm antibodies predominantly.

Boys with sickle cell anemia often exhibit impaired Leydig cell function caused by ischemia of the testes, gonadotropin deficiency, or both factors. Chronic gastrointestinal disease such as Crohn's disease is often accompanied by delayed puberty; therapy to restore nutrition, if successful, enables puberty to progress through the stages of puberty. As GH secretion is usually not affected in AIDS, the poor growth appeared more related to the delay in pubertal development.

Chronic renal disease has been associated with delayed pubertal development and decreased pulsatile gonadotropin secretion related to a decrease in the mass of bioactive and immunoactive LH secreted rather than an alteration of the frequency; successful renal transplantation usually restores gonadotropin secretion.

Patients with nephrotic syndrome have poor pubertal growth, poor secondary sexual development, and deficient gonadotropin secretion in a pattern resembling constitutional delay in puberty. Treatment of glucocorticosteroids with alternate-day glucoocorticoid therapy leads to a late, diminished but prolonged pubertal growth spurt that can result in a normal final height. Children with end-stage renal disease receiving renal or peritoneal dialysis are often delayed in reaching sequential pubertal stages and deficient in linear growth; this loss of growth leads to decreased final height despite the improved growth experienced after renal transplantation. Immuneactive gonadotropin concentrations may be elevated, presumably because of impaired renal clearance, but the response to LHRH is blunted in severe renal impairment. TeBG is elevated in chronic renal failure and free testosterone is low. Although improved growth and pubertal development usually ensue after renal transplantation, the glucocorticoid treatment that follows transplantation presents its own problems. Survivors of renal transplantation who have immune suppression and alternate-day steroid treatment often have delayed onset of puberty and decreased pulsatility of GH and gonadotropins at night.

Advances in the treatment of leukemia have improved the prognosis. Children with early onset and long-term remission experience puberty at an appropriate age or with only slight delay, whereas patients with initial symptoms of leukemia in late childhood may have considerable delay of pubertal development.

The type of therapy for malignancy also influences the age of puberty; radiation to the head may cause hypogonadotropic hypogonadism or GH deficiency, or both, and radiation to the abdomen or pelvis and certain types of chemotherapy, especially if administered during puberty, may impair gonadal function and cause primary hypogonadism. Total-body irradiation for bone marrow transplantation may lead to a decrease in growth in the presence of normal GH secretion. Girls with leukemia treated with CNS radiation demonstrated a diminished pubertal growth spurt and diminished final height; this effect appears to be true whether 24 or 18 Gy is used at a later age, but the final height in boys was reduced only with the higher dose. Further, treatment with 24 Gy before the age of 6 years carries a high risk of short stature. Remarkably, chemotherapy combined with radiation therapy limited to the CNS carries a risk of short stature mainly related to decreased growth of the spine. However, patients treated with chemotherapy without radiation had a normal final height following a period of catch-up growth after the chemotherapy. Secondary malignancies, such as papillary thyroid carcinoma and pulmonary fibrosis, are additional risks with total-body radiation. A follow-up study of over 100 patients treated for acute lymphocytic leukemia before puberty indicated an incidence of obesity of over 45%, indicating the need for dietary counseling in such cases. Hypothyroidism may delay the onset of puberty or menarche; treatment with levotiroxine reverses this pattern. There is likely to be a permanent loss of height if diagnosis is delayed; with thryoxine (T_4) replacement, growth may continue for a longer period after menarche than is the norm but the deficit in height is not regained. Poorly controlled diabetes mellitus can lead to poor growth, fatty infiltration of the liver, and sexual infantilism (Mauriac's syndrome). probably related to poor nutritional status; prepubertal children are most vulnerable to poor glycemic control, and pubertal subjects exhibit normal growth unless severe hyperglycemia occurs. The degree of control necessary to avoid these complications cannot be exactly quantified, but adolescents with even moderately poor control frequently manifest some degree of growth impairment and delayed puberty or irregular menses. Serum IGF-I is decreased in children and adolescents with poorly controlled diabetes mellitus regardless of pubertal stage.

Cushing's disease can be associated with delayed onset or arrest of gonadarche, which is usually corrected by trans-sphenoidal removal of an ACTH-secreting pituitary adenoma. The corticotroph adenoma is the most common prepubertal adenoma. Anorexia nervosa, a common cause of gonadotropin deficiency in adolescence, is a functional disorder, apparently increasing in prevalence in girls but rare in boys, characterized by a distorted body image, obsessive fear of obesity, and food avoidance that can cause severe self-induced weight loss (to less than 85% of normal
weight for age and height or BMI < 17.5 kg/m² after cessation of growth), primary or secondary amenorrhea, widespread endocrine disorders, and even death (specific diagnostic details are in the DSM-IV criteria of the American Psychiatric Association). Other common features include onset in middle adolescence, hyperactivity, defective thermoregulation with hypothermia and sensitivity to cold, constipation, bradycardia and hypotension, decreased basal metabolic rate, dry skin, fine downy hypertrichosis, peripheral edema, and parotid enlargement. The clinician should be aware of the subclinical form. The pathogenesis is multifactorial and includes a genetic factor and a well-characterized psychological component. Anorexia nervosa may rarely occur in association with a primary psychiatric disorder.

It is important to rule out organic disease before the diagnosis of anorexia nervosa is assigned; one girl with macroprolactinoma presented with signs consistent with anorexia nervosa. The prevalence of anorexia nervosa is increased in Turner's syndrome. Hypogonadotrophic hypogonadism is documented in many patients with anorexia nervosa and, in at least part, is related to weight loss. However, unidentified factors may contribute to the amenorrhea of anorexia nervosa, especially when the onset of amenorrhea precedes the onset of severe weight loss. It is not uncommon for a patient with anorexia nervosa to be referred months after the onset of the condition; growth failure may be the first sign of anorexia nervosa, and this condition must be considered in the differential diagnosis of growth failure.

In anorexia nervosa, the concentrations of plasma FSH, LH, leptin, and estradiol and the excretion of urinary gonadotropins are characteristically low. In adult women, there may be a reversion to a circadian rhythm of LH secretion and to the sleep-associated increase in episodic LH secretion characteristic of puberty; in severe cases, the amplitude of the pulsatile episodes is diminished and resembles the pattern in prepubertal children. Similarly, the LH response to LRHR correlates with the severity of the weight loss. In patients who weigh less than 75% of the appropriate weight and have strikingly reduced BMI and percent body fat, there is either a blunted or an absent LH response to the administration of synthetic LRHR and undetectable or small LH pulses. Administration of intravenous LRHR at 90- to 120-minute intervals can stimulate the pituitary to produce LH pulses that are indistinguishable from the normal pubertal pattern. This response further supports the important role of functional LRHR deficiency in the amenorrhea of anorexia nervosa. Serum leptin levels are low, remarkably so with severe malnutrition consistent with the strikingly decreased mass of adipose tissue, and increase when weight is regained. Other hormonal changes include an increased mean concentration of plasma GH and plasma cortisol; low levels of plasma IGF-I, DHEAS, and plasma thyroid stimulating hormone (TSH); a decreased rise in serum prolactin after the administration of thyrotropin-releasing hormone (TRH) or insulin-induced hypoglycemia; and a diminished capacity to concentrate urine.

The restoration of normal endocrine and metabolic function after weight gain suggests that many of these changes are secondary to starvation and severe weight loss; nevertheless, the amenorrhea may persist for months after weight gain, suggesting persistent hypothalamic dysfunction. Treatment of this disorder requires skillful management, understanding, patience, and psychiatric consultation. Various approaches have been used to increase the food intake. In view of the associated mortality, parental alimentation may be indicated in resistant patients with severe weight loss, especially in the presence of infection or an electrolyte imbalance.

In functional amenorrhea, LH and estradiol can be normal, with normal plasma estrogen levels. In swimmers, menstrual cycles were frequently irregular and anovulatory rather than absent, and the plasma concentrations of DHEAS and LH were higher than in normal, with normal plasma estrogen levels.

Exercise, Hypo-Ovarianism, and Amenorrhea (the Female Athlete)

In the late 1970s, reports of amenorrhea in female long-distance runners and delayed menarche in other female athletes, including ballet dancers, figure skaters, and gymnasts, appeared. In 1992 the American College of Sports Medicine defined the female athletic triad of primary or secondary amenorrhea, disordered eating, and osteoporosis or osteopenia derived from the chronic lack of estrogen. Although there are substantial endocrine effects of excessive athletic training in girls, elite prepubertal and pubertal athletes suffer relatively few physical injuries.

Increasing information strengthened the link between increased physical activity and abnormalities of puberty. An incidence of 15% of bulimia, anorexia nervosa, or anorexia athletica was found in 603 Norwegian girls; the athletes most affected were those engaged in sports emphasizing weight. In healthy ballet dancers and female athletes, factors other than

Figure 24-53 47.XXY Klinefelter's syndrome in 17-year-old identical twins. At age 15 gynecomastia was noted. The twins had a eunuchoid habitus and poorly developed male secondary sexual characteristics. Both were 187 cm in height; arm spans were 187 cm and 189.5 cm; the voices were high-pitched; the testes measured 1.8 × 1.5 cm; penis length was 7.5 cm.
intensively trained adolescent girls and their mothers showed a positive correlation between the delayed menarche found in the girls and the age of menarche of their mothers. Likewise, another study of 96 girls demonstrated a relationship between the age of onset of puberty and menarche in athlete's mothers; there is a relationship between the choice of sport and constitutional factors, according to these authors, with no indication that the sport causes changes in growth rate or height. These studies emphasize the role of genetic factors in the age of menarche, pubertal development, and growth rather than the role of energy expenditure. Thus, the biology of pubertal delay in female athletes remains controversial and uncertain.

Although men are less affected than women, males may also be affected by rigorous physical training. Males may have decreased LH response to LHRH and decreased spontaneous LH pulse frequency and amplitude; the serum testosterone is normal or low.

Ballet dancers have a higher incidence of scoliosis than the general population and, as already noted, often have delayed puberty; idiopathic scoliosis in the general population has an association with a statistically earlier age of menarche (0.4 years earlier) and an early adolescent growth spurt. The strongest association with scoliosis is taller stature at the time of the pubertal growth spurt, which, in this study, occurred at an earlier than average age; this combination leads to only a slight increase in final height. Scoliosis usually develops during the pubertal growth spurt and occurs more often in girls with a more rapid pubertal growth spurt. Final height in familial constellations of scoliosis does not vary from the family norm.

Prolactin levels may be elevated in women athletes and could contribute to the delayed menarche found in this group.

Other Causes of Delayed Puberty

Marijuana use has been associated with gynecomastia and is a putative cause of pubertal delay.

Gaucher's disease caused delay in pubertal development in two of three patients in one study.

Girls with familial dysautonomia have delayed menarche and often a severe premenstrual syndrome. The condition is ultimately compatible with pregnancy.

Delayed Puberty and Mood

A prospective study of the intramuscular administration of long-acting testosterone preparations to boys with delayed puberty, aged 14 to 17 years, revealed an effect on mood. The boys were randomly assigned to a course of 200 mg of testosterone enanthate, administered intramuscularly four times at 3-week intervals, or to no treatment. At 1-year follow-up, all of the boys in the testosterone group exhibited excellent growth in stature; growth in the control subjects was significantly lower than that of the testosterone group. Both groups showed improved self-image, and the treated subjects also exhibited notable increases in both school-related and extracurricular social activity. Thus, a relatively brief course of testosterone enanthate had beneficial effects on growth and on inducing or advancing pubertal maturation that was related to improved social function over that achieved simply by the passing of 1 year.

In contrast, however, a study of psychological tests in boys and girls with delayed puberty of mixed causes, including constitutional delay, treated with periods of three doses of steroid alternating with no treatment, demonstrated only one significant treatment effect, namely an increase in withdrawn behavior problems during administration of low-dose estrogen in girls. There were no consistent sex differences. The authors concluded that the administered testosterone or estrogen had minimal effects on behavior problems or mood in adolescents (see earlier for the effects of this treatment schema on sexuality).

Hyponadotropic Hypogonadism: Sexual Infertility Caused by Primary Gonadal Disorders

Primary gonadal failure and the impaired secretion of gonadal steroids lead to decreased negative feedback and elevated LH and FSH levels. The most common forms of primary gonadal failure are associated with sex chromosome abnormalities and characteristic physical findings. Testicular or ovarian dysfunction as an isolated finding is less commonly a cause of pubertal delay.

Klinefelter's Syndrome (Syndrome of Seminiferous Tubular Dysgenesis) and Its Variants

Klinefelter's syndrome, or seminiferous tubular dysgenesis, and its variants occur in approximately 1 in 1000 males and are the most common forms of male hypogonadism. The invariable clinical features include small, firm testes (less than 3.5 cm in length), impaired spermatogenesis, and a male phenotype, usually with gynecomastia and eunuchoid proportions. Elevated gonadotropin levels are found postpubertally; before the age of 12, gonadotropin concentrations are in the prepubertal range. Rarely, low gonadotropin concentrations occur when hyponadotropin hypogonadism is associated with 47,XXY Klinefelter's syndrome.

Hyalinization and fibrosis of the seminiferous tubules and pseudocarcinomatous changes of the Leydig cells develop after puberty; prepubertal testes show only subtle histologic changes, although the testes are small and the germ cell content is reduced. Prepubertally, the disproportionate length of the lower extremities and decreased upper/lower body ratio can identify patients without an increase in arm span. There is variation in Leydig cell function, but the plasma concentration of testosterone tends to be in the normal range until about age 14, after which age it may fail to rise to normal adult levels. The onset of puberty is usually not delayed, but impaired Leydig cell reserve and postpubertal testes may lead to slow progression or arrest of pubertal changes.

Testosterone replacement should be considered when the LH level rises above the normal range of values. Serum estradiol/testosterone ratios and TeBG levels are decreased, but impaired Leydig cell reserve and postpubertal testes may lead to slow progression or arrest of pubertal changes.

Testosterone administration does not appear to reduce the gynecomastia, but dihydrotestosterone and aromatase inhibitors or estrogen receptor antagonists may be effective. If the gynecomastia does not regress, a reduction mammaplasty is required. Tall stature for family size is common in this disorder because of the disproportionate growth of the legs.

Neurobehavioral abnormalities, primarily in language and frontal executive functions, are frequent, and some say universal, in Klinefelter's syndrome. These problems may be severe enough to lead to evaluation in childhood and the postpubertal recognition of the syndrome.

The global I.Q. in unselected populations of subjects with Klinefelter's syndrome is normal or near normal, but verbal I.Q. (VIQ), in contrast to that in Turner's syndrome, is usually lower than performance I.Q. (PIQ). As patients with clinical or psychological problems are referred more often for evaluation, some studies are skewed to suggest more significant deficits than are prevalent in an unselected population of XXY individuals.

Whereas younger patients with Klinefelter's syndrome have a VIQ that is less than their PIQ, there are older adults who have PIQ less than VIQ. It was suggested that PIQ drops in late puberty while VIQ remains stable. Further, prepubertal patients with Klinefelter's syndrome have a VIQ that is less than their PIQ.
relatively high estrogen concentrations characteristic of some patients with Klinefelter's syndrome during puberty, which is reflected as well in the development of gynecomastia. Estrogen is known to enhance verbal skills, and reduced androgen levels decrease visual-spatial function. However, the local aromatization of testosterone to estrogen that is not fully reflected in serum values of these hormones and the varying effect of testosterone and estrogen in Klinefelter's syndrome on physical features such as gynecomastia and habitus make detailed interpretation of these cognitive changes difficult.

Hypotheses have been advanced supporting the effect of prenatal testosterone on cerebral dominance and language and reading pathology, but such explanations are unlikely to explain the difficulties faced by patients with Klinefelter's syndrome as androgen deficiency is not apparent until puberty begins. Anecdotal clinical observation suggests that improvement in psychosocial and self-image problems occurs with testosterone administration, but convincing studies documenting these observations are not yet at hand. Although there is a growing feeling among parents that testosterone treatment in the early pubertal period improves language, reading, and behavior in boys with Klinefelter's syndrome, well-controlled studies supporting this contention are not available. One study did report better mood, less irritability, more energy and drive, less tiredness, more endurance and strength, less need for sleep, better concentration ability, and better relations with others during testosterone treatment of mid-20-year-old adults with Klinefelter's syndrome.

Affected individuals detected by karyotype analysis at birth and in screening studies had minimal impairment (10 to 20 points) in VIQ compared with control subjects and normal full-scale I.Q. Severe retardation is uncommon, although there is an increased prevalence of speech and learning disorders and adjustment problems in adolescence. Psychopathology is rare in most studies, and a 20-year follow-up of 47,XXY individuals showed little or no variation from unaffected controls in employment, social status, mental or physical health, or criminality.

Conditions associated with Klinefelter's syndrome include acrocyanal valvular disease and ruptured berry aneurysms (six times the normal rate), breast carcinoma (20 times the rate in normal men and one fifth that of women); other malignancies such as acute leukemia, lymphoma, and germ cell tumors at any midline site systemic lupus erythematous; and osteoporosis. There is an increased risk of diabetes mellitus and thyroid disease. About 25% of men with Klinefelter's syndrome have osteoporosis.

About 20% of mediastinal germ cells are associated with Klinefelter's syndrome, and they occur at a younger age than the mediastinal germ cell tumors that are not associated with Klinefelter's syndrome (average age 16 versus 27 years in one study). With rare exceptions, these germ cell tumors, which may be located in the midline anywhere from the CNS to the pelvis, secrete hCG and induce sexual precocity. Klinefelter's syndrome needs to be considered in boys with hCG-secreting germ cell tumors, especially if the tumor is located in the mediastinum or CNS.

Survival of childhood cancer is increasing. Most cancer therapy affects testicular function and can lead to adult infertility. Chemotherapeutic agents used in the treatment of nephrotic syndrome or leukemia, such as cyclophosphamide or chlorambucil, have led to Sertoli cell, Leydig cell, and germ cell damage in prepubertal patients; these effects are sometimes reversible. Chemotherapy for childhood Hodgkin's disease, including chlorambucil, vinblastine, mechloethamine (Mustargen), vincristine (Oncovin), procarbazine, and prednisone, may allow spontaneous progression through puberty, but both FSH and LH concentrations may be elevated and the inhibin B concentrations decreased during puberty, indicative of gonadal damage.

The basal serum FSH and the rise in LH and FSH after LHRH are correlated with the dose of cyclophosphamide. Therapy for Hodgkin's disease with COPP and Mustargen, Oncovin, procarbazine, and prednisone (MOPP) can cause severe damage to germinal cells apparently without much effect on Leydig cells even if therapy occurred in the prepubertal period.

Serum FSH is often elevated and inhibit B levels are low in such patients treated with chemotherapy and basal LH is normal although LHRH-stimulated serum LH is elevated; thus, germinal cell damage is evident but Leydig cell function appears normal. In addition, doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine can cause germ cell death. Although some degree of gonadal maturation such as that noted during puberty was considered to be necessary before these drugs could cause gonadal damage, gonadal damage can occur earlier as a result of therapy in the prepubertal period but may not be demonstrable until the age of puberty.

Radiation of the gonads can cause primary testicular failure, usually resulting in azoospermia, although normal testosterone secretion may be associated with elevated LH and FSH values (compensated Leydig cell failure). Because they might be included in a radiation therapy field, the gonads must be shielded from the treatment, if possible. Doses of 0.35 Gy to the testes may lead to temporary aspermia, doses over 2 Gy lead to permanent aspermia, and doses over 15 Gy may cause Leydig cell dysfunction.

Sperm preservation is possible in a boy who will undergo chemotherapy or radiotherapy, although the patient's parents may express concern about the collection of sperm in teenagers by masturbation or electroejaculation. Cryopreservation of sperm in a sperm bank, as carried out for adult patients undergoing orchietomy, is an option. For a prepubertal or early pubertal boy, standard sperm banking techniques may not be appropriate. However, testicular tissue can be preserved freezable and reimplanted later in the subject's own testis or be stimulated to mature for use in intracytoplasmic sperm injection. Other methods of preserving fertility years after treatment for childhood cancers are under consideration. Advances in germ cell preservation are promising, and unexpected developments will undoubtedly emerge over the next two decades.

Male pseudohypoparathyroidism caused by 17-hydroxylase/17,20-lyase (P450c17) deficiency related to mutations in CYP17 is associated with sexual infantilism and a female phenotype; the testosterone biosynthetic defect blocks the synthesis of testosterone and adrenal androgens, impairing masculinization at all stages of development. Associated cortical deficiency and increased mineralocorticoid secretion in this condition lead to hypertension, decreased serum potassium levels, and metabolic alkalosis. Glucocorticoid replacement suppresses ACTH and mineralocorticoid excess and corrects the electrolyte abnormalities, but no sexual development occurs unless exogenous gonadal steroids are administered. Less severe deficiencies are associated with ambiguous genitalia; one case of delayed puberty in a phenotypic male was attributed to partial deficiency of 17,20-desmolase activity. CYP17 mutations leading to isolated 17,20-lyase deficiency are quite rare.

A rare autosomal recessive condition is steroidogenic acute regulatory protein (StAR) deficiency in which the ability to produce C17,20-lyase deficiency are quite rare. Delayed puberty in a phenotypic male was attributed to partial deficiency of 17,20-desmolase activity.

The large adrenal glands may be visualized on sonographic, CT, or MRI scans. Death often occurs in infancy because of unrecognized glucocorticoid and mineralocorticoid deficiency. Affected individuals appear physically to be sexually infantile females, whether their karyotype is 46,XY or 46,XX; because of the absence of gonadal or adrenal androgen production, the affected XY patients develop secondary sexual characteristics including pubic hair. However, surprisingly, XX females even with a null mutation develop female sex characteristics at puberty, including pubic hair and multicystic ovaries, but have either primary or secondary amenorrhea. Apparently, in contrast to the fetal testis, the fetal ovary, which is insensitive to FSH and steroidogenically inactive, is undamaged in fetal life; it remains so until the onset of puberty, when, under FSH stimulation and the recruitment of ovarian follicles, the ovaries undergo progressive

Other Forms of Primary Testicular Failure

Psuedohermaphroditism is a condition in which an individual, who is chromosomically male (46,XY), appears to be female at birth. This condition can occur due to a variety of factors, including genetic, hormonal, and environmental factors. The condition is often associated with internal male reproductive organs and external female genitalia. The cause of pseudohermaphroditism is not always clear, and the condition can be difficult to diagnose.

In most cases, the condition is not progressive and the individual may lead a normal life. However, in some cases, the condition can be associated with fertility issues, and in rare cases, it can be associated with an increased risk of certain types of cancer.

Psychological and Social Aspects

The psychological and social aspects of pseudohermaphroditism can be complex and can vary from individual to individual. The condition can be associated with a range of emotional and psychological issues, including low self-esteem, loneliness, and feelings of isolation.

In some cases, the condition can lead to social and emotional problems, such as social isolation, bullying, and discrimination. In some cases, the condition can also lead to a lack of understanding and acceptance from others, which can further exacerbate the individual's psychological and social issues.

However, with appropriate support and guidance, individuals with pseudohermaphroditism can lead fulfilling and productive lives. It is important to provide them with the necessary support and resources to help them navigate the challenges associated with the condition.

Conclusion

Pseudohermaphroditism is a rare condition that affects individuals with a 46,XY karyotype. Although the cause of the condition is not always clear, it can be associated with a range of physical, psychological, and social issues. With appropriate support and guidance, individuals with pseudohermaphroditism can lead fulfilling and productive lives.
damage and cyst formation.

Luteinizing Hormone Resistance

Presumptive evidence of LH resistance caused by an LH receptor
abnormality on the Leydig cell was reported in an 18-year-old boy with a male phenotype, no male secondary sexual development, gynecomastia, elevated plasma LH levels, and early pubertal plasma testosterone concentrations that did not increase after hCG administration; there was no elevation of testosterone precursor levels.\textsuperscript{1} The testosterone were prepubertal in size and had the microscopic appearance of normal prepubertal testes. Plasma membrane receptor preparations from the testes bound only half as much radiolabeled hCG as control testes.

This autosomal recessive disorder is due to a mutation in the gene encoding the G protein-coupled, seven-transmembrane LH/hCG receptor cell receptor.\textsuperscript{2} in affected males (see Chapter 22): mutations causing a severe compromise in LH/hCG receptor function are associated with XY male pseudohermaphroditism. Another affected phenotype male had a homozygous deletion of exon 10 of the LH receptor.\textsuperscript{3} This deletion causes incomplete loss of function of the LH receptor. Homozygous missense mutations, Ser 616 Tyr, and Ile 625 Lys, are associated with micropenis (but not hypospadias) related to partial impairment of LH receptor function. The Ser 616 Tyr mutant receptor shows an interesting discordance: a poor response to LH but not to hCG.

Nephropathic cystinosis in boys leads to hypergonadotropic hypogonadism.\textsuperscript{4}

Anorchia and Cryptorchidism\textsuperscript{5,6}

In the 46,XY male without palpable testes, it is important to determine whether any testicular tissue is present. The patient may have intra-abdominal testes, which carry an increased risk of malignant degeneration, anorchia (the "vanishing testes" syndrome), in which no testes are found at laparotomy; or retractile testes, a variation of normal.\textsuperscript{7} The presence of a male phenotype and male internal ducts indicates that functioning fetal testes capable of secreting testosterone and AMH were present early during fetal life but degenerated thereafter.

Administration of 3000 U per m\textsuperscript{2} hCG intramuscularly usually evokes an increased concentration of plasma testosterone after 72 hours when functional Leydig cells are present;\textsuperscript{8} lack of a rise in testosterone concentration, in conjunction with an increased plasma concentration of FSH and LH or an augmented gonadotropin response to LRHR,\textsuperscript{9} is evidence for the diagnosis of bilateral anorchia. Alternatively, measurement of AMH indicates the presence of testicular tissue in a range of suspected conditions in prepubertal boys, from anorchia to male pseudohermaphroditism and true hermaphroditism.\textsuperscript{10} Serum inhibin B is a useful indicator of the presence of functional testicular tissue; values were correlated with the testosterone response to hCG administration, values less than 15 pg/mL indicating anorchia.\textsuperscript{11}

Unilateral cryptorchidism versus the presence of a descended testes on one side and none on the other side presents a diagnostic dilemma. In most, but not all (90%)\textsuperscript{12} cases there is testicular compensatory hypertrophy of the descended testes if there is absence of the contralateral testes,\textsuperscript{13} probably because of elevation of FSH secretion. As the finding does not universally predict monorchia, laparoscopy is recommended in this condition.

Cryptorchid testes may descend into the scrotum during more prolonged treatment with hCG (3000 U/m\textsuperscript{2} surface area intramuscularly every other day for six doses),\textsuperscript{14} incremental LRHR,\textsuperscript{15} or a combination of hCG and LRHR treatment.\textsuperscript{16} Although such descent occurs in retractile testes, it can occur in true cryptorchid testes in which descent is not prevented by local anatomical factors. Normally, testicular descent has occurred by 1 year of age; although later descent is described, the incidence is low.\textsuperscript{17,18} Orchidopexy is recommended between 12 and 18 months of age in testes not expected to descend spontaneously.

Two critical steps in the maturation of germ cells are described in the prepubertal testis: (1) at 2 to 3 months of age, the gonocytes (primitive spermatogonia), the fetal stem cell pool, transform into the adult dark spermatogonia, the adult stem cell pool (possibly related to the surge in LH, FSH, and testosterone in early infancy); (2) at 4 to 5 years of age, the onset of meiosis and the appearance of primary spermatocytes occur.\textsuperscript{19} The identification of the gonocyte transformation has influenced recommendations concerning the timing of orchidopexy. Postpubertal orchidopexy is associated with a high (>85%) prevalence of azoospermia or oligospermia.\textsuperscript{20,21} In a study in Copenhagen, the risk of neoplasia was 5% in patients with an intra-abdominal testis, abnormalities of the external genitalia, or an abnormal sex chromosome karyotype compared with 10% (1185) in patients with cryptorchidism who lacked these characteristics.\textsuperscript{22} It has been surmised that cryptorchid testes, even if replaced in the scrotum, may never have normal spermatogenic function as a consequence of an early abnormality in germ cell maturation. vascular damage to the testicular circulation during orchidopexy, or an intrinsic testicular defect.\textsuperscript{23} However, the phenomenon may have been based on a sample of boys who underwent orchidopexy later than is currently believed to be optimal. In a follow-up study of men with cryptorchidism who had an orchidopexy between 1955 and 1975, the paternity rate was 65% for men who had had bilateral cryptorchidism compared with 90% for the formerly unilateral cryptorchid and 93% for control men. The reduction in fertility was supported by semen and hormone analyses.\textsuperscript{24}

Successful fertilization by the use of intracytoplasmic injection of sperm extracted from the testes of cryptorchid men who had orchidopexy after puberty was reported.\textsuperscript{25,26}

Early orchidopexy seems to reduce the risk of carcinoma of the testes,\textsuperscript{27} although dysgenetic testes, even if located in the scrotum, carry an increased risk of malignant transformation.\textsuperscript{28} Undescended testes remain at a higher temperature than descended testes and have a maturation arrest at the conversion of the gonocyte to the spermatogonia, which appears to direct the testes toward malignant degeneration.\textsuperscript{29} Estimates place the incidence of testicular carcinoma at 0.5 per 100,000 boys with an increase of 6% per year in adolescents.\textsuperscript{30} Skakkebaek and co-workers\textsuperscript{31} expressed concern that adverse environmental factors may be important in the apparent increase in testis cancer, cryptorchidism, hypospadias, and low semen quality. A study of 794 men with testicular cancer in England reported that the increasing performance of orchidopexy before 10 years of age appears to have reduced the increased risk of testicular carcinoma associated with undescended testes.\textsuperscript{32} There is a small risk of carcinoma of the testes in puberty, but the absence of carcinoma in situ in puberty is not an assurance that carcinoma will not develop in adult life. Periodic sonography of the testis is recommended after the onset of puberty.\textsuperscript{33} At present, the earlier the orchidopexy is carried out, the better for ultimate function and reduced risk of malignant degeneration.\textsuperscript{34} One year is a useful age at which to consider orchidopexy for undescended testes because it is an age at which the likelihood of spontaneous descent lessens but the benefits to the testes of orchidopexy remain.

The risk of breast cancer is increased in men with a history of undescended testes, orchidopexy, orchitis, testicular injury, infertility, or any cause of delayed puberty. This risk is associated with the gynecomastia that occurs in these conditions.\textsuperscript{35}

Syndrome of Gonadal Dysgenesis and Its Variants (Turner's Syndrome)

See also Chapter 22.\textsuperscript{36} The most common form of hypergonadotropic hypogonadism in the female is the syndrome of gonadal dysgenesis or Turner's syndrome and its variants, a sporadic disorder with an incidence of 1 per 2500 liveborn girls.\textsuperscript{37} In which all (X chromosome monosomy with haploinsufficiency) or part of the second sex chromosome (partial sex chromosome monosomy) is absent. About 99% of 45,X concepts abort spontaneously and 1 in 15 spontaneous abortions has a 45,X karyotype.\textsuperscript{38} The 45,X karyotype is associated with female phenotype, short stature, sexual infantilism, various somatic abnormalities, and frequent fetal demise.

Sex chromosome mosaicism or structural abnormalities of an X or Y chromosome may modify the features of this syndrome, although about 40% of individuals with the five features noted previously have mosaicism or structural abnormalities of the X chromosome. Thus, we may view the syndrome of gonadal dysgenesis and its variants as a continuum ranging from the typical 45,X phenotype to a normal male or female phenotype.\textsuperscript{39} Comprehensive recommendations for the diagnosis and management of Turner's syndrome have been presented by an international committee.\textsuperscript{40}
This karyotype is found in approximately 60% of cases of Turner's syndrome. \[22\] The short stature is due to loss of a homeobox-containing gene located on the pseudoautosomal region (PAR 1) of the short arms of the X (Xp22) and Yp11.3 chromosomes. \[23\] The gene is called \textit{SHOX} (short stature homeobox-containing gene) \[24\] or \textit{PHOG} (pseudoautosomal homeobox osteogenic gene). \[25\] Because it is located on the pseudoautosomal region of the short arm of the X and Y chromosomes, it escapes X inactivation.

\textit{SHOX} haploinsufficiency is responsible for, in addition to abnormal growth, mesomelic growth retardation and Madelung's deformity of the wrist (bilateral bowing of the radius with a dorsal subluxation of the distal ulna) \[26\] in Leri-Weill dyschondrosteosis (\textit{SHOX} haploinsufficiency). Langer mesomelic dysplasia, which includes severe dwarfism with striking hypoplasia or aplasia of the ulnar and fibula, is due to \textit{SHOX} nullizygosity. \textit{SHOX} haploinsufficiency appears to be responsible for -2.0 SD of the approximately -3.0 SD deficit in stature and the skeletal abnormalities in Turner's syndrome. \[27\] A patient with complete gonadal dysgenesis and tall stature had a 45,X/46,der(X) and three doses of the \textit{SHOX} gene because of the \textit{SHOX} duplication on the der(X) chromosome. \[28\]

Turner's syndrome may be seen in the newborn period. In 45,X abortuses there have edema and large hygromas of the neck that may be seen with prenatatal ultrasound studies; this lymphectic defect is the basis for the loose skinfolds that ultimately form the webbed neck (pterygium colli). Affected newborn infants may also have lymphedema of the extremities; the term Bonnevie-Ullrich syndrome has been applied to newborn infants with these features of Turner's syndrome. It is important to determine whether coarctation of the aorta or a bicuspid aortic valve or both are present because of the risk of hypertension and aortic rupture (see Chapter 22).

Features noted during childhood are spread to various locations in the body. Frequent features are distinct faces with micrognathia, "fishmouth" appearance, high-arched palate with dental abnormalities, epicanthal folds, ptosis, low-set or deformed ears, short neck with low hairline and webbing (pterygium colli), and recurrent otitis media often leading to hearing impairment; about 25% of affected adults require hearing aids. \[29\] A broad, shield-like chest leads to the appearance of widespread nipples; the areolae are often hypoplastic. Skeletal defects include short fourth metacarpals and cubitus valgus (which may develop after birth), Madelung's deformity of the wrist (in about 7%), genu valgum, and scoliosis. The skin demonstrates extensive pigmented nevi, a tendency to keloid formation, and hypoplastic nails. \[30\] Lymphatic obstruction leads not only to the infantile puffiness of extremities and pterygium colli but also to a distinctive shape of the ears. Cardiovascular anomalies include coarctation of the aorta in about 10% (40% have associated webbing of the neck), aortic stenosis, and bicuspid aortic valves; the latter individuals are at risk for a dissecting aortic aneurysm. \[31\]

An echocardiogram of the cardiovascular system must be obtained. Prophylactic antibiotics are indicated if an anatomic abnormality is demonstrated. Abnormal phevocalceal collecting systems, abnormal position or alignment of the kidneys, and abnormalities of the gonadals are found in Turner's syndrome. The X chromatin pattern was negative, and the karyotype was 45,X. She was short (height 134.5 cm; height age 9.5 years) and sexually infantile except for the appearance of sparse pubic hair, and exhibited characteristic stigmata of the syndrome: a short webbed neck, shield-like chest with widely separated nipples, bilateral metacarpal signs, ptosis over the dorsum of the fingers, cubitus valgus, increased number of pigmented nevi, characteristic facies, and low-set ears. The bone age was 13 /2 years; urinary 17-ketosteroids 5.1 mg/day; urinary gonadotropin greater than 100 mIU/day. Vaginal smears and the urocytogram showed an immature pattern in which only squamous cells were absent. With estrogen therapy, female secondary sexual characteristics were induced; the cyclic administration resulted in periodic estrogen withdrawal bleeding. Right, A 45,X, 9/11/2-year-old patient with Turner's syndrome. Apart from short stature (height 118 cm; age 8 10/2 years), increased pigmented nevi, and subtle changes in the fingers and toes, she had few somatic anomalies. In contrast to the patient at the left, the main clinical feature was short stature.

Abnormal vascular supply to the kidney are encountered in 30% to 60% of patients, and recurrent urirary tract infections are uncommon. \[32\] Defects of the gastrointestinal system include intestinal telangiectasias and hemangiomatose that rarely lead to massive gastrointestinal bleeding. Furthermore, the prevalence of inflammatory bowel disease, chronic liver disease, and colon cancer is increased. \[33\] The uterus and fallopian tubes are infantile. Pelvic ultrasonography or MRI usually permits the detection of even a small uterus in these patients and commonly streak gonads. Autoimmune diseases, such as Hashimoto's thyroiditis (a 16-fold relative risk) and Graves' disease, are common, \[34\] and an association with juvenile rheumatoid arthritis and psoriatic arthritis is described. Glucose intolerance resulting from increased insulin resistance is also common after the age of puberty; in some, this may be due to associated obesity. The risk of type 2 diabetes mellitus is increased. \[35\]

Affected patients are usually small at birth because of intrauterine growth retardation with a mean deficit in length of 2.6 cm (-1.24 SD) and exhibit a slow childhood growth rate that results in a loss of about 8 to 9 cm (-3.0 SD) by age 3 years. \[36\] This study, derived from longitudinal measurements on 47 full-term patients with Turner's syndrome, indicates that the first 3 years of life contribute a major part of the height deficit. Further, there is a decrease in growth rate at the time of expected puberty and failure to undergo a pubertal growth spurt. \[37\] Individuals with Turner's syndrome in the United Kingdom and United States have a mean final height of approximately 142 to 143 cm, about 20 cm less than the average height of normal women; the adult stature of these patients correlates with midparental height and with the height of unaffected women of the same ethnic group. \[38\] Their pattern of growth does not suggest that these individuals are GH-deficient. \[39\] Rather, haploinsufficiency of the \textit{SHOX} gene located in the pseudoautosomal region on the short arm of X and Y (see earlier) is estimated to contribute two thirds of the height deficit. It is postulated that a second gene on the short arm of X that does not undergo X inactivation contributes the other one third of the deficit.

Specific growth curves are available for plotting the growth of affected children. \[40\] In a group of girls with Turner's syndrome and spontaneous puberty, height velocity was transiently higher during puberty than in girls with ameneorrhea, but final adult height was not different (see Chap. 22). GH treatment is now approved by the FDA for Turner's syndrome to increase height. Trials of the effect of treatment with rhGH in children with Turner's syndrome began in 1983. It soon became apparent that hGH administration increased the rate of growth, and data are now available on final height including the results of some randomized dose-response trials from groups around the world.

The average height gain has varied from 4 to 16 cm. \[41\] This variability in gain in height is incompletely understood, but many factors have been implicated including the age of initiation of therapy, dose duration, age of beginning estrogen replacement (especially number of years from beginning hGH treatment), number of injections per week, compliance, and whether the last measured height represented final height. \[42\] The weekly dose of hGH is 0.375 mg/kg divided into seven daily doses. It is important to individualize the dose. The Dutch Advisory Group on Growth Hormone reported that a treatment regimen that gradually increased the dose 0.63 mg/kg per week elicited a 16.0 to 4.1 cm increase in height. It is now apparent that the early initiation of hGH therapy (e.g., 2 to 8 years of age) and a mean duration of treatment of about 7 years can lead to the majority of treated patients achieving a final height greater than 150 cm; in the Dutch study, the mean final height was 162.3 ± 6.1 cm with the high-dose schedule. \[43\] The timing of the introduction of estrogen can have an important effect on final height, \[44\] but with an early age of initiation of GH therapy, low-dose estrogen can be introduced at an appropriate age (about age 13) without compromising adult height. At present, hGH treatment of patients with Turner's syndrome has been safe; untoward events are infrequent.

It is essential that the parents are fully informed about the pros and cons of hGH treatment and that the child is informed in an age-appropriate manner about the use of hGH. The long-term protocol is laborious and expensive and the treatment is invasive but, with the use of new devices for administration, minimally painful.
The appearance of pubic hair is often delayed in the syndrome of gonadal dysgenesis, even though adrenarche, as assessed by the increase in concentration of plasma DHEAS, occurs at the normal age. The pubic hair of affected individuals is sparse, but estrogen therapy increases the growth of pubic hair despite a lack of increase in adrenal androgen secretion. The streak gonads result in sexual infantilism; rarely, probably in about 10% of cases, puberty, menarche, and, even more rarely, pregnancy may occur.

As described earlier, skeletal abnormalities are a common feature and may affect areal BMD determinations. Most untreated children have a normal volumetric bone density (by phalangeal radiographic absorptiometry), in contrast to the less accurate areal BMD in patients with Turner's syndrome, compared with normal girls. Recent studies have not confirmed an increased prevalence of wrist fractures. In an HGH-treated group of girls in whom estrogen therapy was begun at 12 years of age, BMD SD scores were above the mean value. When peripheral quantitative CT, a state-of-the-art technique for assessing volumetric BMD, was used to determine volumetric BMD at two radial sites, a decrease in radial bone mass was found because of a reduction in cortical bone thickness (the endocortical bone surface) with a corresponding increase in bone marrow cross-sectional area, but trabecular volumetric BMD was normal. These reports reiterated the limitations of estimates of areal BMD by DEXA scans in contrast to volumetric BMD in Turner's syndrome. Human GH treatment in childhood appears to have a positive effect on BMD. Estrogen therapy is critical for the prevention and repair of osteoporosis. Although estrogen therapy is important in adolescents and adults, the optimal dose preparation and site of delivery for the prevention of osteoporosis are not known. Nor are data available on the usefulness or adverse effects of continuing of rhGH treatment after final height is achieved in adolescence.

The IQ is normal when verbal ability including comprehension and vocabulary is considered, but spatiotemporal processing, visuomotor coordination, mathematical ability (particularly in geometry) may be impaired, leading to a decrease in the performance IQ. The neurocognitive phenotype associated with Turner's syndrome maps to distal Xp.

Girls with Turner's syndrome have a normal VIG but a discrepancy between VIQ and PIQ, with the latter about 1 SD below the mean value. This is opposite to the pattern found in Klinefelter's syndrome (see earlier). Turner's syndrome is associated with impaired visuconstructional or visual-perceptual abilities in association with executive dysfunction and decreased attention span, which can lead to learning difficulties. In most studies visual-spatial abilities are impaired in girls with Turner's syndrome, but one study found no specific deficits in visual-spatial or tactile-spatial tasks.

Normal girls perform better on motor tasks as they get older, a trend that is not found in Turner's syndrome. Although one study found diminished lateralization of motor tasks, a later study found no difference in lateralization and performance of motor tasks in individuals with Turner's syndrome compared with control subjects; there was superior performance of the dominant or right hand in contrast to the nondominant or left hand.

Anatomic changes of the brain and neurocognitive changes occur in Turner's syndrome. There are consistent MRI abnormalities in the right parietal lobe and the occipital lobes that show decreased volumes in these areas implicated in visuospatial processing. Using positron emission tomography, Murphy and colleagues showed decreased glucose metabolism in the right parietal and occipital lobes. These anatomic data relate to the difficulties in visual-spatial skills found in most studies of girls with Turner's syndrome because these problems are most closely linked to the right parietal region.

Girls with Turner's syndrome resemble normal girls in verbal and language skills, but there are frequently difficulties with memory and attention and decreased arithmetic skills, related to mistakes on operation and alignment processes; and girls with 45,X mosacom with a 46,XX cell line, 45,X/46,XX, scoring closer to normal than those with other types of mosaicsisms. However, girls with Turner's syndrome can score higher on reading achievement tests than predicted by I.Q. or age; this hyperliteracy is a strength in many girls with this disorder. Only 3.3% of girls with Turner's syndrome have mental retardation in the absence of a variant of the syndrome caused by a ring X chromosome.

Because most girls lack ovarian estrogen production and are treated during the teenage years with exogenous estrogen (hormone replacement therapy), Turner's syndrome provides an opportunity to determine the effects of estrogen on neurocognitive function. There appear to be estrogen-dependent and estrogen-independent tasks that are affected in Turner's syndrome. However, there is controversy about which are estrogen-dependent and which are not. For example, visual-spatial perceptual deficits appear to begin in childhood and persist into adult life unaffected by estrogen treatment according to some studies. However, another group of studies show that the effects of estrogen are dependent on dose and time, with untreated patients and those treated with high-dose or long-term therapy performing equally poorly.

Thus, girls with Turner's syndrome improve spontaneously in testing on visuospatial abilities from younger than 12 years to older than 15 years of age, and the older girls treated with estrogen for 3 to 24 months improved further. However, the ability of those treated with estrogen for more than 2 years decreased to that of untreated age-matched Turner's patients. A decrease in spatial abilities has been reported in normal girls going through puberty; it is suggested that this is another example of a biphasic effect of estrogen, with low levels, as in puberty, fostering spatial ability but higher levels, at the end of puberty and thereafter, suppressing such ability. Some motor-related skills and nonverbal processing were performed more rapidly in estrogen-treated girls with Turner's syndrome. Study of event-related potentials in preteen and post-teen girls with Turner's syndrome compared with age-matched controls demonstrated congenital and age-related abnormalities; age-related abnormalities are later ameliorated by estrogen treatment if started early enough. The results of a double-blind study of estrogen versus placebo treatment for 1 to 3 years in 7- to 9-year-old girls with Turner's syndrome show direct effects of estrogen. These girls were part of a larger double-blind study to determine the effect of GH and estrogen on final height. GH therapy in Turner's syndrome led to an increased growth rate. In addition, the girls felt better about their attractiveness, intelligence, and popularity; they perceived that they experienced less teasing, and there was no effect on school performance with GH therapy. Girls with Turner's syndrome younger than 6 years did not perceive that they had a problem with height, but by 7 to 12 and especially 13 to 15 years, affected girls have a strong desire for GH therapy and even unrealistic expectations of what GH therapy might accomplish in terms of adult height. Estrogen therapy improved self-esteem even if there remained a significant difference in height between Turner girls and RGW normal range. GH did not affect the nonverbal neuron-cognitive defects in Turner's syndrome, nor did it affect IQ or achievement scores.

Placebo-treated girls with Turner's syndrome performed less well than either control or estrogen-treated individuals with Turner's syndrome in recall of digit span backward and immediate and delayed recall of the children's word list, suggesting that estrogen replacement therapy improves verbal and nonverbal memory. This observation raises the possibility that a prepubertal deficit in estrogen may affect performance of these tasks as well as suggesting a potential role for low-dose estrogen replacement therapy in late prepuberal girls with Turner's syndrome. These results are similar to the improvement in short-term and long-term verbal memory found in postmenopausal or surgically castrated women treated with estrogen replacement therapy.

Treatment with estrogen for more than 4 years appeared to move the scores for girls with Turner's syndrome on self-esteem and psychological well-being toward normal control values as they reached 16 years of age, compared with a significant difference documented at 12 years of age. No such change occurred in the nonestrogen-treated group, suggesting that the estrogen effects caused the change rather than the passage of years.
Several mechanisms are proposed to explain these estrogen effects: (1) estrogen acts as a neuromodulator in a transient time frame, (2) estrogen alters synapse formation and remodeling in a permanent time frame, or (3) both mechanisms. Thus, estrogen may function as an organizational agent in the brain of the young but as a stabilizing agent in older individuals.

The increase in mental health problems documented in Turner's syndrome may be rooted in the increased peer ridicule experienced by girls with Turner's syndrome as opposed to a biologic abnormality. The teasing can by itself lead to decreased self-image and depression. There is an increased risk of impaired social adjustment in Turner's syndrome. 45,X females with Turner's syndrome have higher ratings of social and attention problems and withdrawn behaviors than their own sisters. The risk is higher if the single X chromosome comes from the mother (X0) rather than the father (X0). Individuals with Turner's syndrome have difficulty in inferring affective intention from facial appearance. As an explanation for these phenomena, there appears to be a locus on the X chromosome on Xq or close to the centromere on Xp that escapes X inactivation and affects social cognition. When the locus was inherited from the father, the 45,X individuals were significantly better adjusted, with superior verbal and higher order executive function skills, which mediate social interactions. If expressed only on the paternally derived X chromosome, the existence of this putative locus may explain, in part, why 46,XY males (whose single X chromosome is maternal) are more vulnerable to developmental disorders of language and social cognition, such as autism, and 46,XX males. Additionally, in addition to haploinsufficiency and its consequences, sex chromosome imprinting appears to be a factor in the Turner syndrome phenotype.

In the first example of an imprinted gene on the X chromosome, the locus resides in the pericentric region of the short arm or on the long arm of the X chromosome. Skuse and coworkers postulated that this imprinted gene may play a role in male-female differences in social behavior and developmental disorders. It is useful to monitor the patient's progress in high school mathematics. Gender identity and sexual orientation are female. Although it has been generally accepted that these patients do well in their psychological development, consistent with the report of Skuse and associates. A study of 103 children with Turner's syndrome demonstrated a significant decrease in social competence score, an increase in total behavior problems, and social and attention problem scales with difficulty in schooling, in peer relationships, and in concentration as well as immaturity, hyperactivity, and nervousness; the origin of the X chromosome was not determined. Structural abnormalities of the X chromosome were associated with more behavior problems than a missing X chromosome or mosaicism of the X chromosomes. Hyperactive behavior usually improves after the age of puberty. Mental retardation and a "severe" phenotype are associated with a small ring X chromosome to undergo X inactivation resulting in X chromosome disomy for genes that undergo X inactivation.

The origin of the single X chromosome affects memory performance as well because those with a maternally derived X have increased verbal forgetting but normal nonverbal forgetting whereas those with a paternally derived X chromosome have the opposite pattern of problems. Sex Chromatin Positive Variants of the Syndrome of Gonadal Dysgenesis

Mosaicism of 45,X/46,XX, 45,X/47,XXX, or 45,X/46,XX/47,XXX chromosomes is associated with a chromatin-positive buccal smear and usually fewer manifestations of the syndrome of gonadal dysgenesis. Likewise, structural abnormalities of the X chromosome can be associated with fewer phenotypic features of the syndrome. Lack of genetic material on the long or the short arm of the second X chromosome can cause decreased gonadal function; loss of all or part of the short arm of the X leads to the physical findings of Turner's syndrome (see Chapter 22). Depending on the location and extent of the deletion on the short arm of the X chromosome, these patients are more likely to have modest pubertal growth and some spontaneous pubertal development.

Sex Chromatin Negative Variants of Gonadal Dysgenesis

These variants include 45,46,XY mosaicism and structural abnormalities of the Y chromosome. Affected individuals vary in phenotype from that of classical gonadal dysgenesis to that of ambiguous genitalia to phenotypic males. Patients present with short stature, delayed puberty, and a history of hypospadias repair. There is variable testicular differentiation, ranging from a streak gonad to functioning testes. Patients with mosaicism involving a Y cell line or abnormalities of the Y chromosome are at risk for neoplastic transformation of the dysgenetic testes. Gonadoblastomas, benign nonmetastasizing tumors, may arise within the gonad and produce either testosterone or estrogen; the neoplasm may be calcified sufficiently to be detected on an abdominal radiograph. Thus, the appearance of feminization or virilization in a patient with dysgenetic gonads and a Y cell line may indicate gonadoblastoma formation. Of greater significance is the increased prevalence of malignant germ cell tumors arising within the dysgenetic gonad or gonadoblastoma. Such tumors occur more often in postpubertal subjects and rarely in children. The management of gonads in patients with a Y cell line is discussed in Chapter 22.

46,XX and 46,XY Gonadal Dysgenesis

Pure gonadal dysgenesis refers to phenotypic females with sexual infantilism and a 46,XX or 46,XY karyotype without chromosomal abnormalities. Familiar and Sporadic 46,XX Gonadal Dysgenesis and Its Variants

The usual phenotype of 46,XX gonadal dysgenesis includes normal stature, sexual infantilism, bilateral streak gonad, normal female internal and external genitalia, and primary amenorrhea. The streak gonad occasionally produces estrogen or androgens, but malignant transformation is rare. Incomplete forms of this condition may result in hypoplastic ovaries that produce enough estrogen to cause some breast development and a few menstrual periods followed by secondary amenorrhea. This heterogeneous syndrome occurs sporadically or with autosomal recessive inheritance and in some instances is associated with other congenital malformations; some familial cases have been associated with sensorineural deafness (Perrault's syndrome) (see later).

Familiar and Sporadic 46,XY Gonadal Dysgenesis and Its Variants

A phenotype that includes female genitalia with or without clitoral enlargement, normal or tall stature, bilateral streak gonads, normal müllerian structures, sexual infantilism, and a eunuchoid habitus is typical of 46,XY gonad dysgenesis. About 15% of the patients have a deletion or mutation in the SRY gene. If the dysgenetic testes produce significant amounts of testosterone, slight clitoral enlargement may occur at birth and virilization may ensue at puberty. The incomplete form of 46,XY gonadal dysgenesis may involve any degree of ambiguity of the external genitalia and internal ducts. The risk of neoplastic transformation of the streak gonads or dysgenetic testes is increased, and gonadectomy is indicated. The disorder is usually transmitted as an X-linked or sex-limited autosomal dominant trait, less commonly as an autosomal recessive trait. A novel homozygous missense mutation in exon 1 of the desert hedgehog gene was reported in a patient with polyneuropathy associated with partial 46,XY gonadal dysgenesis.

Other Causes of Primary Ovarian Failure

Primary ovarian failure is increasing in prevalence as a consequence of the long-term effects of cytotoxic chemotherapy and radiation as these agents prolong life in children and adolescents with cancer. Radiation Therapy

Radiation therapy that includes the ovaries within the field can cause primary ovarian failure; a dose of 4 Gy to the ovaries leads to sterility in 30% of young women and 100% of older women. It is useful surgically to move the ovaries out of the radiation field; ovarian transposition before radiation therapy is compatible with normal menses, pubertal development, and pregnancy in most cases. The uterus may also be affected by radiation and may not expand normally during pregnancy. Careful endocrine follow-up of these children and adolescents is essential.
Successful treatment of childhood acute lymphoblastic leukemia is now commonplace. In a large study by Quigley and colleagues, after cytotoxic chemotherapy boys and girls had enhanced germ cell damage as evidenced by increased FSH secretion and boys had decreased testicular size for the stage of puberty. The concentration of plasma inhibin B is usually decreased, a sensitive indicator of damage to the germinal epithelium, and the girls at puberty had evidence of a compensated decrease in ovarian follicular function. Quite likely as a result of cranial radiation, the mean age of menarche was advanced about 12 months despite the primary ovarian damage; puberty was not advanced in the boys. The type of chemotherapy is related to the effects on the gonads. Nitroso compounds (carmustine and lomustine) or procarbazine for the treatment of brain tumors has been linked to primary gonadal failure manifested by elevated plasma gonadotropin levels in boys and girls; the boys had small testes but were able to secrete adequate testosterone for their pubertal stage. Adjuvant chemotherapy for localized osteosarcoma in the prepubertal period is compatible with ovarian function and fertility.

Although it was previously thought that cancer therapy does not cause gonadal damage in prepubertal individuals, current evidence suggests otherwise. Prepubertal boys and girls treated with abdominal radiation for Wilms' tumor plus chemotherapy (dacarbazine, vincristine with Adriamycin, or cyclophosphamide in most) may experience gonadal damage, whereas those given chemotherapy alone usually do not. The ovary is less vulnerable to the effects of radiation and chemotherapy than the testis. The prevalence of ovarian damage does not appear to be as high as testis. Regular menses are reported in a majority of females treated as children. Nevertheless, age at treatment has a significant role: treatment between 13 and 19 years of age was associated with a more than twofold increase in premature ovarian failure during the third decade. Attempts to protect the gonads by suppressing the pituitary-gonadal axis with gonadal steroids or LHRH agonists are ineffective.

Autoimmune Oophoritis

Premature menopause may occur at any age before the normal climacteric and has been reported in adolescent girls; cessation of ovarian function usually occurs as secondary amenorrhea. Autoimmune oophoritis can cause ovarian failure leading to primary amenorrhea, oligomenorrhea, arrest of puberty, and occasionally cystic enlargement of the ovaries. Most often it is associated with other autoimmune endocrinopathies, especially autoimmune Addison's disease, in which it may precede the onset of adrenal insufficiency, but it rarely, if ever, occurs in isolated premature ovarian failure.

Autoimmune oophoritis is present in more than 20% of patients with autoimmune adrenal insufficiency. Various autoantibodies have been detected in autoimmune oophoritis, including autoantibodies to cytotome P450 steroidogenic enzymes (P450scc, P450c17, P450aromatase), some are organ-specific, whereas others react with antigens in more than one tissue and more than one cell type. Glucocorticoid therapy may improve, at least temporarily, ovarian function.

Miscellaneous Causes of Ovarian Failure

Homogamous galactosemia is commonly associated with primary ovarian failure (from failure to develop puberty to primary or secondary amenorrhea and premature menopause), but puberty is usually normal in males and the risk of testicular dysfunction is low; compound heterozygotes have normal onset of puberty.

Dyspasia and Premature Ovarian Failure

A rare autosomal dominant disorder involving eyelid dysplasia and premature ovarian failure is due to haploinsufficiency of the FOXL2 gene, a member of the winged helix/tailless family of transcription factors. The eyelid abnormalities include small palpebral fissures, ptosis, and a skinfold extending inward and upward from the lower lid (epicanthus inversus). The gene is expressed in the follicular cells and the mutations that lead to haploinsufficiency are associated with an increased rate of follicular atresia; the degree of ovarian failure is variable from primary amenorrhea to irregular menses and premature ovarian failure, ranging from normal-appearing ovaries on ultrasonography to streak gonads and on ovarian biopsy a variable number of primordial follicles. The infertility component of the syndrome is limited to the female.

Congenital disorders of glycosylation-1 (carbohydrate-deficient glycoprotein syndrome type I) constitute an autosomal recessive disorder associated with circulating glycoproteins deficient in their terminal carbohydrate modifications, including a wide range of glycoproteins, enzymes, binding proteins, and coagulation factors. A typical isoform pattern of serum transferrin on isoelectric focusing is used as a diagnostic test. The dominant clinical features are neurologic manifestations of involvement of the central and peripheral nervous system. Among the other organ systems affected is the pituitary-gonadal system.

The hypergonadotropic hypogonadism is more severe in females than males who virilize at puberty. There are two interesting aspects: both the ovary and the pituitary gland are affected. The affected girls have sexual infantilism; the ovaries are hypoplastic or atrophic. High serum FSH and LH levels exhibit normal electrophoretic patterns but appear to have decreased but not absent FSH bioactivity in an FSH bioassay, and in the only three girls tested, a response to the administration of human menopausal gonadotropin was indicated by an increase in serum estradiol and, in one patient, ovarian follicular growth. These observations suggest an abnormality in both the FSH molecule and the ovary, in the latter case a defect in the configuration and activation of the FSH receptor itself and the binding of ligand or a postreceptor defect.

Resistant ovary is a heterogeneous cause of primary hypogonadism, a syndrome associated with elevated concentrations of plasma FSH and LH and ovaries that contain primordial follicles. The syndrome is usually idioptic, but an increasing number of genetic abnormalities have been described in addition to the more common X-chromosomal defects.

Follicle-Stimulating Hormone Receptor Gene Mutations and Hypergonadotropic Hypogonadism

The FSH receptor is a member of the G protein-linked receptor seven-transmembrane superfamily; it has a large, extended extracellular ligand-binding domain. The eye of abnormalities include small palpebral fissures, ptosis, and a skinfold extending inward and upward from the lower lid (epicanthus inversus). The gene is expressed in the follicular cells and the mutations that lead to haploinsufficiency are associated with an increased rate of follicular atresia; the degree of ovarian failure is variable from primary amenorrhea to irregular menses and premature ovarian failure, ranging from normal-appearing ovaries on ultrasonography to streak gonads and on ovarian biopsy a variable number of primordial follicles. The infertility component of the syndrome is limited to the female.

The FSH receptor mutation in the Finnish patients is not a null mutation. It remains to be determined whether the loss or complete inactivation of the FSH receptor leads to failure of puberty and sexual infantilism or to estrogen synthesis by the immature ovarian follicles described in the FSH subunit knockout mouse. Affected males in these families are normally masculinized at puberty but tend to have small testes. They have a variable degree of spermatogenic insufficiency but not azoospermia, increased plasma concentrations of FSH and LH, decreased inhibin levels, and normal plasma testosterone values.
could be associated with delayed puberty. In the affected female, on the other hand, LH/hCG resistance does not affect pubertal maturation but leads to amenorrhea with high serum LH levels but normal FSH and estradiol concentrations.\footnote{1508}

**Polycystic Ovary Disease**

Polycystic ovary disease or functional ovarian hyperandrogenism does not delay the onset of puberty but often delays menarche or causes menstrual abnormalities\footnote{1509} (see Chapter 22).

**Noonan's Syndrome (Pseudo-Turner's Syndrome, Ullrich's Syndrome)**

Individuals with Noonan's syndrome (see Chapter 29) have webbed neck, phtosis, down-slaning palpebral fissures, low-set ears, short stature, cubitus valgus, and lymphedema, and hence this phenotype has been called pseudo-Turner's syndrome.\footnote{1510} Features that differentiate these individuals from those with Turner's syndrome include triangular faces, pectus excavatum, right-sided heart disease (e.g., pulmonic stenosis), often with valve dysplasia, or atrial septal defect, hypertrophic cardiomyopathy, varied blood clotting defects, and an increased incidence of mental retardation. Females with Noonan's syndrome have normal ovarian function. Males have normal differentiation of external genitalia but may have undescended testes; germinal aplasia or hypoplasia and impaired Leydig cell function may be present.\footnote{1511} Puberty may be delayed an average of 2 years.\footnote{1512} Stature is decreased, usually following the -2 SD curve; the pubertal growth spurt is often delayed or attenuated but final height is usually at the low limits of normal.\footnote{1513} Administration of hGH increased the growth rate, but long-term effects are not yet available.\footnote{1514}

Adult males with Noonan's syndrome are reported to have osteopenia, which has been attributed to estrogen deficiency because estrogen administration improves the decreased bone mineral content.\footnote{1515} Patients who have sufficient ovarian function to undergo spontaneous pubertal development and menarche have adequate BMD compared with those in whom puberty was induced by estrogen and who exhibited osteopenia despite hormone replacement.\footnote{1516} Noonan's syndrome is usually inherited as an autosomal dominant trait.\footnote{1517} A gene implicated in Noonan's syndrome has been localized to the long arm of chromosome 12 (12q 24.1).\footnote{1518} Mutations in PTPN11, the gene encoding the non-receptor protein tyrosine phosphatase SHP-2, which contains RE Src homology-2 (SH2) domains, account for about 50% of cases. The incidence is estimated as 1 in 1000 to 1 in 5000. One parent may have features of the syndrome in 40% to 60% of cases. About 50% of cases are thought to be the result of new mutations.

**Frasier Syndrome**

Chronic renal failure is combined with gonadal dysgenesis in the Frasier syndrome.\footnote{1519} This diagnosis should be considered in any phenotypic female with end-stage renal disease (related to focal segmental glomerulosclerosis) and sexual infantilism; the karyotype may be 46,XY or 46,XX.\footnote{1520}

**Diagnosis of Delayed Puberty and Sexual Infantilism**

See Figure 24-55 and Figure 24-56 and Table 24-26. Signs of puberty have not yet appeared in 0.4% of normal boys by age 13 years old or 15% of normal girls by age 13 years old.\footnote{1521}

The diagnosis of hypergonadotropic hypogonadism is readily established by elevation of random plasma LH and FSH concentrations. However, the differential diagnosis of hypergonadotropic hypogonadism versus constitutional delay in growth and adolescence is more difficult because of the overlap in physical and laboratory findings in the two conditions, including inability to differentiate between normal and low concentrations of serum gonadotropins  (Table 24-27). No single test consistently makes this distinction. The majority of boys with pubertal delay have a self-limited variant in the tempo of growth and pubertal onset. The task of the physician is, on the one hand, to avoid a costly investigation of an essentially healthy boy while, on the other, identifying those who have an underlying disorder compromising the hypothalmic-pituitary-gonadal system.

Unfortunately, many patients with Kallmann's syndrome wait years for the correct diagnosis to be made even in the presence of classical findings\footnote{1522}; a high index of suspicion by the physician is important.

A presumptive diagnosis can usually be formed during the initial evaluation on the basis of the history and physical examination. Has puberty failed to occur or did it begin but fail to progress or regress? History taking must elicit all symptoms of chronic or intermittent illnesses and all details pertaining to growth and development as well as questioning about the patient's sense of smell. Disorders of pregnancy, abnormalities of labor and delivery, and birth trauma, if present in the patient's history, suggest that a congenital or neonatal event may be related to the delay in puberty. Poor linear growth and poor nutritional status during the neonatal period and childhood may reflect long-standing abnormalities of development. A growth chart is plotted to represent graphically the increase in stature and to assess growth velocity from birth. Late onset of growth failure usually indicates a serious condition requiring evaluation as soon as it is noted. Family history may reveal disorders of puberty or infertility, anosmia, or hyposmia in relatives as well as delay in the age of onset of puberty in parents or siblings. Recalled age of pubertal onset is relatively reliable in women\footnote{1523} but less often accurate in men. A history of consanguinity is important in the detection of autosomal recessive disorders.

The physical examination starts with determination of height and weight; the upper/lower segment ratio or sitting height is calculated, and the arm span is measured and compared with

The length and width of the tests are measured or the volume is assessed using an orchidometer. The length and diameter of the stretched penis are determined in boys, and the diameter of glandular breast tissue and areolar size are noted in girls. The presence or absence of galactorrhea is defined. Obese boys often appear to have a small penis because of excessive adipose tissue surrounding the phallus; therefore, the determination of pubic and axillary hair, and the degree of acne, is important in the search for a chronic disorder that may delay puberty.

Laboratory studies (Table 24-28) include determination of plasma LH and FSH concentrations, measurement of the rise in LH level after LHRH administration, determination of testosterone concentrations in boys and estradiol levels in girls, and measurements of T4 and prolactin concentrations in boys and girls if the clinical features warrant. It is important to use one of the few national endocrine laboratories for the determinations of the hormones of puberty because most local laboratories are interested only in differentiating normal, higher, adult values from inappropriately low levels and not the low concentrations characteristic of the early stage of pubertal development. For example, levels of estradiol below 15 pg/mL are not measured routinely or with confidence in many clinical laboratories despite the availability of methods and commercial kits to measure accurately values as low as 1.5 pg/mL.

**Follow-up studies**

- Karyotype (short, phenotypic females)
- MRI with contrast enhancement
- Pelvic ultrasonography (females)
- LHRH test
- hCG test (males)
- Pattern of pulsatile LH secretion
- Visual acuity and visual fields
FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging.

Radiographic examination includes bone age determination and, if the diagnosis is at all consistent with a CNS lesion, an MRI of the brain with specific attention to the pituitary and hypothalamic area using contrast; only advanced pituitary tumors or significantly calcified craniohypophysis appear on lateral skull films, and, although a positive result is useful, a negative radiograph cannot rule out a CNS defect. In contrast to MRI scans, CT scanning can detect calcification. Ultrasonic evaluation of the uterus and ovaries is not usually indicated initially in work-up of delayed puberty but provides useful information about the state of development of these structures. Again, it is important that the ultrasonographer has experience with children and young adolescents. Regrettably, individuals with normal internal genital organs have been told that they lack a uterus or ovaries, or both, by ultrasonographers inexperienced with this age group. One study demonstrated streak gonads in 50% of the patients with Turner’s syndrome who were choosing orif therapy. Assessment of chromosomal abnormalities should be considered in all short girls, even in the absence of somatic signs of Turner's syndrome and especially if puberty is delayed, and in boys with suspected Klinefelter stigma or behavior.

A presumptive diagnosis of constitutional delay in growth and adolescence is made if the history and growth chart reveal a history of short stature but consistent growth rate for bone age (and no signs or symptoms of hypothalamic lesions), if the family history includes parents or siblings with delayed puberty, if the physical examination (including assessment of the olfactory threshold) is normal, if optic discs and visual fields are normal, and if the bone age is significantly delayed. In classical cases, an MRI scan of the hypothalamic-pituitary region may not be necessary. The rate of growth in these patients is usually appropriate for bone age; a decrease in growth velocity occurs in some normal children just before the appearance of secondary sexual characteristics and may awaken concerns if such a pattern occurs in these subjects. Further, in these individuals the onset at puberty correlates better with bone age than with chronologic age. Elevated concentrations of gonadotropins and gonadal steroids to early pubertal levels precede secondary sexual development by several months; thus, measurements of serum LH, FSH, estradiol, or testosterone levels may help in predicting future development. The third-generation LH assays are reported to be sufficiently sensitive to allow the determination of the onset of endocrine puberty with a single blood sample in most boys, but an LH/FSH test is still often performed. An increase in the concentration of LH of more than 7.5 IU/L (2 ng/mL LER-960) determined by conventional polyclonal radioimmunoassay after intravenous administration of 100 pg of LH usually precedes the first physical sign of sexual maturation by less than 1 year.

Clomiphene citrate, an antiestrogen with weak estrogenic effects, decreases secretion of gonadotropins in pubertal patients but increases gonadotropin secretion in pubertal patients and in adults. However, we have not found administration of clomiphene citrate to be useful in the diagnosis of constitutional delay of growth and adolescence.

Various tests have been proposed for differentiating hypogonadotrophic hypogonadism from constitutional delay in puberty. Trials assessing the prolactin response to TRH, chlorpromazine, metoclopramide, or domperidone for differential diagnosis either failed or gave inconsistent results. The combination of the prolactin response to metoclopramide and the gonadotropin response to LHRH has been suggested, as has the use of priming doses of LHRH with evaluation of the gonadotropin response to a subsequent dose of LHRH or to a superactive LHRH agonist. The FSH response is higher in patients with hypothalamic-pituitary deficiencies who undergo development. A sensitive immunofluorometric assay for LH may help to distinguish between constitutional delay of growth and adolescence and hypogonadotropic hypogonadism better than the polyclonal LH radioimmunoassay. Urinary gonadotropin excretion is lower in hypogonadotropic patients than in delayed puberty, but this method of differential diagnosis may require years of observation before the difference is apparent. Although some methods are promising, their efficacy remains to be confirmed. There is a tendency for hypogonadotropic patients to undergo adrenarche at a normal age and to have a higher DHEAS concentration than those with constitutional delay in growth, and this pattern is helpful in the differential diagnosis.

Measurement of L as serum testosterone is proposed to be an accurate indication of impending pubertal development; a value greater than 0.7 nmol/L (20 ng/dL) predicts enlargement of testes to greater than 4 mL by 12 months in 77% of cases and by 15 months in 100% of cases, whereas of those with a value less than 0.7 nmol/L only 12% entered puberty in 12 months and only 25% entered puberty in 15 months. This technique may help predict spontaneous pubertal development but still requires considerable watching and waiting.

At present, there does not appear to be a practical and reliable endocrine test for indisputably differentiating between constitutional delay in growth and adolescence and hypogonadotropic hypogonadism. Watchful waiting remains the procedure of choice.

A typical patient with isolated gonadotropin deficiency is of average height for age and has eunuchoid proportions; low plasma concentrations of gonadal steroids, LH, and FSH, and no increase or a blunted response of LH after LHRH administration. The amplitude and usually the frequency of LH pulses are decreased when serial blood samples are studied over a 24-hour period. In some but not all forms of Kallmann’s syndrome, the sense of smell is absent or impaired. However, differentiation of isolated gonadotropin deficiency in the absence of hyposmia or anosmia from constitutional delay in puberty may be difficult at initial study. Gonadotropin-deficient patients may be as short as those with constitutional delay in growth and adolescence, and concentrations of LH and FSH in hypogonadotropic hypogonadism may be indistinguishable from those of normal prepubertal children or children with constitutional delay. Sometimes years of observation are necessary to detect the appearance of spontaneous and progressive signs of secondary sexual development or to document rising concentrations of gonadotropins or gonadal steroids before the diagnosis is clear. In general, but not in all cases, absence of the first signs of sexual maturation or failure of a rise in gonadotropins or gonadal steroid levels by age 18 in the presence of a normal concentration of serum DHEAS for chronologic age supports the diagnosis of isolated gonadotropin deficiency.

Patients with deficiency of gonadotropins combined with deficiency of other pituitary hormones require careful evaluation for a CNS neoplasm. Visual field or optic disc abnormalities support the diagnosis of CNS tumor; even if these tests are normal, cranial MRI should be performed to evaluate the pituitary gland and stalk and the hypothalamic region. CT scans but especially MRI scans of the head are valuable in detecting mass lesions and developmental abnormalities of the hypothalamic-pituitary region.

Treatment of Delayed Puberty and Sexual Infertility

Treatment of delayed puberty (Table 24-29) depends on the diagnosis and the nature of the disorder. Patients with constitutional delay in growth and adolescence ultimately have spontaneous onset and progression through puberty. Often, reassurance and continued observation to ensure that the expected sexual maturation occurs are sufficient. However, the stigma of appearing less mature than one's peers can cause psychological stress; such individuals may be unable to participate in the dating activities their friends are starting. Smaller size may lead them to avoid participation in sports and physical activities, in some but not all forms of Kallmann’s syndrome, the sense of smell is absent or impaired. However, differentiation of isolated gonadotropin deficiency in the absence of hyposmia or anosmia from constitutional delay in puberty may be difficult at initial study. Gonadotropin-deficient patients may be as short as those with constitutional delay in growth and adolescence, and concentrations of LH and FSH in hypogonadotropic hypogonadism may be indistinguishable from those of normal prepubertal children or children with constitutional delay. Sometimes years of observation are necessary to detect the appearance of spontaneous and progressive signs of secondary sexual development or to document rising concentrations of gonadotropins or gonadal steroids before the diagnosis is clear. In general, but not in all

1200

For psychological reasons, in boys of age 14 or older who show no signs of puberty, a 4- to 6-month course of testosterone enanthate, cypionate, or propionate (50 to 100 mg intramuscularly every 4 weeks) may be helpful. The low dose of testosterone enanthate is generally considered to be safe but can raise LDL and lower HDL cholesterol values as an expected effect.

Oral treatment with 2.5 mg of fluoxymesterone (Halotestin) for 6 to 60 months allows increased pubertal development without adverse effects on final height, although the necessity to take a daily dose may decrease compliance. Low-dose oxandrolone (2.5 mg/day orally) is sometimes used as an oral alternative to intramuscular testosterone enanthate; this agent increases growth through androgenic effects reflected by suppression of LH and FSH but does not stimulate GH secretion as it is not aromatized to estrogen. The temporary increase in growth velocity found with oxandrolone does not affect final height. Short-term treatment with fluoxymesterone (2.5 mg/day orally) was also reported to be a safe treatment that does not compromise adult height. Transdermal testosterone may be applied as a daily patch or a gel, although experience with these forms of androgen is more limited than with the other forms. Preliminary experience suggests that overnight (approximately 8 to 9
hours) or every other night use of 2.5 mg is effective. Testosterone gel is being investigated as a daily topical preparation to advance pubertal development.

For girls of age 13 or older, a 3- to 4-month course of ethinylestradiol (5 µg/day orally) or conjugated estrogens (0.3 mg/day orally) may be used to initiate maturation of the secondary sexual characteristics without unduly advancing bone age or limiting final height. A fourth-generation aromatase inhibitor, letrozole, administered along with testosterone in a randomized controlled trial in boys with constitutional delay in puberty and growth decreased the advancement in bone age, an effect that will presumably lead to a greater adult height by strikingly decreasing the synthesis of estradiol from testosterone. Estradiol is the sex steroid that has the major effect on skeletal maturation. Letrozole does not block the virilizing effects of testosterone. This promising treatment is experimental; it may improve the decreased adult height in some boys with constitutional delay compared with their predicted genetic potential, but the slower rate of growth may be accompanied by a decrease that testosterone cannot overcome.

If, during the 3 to 6 months after discontinuing gonadal steroid therapy, spontaneous puberty does not ensue or the concentrations of plasma gonadotropins and plasma testosterone in boys or plasma estradiol in girls do not increase toward pubertal values, the treatment may be repeated. Usually, only one or two courses of therapy are necessary. When treatment is discontinued after bone age has advanced, for example, to 12 to 13 years in girls or 13 or 14 years in boys, patients with constitutional delay usually continue pubertal development on their own, whereas those with gonadotropin deficiency do not progress and may, in fact, regress.

Alleviating the underlying problem treats functional gonadotropin deficiency associated with chronic disease. Delayed puberty in this situation is usually a result of inadequate nutrition and low weight; when weight returns to normal values, puberty usually occurs spontaneously. Treatment with T allows normal pubertal development in hypothyroid patients with delayed puberty.

Congenital or acquired gonadotropin deficiency as a result of a lesion or surgery requires replacement therapy with gonadal steroids at an age approximating the normal age of onset of puberty. An exception may occur when GH deficiency coexists with gonadotropin deficiency; if bone age advancement and epiphyseal fusion are brought about by testosterone or estradiol replacement before therapy with GH causes adequate linear growth, adult height is compromised. However, if puberty is not initiated early enough, the patient may well suffer psychological damage. It is generally advisable to initiate puberty in such patients with low-dose

Patients with isolated GH deficiency may have a delayed onset of puberty; with GH administration, puberty usually occurs at an appropriate age but may progress faster than in normal individuals. A study of over 200 children with GH deficiency treated with hGH showed a correlation between the age of onset of induced puberty and final height in patients who were also gonadotropin-deficient, whereas those who underwent spontaneous puberty, which occurred earlier than the age of hormone-induced puberty in the gonadotropin-deficient children, had a lower final height; this supports the advisability of waiting to initiate puberty in GH- and gonadotropin-deficient subjects. Height at the onset of puberty is also correlated with final height in GH-deficient children. Clinical trials are in progress to determine the effects of artificially delaying puberty with an LHRH analogue to attempt to achieve a greater final height in patients with isolated GH deficiency treated with hGH (see earlier).

---

**TABLE 24-31 — Hormonal Substitution Therapy in Girls with Hypogonadism**

Micropenis resulting from fetal androgen deficiency caused by a primary testicular defect or gonadotropin deficiency can be successfully treated with small doses of testosterone enanthate (25 to 50 mg/month intramuscularly) administered for short periods during infancy (also see Chapter 22). Patients with isolated congenital GH deficiency occasionally have micropenis that may be successfully treated with GH replacement alone.

As discussed earlier, episodic administration of LHRH can elicit pulsatile LH and FSH release and gonadal stimulation in prepubertal children or hypogonadotropic patients. Portable pumps have been used to administer LHRH in episodic fashion over prolonged periods. Pulsatile LHRH therapy can induce puberty and promote the development of secondary sexual characteristics and spermatogenesis in men and ovulation in women; pregnancy has been achieved with this regimen in women with hypogonadotropic hypogonadism. A lower frequency of LHRH administration favors FSH secretion and a higher frequency favors LH secretion and, ultimately, has been associated with a PCOS-like picture. A comparison of two different frequencies of LHRH administration did not reveal a difference between an LH pulse given subcutaneously every 3 hours or every 45 minutes in the rapidity of onset of pubertal development or serum LH, FSH, or sex steroid concentrations, this indicates that the hypothalamic-pituitary-gonadal axis is sufficiently robust to accommodate various frequencies of LHRH secretion. The use of pulsatile LHRH administration is not practical for the routine induction of puberty in adolescent boys and girls with gonadotropin deficiency. Both hCG and human menopausal gonadotropin can be used as effective substitutes for recombinant human pituitary LH and FSH to produce full gonadal...
When diagnosis of hypogonadism is firmly established (e.g., girls with 45,X gonadal dysgenesis), begin hormonal substitution therapy at 1213 yr of age.

**Goal:** to approximate normal adolescent development

**Initial therapy:** ethinyl estradiol 5 µg by mouth or conjugated estrogen 0.3 mg (or less) by mouth daily for 46 mo

After 6 mo of therapy (or sooner if “breakthrough” bleeding occurs) begin cyclic therapy:

**Ethinyl estradiol:**

- **Progesterone:**
  - **Progestagen (e.g., medroxyprogesterone acetate 5 mg by mouth)** 12th to 21st day of month
  - Gradually increase dose of estrogen over next 23 yr to conjugated estrogen 0.6125 mg or ethinyl estradiol 1020 µg daily for first 21 days of month

In hypogonadotropic hypogonadism: to induce ovulation at appropriate time: pulsatile LHRH or FSH and hCG therapy

Maturation, especially in those with pituitary pathology. But, again, this regimen is cumbersome and expensive. Thus, long-term gonadal steroid replacement therapy is the treatment of choice for hypothyroidic or pituitary gonadotropin deficiency until fertility is achieved.

Hypergonadotropic hypogonadism is treated by replacement of testosterone in boys and estradiol in girls. For treatment of gonadal dysgenesis, estrogen therapy should be initiated when the patient is age 13 (bone age > 11 years) to allow secondary sexual development at an appropriate chronologic age. The Kinleffel syndrome is compatible with varying degrees of masculinization at puberty, but some patients require testosterone replacement. The concentrations of plasma testosterone and LH should be monitored every 6 months during puberty and yearly thereafter. If the LH level rises more than 2.5 SD above the mean value or the testosterone level decreases below the normal range for age, testosterone replacement therapy is indicated.

Patients receiving gonadal steroid replacement follow the same treatment regimen whether the diagnosis is hypogonadotropic hypogonadism or hypergonadotropic hypogonadism (see Table 24-30 and Table 24-31). Various testosterone preparations with several routes of administration are available. Alkylated testosterone preparations are to be avoided because of the risk of peliosis hepatis (hemorrhagic liver cysts), which is not related to dose or duration of treatment; although regression is possible with discontinuation of testosterone treatment, progression to liver failure can occur. Males may receive testosterone enanthate, propionate, or cypionate. 50 to 100 mg every 4 weeks intramuscularly at the start; later the dosage is gradually increased to 200 to 300 mg every 2 to 3 weeks.

Low-dose replacement therapy is appropriate until well into the pubertal growth spurt.

Testosterone may be administered by cutaneous patch on scrotal skin or nonsexual skin to cause secondary sexual development in hypogonadal adolescents: patches may be given at night to increase the diurnal variation of testosterone seen in early puberty. Physiologic values of serum testosterone are possible along with secondary sexual development. A teenage boy may be less likely to apply a patch daily, and biweekly or monthly injections may allow better compliance; nonetheless, we and others find that 2.5- and 5-mg dermal testosterone patches may be useful in motivated teenagers. New testosterone gel preparations, usually rubbed onto the forearms, are approved for adults and may be used in a similar manner. Testosterone ointment may be used as therapy for micropenis to enlarge the size of the phallus intentionally, but an infant coming in contact with the skin of an individual with testosterone gel (before it is absorbed into the intended subject’s skin) runs the risk of unplanned testosterone effects.

Initially, girls 12 to 13 years of age are given ethinyl estradiol, 5 µg/day orally, or conjugated estrogens, 0.3 mg/day by mouth, on the first 21 days of the month. The dose is gradually increased over the next 2 to 3 years to 10 µg of ethinylestradiol or 0.6 to 1.25 mg of conjugated estrogen for the first 21 days of the month. The maintenance dose should be the minimal amount to maintain secondary sexual characteristics, sustain withdrawal bleeding, and prevent osteoporosis. After breakthrough bleeding occurs, or no later than 6 months after the start of cyclic therapy, a progestagen (e.g., medroxyprogesterone acetate, 5 mg/day) is added on days 12 through 21 of the month. Undesirable effects are uncommon but may include weight gain, headache, nausea, peripheral edema, and mild hypertension. Application of portions of transdermal 17-estradiol patches at night was shown to mimic levels of estrogen produced in early puberty and to bring about breast development slowly; other therapeutic schedules are possible. As with testosterone, there must be care that the preparation is not placed in contact with young children or untoward estrogen effects may occur.

There is concern about the increased risk of endometrial and breast carcinoma in patients receiving chronic estrogen replacement therapy including patients with Turner’s syndrome. This is not an issue in adolescents or young children but is a consideration in older women. The use of postmenopausal agents to antagonize the effect of estrogens reduces the risk of endometrial cancer, but knowledge of the optimal dose of estrogen and progesterone to enhance development without unduly increasing the risk of cancer must come from future studies. Estrogen replacement is important for its antosteoporotic action on bone. Surprisingly, we lack controlled studies on optional sex steroid replacement regimens in adolescent women.

Patients with hypopituitarism may complain of sparse pubic hair growth or, in girls, total absence of public hair. Pubic hair thickens further in affected males with hCG treatment that adds the testicular contribution of testosterone to the exogenous testosterone therapy. GH therapy in males with GH and gonadotropin deficiency enhances the steroidogenic response of the testes to hCG administration. Further, adolescent or young adult women have been given low doses (25 mg) of long-acting intramuscular testosterone every 4 weeks to stimulate the growth of pubic hair without virilization.

The result of treatment with testosterone in boys with radiation-induced primary testicular failure is normal final height, although in a group of patients with concomitant spinal radiation, the upper/lower segment ratio was much reduced, indicating impaired spinal growth. The results of clinical trials of biosynthetic hGH therapy in Turner’s syndrome indicate that an increase in growth rate with a substantial increase in final height into the lower range of the normal growth curves is possible, especially with a dose higher than used in GH deficiency (see more detailed earlier discussion in the section on Turner’s syndrome). There is some degree of improvement of the abnormal body proportions of Turner’s syndrome with hGH treatment, but the disproportionate growth of the foot may dissuade some girls from continuing treatment to maximal benefit for height.

The addition of estrogen therapy at low doses has been reported either to exert no effect on adult height or to reduce the adult height obtained with GH therapy administered alone. Indeed, the length of time of exposure to GH before estrogen treatment is said to be the major determinant of whether GH and estrogen treatment increased final height. However, it is postulated that if GH is started early enough (e.g., 2 to 8 years of age), estrogen therapy may be added at an age (13 years) appropriate for the institution of puberty (see discussion in Turner’s syndrome section). Counseling and a peer support group are exceedingly important components of the long-term management.

The bone density is decreased in Turner’s syndrome, at least in part, because of hypogonadism at puberty, and this tendency becomes more severe with age in patients who discontinue or do not receive estrogen replacement therapy. Transdermal estrogen was shown to increase bone density in subjects with Turner’s syndrome who have finished statural growth.
DISORDERS OF PUBERTY (Continued)

Sexual Precocity

Sexual precocity (Table 24-32) is defined as the appearance of any sign of secondary sexual maturation at an age more than 2.0 SD below the mean; in the past, the ages of 8 years in girls and 9 years in boys were considered the lower limits of the normal onset of puberty. Present data detailed previously indicate that the limits in normal boys remain at 9 years but that the lower limit for white girls is 7 years and for black girls is 6 years, assuming that there is no sign or symptom of CNS disorders or other serious or chronic disease that might cause sexual precocious puberty. These guidelines are similar to those proposed by the Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society. The new data noted in the first section of this chapter show that breast development and pubic hair development may occur in girls as young as 6 years in substantial numbers, especially in black girls, leading to a need for careful evaluation and conservatism, even in these young years, in evaluating and treating girls with only minimal, relatively non-progressive signs of sexual precocity.

If the sexual precocity results from premature reactivation of the hypothalamic LHRH pulse generator (or LHRH-independent sexual precocity), the condition is called complete isosexual precocity or true or central precocious puberty and is LHRH-dependent. Pulsatile LH release has a pubertal pattern in this form, and the rise in the concentration of LH after LHRH administration is indistinguishable from the normal pubertal pattern of serum LH. If extrapituitary secretion of gonadotropins or secretion of gonadal steroids independent of pulsatile LH release leads to virilization in boys or feminization in girls, the condition is termed incomplete isosexual precocity, pseudoprecocious puberty, or LHRH-independent sexual precocity. The production of excessive estrogens in males leads to inappropriate feminization, and the production of increased androgen levels in females leads to inappropriate virilization; these conditions are termed contrasexual precocity (also termed heterosexual precocity). Hence, the disorders that cause sexual precocity can be separated into those in which the increased secretion of gonadal steroids depends on LHRH stimulation of pituitary gonadotropins and those in which it is unrelated to activation of the hypothalamic LHRH pulse generator.

In all forms of sexual precocity, the increased gonadal steroid secretion increases height velocity, somatic development, and the rate of skeletal maturation and, because of premature epiphyseal fusion, can lead to the paradox of tall stature in childhood but short adult height. Data on the final height in true precocious puberty are scarce (see Table 24-34), but several studies of untreated females with idiopathic central precocious puberty demonstrated a mean final height of 151 to 155 cm (Table 24-34). In the boys followed to adult stature by Thamdrup the mean height was 155.4 cm ± 8.3 (SD) and all were well below midparental height and far below the fathers' height. Blood pressure matches that of height- and weight-related

True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia or other previous chronic exposure to sex steroids

Incomplete Isosexual Precocity (Hypothalamic LHRH-Independent)

**Males**

Gonadotropin-secreting tumors

hCG-secreting CNS tumors (e.g., chorioepitheliomas, germinoma, teratoma)

hCG-secreting tumors located outside the CNS (hepatoma, teratoma, chorionicarcinoma)

Increased androgen secretion by adrenal or testis

Congenital adrenal hyperplasia (CYP21 and CYP11B1 deficiencies)

Virilizing adrenal neoplasm
Leydig cell adenoma
Familial testotoxicosis (sex-limited autosomal dominant pituitary gonadotropin-independent precocious Leydig cell and germ cell maturation)
Cortisol resistance syndrome

**Females**
- Ovarian cyst
- Estrogen-secreting ovarian or adrenal neoplasm
- Peutz-Jeghers syndrome

**In Both Sexes**
- McCune-Albright syndrome
- Hypothyroidism
- iatrogenic or exogenous sexual precocity (including inadvertent exposure to estrogens in food, drugs, or cosmetics)

**Variations of Pubertal Development**
- Premature thelarche
- Premature isolated menarche
- Premature adrenarche
- Adolescent gynecomastia in boys
- Macro-orchidism

**Feminization in Males**
- Adrenal neoplasm
- Chorioepithelioma
- CYP11B1 deficiency
- Late-onset adrenal hyperplasia
- Testicular neoplasm (Peutz-Jeghers syndrome)
- Increased extraglandular conversion of circulating adrenal androgens to estrogen
- iatrogenic (exposure to estrogens)

**Virilization in Females**
- Congenital adrenal hyperplasia
- CYP21 deficiency
- CYP11B1 deficiency
- 3-HSD deficiency
- Virilizing adrenal neoplasm (Cushing's syndrome)
- Virilizing ovarian neoplasm (e.g., arhenoblastoma)
- iatrogenic (exposure to androgens)
- Cortisol resistance syndrome
- Aromatase deficiency

LHHR, luteinizing hormone-releasing factor (GnRH); CNS, central nervous system; CYP21, 21-hydroxylase; CYP11B1, 11-hydroxylase; 3-HSD, 3-hydroxysteroid dehydrogenase 4,5-isomerase.

**Long-Term Follow-up of True Precocious Puberty**

Pregnancy has occurred in patients with true or central precocious puberty as early as 5 years of age. Of course, such pregnancies are in fact the result of childhood sexual abuse of a child with true precocious puberty, a fact rarely reported by the sensational press. Fertility in later life is less well documented, but in our experience as well as that of others, normal pregnancies have occurred in women who had idiopathic true precocious puberty, a CNS abnormality triggering true precocious puberty, or premature menarche. In the isosexual precocity of the McCune-Albright syndrome, there are also reports of adult fertility. 

**Idiopathic True or Central Precocious Puberty**

By common definition, 2.5% of normal children develop signs of puberty before the lower limits of normal. The Hermann-Giddens study found that 27% of black and 7% of white girls have some manifestation of secondary sex development by 7 years of age. Thus, as stated previously, a useful definition of sexual precocity is onset before 6 years in black girls, before 7 years in white girls, and before 9 years in boys, assuming there

is no sign or symptom of CNS or other serious disease. Although this definition is a useful guideline, a significant proportion of girls 6 to 8 years of age with idiopathic precocious puberty represent one end of the bell-shaped curve for normal puberty onset, as described at the beginning of the chapter, and are examples of early normal puberty, just as those with constitutional delay in growth and adolescence are healthy but late maturers who fall in the older age segment of the normal distribution.

The nature of the striking sex difference in the prevalence of idiopathic true precocious puberty (females >> males) in contrast to constitutional delay in growth and puberty (males >> females) is poorly understood. There may be a history of early maturation in the family; rarely, true precocious puberty is transmitted as an autosomal recessive trait in boys and girls. A larger group of children, however, develop true precocious puberty with no familial tendency toward early maturation and no signs of organic disease; these children have idiopathic true precocious puberty. This condition, which may be manifest in infancy, is about nine times more common in girls than in boys (see Table 24-35) and is commonly associated with electroencephalographic abnormalities. The age at onset in girls in about 50% of cases is 6 to 7 years, in about 25% is 2 to 6 years, and in 18% is in infancy (see Fig. 24-57). Organic forms of true precocious puberty, especially if associated with hypothalamic hamartoma, have an earlier mean age of onset than the idiopathic form.

In boys (see Fig. 24-58) the testes usually enlarge under gonadotropin stimulation before any other signs of puberty are seen; in girls (see Fig. 24-57) an increase in the rate of growth, the appearance of breast development, enlargement of the labia minora, and maturational changes in the vaginal mucosa are the usual presenting signs, with variable manifestations of public hair depending on the age at onset. Progression of secondary sexual maturation is often more rapid than the normal pattern of pubertal maturation. A waxing and waning course of development may be encountered. The rapid growth is associated with the rise in estrogen synthesis and secretion and the increased GH secretion and elevation of serum IGF-I levels because of stimulation by estradiol. The ratio of bone age to chronologic age and the rise of IGF-I above normal values for age are predictive of outcome; more mildly affected children progress less rapidly and tend to maintain their target height. Patients with slowly progressive

*Data from University of California, San Francisco, Pediatric Endocrine Clinic.

From Paul D, Conte FA, Grumbach MM, Kaplan SL. Long-term effect of gonadotropin-releasing hormone agonist therapy on final and near-final height in 26 children with true precocious puberty treated at a median age of less than 5 years. J Clin Endocrinol Metab, 80:546551.
When photographed, the patient had been treated with medroxyprogesterone acetate for 1.5 years. His height was 95.2 cm (+1 SD), the phallicus was 6 × 3 cm, and the testes were 2.4 × 1.3 cm. Basal concentrations of LH (LER-960) were 0.9 ng/mL; FSH (LER-869) 0.8 ng/mL; and testosterone 7 ng/dL. After 100 µg of LHRH, LH concentrations rose to 2.3 ng/mL, whereas FSH concentrations did not change. We have been treating with medroxyprogesterone acetate since 1982; during this time, he has had no treatment change except for the testosterone loss. His height was 150 cm at the age of 8 years 1671 and 168 cm at the age of 10 years 1672.

Figure 24-59 Left, Mean basal plasma lutinizing hormone (LH) level (LER-960) and mean peak and increment after intravenous LH-releasing hormone (LHRH) (100 µg) in normal prepubertal and pubertal females and in females with idiopathic true precocious puberty. The mean peak and increments of plasma LH are higher in true precocious puberty than in normal puberty. Right, Basal follicle-stimulating hormone (FSH) level (LER-1364) and mean peak and increment after intravenous LH (100 µg) in normal prepubertal and pubertal females with true precocious puberty. The concentration of FSH and the response to LH were greater in females with true precocious puberty and normal puberty than in prepubertal females. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620–660. © 1990, the Williams & Wilkins Co., Baltimore.)

The pituitary gland undergoes hypertrophy in early infancy, puberty, and pregnancy and is increased in size on MRI in patients with central precocious puberty. Growth hormone, thyroid-stimulating hormone, and, rarely, prolactin and gonadotropins' concentrations are increased. In our experience, a CNS tumor was present in at least half of this group. Central Nervous System Tumors Causing True Precocious Puberty

The pituitary gland undergoes hypertrophy in early infancy, puberty, and pregnancy and is increased in size on MRI in patients with central precocious puberty. Growth hormone, thyroid-stimulating hormone, and, rarely, prolactin and gonadotropins' concentrations are increased. In our experience, a CNS tumor was present in at least half of this group. T1 images indicate a convex upper border of the pituitary gland in patients in normal or central precocious puberty, indicating the similarity in the physiologic changes of both conditions. Two sisters have been reported with the rare finding of pituitary gland hypertrophy (height greater than 1 cm) in central precocious puberty. Although empty sella may be associated with central precocious puberty, the empty sella syndrome is less frequently observed in patients with central precocious puberty than in patients with pituitary hypofunction. Although empty sella was found in 10% of children imaged for suspected hypothalamic-pituitary disorders including hypogonadotropic hypogonadism, the incidence in the general population is not known. 1673 1674

The dependent and gonadotropin steroid concentrations in plasma, the LH response to LHRH administration, and the amplitude and frequency of LH pulses are in the normal pubertal range. (Fig. 24-59 and Fig. 24-60; see Fig. 24-41.) The new third-generation gonadotropin assays may allow the diagnosis of true precocious puberty by determination in a single serum sample for LH in the basal state or 40 minutes after a single subcutaneous dose of LHRH. 1675 1676 1677 1678 1679 1680 1681 1682 1683

The notable improvement in the discriminatory power and specificity of the new commercial LH and FSH assays in the diagnosis of true precocious puberty is well illustrated by the observations of Brito and co-workers. 1684 The mean basal concentration of LH in 100 prepubertal children (60 males, 40 females) was 0.6 µIU/mL, the minimal detectable concentration. In Tanner stage 2 (breast development in girls, testes size in boys), the LH levels ranged from less than 0.6 to 2.7 µIU/mL in boys and less than 0.6 to 1.2 µIU/mL in girls. In 28 children with true precocious puberty, the mean basal LH concentration was 1.6 µIU/mL in boys, with a sensitivity of 71% and a specificity of 100%. In girls the sensitivity was 62% and the specificity 100%. In 10 children with LHRH-independent sexual precocity, the LH level was undetectable (<0.6 µIU/mL).

After the administration of an intravenous bolus of LHRH, the mean peak LH value in 16 prepubertal boys and 11 prepubertal girls was 3.1 µIU/mL, whereas in the children with true precocious puberty the mean peak LH value was greater than 21.6 µIU/mL, in contrast to LHRH-independent sexual precocity, in which the value was 1.5 µIU/mL. Peak LH levels above 9.6 µIU/mL in boys and 6.9 µIU/mL in girls were set as a pubertal response to LH stimulation. In boys and girls with true precocious puberty the combination of an elevated basal LH value and LHRH-stimulated peak value had a specificity and a positive predictive value of 100%.

Adrenarche usually does not accompany gonadarche in girls with true precocious puberty younger than 5 or 6 years. 1685 Pubic hair is sparse or absent initially in girls of this age. 1686 When the onset of true precocious puberty occurs after age 6, it is usually associated with early adrenarche for chronologic age but not for bone age. 1687

Girls with true precocious puberty have a tendency toward obesity (a mean BMI greater than that of normal girls of the same chronologic age), unrelated to treatment with LHRH agonist. 1688 1689

A small proportion of patients with central precocious puberty, including a pubertal response of LH to LHRH and increased pulsatile LH secretion at night, may either revert spontaneously to a more immature pubertal state, persist without further progression, or fluctuate between progression and regression. In some patients the course is inexorably progressive and, indeed, clinical evidence suggests a continuum in girls from premature thelarche through unsustained or slowly progressive precocious puberty to the relatively rapid progression of sexual maturation, once begun, in true precocious puberty. 1690

Central Nervous System Tumors Causing True Precocious Puberty

True precocious puberty resulting from CNS tumors (see Table 24-33 and Table 24-34) has about the same prevalence in boys and girls; however, in boys, neurologic abnormalities account for two thirds of those with true precocious puberty, and in our experience a CNS tumor was present in at least half of this group. A CNS neoplasm must be considered in the differential diagnosis for any patient with true precocious puberty. Optic and hypothalamic glioma (often associated with neurofibromatosis) and craniopharyngioma may cause true precocious puberty, either by impinging on the neural pathways that inhibit the LHRH pulse generator in childhood or as a consequence of cranial radiation for therapy of a brain tumor. The prevalence of true precocious puberty is increased after cranial radiation for local tumors or leukemia. Even radiotherapy targeting the pituitary gland may result in true precocious puberty. 1691

The unusual combination of GH deficiency and central precocious puberty can occur in children previously subjected to

therapeutic radiation of the CNS in association with a CNS neoplasm or, because of a variety of CNS abnormalities, including developmental malformations and head trauma. The lack of GH may not be apparent because of the increased growth resulting from the elevated gonadotropin levels. Nonetheless, GH-deficient children with central precocious puberty grow more slowly than GH-sufficient children with central precocious puberty but faster than GH-deficient children without sexual precocity. Further, in GH-deficient children with central precocious puberty the IGF-I concentrations are intermediate between the higher levels found in GH-sufficient children with sexual precocity and the lower levels found in the prepubertal GH-deficient children. 

GH deficiency and true precocious puberty can occur with CNS radiation doses of only 18 Gy, and gonadotropin deficiency, thyrotropin deficiency, and adrenocorticotropic deficiency occur with doses greater than 40 Gy, as does hypoprolactinemia. Boys and girls are both subject to an earlier onset of puberty in combination with GH deficiency with CNS irradiation of 25 to 47 Gy for tumors outside the hypothalamic-pituitary area. Treatment with a combination of GH and LHRH agonist is indicated in these patients and results in better growth and improved height compared with the use of LHRH agonist alone. Because GH secretion is related to BMI, it is important to rule out a decrease of GH secretion because of increased BMI in true precocious puberty on this basis before interpreting the decrease as evidence of GH deficiency.

Hamartomas of the tuber cinereum include malformations composed of a heterotopic mass of neurosecretory neurons, fiber bundles, and glial cells. This is frequently associated with true precocious puberty. The occurrence of seizure is uncommon when the mass diameter of the hamartoma is less than 10 mm, whereas a larger mass is associated with a high risk. 

With CT and MRI brain scans, hamartomas of the tuber cinereum are now being detected in young boys and girls previously thought to have idiopathic true precocious puberty and are now considered the most common known cause of true precocious puberty (Fig. 24-61). Before 1980 there were 37 patients in the literature with hamartomas of the tuber cinereum, and since 1980 another 80 have been reported (see Table 24-37). This increase is attributable to use of CT and MRI brain scans. For example, Pescevitz and colleagues, in reviewing the experience at the National Institutes of Health, reported that of 87 girls with true precocious puberty, 16% had a hypothalamic hamartoma, 40% had other CNS abnormalities, and 60% had idiopathic true precocious puberty. Among 20 boys with true precocious puberty, 2 had idiopathic true precocious puberty, 10 had a hypothalamic hamartoma, and 8 had other CNS abnormalities including hypothalamic neoplasms. The LHRH-secreting hypothalamic hamartoma consists of a heterotopic mass of nervous tissue containing LHRH neurosecretory neurons; it may be sessile or pedunculated and is usually attached to the posterior hypothalamus between the tuber cinereum and the mammillary bodies. These masses project into the suprasellar cistern, and the pedunculated hamartoma has a distinct stalk; hamartomas have a characteristic appearance that does not change with time. They appear on a CT or MRI scan as an isodense, abnormal fullness of the interpeduncular, preoptine, and posterior suprasellar cisterns, occasionally with distortion of the anterior third ventricle. This there is no enhancement with contrast material. MRI gives the best visualization of the lesion (see Fig. 24-62). Hamartomas of the tuber cinereum commonly cause true precocious puberty but are also associated with seizures, often gelastic (laughing) in type, developmental disorders, and behavior abnormalities. The etiology of the development of the hypothalamic hamartoma may be the converse of the lack of migration of LHRH neurons in Kallmann's syndrome because of the lack of production of adhesion molecules encoded by the KAL gene. We may postulate that in the hypothalamic

1208
Hamartomas of the tuber cinereum are not true neoplasms and do not progress or enlarge. Analysis of hamartomas associated with true precocious puberty has revealed the presence of ectopic LH-releasing neurosecretory cells similar to the LH-releasing-neurosecretory neurons in the median basal hypothalamus. This developmental abnormality exerts its endocrine effects by the elaboration and pulsatile release of LH-RH.

Indeed, LH-RH-containing fibers have been identified passing from the hamartoma toward the median eminence. We have suggested that the LH-RH-containing neurosecretory neurons in the tumor are unrestrained by the intrinsic CNS mechanism that inhibits the normal LH-RH pulse generator and act as an ectopic LH-RH pulse generator, either independently or in synchrony with the LH-RH neurosecretory neurons in the medial basal hypothalamus, to produce intermittent secretory bursts of LH-RH (see Fig. 24-38). The LH-RH is transported to the pituitary by way of the portal circulation and elicits pulsatile release of LH.

If the hamartoma secreted LH-RH in a continuous fashion, true precocious puberty should not occur as the LH-RH receptors would be desensitized. (About 10% of hypothalamic hamartomas are not associated with true precocious puberty.)

The hypothalamic hamartomas of two young girls with rapidly progressive true precocious puberty did not contain immunoreactive LH-RH neurons on biopsy, but with use of a variety of techniques, including light microscopy, immunohistochemistry, and in situ hybridization for cells containing TGF-α protein or mRNA, respectively, the mass showed a network of TGF-α-containing astroglial cells. As discussed earlier, the hypothesis is that some hypothalamic hamartomas, by virtue of the increased production of TGF-α, a member of the epidermal growth factor family, and neuregulins synthesized by hypothalamic and astroglial cells through paracrine mechanisms, effect the release of bioactive factors including prostaglandin E₂ that act on LH-RH neurons to increase LH-RH secretion. This is a novel hypothesis to explain the occurrence of true precocious puberty with hypothalamic hamartomas that apparently lack LH-RH neurons. Several unusual features of the hamartomas in both patients, however, confound this interpretation. These hamartomas were much larger than the typical hypothalamic hamartomas associated with true precocious puberty; in one patient the mass bulged into the third ventricle, and in the other the pituitary gland was hypertrophic and bulged through the diaphragm sellae.

Hamartomas of the tuber cinereum should not be approached surgically except in unusual circumstances. Although there are cases in which removal of a hypothalamic hamartoma has led to reversal of the pubertal process, deaths have been reported after attempted operative removal. Long-term follow-up of the hypothalamic hamartomas associated with true precocious puberty demonstrated lack of growth on monitoring with periodic CT or MRI scans. Accordingly, although some have advocated neurosurgical removal of these hamartomas, we do not recommend neurosurgical extirpation in the absence of strong evidence of growth of the mass or of an associated complication such as intractable seizures or hydrocephalus.

Central Nervous System Neoplasms

Sexual precocity may be the first manifestation of a hypothalamic tumor of any cell type when it arises in or impinges on the posterior hypothalamus. However, neurologic symptoms such as headaches and visual disturbances may develop, and children may have diabetes insipidus, hydrocephalus, or optic atrophy caused by an enlarging tumor.

The location of CNS tumors causing true precocious puberty makes surgical removal difficult. A conservative approach calls for biopsy of the neoplasm and radiation therapy or chemotherapy or both, depending on the pathologic findings.

Other Central Nervous System Conditions

True precocious puberty may be secondary to encephalitis, static cerebral encephalopathy, hydrocephalus, brain abscess, or sarcoid granulomas or tuberous granulomas of the hypothalamus, with or without tuberculous meningitis. Central precocious puberty can occur after severe head trauma (usually in girls), and it has been associated with the cerebral atrophy or focal encephalomalacia following cerebral edema complicating the treatment of severe diabetic ketoacidosis.

Children with nontumor hydrocephalus, even if shunted, experience earlier pubertal development, and those who have not been adequately treated may develop true precocious puberty. Delayed puberty is an alternative outcome in a minority of affected children. The growth pattern of children with severe hydrocephalus often includes poor prepubertal growth and an early pubertal growth spurt leading to decreased final height.

Arachnoid cysts arising de novo, after infection, or after surgery can cause premature sexual development, possibly with associated GH deficiency.
Neurofibromatosis type 1 (von Recklinghausen’s disease) is associated with a propensity to develop the optic chiasmal tumors that are the most common but not the only cause for development of true precocious puberty in a child with neurofibromatosis. The prevalence of optic gliomas in neurofibromatosis type 1 is about 17%, most occurring in the first decade, but only about 20% to 30% become symptomatic; these tumors rarely progress in the years after diagnosis. The tumor suppressor NF1 gene located on the long arm of chromosome 17 (q11.2), which has a high mutation rate, encodes a 327-kd protein, neurofibromin, which is widely expressed, even though neurofibromatosis type 1 involves mainly tissues derived from the neural crest. A wide variety of mutations of the gene have been reported, especially deletions and nonsense and truncating mutations distributed over the coding region of the NF1 gene. In sporadic cases, the new mutation originates in the paternally derived NF1 allele in the vast majority of instances, which suggests a role for genomic imprinting.

Neurofibromatosis type 1 is characterized by multiple pigmented areas and overgrowth of nerve sheaths and fibrous tissue elements. Multiple café-au-lait spots are frequent and are smoother in outline than those of those of the McCune-Albright syndrome. The diagnosis is made if two or more of the following are present: (1) six or more café-au-lait macules, the greatest diameter of which is more than 5 mm in prepubertal and more than 12.5 mm in postpubertal subjects; (2) two or more neurofibromas of any type or one plexiform neurofibroma; (3) freckling in the axilla or inguinal region; (4) optic glioma; (5) two or more iris Lisch nodules (ophthalmic hamartomas); (6) a distinctive osseous lesion such as sphenoid dysplasia or pseudoarthrosis; and (7) a first-degree relative with neurofibromatosis type 1 according to the preceding criteria.

Neurofibromas of the skin in neurofibromatosis may be subcutaneous sessile or deep plexiform masses in children; pedunculated lesions develop in later childhood. Internal neurofibromas cause most of the complications. Bone abnormalities such as cysts and pseudarthrosis, hemihypertrophy, bowing, scoliosis, and skull and facial defects are common (20%); dumbbell-shaped tumors of spinal nerve roots may cause pain, sensory and motor dysfunction, and bone erosions; gliomas or neurofibromas of any part of the CNS, including the optic nerves and hypothalamus, may calcify. Lisch nodules of the iris are frequent, particularly in adults. Sarcomatous degeneration occurs in 5% to 15% of patients. Other neoplasms include CNS astrocytomas often involving the visual pathways, ependymomas, meningiomas, neurofibrosarcomas, rhabdomyosarcomas, and nonlymphocytic leukemias. Neurofibromatosis may develop in affected adults.

The clinical manifestations of neurofibromatosis include seizures, visual defects, and either delayed or true precocious puberty. Mental retardation occurs more often in this population but is usually not severe; there is also an increased incidence of psychiatric disease. Most affected children have some manifestations of the disease by 1 year of age.

In addition, both medroxyprogesterone acetate and cyproterone acetate have undesirable effects in high doses. A hypothesis involving the primary role of recovery from nutritional deprivation has been challenged. In a retrospective study of true precocious puberty from Belgium, 28% (39 families in Sweden and in children referred after kwashiorkor prior to 3 years of age, 1055 screening MRI scans are recommended for early detection of CNS tumors.

Other CNS abnormalities associated with true precocious puberty but without demonstrable lesions on imaging study include epilepsy, laughing seizures, mental retardation, and the post-traumatic state. Septo-optic dysplasia (described earlier) may be associated not only with multiple pituitary hormone deficiencies and delayed puberty but also rarely with true precocious puberty. True precocious puberty may be consisting of some pituitary hormones and excessive secretion of others, including prolactin. Patients with myelomeningocele (myelodysplasia) have an increased prevalence of endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, that in some patients are associated with true precocious puberty.

Neurofibromatosis type 1 (von Recklinghausen’s disease) is widely expressed, even though neurofibromatosis type 1 involves mainly tissues derived from the neural crest.

Neurofibromatosis type 1 is characterized by multiple pigmented areas and overgrowth of nerve sheaths and fibrous tissue elements. Multiple café-au-lait spots are frequent and are smoother in outline than those of the McCune-Albright syndrome. The diagnosis is made if two or more of the following are present: (1) six or more café-au-lait macules, the greatest diameter of which is more than 5 mm in prepubertal and more than 12.5 mm in postpubertal subjects; (2) two or more neurofibromas of any type or one plexiform neurofibroma; (3) freckling in the axilla or inguinal region; (4) optic glioma; (5) two or more iris Lisch nodules (ophthalmic hamartomas); (6) a distinctive osseous lesion such as sphenoid dysplasia or pseudoarthrosis; and (7) a first-degree relative with neurofibromatosis type 1 according to the preceding criteria.

Internal neurofibromas cause most of the complications. Bone abnormalities such as cysts and pseudarthrosis, hemihypertrophy, bowing, scoliosis, and skull and facial defects are common (20%); dumbbell-shaped tumors of spinal nerve roots may cause pain, sensory and motor dysfunction, and bone erosions; gliomas or neurofibromas of any part of the CNS, including the optic nerves and hypothalamus, may calcify. Lisch nodules of the iris are frequent, particularly in adults. Sarcomatous degeneration occurs in 5% to 15% of patients. Other neoplasms include CNS astrocytomas often involving the visual pathways, ependymomas, meningiomas, neurofibrosarcomas, rhabdomyosarcomas, and nonlymphocytic leukemias. Neurofibromatosis may develop in affected adults.

The clinical manifestations of neurofibromatosis include seizures, visual defects, and either delayed or true precocious puberty. Mental retardation occurs more often in this population but is usually not severe; there is also an increased incidence of psychiatric disease. Most affected children have some manifestations of the disease by 1 year of age.

In addition, both medroxyprogesterone acetate and cyproterone acetate have undesirable effects in high doses. A hypothesis involving the primary role of recovery from nutritional deprivation has been challenged. In a retrospective study of true precocious puberty from Belgium, 28% (39 girls, 1 boy) were foreign children who had emigrated from developing countries. A toxicologic screen found a greatly elevated mean concentration of the p,p’-DDE), which raised the possibility of a role of organochlorine pesticide dichlorodiphenyltrichloroethane (DDT) derivative. The etiology is not established but may be related to the effects of undernutrition or its rapid repair during a sensitive time in development. In Sweden, the adopted Indian children had pubertal growth spurts similar to those of Swedish children, but the loss of height in childhood and the early puberty after virilizing disorders.

Sarcomatous degeneration occurs in 5% to 15% of patients. Other neoplasms include CNS astrocytomas often involving the visual pathways, ependymomas, meningiomas, neurofibrosarcomas, rhabdomyosarcomas, and nonlymphocytic leukemias. Neurofibromatosis may develop in affected adults. 

True Precocious Puberty in Children Adopted from Developing Countries

An increased prevalence of true precocious puberty occurred in children (with established birth dates) from developing countries adopted after 3 years of age into families in Sweden and in children referred after kwashiorkor prior to 3 years of age, as well as in The Netherlands, France, and Italy. A hypothesis involving the primary role of recovery from nutritional deprivation has been challenged. In a retrospective study of true precocious puberty from Belgium, 28% (39 girls, 1 boy) were foreign children who had emigrated from developing countries. A toxicologic screen found a greatly elevated mean concentration of the organochlorine pesticide dichlorodiphenyltrichloroethane (DDT) derivative. This phenomenon, secondary true precocious puberty, occurred in boys and girls with congenital virilizing adrenal hyperplasia in whom glucocorticoid replacement therapy was begun after age 4 to 8 and who had an advanced bone age. True precocious puberty has also been documented in children who received or were exposure to androgens or estrogens for long periods during early childhood for a variety of conditions.

Management of True Precocious Puberty

The objectives in the management and therapy of true precocious puberty are summarized in Table 24-38, which addresses the major psychosocial and clinical goals. Three principal agents have been used in the treatment of true precocious puberty whether idiopathic or neurologic: medroxyprogesterone acetate, cyproterone acetate, and superactive LHRH agonists.

Medroxyprogesterone and cyproterone reversed or arrested the progression of secondary sexual characteristics but had no apparent effect or a small effect on final height, especially in affected girls. This failure may be due in part to the disproportionate action of the small amount of circulating estradiol on skeletal growth relative to its effect on secondary sexual characteristics. In any event, in none of the early studies with medroxyprogesterone or cyproterone was the concentration of plasma estradiol in girls and of testosterone in boys systematically monitored and the dosage of these agents adjusted accordingly. More encouraging effects of long-term treatment with medroxyprogesterone acetate on final height were reported in the latest study. In addition, both medroxyprogesterone acetate and cyproterone acetate have undesirable effects in high doses.

The dosage of medroxyprogesterone acetate is 5 to 20 mg twice a day orally or 100 to 200 mg/m² surface area intramuscularly every 1 or 2 weeks. We prefer the oral route.[2138] This agent inhibits gonadotropin secretion by its action on the hypothalamic LHRH pulse generator/pituitary gonadotropin unit and has a direct suppressive effect on gonadal steroidogenesis through type II 3-hydroxysteroid dehydrogenase/isomerase. Medroxyprogesterone acetate has glucocorticoid action and can suppress ACTH and cortisol secretion, increase appetite and lead to excessive weight gain, and induce hypertension and a cushingoid facies and appearance.[2138]

Cypreterone acetate has antiandrogenic, antigonadotropic, and gestational properties. It has been used outside the United States for the treatment of true precocious puberty.[195] Its advantages and disadvantages are similar to those of medroxyprogesterone acetate. The usual oral dose is 70 to 100 mg/m² surface area daily, given in two divided doses; the intramuscular dose is 100 to 200 mg/m² every 14 to 28 days. Cypreterone acetate suppresses the secretion of ACTH and the plasma concentration of cortisol. Fatigue and weakness are common side effects, probably as a consequence of secondary adrenal insufficiency. This agent lacks glucocorticoid activity and does not appear to produce cushingoid features.

The long-term effect of either of these agents is not known. For the treatment of true precocious puberty, medroxyprogesterone and cypreterone acetate have been replaced by the much more effective LHRH agonists; however, these are useful backup agents for the occasional patients who experience untoward effects of LHRH agonist therapy.

**Supraventricular Luteinizing Hormone-Releasing Hormone Agonists**

The LHRH agonists, synthetic analogues of the amino acid sequence of the natural LHRH decapetide, are the treatment of choice for true precocious puberty, whether idiopathic or not.[1213] (Table 24-39 and Table 24-40).

**TABLE 24-39 – Action of Luteinizing Hormone-Releasing Hormone Agonists in True Precocious Puberty**

Paradoxically, these pharmacologic agents, when administered chronically, suppress pulsatile LH and FSH release, gonadotroidal output, and gametogenesis. In contrast to the effects of pulsatile administration at physiologic doses and frequency, continuous administration of natural LHRH suppresses gonadotropin secretion[726] after an initial, brief stimulation of gonadotropin release. Suppression results from binding of the agonist to the LHRH receptor on gonadotrophs and subsequent desensitization of the gonadotroph to LHRH. Initially, down-regulation and loss of receptors occur. When receptor levels return to normal, desensitization persists as a result of uncoupling of the receptors from the intracellular signaling effectors pathway.[711] Administration of a potent LHRH agonist subcutaneously once a day, although it initially stimulates gonadotropin release, induces desensitization of the gonadotrophs to LHRH within a few days. In children with true precocious puberty, this regimen blocks the effect of endogenous LHRH and functions as a selective, highly specific pharmacologic clamp on the secretion of gonadotropins without interfering directly with release of the other pituitary hormones. In essence, the regimen produces a reversible medical gonadectomy (see Table 24-39). The superactive agonist analogues of LHRH have about 15 to 200 times the potency of the natural LHRH decapetide, prolonged action, and low toxicity (see Table 24-40).

Replacing the glycine-amide terminus of LHRH with alkyl amines as in (Pro9-ethylamide(NEt))LHRH, substituting certain -amino acids at position 6 as in (o-Trp6)LHRH, and making bulky hydrophobic alterations at position 6 as in (-Trp3)6)LHRH, increase the potency and duration of action.

The suppressive effects of the agonists on gonadotropin secretion make them useful in the treatment of true precocious puberty. Various agonists are available, some for subcutaneous administration, some for intranasal treatment, and some for injection intramuscularly in depot formulations (see Table 24-40). A comparison of intranasal treatment with buserelin to monthly intramuscular treatment with triptorelin demonstrated the superiority of the latter in men and the plaater final height, although intranasal preparations given in adequate amounts are able to improve final height in affected children.[1718] At present, the depot formulation of leuprolein (leuprolide acetate) is the only depot preparation that may be given every 4 weeks that is approved by the FDA; long-term studies have established its efficacy and safety.[1765] The bioavailability of agonists given intranasally is much reduced, as reflected in the need to use a high dose at more frequent intervals. The effectiveness of LHRH agonist in the treatment of true precocious puberty varies with the potency of the analogue, dose, route of administration, and compliance.[1766] The addition of GH treatment to the LHRH regimen is a consideration when growth velocity is reduced sufficiently over a 6-month period to compromise predicted final height.[1767]

In both the idiopathic and organic forms of true precocious puberty, treatment with a potent LHRH agonist initially results in 1 to 3 days of increased FSH and LH release and a rise in circulating gonadotroidal levels; chronic therapy suppresses the pulsatile secretion of LH and FSH and blocks the pulsatile LH response to the administration of native LHRH after 7 to 14 days of treatment (Fig 24-65 and Fig 24-66). There is, as well, a change in the isofoms of gonadotropins toward a more basic charge, suggesting a differential effect of the LHRH agonist on pituitary secretion of gonadotropins. Within 2 to 4 weeks in girls and 6 weeks in boys, gonadal steroid secretion is reduced to prepubertal levels and maintained in the prepubertal state by chronic treatment (Fig 24-67; see Fig 24-65 and see Fig 24-66). A plasma estradiol concentration less than 18 pmol/L (5 pg/mL) in girls and a plasma testosterone level less than 0.7 nmol/L (20 ng/dL) in boys indicate adequate supression of gonadal steroidogenesis through type II 3-hydroxysteroid dehydrogenase/isomerase. Careful monitoring of serum gonadotropins and sex steroid is necessary for evaluation of the effectiveness of LHRH agonist treatment, and the same laboratory should be used for these studies to allow consistency of interpretation of the results.

Changes in secondary sexual characteristics occur within the first 6 months of therapy (see Fig 24-67). In girls, these effects include reduction in breast size and decrease in pubic hair, cessation of menses if present before treatment, and decreased size of the uterus and ovaries as assessed by pelvic ultrasonography.

**Medroxyprogesterone Acetate and Cyproterone Acetate**

This agent inhibits gonadotropin secretion by its action on the hypothalamic LHRH pulse generator/pituitary gonadotropin unit and has a direct suppressive effect on gonadal steroidogenesis through type II 3-hydroxysteroid dehydrogenase/isomerase. Medroxyprogesterone acetate has glucocorticoid action and can suppress ACTH and cortisol secretion, increase appetite and lead to excessive weight gain, and induce hypertension and a cushingoid facies and appearance.
sonography. A small proportion of girls have recurrent episodes of hot flushes and moodiness. In boys, pubic hair thickens, the testes decrease in size, acne and seborrhea regress, genitile erections and masturbation become much less frequent, the high energy level and aggressive behavior diminish, and self-esteem improves.

Height velocity, expressed in centimeters per year or as standard deviations above the mean height velocity for chronological and bone age, decreases about 60% during the first year of therapy. Skeletal maturation slows dramatically during the first 3 years, to a rate often less than the progression in chronological age. From the second year on, height velocity for bone age is usually appropriate. At present, the growth data for compliant patients strongly suggest improved adult height potential as a result of therapy in young children (6 years of age) with true precocious puberty, especially when treatment is begun soon after the onset of precocity and when the bone age is advanced only a few years. Even with the limitations of estimates of predicted height taken into account, effective therapy improves final height predictions or maintains the normal target height in young children.

The accumulating data on final height in children treated with LHRH agonists support this contention. A study of 26 children treated with Leuprolide demonstrated a striking benefit in the children treated before 5 years of age (girls, height 164.3 ± 7.7 cm) compared with those treated after age 5 years (157.6 ± 6.6 cm) and with untreated patients (152.7 ± 8.6 cm). We recommend the treatment of all affected children in whom puberty began before 6 years of age to ensure an optimal prognosis for adult height. European studies confirmed that final height is improved more with therapy starting before 6 years of age than after 6 years of age: the age that is optimal for discontinuation of therapy is still open to question as the post-treatment growth spurt is important in determining adult height. The remaining challenge is the rapid diagnosis of central precocious puberty and early initiation of GnRH therapy if final height is to be preserved.

Children with true precocious puberty have higher mean concentrations of circulating IGF-I for chronological age, consistent with the increased secretion of gonadal steroids. Treatment with LHRH agonists reduces the level of IGF-I to the normal range for bone age but not for chronological age. This indicates that gonadal steroids increase plasma IGF-I concentrations in true precocious puberty as well as in normal puberty. Secretion of GH is increased in true precocious puberty to a level comparable to that in normal puberty.
compliance. However, irregular or inadequate treatment or poor compliance results in persistent or intermittent increases in the concentrations of plasma gonadal steroids. Regular assessment is essential, initially at intervals of 1 to 3 months. Such assessment involves periodic determinations of plasma testosterone levels in boys and estradiol levels in girls; the change in basal concentrations of LH and FSH in third-generation assays or the LH and FSH response to exogenous LHRI; measurement of growth, bone age, and secondary sexual characteristics; and in girls serial evaluations of ovarian morphology and uterine size by pelvic sonography. Although the urinary excretion of LH correlates with the stage of pubertal development in normal individuals, urinary gonadotropin determinations are not sufficiently sensitive to be used for monitoring purposes.

**Figure 24-67** A 2 5/12-year-old girl with true precocious puberty after 6 weeks of desloralin therapy (4 µg/day subcutaneously). Note the regression in the size of the breasts; however, the rapid rate of growth had not decreased. At the end of 1 year of therapy, growth rate was suppressed to 4 cm/year, and bone age advanced only 1 year. CA, chronologic age; HT, height; WT, weight; BA, bone age. (From Syne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986; pp 313384.)

**Figure 24-68** Effect of luteinizing hormone-releasing hormone (LHRH) agonist therapy in true precocious puberty on growth. Left, Changes in mean height velocity (cm/year ± 1 SE) after the initiation of LHRH agonist therapy with DTrp6 Pro2 Net (LHRH) (filled bars) or with nafarelin (hatched bars). A sharp decrease in height velocity occurred within 1 year. Right, Mean (±1 SE) height for bone age before and during LHRH agonist treatment. The discrepancy between height and the more advanced bone age decreases (reverts to normal) with chronic LHRH agonist treatment. (From Kaplan SL, Grumbach MM. True precocious puberty: treatment with GnRH agonists. In Delemarre-Van de Waal H, Plant TM, van Rees GP, et al [eds]. Control of the Onset of PubertyIII. Amsterdam, Elsevier, 1989; pp 357373.)

Regularly scheduled visits also provide the opportunity for continued counseling. Increasing numbers of patients are now completing treatment after years of therapy, and the return of gonadal function has been assessed. In 46 girls treated for at least 2 years who completed therapy at a mean age of 11 years, menarche occurred at a mean age of 12.1 years, which represents an average of 1.2 years after discontinuing therapy. Ovulation occurred in 50% of girls 1 year after menarche and in 90% of those studied 2 or more years after menarche. Spontaneous menstrual cycles occurred at a mean of 18 months in another follow-up study after LHRH agonist therapy ceased with a range of 0 to 60 months. This pattern is quite similar to that of normal pubertal maturation. There is no delay in the development of the hypothalamo-pituitary axis in girls with true precocious puberty treated with LHRH agonist therapy. Reports on boys with true precocious puberty after LHRH therapy was discontinued confirm the reversible nature of the therapy. Gonadotropins in the basal or LHRH-stimulated state return to normal pubertal values by 1 year after cessation of therapy. However, testicular size may take longer to reach normal values.

The criteria for treatment of patients with true precocious puberty are listed in Table 24-42. Therapy is not indicated if a pubertal pattern of pulsatile LH secretion during sleep is not present or if the LH response to exogenous LHRH is prepubertal. Before beginning treatment, it is essential to establish the rapidly progressive nature of the sexual precocity. Girls without a reduced height potential do not require LHRH agonist therapy to ensure an appropriate final height outcome; these girls tend to have lower serum IGF-I and estradiol concentrations and may have fewer signs of estrogenization. The most severely affected girls are the ones who respond best to LHRH agonist therapy. In a subset of girls, the tempo is relatively slow and the sexual precocity may not be sustained. The growth rate slows to normal for age, skeletal maturation progresses in accordance with chronologic age, and there is little to no risk of impairment of final height. In some girls, we have observed within a 1- to 2-month period the return of a pubertal pattern of LH pulsatility during sleep, of a pubertal LH response to LHRH, and of the concentration of plasma estradiol to a pubertal state; unlike the typical patients, such girls do not exhibit the initial hyperresponse of plasma estradiol and LH to the LHRH agonist. Many girls in this subset have clinical and hormonal features that fall between those of premature thelarche and true precocious puberty and are typical of neither condition, so-called exaggerated thelarche.

Many girls in this subset have clinical and hormonal features that fall between those of premature thelarche and true precocious puberty and are typical of neither condition, so-called exaggerated thelarche.

About 10% of girls with apparently classical premature thelarche progress to definite true precocious puberty with no signs at the time of first presentation to differentiate them from girls who continued with the pattern of premature thelarche; in the majority of this situation, the onset of breast development is noted after 2

years of age. Psychosocial factors and parental anxiety that adversely affect the well-being of the child need to be assessed in the decision to initiate LHRH agonist treatment.

**Adverse Effects**

Unwanted reactions to LHRH agonists in the treatment of true precocious puberty have so far been minimal but include local and systemic allergic reactions in a few patients, including asthmatic episodes when the agent is given intranasally. However, the prevalence of a sterile abscess at the site of intramuscular injection of long-acting repository preparations, including leuprolein and triptorelin, is clearly increased (5% to 10%), unpredictable, and intermittent and in most instances is related to the polyactic and polyglycolic polymer and not to the LHRH agonist itself. Switching to daily subcutaneous injections or to intranasal administration of nondepot preparations is rarely associated with a recurrence.

When treatment is discontinued, even after 8 years, the gonadal suppression is reversed within a few weeks to months with a rise in the concentration of plasma gonadal steroids, progression of sexual maturation, and return of menses. A small increase in serum prolactin above normal limits, but not galactorrhea, has been described in girls following treatment with LHRH agonist. Areal BMD, but not volumetric bone, is increased in children with central precocious puberty. Although a decrease in bone density has been reported in LHRH agonist-treated patients, later studies indicated that volumetric BMD and peak bone mass are normal during and after discontinuation of LHRH therapy. Despite these encouraging results, one must be alert to the possible emergence of unforeseen long-term side effects. Four patients developed slipped capital femoral epiphyses during or just after treatment of central precocious puberty with LHRH agonist.

LHRH agonists are effective in both boys and girls with idiopathic true precocious puberty, the androgen-induced form of secondary true precocious puberty after therapy for virilizing congenital adrenal hyperplasia with glucocorticoids, and organic or neurogenic forms of true precocious puberty associated with hamartomas of the tuber cinereum, hypothalamic neoplasms, and other CNS lesions. Although there are reports in the literature of surgical removal of hamartomas of the tuber cinereum, the ease of medical treatment of the sexual precocity associated with this congenital malformation, the finding that the mass does not enlarge on MRI or CT brain scans, and the risks of an adverse outcome of surgical intervention in this region of the CNS, the use of LHRH agonists in idiopathic true precocious puberty has increased in recent years. Psychosocial factors and parental anxiety, including evidence that the child's psychosocial well-being is adversely affected, are important factors in the decision to initiate treatment with LHRH agonists.

In children with neurogenic or organic true precocious puberty, especially those with associated GH deficiency, the course is almost invariably progressive and LHRH treatment should not be delayed.

**Psychosocial Aspects**

Psychological management is an important aspect of the care of children with true precocious puberty. With the advanced physical maturation for chronologic age, they tend to seek friends closer to their size, strength, and physical development. Difficulties may arise because they lack the social skills of older children. Sex education of the child and the family is essential and must be given in a skilful, sensitive, and explicit manner; the risks of sexual abuse in both sexes and of pregnancy in girls need to be discussed. The parents need to be informed about the management of menses. The onset of sexual activity may be earlier than average but generally remains within the normal range.

It is imperative to provide support in handling the increased height, advanced sexual maturation, and effects of gonadal steroids on behavior, activity, and emotional
In this group of disorders, the secretion of testosterone in boys and of estrogen in girls is independent of the hypothalamic LHRH pulse generator (see Table 24-32). Affected individuals do not exhibit a pubertal-type LH response to administration of LHRH or a pubertal pattern of pulsatile LH secretion, nor do they respond to chronic administration of an LHRH agonist with suppression of gonadal steroid output. Incomplete isosexual precocity or precocious pseudopuberty is a consequence of both gonadal and adrenal steroid secretion independent of LHRH, of iatrogenic exposure to gonadal steroids, or, in boys, of rare hCG- or LH-secreting tumors.

Boys

Choricontin Gonadotropin-Secreting Tumors

Several types of germ cell tumors can secrete a glycoprotein hormone that has the bioactivity of LH or hCG and can cross-react in some polyclonal LH radioimmunoassay systems. Studies using highly specific antisera to the subunit of hCG, however, confirm that the gonadotropin is hCG. Boys with hCG-secreting neoplasms may have slightly enlarged testes (although not usually to a size consonant with the size of the phallus and other male secondary sex characteristics) and may be difficult to differentiate from boys with accelerated puberty on the basis of physical examination alone. However, plasma hCG levels are elevated without an increase in the concentration of FSH or LH. Hepatomas and hepatoblastomas are among the most serious of these tumors and cause firm, irregular nodular or smooth hepatic enlargement (Fig. 24-69). The hCG has been localized to the multicellular tumor giant cells; in one case, -fetoprotein was found in the embryonal-type tumor cells spread throughout the hepatoblastoma. The average survival is only 10.7 months after diagnosis; the mean age at onset is 2 years, 8 months.

Some teratomas, chorioepitheliomas, or mixed germ cell tumors in the hypothalamic region (or in the mediastinum, the lungs, or the retroperitoneum) and certain hypothalamic pineal tumors (usually a germ cell tumor or mixed germ cell tumor, less commonly a chorioneplithelioma or its variants) cause sexual precocity in boys by secreting hCG rather than by activating the hypothalamic LHRH pulse generator and the pituitary gonadotropin gonadotropin axis. The prevalence of hCG-secreting embryonal neoplasms, especially of the mediastinum, is increased in boys with 47,XXY or mosaic Klinefelter's syndrome. About 20% of mediastinal germ cell tumors occur in boys with Klinefelter's syndrome, a prevalence 30 to 50 times that in unaffected boys. Plasma -fetoprotein is a useful additional marker for yolk sac (endodermal sinus) or mixed germ cell tumors; the cells in the tumor that secrete -fetoprotein appear to differ from those that secrete hCG. Intracranial germ cell tumors are 2.6 times more common in males than females; in females, germ cell tumors do not cause gonadotropin-induced isosexual precocity because of the paucity of effects of hCG in prepubertal females. However, they can cause true precocious puberty through disinhibition of the hypothalamic LHRH pulse generator by local effects; rarely, the germ cells contain sufficient aromatase activity to convert circulating C19 precursors (of adrenal origin after adrenarche) to estradiol, which in some instances is sufficient to induce breast development. In mixed germ cell tumors, on the other hand, hCG is commonly present in the blood as well as in cerebrospinal fluid.

"True" pure CNS germ cell tumors (germinomas) secrete insufficient hCG to be readily detectable in the circulation, but in some patients hCG can be detected in the cerebrospinal fluid. In mixed germ cell tumors, on the other hand, hCG is commonly present in the blood as well as in cerebrospinal fluid.

In children, germ cell tumors in the suprasellar-hypothalamic region do not exhibit a sex predominance and are generally associated with pituitary hormone deficiencies including diabetes insipidus. Germ cell tumors that secrete hCG are rarely located in the thalamus and basal ganglia. Intracranial germ cell tumors account for 3% to 11% of malignant CNS tumors in children and adolescents, with a predominance in the Far East. Germ cell tumors of the hypothalumus or pineal region constitute less than 1% of primary CNS tumors in Western countries but account for 4.5% of such tumors in Japan. Mixed germ cell tumors and especially pure germinomas are radiosensitive, and regression of sexual precocity may occur if the bone age is less than 11 years, only to progress later into normal puberty. Long-term survival was reported to be 88% after appropriate therapy. Calcification of the pineal is found in 8% to 11% of 8- to 11-year-old children and by itself is not indicative of a tumor. Gonadotropin-secreting pituitary adenomas are exceedingly rare in children. An LH- and prolactin-secreting pituitary adenoma caused sexual precocity in two boys. The concentration of serum LH was strikingly elevated (900 IU/L) and did not rise further after the administration of LHRH. The elevated serum testosterone (7 mmol/L, 200 ng/dL) and prolactin (215 μg/L) levels and the high concentration of LH fell to prepupal values after removal of a "chromophobe" adenoma with suprasellar extension.

Precocious Androgen Secretion Caused by Congenital Adrenal Hyperplasia, Virilizing Adrenal Tumor, or Leydig Cell Tumor

Virilizing congenital adrenal hyperplasia caused by a defect in 21-hydroxylase (CYP21, cytochrome P450 21α deficiency) leads to elevated androgen concentrations and masculinization and is a common cause of LH- and hCG-independent sexual precocity in boys (see Chapter 22). Approximately 75% of patients with P450 21α deficiency have salt loss resulting from impaired aldosterone secretion and have low serum sodium and high serum potassium concentrations. Increased plasma concentrations of 17-hydroxyprogesterone, increased levels of urinary 17-ketosteroids and pregnanetriol, and advanced bone age and rapid growth are characteristic. Treatment with glucocorticoids suppresses the abnormal androgen secretion and virilization; treatment with mineralocorticoids, when necessary, corrects the electrolyte imbalance. A rarer form of virilizing adrenal hyperplasia is usually accompanied by hypertension and is caused by 11-hydroxylase deficiency; the plasma hCG levels are elevated without an increase in the concentration of FSH or LH. Calcium and phosphorus and ketogenic hyperplasia are among the most serious of these tumors and cause firm, irregular nodular or smooth hepatic enlargement (Fig. 24-69). The hCG has been localized to the multicellular tumor giant cells; in one case, -fetoprotein was found in the embryonal-type tumor cells spread throughout the hepatoblastoma. The average survival is only 10.7 months after diagnosis; the mean age at onset is 2 years, 8 months.

Some teratomas, chorioepitheliomas, or mixed germ cell tumors in the hypothalamic region (or in the mediastinum, the lungs, or the retroperitoneum) and certain hypothalamic pineal tumors (usually a germ cell tumor or mixed germ cell tumor, less commonly a chorioneplithelioma or its variants) cause sexual precocity in boys by secreting hCG rather than by activating the hypothalamic LHRH pulse generator and the pituitary gonadotropin gonadotropin axis. The prevalence of hCG-secreting embryonal neoplasms, especially of the mediastinum, is increased in boys with 47,XXY or mosaic Klinefelter's syndrome. About 20% of mediastinal germ cell tumors occur in boys with Klinefelter's syndrome, a prevalence 30 to 50 times that in unaffected boys. Plasma -fetoprotein is a useful additional marker for yolk sac (endodermal sinus) or mixed germ cell tumors; the cells in the tumor that secrete -fetoprotein appear to differ from those that secrete hCG. Intracranial germ cell tumors are 2.6 times more common in males than females; in females, germ cell tumors do not cause gonadotropin-induced isosexual precocity because of the paucity of effects of hCG in prepubertal females. However, they can cause true precocious puberty through disinhibition of the hypothalamic LHRH pulse generator by local effects; rarely, the germ cells contain sufficient aromatase activity to convert circulating C19 precursors (of adrenal origin after adrenarche) to estradiol, which in some instances is sufficient to induce breast development. In mixed germ cell tumors, on the other hand, hCG is commonly present in the blood as well as in cerebrospinal fluid.

"True" pure CNS germ cell tumors (germinomas) secrete insufficient hCG to be readily detectable in the circulation, but in some patients hCG can be detected in the cerebrospinal fluid. In mixed germ cell tumors, on the other hand, hCG is commonly present in the blood as well as in cerebrospinal fluid.

In children, germ cell tumors in the suprasellar-hypothalamic region do not exhibit a sex predominance and are generally associated with pituitary hormone deficiencies including diabetes insipidus. The elevated serum testosterone (7 mmol/L, 200 ng/dL) and prolactin (215 μg/L) levels and the high concentration of LH fell to prepupal values after removal of a "chromophobe" adenoma with suprasellar extension.

Precocious Androgen Secretion Caused by Congenital Adrenal Hyperplasia, Virilizing Adrenal Tumor, or Leydig Cell Tumor

Virilizing congenital adrenal hyperplasia caused by a defect in 21-hydroxylase (CYP21, cytochrome P450 21α deficiency) leads to elevated androgen concentrations and masculinization and is a common cause of LH- and hCG-independent sexual precocity in boys (see Chapter 22). Approximately 75% of patients with P450 21α deficiency have salt loss resulting from impaired aldosterone secretion and have low serum sodium and high serum potassium concentrations. Increased plasma concentrations of 17-hydroxyprogesterone, increased levels of urinary 17-ketosteroids and pregnanetriol, and advanced bone age and rapid growth are characteristic. Treatment with glucocorticoids suppresses the abnormal androgen secretion and virilization; treatment with mineralocorticoids, when necessary, corrects the electrolyte imbalance. A rarer form of virilizing adrenal hyperplasia is usually accompanied by hypertension and is caused by 11-hydroxylase deficiency; the progressive virilization ceases and the blood pressure falls to normal with glucocorticoid therapy.

All forms of congenital adrenal hyperplasia are inherited as autosomal recessive traits. Virilizing congenital adrenal hyperplasia, if untreated, can cause anovulatory amenorrhea in females and oligospermia in males; with treatment, the infertility is usually corrected (see Chapter 22). Treatment of virilizing congenital adrenal hyperplasia may unmask LH- and hCG-dependent sexual precocity (secondary true precocious puberty) as a consequence of the advanced somatic and presumably hypothalamic maturation because of exposure to androgen before glucocorticoid therapy is initiated.
canceroma may cause isosexual precocity and growth failure in boys. Rarely, an adrenal adenoma may produce both testosterone and aldosterone, leading to sexual precocity and hypertension with hypokalemia.  

Adrenal rests, or heterotopic adrenal tissue in the testes, may enlarge with endogenous ACTH stimulation in boys with untreated or inadequately treated virilizing congenital adrenal hyperplasia and may mimic bilateral or unilateral interstitial cell tumors. Rarely, the adrenal rests may lead to massive enlargement of the testes (see Chapter 22). MRI sonography including Doppler flow studies of the testes is useful in defining the extent and nature of the testicular masses. In boys in whom the testicular tumors are unresponsive to glucocorticoid therapy or improved compliance, surgical management including enucleation of the tumor has been useful in preventing further damage to the testes and improving the potential for fertility. LH receptors have been detected on adrenal or cortical cells. Although some of the testicular masses may become autonomous, it seems possible that LH stimulation is a factor in some patients.

Infrequently, a Leydig cell tumor in boys is the cause of sexual precocity; unilateral enlargement (often nodular) of the testis usually occurs in this neoplasm (although 5% to 10% are bilateral), in contrast to the usually normal size of both testes for chronologic age in boys with congenital adrenal hyperplasia or a virilizing adrenal tumor. Of interest, an LH receptoractivating mutation was detected in three boys with a sporadic Leydig cell adenoma (see later).  

Women with a previous history of congenital adrenal hyperplasia may exhibit ovarian hyperandrogenism associated with persistent elevation of LH in spite of successful treatment of their initial virilizing condition in childhood: this is not usually the case in women who have late-onset congenital adrenal hyperplasia.  

A unique form of sexual precocity in males is pituitary gonadotropin-independent familial premature Leydig cell and germ cell maturation, or testotoxicosis.  

Although it has been recognized as an LHRH-independent form of male isosexual precocity only since 1981, this disorder was described more than 50 years ago. Indeed, Andrew Shenker brought to our attention a report by Stone in 1852. Affected boys have secondary sexual development with penile enlargement and bilateral enlargement of testes to the early or midpubertal range, although the testes are often smaller than expected in relation to penile growth and pubertal maturation (Fig. 24-70). The tests show premature Leydig and Sertoli cell maturation and spermatogenesis; in some instances, Leydig cell hyperplasia is present. The rate of linear growth is rapid, skeletal maturation is advanced, and muscular development is prominent. Serum hormone determinations reveal prepubeal basal and LHRH-stimulated gonadotropin concentrations and lack of a pubertal pattern of LH pulsatility, with LH being stimulated by immunologic or biologic techniques (Table 24-44). In affected boys, plasma testosterone values are in the normal pubertal or adult range with normal clearance of testosterone. The onset of adrenarche and its biochemical marker, serum DHEAS, correlates with bone age rather than chronologic age.

Treatment with an LHRH agonist does not suppress the testicular function or maturation. When most untreated affected individuals reach late childhood or early adolescence, fertility is achieved and an adult pattern of LH secretion and response to LHRH is demonstrable; secondary LHRH-dependent true precocious puberty is superimposed on the substrate of testotoxicosis. In some adults, impaired spermatogenic function is associated with elevated concentrations of plasma FSH. This disorder, although it occurs sporadically, quite likely as a consequence of a germ line mutation or even a postzygotic one, is inherited as a sex-linked autosomal dominant trait and probably accounts for the earlier descriptions of "true" precocious puberty in families in which only males were affected. A kindred with nine generations of affected males has been reported; obligatory female carriers of the trait were unaffected as constitutional activation of the LH receptor on the ovary causes no ill effects.

In 1993, Shenker and Kremers and their colleagues independently described heterozygous activating mutations of the heterotrimeric G protein-coupled LH/CG receptor that in concert transduce the LH/CGR signal to the main effector, adenylyl cyclase (Fig. 24-71). The receptors for pituitary and placental gonadotropins and TSH belong to a subfamily of the seven-transmembrane-spanning, G protein-coupled receptors. The LH receptor, first cloned from the rat  and pig  and later the human, is a glycoprotein of 80 to 90 kDa. It is encoded by a gene localized to chromosome 2q21 (the same as the FSH receptor) that spans at least 70 kb and contains 11 exons separated by 10 introns. The large glycosylated amino-terminal extracellular hormone-binding domain of the 701-amino-acid LH/CG receptor is encoded by exons 1 to 10. A single exon, the large exon 11, encodes the entire G-linked transmembrane domain with its 7-helical segments connected by alternating extracellular and intracellular loops, the intracellular domain, and the 3 untranslated region. Most two-thirds of the receptor  and (see Fig. 24-71).

Thirteen constitutively activating heterozygous missense mutations (in over 60 reported patients) all residing within exon 11 have been reported (see Fig. 24-71): six involve the transmembrane helix VI, two involve the flanking third cytoplasmic loop, there is one each in helix V and helix II, and less commonly there are mutations in the first transmembrane helix . Thus, nine mutations are between amino acid residues 542 and 561, suggesting a hot spot. There appears to be a limited repertoire of mutations in American boys, consistent with a founder effect; European pedigrees are more diverse. A model of the transmembrane domain of the receptor provides novel suggestions concerning the structural and functional effects of these activating mutations. Transfected cultured cells with these mutations exhibited increased basal cAMP production in the absence of agonist, observations consistent with a constitutive activating mutation. The conformational changes in the LH receptor that lead to its constitutive activation have yet to be established, but various possibilities have been considered. The LHRH-dependent puberty usually ensues in adolescence. Infertility related to testicular damage can occur in adult men. Inactivating mutations of the LH receptor and their clinical consequences are discussed in Chapter 22.

In one Polish family, the disorder, a mutation of M298T in the second transmembrane domain of the LH receptor, led to sexual precocity in one boy but not in the mother, who carried the same mutation, or in her father or his son, the male uncle, suggesting the involvement of epigenetic factors. Three boys with sexual precocity related to a sporadic Leydig cell adenoma had an Asp 578 His mutation in the tumor (Fig. 24-72) (Fig. Not Available). The remarkable association of testotoxicosis and pseudohermaphroditism type Ia due to a mutation in the subunit of Gs is considered in the following. Boys with LHRH-independent, pituitary gonadotropin-independent maturation of the testes do not respond to chronic administration of an LHRH.
agonist with suppression of testosterone secretion, in contrast to the characteristic response in patients with true precocious puberty. However, testosterone secretion, height velocity and rate of bone maturation, and aggressive and hyperactive behavior have been decreased by treatment with oral medroxyprogesterone acetate.

Two other therapies have been used (Table 24-45). Ketoconazole, an orally active substituted imidazole derivative, suppresses gonadal and adrenal biosynthesis at several steps. At the dosage used in testotoxicosis (200 mg every 8 to 12 hours orally), ketoconazole mainly inhibits the enzyme cytochrome P450, which regulates both 17β-hydroxylation and the scission (17,20-lyase) of hydroxypregnenolone to dehydroepiandrosterone (see adrenarche in this chapter). However, even at the recommended dose, the agent produces a mild transient decrease in cortisol secretion and interferes with binding of testosterone to TeBG. Secondary true precocious puberty often occurs when the bone age advances to or has already reached the pubertal range (usually > 11.5 years), at which time addition of an LHRH agonist is appropriate. Ketoconazole can cause hepatic injury, which is usually mild and reversible, but hepatotoxicity is rarely severe. Further, reversible renal injury, rash, and interstitial pneumonia have been reported in a patient who tolerated lower doses, suggesting a dose-response effect.

Another therapeutic approach has been the use of the antiandrogen (and antiminalarcolcorticoid) spironolactone combined with testolactone, an inhibitor of cytochrome P450 aromatase.

![Figure 24-71](https://example.com/figure24-71.png) A, The serpentine seven transmembrane Gq protein coupled LH/hCG receptor with its large extracellular domain and the intracellular domain. The seven helical transmembrane domains are indicated by Roman numerals. E, The two-dimensional seven-transmembrane topology of the LH/hCG receptor with positions of constitutively activating mutations causing testotoxicosis (male-limit ed autosomal dominant sexual precocity). The mutations are indicated by solid circles and the residue number. Note the cluster of mutations in the VI transmembrane helix and third cytoplasmic loop. The aspartine 578 glycine mutation is the most common. (Redrawn from Yano K, Kohn LD, Saij M, et al. A case of male limited precocious puberty caused by a point mutation in the second transmembrane domain of the luteinizing hormone chorionadotropin receptor gene. Biochim Biophys Acta 1996; 220:10381042.)

(CYP19), the key enzyme in the conversion of androgens to estrogens. Because these boys often experience secondary central precocious puberty after control with spironolactone and testolactone, the addition of an LHRH agonist is a useful step to suppress pituitary gonadotropin secretion.

Girls

Incomplete isosexual precocity in girls (see Table 24-32) is caused by conditions in which estrogen is secreted autonomously by an ovarian cyst or tumor, by an adrenal neoplasm, or because of inadvertent exposure to estrogen. In a pure hCG-secreting tumor in girls, signs of isosexual precocity are absent. Girls harboring a teratoma or teratocarcinoma (or a cyst germ cell tumor) that secretes hCG have had sexual precocity caused by concurrent estrogen secretion by the tumor; these girls may also have galactorrhea, especially if chorionic somatomammotropin (human chorionic somatomammotropin, human placental lactogen) is also secreted.

**Autonomous Ovarian Follicular Cysts**

The most common estrogen-secreting ovarian mass and ovarian cause of sexual precocity is the follicular cyst. Antral follicles up to about 8 mm in diameter are common in the ovaries of normal prepubertal girls and may be seen in third-trimester fetuses and newborn infants. They may appear and regress spontaneously. Large follicular cysts may be discovered because of the presence of an abdominal mass or abdominal pain, especially after torsion or as an unexpected finding on pelvic sonography for other reasons. Occasionally, the antral follicles secrete estrogen and may enlarge to form large masses, or the follicular cysts may recur and cause recurrent signs of sexual precocity and acyclic vaginal bleeding.

Enlarged antral follicles or cysts occur in premature thelarche, true precocious puberty, and transient or incomplete sexual precocity. With some ovarian follicular cysts, the transient or recurrent sexual precocity is LH/FSH-independent. The concentration of estradiol fluctuates, usually correlating with changes in the size of the follicular cyst when monitored by pelvic sonography, and may increase to levels found in a granulosa cell tumor. The concentration of LH is suppressed, a pubertal pattern of pulsatile LH secretion is absent, and the LH rise induced by LH/FSH is prepubertal.

It is curious that a constitutive activating mutation of the FSH receptor is undescribed in a female, especially because a heterozygous mutation, Asp 567 Gly, has been detected in the third intracellular loop of the FSH receptor in a hypophysectomized man who, despite the gonadotropin deficiency, was fertile and had normal-sized testes. A constitutive activating mutation of the FSH receptor seems worthy of study. The McCune-Albright syndrome needs to be considered in any girl with recurrent ovarian cysts, even at the recommended dose, the agent produces a mild transient decrease in cortisol secretion and interferes with binding of testosterone to TeBG. Secondary true precocious puberty often occurs when the bone age advances to or has already reached the pubertal range (usually > 11.5 years), at which time addition of an LHRH agonist is appropriate. Ketoconazole can cause hepatic injury, which is usually mild and reversible, but hepatotoxicity is rarely severe. Further, reversible renal injury, rash, and interstitial pneumonia have been reported in a patient who tolerated lower doses, suggesting a dose-response effect.

Another therapeutic approach has been the use of the antiandrogen (and antiminalarcolcorticoid) spironolactone combined with testolactone, an inhibitor of cytochrome P450 aromatase.

An unusual syndrome of estradol-secreting ovarian cysts in preterm infants born before 30 weeks of gestation is associated with edema of the labia majora and, in some instances, of the lower abdominal wall. In four preterm neonates the syndrome appeared weeks after birth and 1 to 4 weeks before the putative date of a full-term gestation. The follicular cysts, which may be unilateral or bilateral, were detected by abdominal
and pelvic sonography. The LH and FSH response to LHRH suggested that the cysts were LHRH-dependent. Treatment with medroxyprogesterone acetate was associated with regression of the cysts. LHRH agonists are useful in the treatment of ovarian follicular cysts associated with true precocious puberty (LHRH-dependent) but not so-called autonomous cysts. However, girls with autonomously functioning ovarian follicular cysts, whether recurrent or an isolated episode, often respond to treatment with oral medroxyprogesterone-one acetate but not to LHRH agonists. Medroxyprogesterone acetate also seems to prevent recurrence and accelerate involution of the follicular cysts and reduce the risk of torsion. The use of one of the new, potent estrogen inhibitors such as letrozole to reduce estradiol secretion is another potential approach to treatment. Surgical intervention is rarely indicated; a large or persistent cyst can be reduced by puncture at laparoscopy. The size of the cyst can be monitored readily by pelvic sonography.

Plasma estradiol concentrations in girls with recurrent cysts (>7 cm) may increase to high levels indistinguishable from those in granulosa cell tumors of the ovary, but they do not have increased plasma granulosa cell tumor markers such as AMH and inhibin. Alternatively, the levels of estrogen in blood and urine may be in the early pubertal range. A characteristic feature in girls with recurrent cysts is waxing and waning of estrogen levels that correlate with changes in the appearance of the ovary on pelvic sonography. Pelvic sonography is useful for visualization of ovarian cysts and estimation of functional activity. Sonograms of the ovary facilitate diagnosis. After surgical removal, measurements of plasma estradiol and inhibin levels are a useful screen for metastases. If the patient is younger than 9 years an elevated estradiol and at any age an abnormal rise in concentration of plasma AMH or inhibin suggests recurrence or metastasis.

Occasionally, gonadoblastomas in streak gonads, rare lipid tumors, cystadenomas, and ovarian carcinomas secrete estrogens, androgens, or both hormones. Even with successful resection of a gonadal sex steroidsecreting neoplasm, the child is at risk for secondary central precocious puberty developing in the future. Gonadal tumors composed of a mixture of germ cells and sex cord stromal cells that are distinct from gonadoblastoma are usually benign when discovered in female infants or children with 46,XX karyotypes, although neoplastic transformation is a risk. Two cases of metastasizing malignant mixed germ cell sex cordstromal tumors have been described in prepubertal girls with isosexual precocity. Some of these neoplasms secrete -fetoprotein and other tumor markers. Ovarian tumors are rare in the prepubertal period, accounting for about 1% of all tumors in girls younger than 17 years, and most are benign. The majority of ovarian tumors arise from germ cells or sex cord stromal cells in childhood and less than 20% are of epithelial origin, whereas in adults the majority of tumors are of epithelial origin. Early diagnosis of most childhood tumors of the ovary, unlike ovarian cancer in women, allows successful cure.

Granulosa Cell Tumor of the Ovary

This tumor is rare in childhood, and theca cell tumors are even less common. Juvenile granulosa cell tumors have distinctive features that differentiate them from the tumors in adults. Characteristic histologic features include nodular architecture, follicle formation, abundant interstitial and intrafollicular acid mucopolysaccharidich fluid, irregular microcysts, individual cell necrosis, and high mitotic activity (mean activity, 11 mitotic figures per 10 high-power fields). Size can vary from 2.5 to 25 cm with a mean diameter of 12 cm. The interstitial mucinous fluid consists predominantly of hyaluronic acid. The prognosis is good as only about 3% of patients die of the disease. Approximately 80% of granulosa cell tumors can be palpated on bimanual examination. Less than 5% are bilateral or clinically malignant. The concentration of plasma estradiol may increase to high levels; FSH and LH concentrations are usually suppressed. The tumor secretes AMH and inhibin, which are sensitive tumor markers. Sonograms of the ovary facilitate diagnosis. After surgical removal, measurements of plasma estradiol and AMH levels are a useful screen for metastases. If the patient is younger than 9 years an elevated estradiol and at any age an abnormal rise in concentration of plasma AMH or inhibit suggests recurrence or metastasis.

This autosomal dominant syndrome of mucocutaneous pigmentation of the lips, buccal mucosa, fingers, and toes; gastrointestinal hamartomatous polyposis; and a predisposition to malignancy is associated with a rare, distinctive sex cord tumor with annular tubules in both boys and girls. Estrogen secretion by the tumor may lead to feminization and incomplete sexual precocity in boys as well as girls. Less frequently, an epithelial tumor of the ovary, dysgerminoma, or a feminizing Sertoli-Leydig cell tumor has been found in patients with Peutz-Jeghers syndrome. Children with this disorder should be examined at regular intervals for the presence of gonadal tumors by pelvic sonography. The syndrome is due to mutations in the gene on 9p13.3 encoding a serine/threonine protein kinase STK11 leading to haplosufficiency of this novel tumor-suppressing gene.

Sex cord-stromal tumors derive from the coelomic epithelium or mesenchymal cells of the embryonic gonads and are composed of granulose, theca, Leydig, and Sertoli cells. Estrogen secretion from these tumors can cause pseudoprecocious puberty, and androgen secretion can cause virilization. Both inhibin A and B activin are produced as well as antimüllerian factor; all serve as useful tumor markers. Sex cord-stromal tumors not associated with Peutz-Jeghers syndrome are malignant in 25% of patients; these tumors may grow quite large, whereas those associated with Peutz-Jeghers syndrome are often small and multiple, and contain

Peutz-Jeghers Syndrome

This autosomal dominant syndrome of mucocutaneous pigmentation of the lips, buccal mucosa, fingers, and toes; gastrointestinal hamartomatous polyposis; and a predisposition to malignancy is associated with a rare, distinctive sex cord tumor with annular tubules in both boys and girls. Estrogen secretion by the tumor may lead to feminization and incomplete sexual precocity in boys as well as girls. Less frequently, an epithelial tumor of the ovary, dysgerminoma, or a feminizing Sertoli-Leydig cell tumor has been found in patients with Peutz-Jeghers syndrome. Children with this disorder should be examined at regular intervals for the presence of gonadal tumors by pelvic sonography. The syndrome is due to mutations in the gene on 9p13.3 encoding a serine/threonine protein kinase STK11 leading to haplosufficiency of this novel tumor-suppressing gene.

Sex cord-stromal tumors derive from the coelomic epithelium or mesenchymal cells of the embryonic gonads and are composed of granulose, theca, Leydig, and Sertoli cells. Estrogen secretion from these tumors can cause pseudoprecocious puberty, and androgen secretion can cause virilization. Both inhibin A and B activin are produced as well as antimüllerian factor; all serve as useful tumor markers. Sex cord-stromal tumors not associated with Peutz-Jeghers syndrome are malignant in 25% of patients; these tumors may grow quite large, whereas those associated with Peutz-Jeghers syndrome are often small and multiple, and contain
Adrenocortical tumors are rare in childhood (reported to be 0.6% of all childhood tumors and 0.3% of all malignant childhood tumors), but most produce steroid hormones in children whereas those in adults usually do not. The median age of diagnosis is 4 years, with various studies stating mean ages of 2, 4.3, and 5 years. Forty-one percent appear before 2 years and 71% before 5 years of age. Most cause virilization or Cushing's syndrome, but adrenal tumors may produce estrogen as well and androgens and cause sexual precocity in a girl or gynecomastia in a boy. One adrenal adenoma found in a 7-year-old girl expressed the gene for aromatase, demonstrating that the tumor could directly produce estrogen. There was substantial production of estrogen leading to a serum estradiol concentration of 145 pg/mL, a value in the range that is found in adrenal carcinomas as well as adrenomas.

McCune-Albright Syndrome

This sporadic syndrome, which occurs about twice as often in girls as in boys, is due to somatic activating mutations in the gene (GNAS1) encoding the subunit of the trimeric guanosine triphosphate (GTP)-binding protein (Gαs) that stimulates adenyl cyclase. It is characterized by the triad of irregularly edged hyperpigmented macules (café-au-lait spots); a slowly progressive bone disorder, polyostotic fibrous dysplasia, that can involve any bone and is frequently associated with facial asymmetry and hyperostosis of the base of the skull; and, more commonly in girls, LHRH-independent sexual precocity. Autonomous hyperfunction most commonly involves the ovary, but other endocrine involvement includes thyroid (nodular hyperplasia with thyrotoxicosis or, remarkably, with euthyroid status).

![Image](https://example.com/image.png)

**Figure 24-74** A 7 4/12-year-old girl with luteinizing hormone-releasing hormone (LHRH)-independent sexual precocity associated with McCune-Albright syndrome. She had breast development since infancy, and it increased noticeably at about 5 years of age; 6 months later episodes of recurrent vaginal bleeding began. Growth of pubic hair was noted at about 4 to 5 years of age. At age 5 1/2 years the bone age was 6 1/2 years; height was +1 SD above the mean value for age. By 6 1/2 years of age, when she was seen at the University of California, San Francisco, the bone age had advanced to 9 years, and height was +1 SD. Breasts were at Tanner stage 4; pubic hair at stage 3. Extensive irregular café-au-lait macules cover the right side of the face, left lower abdomen and thigh, and both buttocks. A bone survey showed widespread involvement of the long bones with typical polyostotic fibrous dysplasia, and the floor of the anterior fossa of the skull was sclerotic and the diploic space widened. She has had two pathologic fractures through bone cysts in the right upper femur. Note the osseous deformities. Plasma estradiol concentrations were consistently in the pubertal range; LH response to LHRH was prepubertal. Results of thyroid function studies were normal, including the thyrotropin response to thyrotropin-releasing hormone administration and antithyroid antibodies were not detected. Treatment with oral medroxyprogesterone acetate suppressed menses and arrested pubertal development but did not slow skeletal maturation. Her final height is 142 cm (+2.5 SD). Menstrual cycles are regular.

Adrenal (multiple hyperplastic nodules with Cushing's syndrome), pituitary (adenoma or mammosomatotroph hyperplasia with gigantism and acromegaly and hyperprolactinemia), and parathyroids (adenoma or hyperplasia with hyperparathyroidism). In addition, hypophosphatemic vitamin D-resistant rickets or osteomalacia can occur in this syndrome because of either overproduction of a phosphaturic factor, phosphatonin, or secreted by the bone lesions or an

**TABLE 24-46** -- Clinical Manifestations of McCune-Albright Syndrome in 158 Reported Patients

The skin manifestations may not be conspicuous in infancy, although the majority of patients have pigmented skin lesions in infancy that usually increase in size along with body growth. The irregular-bordered cafe-au-lait macules usually do not cross the midline, are often located on the same side as the main bone lesions, and have a segmented distribution.
manifested bone abnormalities by 8 years of age. Increased serum GH levels have an adverse effect on the skull deformities.

The sexual precocity, the onset of which is often in the first 2 years of life and is frequently heralded by menstral bleeding, is due to an autonomously functioning luteinized follicular cyst of the ovary (see Table 24-47). The ovaries contain multiple follicular cysts but not corpora lutea and commonly exhibit asymmetrical enlargement as a result of a large solitary cyst that characteristically enlarges and spontaneously regresses only to recur. Serum estradiol is elevated (at times to extraordinarily high levels); in contrast, the LH response to LHRH is prepubertal and the pubertal pattern of nighttime LH pulses is absent at the onset and during the initial years. Later in the course of the sexual precocity, when the bone age approaches 12 years, the LHRH pulse generator becomes operative and ovulatory cycles ensue. Thus, an affected girl may progress from LHRH-independent puberty to LHRH-dependent puberty (see Table 24-47). LHRH agonists are not effective for treatment in the LHRH-independent stage. Testolactone (40 mg/kg per day orally), a relatively weak aromatase inhibitor, has been of equivocal useffulness and some patients become resistant to the drug. The new, highly potent, specific, third-generation aromatase inhibitors, for example, letrozole, should be more effective. Antiestrogens offer another method of control of the estrogenic effects of the disorder. A single case of treatment with tamoxifen showed decreases in the age advancement, growth rate, menses, and pubertal development. Multicenter trials of antiestrogen and antiaromatase therapy in this disorder are in progress.

Sexual precocity is rare in boys with McCune-Albright syndrome. Affected boys may have asymmetrical enlargement of the testes in addition to signs of sexual precocity. The histologic changes are reminiscent of those in testotoxicosis; the seminiferous tubules are enlarged and exhibit spermatogenesis, and Leydig cells may be hyperplastic. The LH response to LHRH was prepubertal in two cases. The hormonal data (although scant) and the testicular findings appear similar to those in boys with familial testotoxicosis. A 3.8-year-old boy with McCune-Albright syndrome (Arg 201 His mutation detected in bone and testis tissue) had the unusual feature of macro-orchidism (right testis 9 mL, left testis 7 mL) and absence of sexual precocity. He had several cafe-au-lait lesions on the back and a radiograph of the skeleton showed polyostotic fibrous dysplasia. Gonadotropins, the LHRH stimulation test, and sex steroid levels were prepubertal but serum inhibin B and AMH concentrations were strikingly elevated. The tests on histology showed that most seminiferous tubules were "slightly" increased in diameter and filled with Sertoli cells but lacked a lumen. The tubules stained intensively for inhibin B subunit; mature Leydig cells were absent.

The pathogenesis of the sporadic McCune-Albright syndrome was uncertain since its first description. It may occur concordantly or discordantly in monozygotic twins; familial cases have not been described. In 1986, Happle posited that the disorder is caused by an autosomal dominant lethal gene that results in loss of the zygote in utero and that cells bearing this mutation survive only in embryos mosaic for the lethal gene. The early somatic mutation would lead to a mosaic pattern of the distribution of cells containing the mutation. The severity of the disorder would depend on the proportion of mutant cells in various embryonic tissues. The description of somatic mutations in human endocrine tumors that convert the peptide chain of the Gs protein into a putative oncogene (referred to as a gsp mutation) raised the possibility of a similar defect in the McCune-Albright syndrome that both affects a differentiated function such as a signaling pathway and mediates the regulation of proliferation. These hypotheses have now been established. Mutations in the gene encoding the subunit of the stimulatory G protein for adenyl cyclase were identified in the tissues of children with the McCune-Albright syndrome.

The heterotrimeric guanine nucleotide binding proteins (G proteins) are a subfamily within the large superfamily of GTP-binding proteins and serve to transduce signals from a large number of cell-surface receptors with a common structural motif of seven membrane-spanning domains to their intracellular effector molecules, including enzymes and ion channels; in essence, they couple serpentine cell-surface receptors to effectors. For Gs, the stimulatory G protein, the effector is adenyl cyclase, which is controlled by Gs and an inhibitory (Gi) G protein. The heterotrimer is composed of (1) an alpha subunit (39 to 45 kDa) that binds GTP and has intrinsic GTPase activity, which converts GTP to guanosine diphosphate (GDP), and (2) a subunit (35 to 36 kDa) and a smaller subunit (7 to 8 kDa) that are tightly but noncovalently associated with each other. A distinct gene encodes each of the subunits.

The G proteins function as conformational switches. The GDP-activated subunit is bound to the (i) subunits and is in an inactivated state. When its ligand or agonists activate the cell-surface receptor, the GTP is catalytically released from the subunit and enables GTP to bind. This leads to dissociation of the GTP-activated subunit, its dissociation from the bound (i) subunits, and activation of the effector, adenyl cyclase. When GTP is hydrolyzed by the intrinsic GTPase activity of G alpha subunit, the (i) subunits reassociate and the subunit is now in the off or inactive conformation. The three-dimensional structure of the heterotrimeric G proteins has been determined. Activating heterozygous mutations in the G subunit that occurred as an early postzygotic event have now been described in the McCune-Albright syndrome. The somatic constitutive activating mutation, which leads to excess cAMP production and in some tissues cAMP-induced hyperplasia, has a mosaic pattern and the proportion of the hyperactive mutant to normal cells varies in different tissues, contributing, at least in part, to the varied clinical findings, its severity, its sporadic nature, and the discordant occurrence in monozygotic twins. A germ line mutation is presumed to be lethal to the embryo. Two gain-of-function somatic missense mutations have been described in this disorder, both of which involve the arginine 201 residue of the subunit. The site of covalent modification by cholera toxin: arginine 201 with either a cysteine or a histidine substitution (see Fig. 24-77). The arginine

<td>A Patient with McCune-Albright Syndrome and Recurrent Ovarian Cysts</td>
<td>![Figure 24-75a](Bone lesions in McCune-Albright syndrome. A, The skull with severe thickening primarily at the base due to fibrous dysplasia. The auditory and optic nerves could be caught in narrowed foramina but that is not the case in these patients. B and C, distortions of the long bones, which can develop into a &quot;shepherd's crook&quot; appearance; note the multiple bone cysts. This mutation survive only in embryos mosaic for the lethal gene. The early somatic mutation would lead to a mosaic pattern of the distribution of cells containing the mutation. The severity of the disorder would depend on the proportion of mutant cells in various embryonic tissues. The description of somatic mutations in human endocrine tumors that convert the peptide chain of the Gs protein into a putative oncogene (referred to as a gsp mutation) raised the possibility of a similar defect in the McCune-Albright syndrome that both affects a differentiated function such as a signaling pathway and mediates the regulation of proliferation. These hypotheses have now been established. Mutations in the gene encoding the subunit of the stimulatory G protein for adenyl cyclase were identified in the tissues of children with the McCune-Albright syndrome.)</td>
<td>![Figure 24-75b](Bone scan showing the areas of remodeling that “light up” depending upon the area affected in individual patients. There are examples of patients primarily affected in the cranial area, in the appendicular area, and in both areas as well as the axial skeleton. (Courtesy of Michael T. Collins, M.D., National Institutes of Health, Bethesda, Maryland and Sandra Gorges, M.D., University of California, Davis.) The heterotrimeric guanine nucleotide binding proteins (G proteins) are a subfamily within the large superfamily of GTP-binding proteins and serve to transduce signals from a large number of cell-surface receptors with a common structural motif of seven membrane-spanning domains to their intracellular effector molecules, including enzymes and ion channels; in essence, they couple serpentine cell-surface receptors to effectors. (Fig. 24-77). For Gs, the stimulatory G protein, the effector is adenyl cyclase, which is controlled by Gs and an inhibitory (Gi) G protein. The heterotrimer is composed of (1) an alpha subunit (39 to 45 kDa) that binds GTP and has intrinsic GTPase activity, which converts GTP to guanosine diphosphate (GDP), and (2) a subunit (35 to 36 kDa) and a smaller subunit (7 to 8 kDa) that are tightly but noncovalently associated with each other. A distinct gene encodes each of the subunits. The G proteins function as conformational switches. The GDP-activated subunit is bound to the (i) subunits and is in an inactivated state. When its ligand or agonists activate the cell-surface receptor, the GTP is catalytically released from the subunit and enables GTP to bind. This leads to dissociation of the GTP-activated subunit, its dissociation from the bound (i) subunits, and activation of the effector, adenyl cyclase. When GTP is hydrolyzed by the intrinsic GTPase activity of G alpha subunit, the (i) subunits reassociate and the subunit is now in the off or inactive conformation. 201 residue is critical for subunit GTPase activity, and each of the two mutations decreases the GTPase activity of the \( \alpha \) subunit and leads to constitutive activation. These activating mutations have been found in all tissues affected in the syndrome, including bone lesions.

Manifestations of the McCune-Albright syndrome in infancy include Cushings syndrome related to macronodular adrenal cortical hyperplasia, hyperthyroidism caused by thyroid adenomas, jaundice associated with hepatobilary disease, and pancreatitis. Another nonendocrine manifestation is cardiac disease that carries the risk of cardiac arrhythmia and sudden death.

** Gonadotropin-Independent Sexual Precocity and Pseudohypoparathyroidism Type Ia Caused by a \( \alpha \) Mutation **

Mutations in \( \alpha \) can either constitutively activate or inactivate adenyl cyclase. Two boys who presented in infancy with classical pseudohypoparathyroidism type Ia, a disorder characterized by resistance to hormones whose action is mediated by cAMP, developed signs of sexual precocity with the hormonal characteristics of testotoxicosis (gonadotropin-independent sexual precocity) at about 24 months of age. They both had a unique alanine 366 to serine mutation in one allele of the \( \alpha \) gene; the alanine residue is absolutely conserved in all heterotrimeric G proteins. Pseudohypoparathyroidism type Ia is due to a wide variety of inactivating mutations in \( \alpha \) that lead to about a 50% reduction in GTPase activity in functional assays.

The paradox of a \( \alpha \) mutation causing both inactivation and pseudohypoparathyroidism and constitutive activation and testotoxicosis was resolved by in vitro studies. In cultured cells, the \( \alpha \) Ala 366 Ser mutant protein was rapidly degraded at 37°C but constitutively activated adenyl cyclase at 33°C. Unlike other activating mutations of \( \alpha \), which involve mutations inhibiting its intrinsic GTPase activity and decreasing the rate of hydrolysis of GTP to GDP, the mutation in the two boys caused accelerated dissociation of GDP at 33°C in transfected Leydig cells but rapid degradation at 37°C in a lymphoma cell line and in skin fibroblasts at both 33 and 37°C. The observations explain the clinical consequences of increased \( \alpha \) activity in the testes, which are 3 to 5°C cooler than the body, and the tissue specificity and temperature dependence of the mutation. The mother of one patient appeared to be a mosaic for the \( \alpha \) mutation, whereas a germ line mutation is likely in the other boy.

** Juvenile Hypothyroidism **

Long-standing untreated primary hypothyroidism, usually a consequence of Hashimotos thyroiditis, is an uncommon cause of incomplete sexual precocity in both girls and boys and occurs in association with impaired growth and delayed skeletal maturation. If the concentration of plasma prolactin is elevated, galactorrhea may be demonstrable, more commonly in affected girls than boys (Fig. 24-78). The signs of sexual maturation are not accompanied by a pubertal growth spurt; instead, growth is impaired. Girls have breast development, enlarged labia minora, and estrogenic changes in the vaginal smear, usually without the appearance of pubic hair, and solitary or multiple ovarian cysts may be demonstrable by pelvic sonography or by physical examination. In about 80% of boys with juvenile hypothyroidism, the testes are enlarged because of an increase in the size of the seminiferous tubules, but signs of virilization and Leydig cell maturation are absent and the plasma concentration of testosterone is prepubertal. Enlargement of the sella turcica and the pituitary gland (see Fig. 24-79) has led to the misdiagnosis of a pituitary neoplasm. The hypothyroidism, incomplete sexual maturation, galactorrhea, and pituitary enlargement are reversed or corrected by levothyroxine therapy within a few months.

In 1960, Van Wyk and Grumbach suggested that the syndrome resulted from hormonal “overlap” in negative feedback regulation with increased secretion of gonadotropins, prolactin, and TSH as a consequence of the chronic hypothyroidism. With the advent of radioimmunoassays for pituitary hormones, increased prolactin secretion was documented in children and adults with primary hypothyroidism and in affected girls with the syndrome.

Hyperprolactinemia correlated with the increased production of TSH. GH release is usually decreased as in uncomplicated primary hypothyroidism. Hypothalamic TRH stimulates the release of both prolactin and TSH, and the increased TRH concentration in children with primary hypothyroidism seems to account
for the rise in serum prolactin and TSH levels.

However, the explanation for the sexual maturation remains uncertain. Pubertal development in primary hypothyroidism is usually delayed and is only rarely advanced for chronologic age. By using radioimmunoassays for FSH and LH in which the cross-reaction with TSH is negligible, an increased (pubertal) concentration of plasma immunoreactive and bioactive FSH but not LH has been detected. 

Bioactive LH activity is also low. In addition, increased FSH pulsatility, mainly at night, but not LH release was demonstrated in patients with the syndrome and in some children with primary hypothyroidism who did not exhibit premature sexual maturation. 

The increased FSH release and the high FSH/LH ratio (in contrast to that in normal puberty) seem to account for the increased ovarian estrogen secretion in girls and for the enlarged testes without signs of virilization in affected boys; the suggestion here is that FSH-induced Sertoli cell proliferation is an important determinant of pubertal testicular size, whereas LH has only minor effects on testicular growth (it is not true that LH does not play a role in testicular development). 

An LH-induced increase in the interstitial cell mass is quite unlikely as LH reactivity of these cells is markedly reduced in primary hypothyroidism. 

Pulsatile TSH release is increased at night, and administration of TRH appears to increase FSH release in normal children (but not adults). Moreover, the FSH response to TRH, but not LHRH, is augmented in primary hypothyroidism and this FSH response to TRH can occur in gonadotropin-secreting pituitary adenomas.

If the latter observations are confirmed, it is likely that the incomplete sexual precocity and the increased prolactin secretion and galactorrhea are a consequence of the increased release of TRH, the increased sensitivity of the mammotrophs and gonadotrophs to TRH, or both. This mechanism, which has gained support, would explain the relatively rapid and complete reversal of the syndrome by levotiroxine treatment. 

Recombinant TSH at a dose about 1000-fold greater than hFSH evoked a dose-dependent cAMP response in COS-7 cells transfected with the human FSH receptor, which suggests another possible but less likely mechanism for the FSH-dependent (or FSH-like-dependent) but LHRH-independent sexual precocity. A direct effect of severe hypothyroidism on the prepubertal tests that leads to overproliferation of Sertoli cells has also been advanced to explain the macro-orchidism.

Diagnosis of Sexual Precocity

See Table 24-48 and Figure 24-80 Figure 24-82 . The separation of patients with self-limited benign disorders, such as premature adrenarche or premature thelarche or normal but early puberty, from those with serious or even potentially fatal disorders is the first step in evaluation. The history may reveal symptoms suggesting perinatal abnormalities or injuries, previous infections, adventitious ingestion of or exposure to gonadal steroids, or the presence of similar conditions in family members. In addition, previous measurements should be plotted on a growth chart to determine height velocity and the age of onset of any increase in the rate of growth.

Important aspects of the physical examination include description of the secondary sexual development according to

![Figure 24-77](https://example.com/figure2477)

Tanner stages; measurement of the penis and the testes in boys and breast tissue in girls; and examination for acne, oily skin, facial and body hair, pubic and axillary hair development, apocrine gland odor, muscular development, and galactorrhea. A careful examination of the external genitalia should be done with a nonrelated chaperone present because the performance of such an examination has been interpreted by patients as sexual abuse in several cases. A thorough neurologic examination is indicated, with emphasis on assessment of the visual fields and optic discs and search for signs of increased intracranial pressure; evaluation for skin lesions of the McCune-Albright syndrome or neurofibromatosis; and examination for abdominal, gonadal, or adnexal masses and for coexisting endocrine disease.

Radiographs should be obtained for determination of bone age and an MRI with contrast (or, if necessary, the less sensitive CT brain scan) for investigation of CNS abnormalities in all boys with evidence of LHRH-dependent sexual precocity as well as all girls 6 years of age or younger and selected girls between 8 and 8 years of age. Ultrasonography of the ovary and uterus is exceedingly useful in evaluation of affected girls. Standards are available for the shape and volume of the uterus and the ovaries. 

The largest measurement of uterine size in infants and children by ultrasonography is found at puberty and in the neonatal period. 

The upper limit of uterine length in the pubertal state is 3.5 cm. Further, a uterine volume greater than 1.8 mL is quite specific for the onset of puberty and an increased ovarian volume is less specific. Patients with premature thelarche were indistinguishable from age-matched controls when this sonographic standard was used. The presence of microcysts and macrocysts of the ovary can be detected by ultrasonography as well. Cysts may be found in the ovaries in true precocious puberty or LHRH-independent isosexual precocity, but the cysts are usually smaller than 9 mm in the former and larger than 9 mm in the latter.

Measurements of plasma gonadotropin concentrations using third-generation assays, the plasma concentration of testosterone in boys and of estradiol in girls, and the LH response to administration of LHRH (or the amplitude and frequency of LH pulses, especially at night) are of primary importance in diagnosis. Girls early in the course of true precocious puberty

**Figure 24-78 Left and center, Steven'a, chronic hypothyroidism of Hashimoto's thyroiditis in a 7 1/2-year-old girl with sexual precocity (without pubic or axillary hair), episodic vaginal bleeding, and galactorrhea. She had symptoms of hypothyroidism and a sharply decreased rate of growth over the previous 2 years (height, 1' 11" SD; bone age, 5 3/12 years). Breast development was Tanner stage 3; the labia minora were enlarged, and the vaginal mucosa was pink, thickened, and rugated with evidence of an estrogenic effect. No acne, seborrhea, or hirsutism was present. The uterus was of adolescent size, and the endometrial mucosa was in a proliferative phase. Urinary gonadotropins were barely detectable by biosay. Right, Striking change in appearance after 8 months of thyroid hormone treatment. She had grown 7 cm in height and lost 8.1 kg in weight; the breasts had decreased in size, galactorrhea was no longer demonstrable, the labia minora had regressed, and the vaginal mucosa was pink and glistening (no estrogen effect). Ten weeks after the initiation of thyroid hormone replacement therapy, she developed a right slipped capital femoral epiphysis that was repaired surgically; recovery was uneventful.**

An elevated hCG level with a prepubertal LH response indicates an ectopic, autonomous, gonadotropin-secreting tumor. If this tumor is in the CNS, abnormalities are present on MRI or CT brain scans. Enlargement of the liver or a mediastinal, retroperitoneal mass in boys with sexual precocity suggests an hCG-producing hepatic or
germ cell tumor; the possibility of Klinefelter's syndrome needs to be considered with the latter. Pubertal concentrations of LH and FSH, a pubertal mode of pulsatile LH secretion (initially during sleep), or a pubertal LH response in the LHRH test confirms the diagnosis of true precocious puberty (and in boys differentiates true precocity from familial testotoxicosis). A CNS tumor must be considered as a potential cause of this premature activation of the hypothalamic LHRH pulse generator.

The evaluation for a CNS tumor as a cause of true precocious puberty is similar to the investigation of an hCG-secreting tumor of the CNS. Although CT scanning is now a well-established procedure for determining the presence of a CNS abnormality, MRI with contrast is more sensitive for the detection of small tumors in the hypothalamus, such as a hamartoma of the tuber cinereum (see Fig. 24-63). The use of contrast adds to diagnostic certainty and is recommended for MRI of the CNS. The height of the pituitary gland on MRI correlates with advancing age and with pubertal development; patients with true precocious puberty and higher peak LH/FSH ratios had pituitary heights exceeding 6 mm on the average whereas those with a lower LH/FSH ratio or precocious thelarche had lower heights of approximately 5 mm. The shape of the pituitary gland is also of importance; a convex appearance rather than a flat top is associated with true precocious puberty of all etiologies. The size and shape of the pituitary gland do not decrease with successful LHRH therapy.

The premature appearance of pubic hair, phallic enlargement, and other signs of virilization in a male without enlargement of the testes or the liver suggests the diagnosis of congenital virilizing adrenal hyperplasia, virilizing adrenal tumor, or, rarely, Cushings syndrome. Measurement of plasma 17-hydroxyprogesterone and DHEAS concentrations and the excretion of urinary 17-ketosteroids and their suppressibility with glucocorticoids distinguishes adrenal hyperplasia from a virilizing adrenal tumor. If growth rate is suppressed, the possibility of primary hypothyroidism or of Cushing's syndrome is raised.

![Figure 24-79](image)

The appearance of pubic hair without other signs of puberty in boys or girls is usually a result of premature adrenarche but may be the first sign of sexual precocity or of adrenal virilism of other causes.

In a girl, breast development associated with dulling and thickening of the vaginal mucosa and enlargement of the labia minora indicates significant estrogen secretion in iatrogenic exposure to estrogen. The differential diagnosis includes true precocious puberty, an estrogen-secreting neoplasm, and a cyst of the ovary. If the plasma concentrations of gonadotropins in girls in early or true precocious puberty are in the pubertal range much of the day, if LH pulses of pubertal amplitude are detected, or if a pubertal LH response to LHRH is elicited, true precocious puberty is present. Estrogen concentrations in girls early in normal or true precocious puberty are in the prepubertal range much of the day, and a single determination may be inadequate to reflect ovarian function (see Fig. 24-60). A CNS tumor is less likely in girls than in boys to be the cause of this premature reactivation of the hypothalamic LHRH pulse generator in a gonadal system. However, studies using MRI or CT brain scans indicate that the hypothalamic hamartoma is more prevalent in both boys and girls with so-called idiopathic true precocious puberty than was previously suspected.

If the concentration of plasma estradiol is elevated but gonadotropin levels are low, an estrogen-secreting cyst or neoplasm is present. Ovarian tumors of moderate size can be palpated by bimanual examination. Advances in pelvic sonography allow the delineation of ovarian cysts or tumors and the determination of uterine size, and this procedure has become an essential component of the diagnostic evaluation. An estrogen-secreting neoplasm of the ovary is usually accompanied by high estradiol concentrations. However, some ovarian cysts are associated with concentrations of estradiol as high as those in granulosa cell tumors; the differential diagnosis between these cysts and ovarian neoplasms rarely requires exploratory laparotomy or laparoscopy and can usually be made by pelvic sonography and by the use of tumor markers. Breast development in the absence of other estrogen effects is almost always a result of premature thelarche.

**Intragenic Sexual Precocity**

Prepubertal children are remarkably sensitive to exogenous gonadal steroids and may show signs of sexual maturation resulting from overlooked sources of androgens or estrogens, such as ingested or absorbed tonics, lotions, or creams that contain or are inadvertently contaminated with an estrogen. Interest in the effects of environmental estrogens or disruptors on reproductive development in girls and boys is mounting. Estrogen exposure may come from cosmetics. Hair creams and straighteners may contain estrogenic substances; this source of exogenous estrogens is more potent than low levels of endogenous estrogen secreted by the thelarche of the ovaries.

who inhaled estrogen dust have developed sexual precocity. A short course of application of estrogen cream is used to treat labial adhesions, but long courses may lead to breast development or even withdrawal bleeding. In addition to breast development, pigmentation of the areolae and the linea alba and the appearance of public hair may be seen in children exposed to estrogen.

Food is another potential source of estrogen. Epidemics of gynecomastia in boys and thelarche in girls have occurred in schoolchildren in Italy; meat contaminated by estrogens was suspected in some cases. However, no etiology was uncovered in Milan and environs, where 21.1% of 1- to 2-year-old girls and 36.6% of 1- to 2-year-old boys were reported with premature thelarche or gynecomastia. During a 10-year period more than 600 cases of gynecomastia in boys and premature thelarche or incomplete sexual precocity in girls were discovered in Puerto Rico, the highest prevalence noted in the world, about 10 to 15 times higher than the prevalence in a survey in Olmsted, Minnesota. Maternal ovarian cysts were demonstrated in two thirds of affected Puerto Rican girls.

The wide publicity given these observations and the questions raised about contamination of the food supply by the clandestine use of estrogens as growth-promoting agents for meat production caused anxiety among parents, cattle raisers, and farmers. It was suggested that the use of estrogen preparations in animals to stimulate weight gain led to ingestion of estrogen-contaminated meat. Although this idea has not been confirmed by selected analyses of meat, poultry, and milk in Puerto Rico by the U.S. Department of Agriculture, it has not been excluded. Guidelines from the FDA define a limit of not more than 1% of normal daily estrogen production of prepubertal children as a safe intake of estrogen, which translates into 0.43 ng/day for boys and 3.24 ng/day for girls using the latest data from extremely sensitive estrogen assays. A possible association has been advanced between plasticizers with documented estrogenic and antiandrogenic activity and premature
thelarche in Puerto Rico. Significantly elevated concentrations of phthalates and their major metabolites were found in 28 girls (68%) of a cohort with premature breast development.  

Girls breast-fed following an accidental exposure of their mothers to polybrominated biphenyls experienced early menarche (by about 1 year) and early appearance of pubic hair but not breast development compared with girls who were not exposed and girls who were not breast-fed.  

The administration of hCG to boys with undescended testes may induce secretion of testosterone sufficient to cause incomplete sexual precocity. From these examples it is clear that careful investigation of sources of possible exposure to exogenous hormones is mandatory in every case of sexual precocity.

Feminization in Boys and Virilization in Girls (Corresponding Precocity)

Boys

Feminization in a boy before the age of puberty is rare. Rarely, an estrogen-secreting adrenal adenoma or a chorioneplithelioma may cause gynecomastia. Gynecomastia has been reported in a 1-year-old boy with 11-hydroxylase deficiency and in boys with late-onset congenital adrenal hyperplasia.

Aromatase Excess Syndrome

Gynecomastia in prepubertal boys can also be caused by increased extraglandular aromatization of C19 steroids of adrenal origin such as androstenedione and hence increased extraglandular estrogen production in sporadic or familial cases. This autosomal dominant disorder leading to excess estrogen synthesis from C19 precursors because of aromatase overexpression, especially in fat and skin, is a consequence of novel gain-of-function mutations of CYP19, the gene encoding aromatase, related to a chromosome arrangement that give rise to a cryptic promoter.

Feminizing Testicular Tumors

Feminizing testicular tumors may cause gynecomastia in boys younger than age 6 with the Peutz-Jeghers syndrome. Both testes may be enlarged, and the histology indicates sex cord or Sertoli cell tumors that form annular tubules and often have areas of calcification; increased estradiol secretion is noted in the basal state, and a further rise occurs after hCG administration. Otherwise, feminizing Sertoli cell tumors are rare in boys. Sonography or MRI scans of the testes may be useful in the diagnosis.

Girls

Virilization in a girl indicates organic disease except for premature adrenarche. Congenital adrenal hyperplasia resulting from 21-hydroxylase or 11-hydroxylase deficiency and androgen-producing tumors of the adrenal can cause virilization, and these were discussed earlier as occurring in males. 3-Hydroxydehydrogenase deficiency is a rare type of congenital adrenal hyperplasia characterized by elevated 5,17-hydroxyepiandrosterone, DHEA, and DHEAS levels and, in the severe form, decreased secretion of aldosterone and cortisol. Severely affected patients have mineralocorticoid and glucocorticoid deficiency and may die in infancy. Excess adrenal androgens lead to virilization in utero and to ambiguous external genitalia, including clitormal enlargement in females with continued virilization after birth (see Chapter 22). Milder forms of this disorder can cause hirsutism in women. 46,XY phenotypic women with incomplete forms of androgen resistance syndrome or with 17-hydroxydehydrogenase deficiency (17-HSD) type 3 deficiency may have virilization as well as breast development at the time of expected puberty. Mutations in the CYP19 gene that encodes aromatase are associated not only with intrauterine masculinization of the external genitalia in affected XX individuals but also with progressive virilization, lack of female secondary sex characteristics, multicystic ovaries at the age of puberty, tall stature, and osteopenia (see Chapter 22).

Cushing's syndrome resulting from adrenal carcinoma is usually manifest as growth failure with or without virilization, obesity, and moon facies; striae may not appear until months to years later.

The syndrome of glucocorticoid resistance is manifest in various degrees. Some patients demonstrate hyperandrogenic signs such as acne, hirsutism, male-type baldness, menstrual irregularities, and oligomenorrhea and infertility. Dexamethasone decreased the excessive adrenal androgen secretion, virilization, and advancing bone age found in a prepubertal boy with general glucocorticoid resistance.

Anthemoblastoma, the most common virilizing ovarian tumor, is rare in children. Lipoid cell tumor of the ovary and gonadoblastoma are even more unusual sources of androgens.

Variations of Pubertal Development

Premature Thelarche

Unilateral or bilateral breast enlargement without other signs of sexual maturation (e.g., sexual hair and growth of the labia minora and the uterus) is not uncommon in infancy and childhood and has been referred to as premature thelarche. The disorder usually occurs by age 2 (in over 80%) and rarely after age 4. In a retrospective study in Minnesota, premature thelarche occurred with an incidence of 21.2 per 100,000 patient-years, 40% of cases were noted during 6 months and 2 years of age, and most regressed in 6 months to 6 years after diagnosis, although a few persisted until puberty. A 10- to 35-year follow-up was available in 25 cases, and no untoward effects on later health, growth, or fertility were evident. The breast enlargement usually regresses after a few months but occasionally persists for years or lasts until the onset of normal puberty; in about half of affected girls the breast development, which is characteristically cyclic, lasts 3 to 5 years. Usually, significant nipple and areola development is absent and estrogen-induced thickening and dulling of the vaginal mucosa are uncommon. Enlargement of the uterus on ultrasonography (>1.8 mL volume and length > 36 mm) is rare. Measurement of the ellipsoid volume of the uterus (V = longitudinal diameter × anteroposterior diameter × transverse diameter × 0.523) is the most sensitive and specific discriminator between premature thelarche and early true precocious puberty and provides better early discrimination than the LH response to LHRH. Growth in stature is normal.

Premature thelarche is a benign, self-limited disorder compatible with normal pubertal development at an appropriate age; only reassurance and follow-up are usually necessary. The appearance of premature thelarche can, however, be the harbinger of further sexual maturation in a minority of cases as discussed earlier. Because the development may be unilateral, it is important to consider the condition in girls with unilateral breast development so that needless worry about a breast neoplasm is not stimulated in the parents and no unnecessary surgical procedure is carried out. Indeed, the removal of tissue in premature thelarche may leave the child with no possibility of future breast development. In selected instances, sonography of the breast is useful in distinguishing unilateral premature...
Although premature adrenarche is usually considered a benign condition with no substantial long-term risk, accumulating observations indicate that girls with hyperandrogenism, hirsutism, anovulation, amenorrhea or oligomenorrhea, and insulin resistance and compensatory hyperinsulinemia with its attendant risk of major

The concept of exaggerated adrenarche was first advanced in relation to a postulated childhood antecedent of PCOS, the hallmarks of which are hyperandrogenism, hirsutism, anovulation, amenorrhea or oligomenorrhea, and insulin resistance and compensatory hyperinsulinemia with its attendant risk of major metabolic sequelae including type 2 diabetes mellitus, dyslipidemia, an increased propensity for coronary artery disease, and in about 50% of affected women obesity. It has been extended to include rare instances of premature adrenarche associated with excessive responses of 17-hydroxyprogrenolone, DHEAS, and androstenedione to ACTH found in women with functional adrenal hyperandrogenism.

Premature adrenarche is commonly slowly progressive and does not have an untoward effect on either the onset or normal progression of gonadarche or final adult height.
premature adrenarche are at increased risk of developing functional ovarian hyperandrogenism and the polycystic ovarian syndrome, hyperinsulinism, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and the birth weight was low. Premature adrenarche is a risk factor for the later development of PCOS and functional ovarian hyperandrogenism in adolescent and adult women; the magnitude of this risk is unknown, but it appears to vary with the exception of girls with a history of decreased fetal growth. Plasma androstenedione levels above the 90th percentile for age may be helpful in predicting hyperandrogenism in girls with premature adrenarche. The risk of PCOS or clinical hyperandrogenism in these subjects may be as high as 50%. 

Girls with reduced fetal growth are at risk for a reduced number of ovarian primordial follicles at birth, small ovaries and uterus at puberty, and an increased serum FSH level and decreased estradiol concentrations, suggesting relative ovarian resistance to FSH. Girls who are short, especially black and Hispanic girls, have a higher risk of the association of premature adrenarche with syndrome X (obesity, hyperinsulinism, dyslipidemia, and later coronary heart disease) and the development of PCOS in late adolescence and early adulthood. Low birth weight, low birth length, and low birth head circumference were independently associated with hyperandrogenism. If women were exposed to androgens during fetal life, they also have increased risk of development of PCOS and hyperandrogenism in adult life.

Of interest, the adrenal steroid pattern in the black and Hispanic patients in the latter study did not differ from that in children with uncomplicated premature adrenarche.

As discussed previously, hyperinsulinism is associated with many metabolic and endocrine conditions and functional ovarian hyperandrogenism that in some cases is heralded by premature adrenarche. When the role of insulin resistance and hyperinsulinism was recognized in the pathogenesis of PCOS, therapeutic approaches to reduce insulin resistance were introduced, especially the use of insulin sensitizers. Among the latter, the most widely used is metformin because of its low prevalence of adverse effects and therapeutic efficacy. In early studies, this agent was shown to decrease insulin resistance and levels of fasting and postprandial glucose. However, in subsequent studies, metformin achieved its effects on insulin resistance and hyperinsulinism, independent of its effects on adiposity, cholesterol, and serum triglycerides in obese adolescents. In this regard, metformin has been shown to decrease fasting serum insulin, improve insulin sensitivity, and reduce circulating levels of the proinflammatory cytokines such as interleukin-6 and tumor necrosis factor-alpha. Although metformin is effective in reducing insulin resistance and hyperinsulinism, the long-term efficacy and safety of metformin in reducing cardiovascular disease risk in adolescents and young adults with PCOS and premature adrenarche remain to be established.

Premature adrenarche can be associated with nonclassical congenital adrenal hyperplasia caused by homozygous or compound heterozygous missense mutations in the CYP21 gene encoding the 21-hydroxylase enzyme. Premature adrenarche is a risk factor for the later development of PCOS and functional ovarian hyperandrogenism in girls with premature adrenarche. Therefore, it is important to identify those with 21-hydroxylase deficiency prior to development of hyperandrogenism and PCOS. The 21-hydroxylase enzyme is necessary for the biosynthesis of cortisol from 11-deoxycortisol and 18-hydroxycorticosterone. Patients with 21-hydroxylase deficiency will present in early childhood with a salt-losing crisis, hypotension, dehydration, and hyperkalemia._cardiovascular disease including women with PCOS, was increased in girls with premature adrenarche, especially those with low birth weights, and may be useful in the identification of those with a greater risk of developing PCOS. In girls with reduced fetal growth are at risk for a reduced number of ovarian primordial follicles at birth, small ovaries and uterus at puberty, and an increased serum FSH level and decreased estradiol concentrations, suggesting relative ovarian resistance to FSH. Girls who are short, especially black and Hispanic girls, have a higher risk of the association of premature adrenarche with syndrome X (obesity, hyperinsulinism, dyslipidemia, and later coronary heart disease) and the development of PCOS in late adolescence and early adulthood. Fragile X syndrome is the most common inherited cause of mental retardation. This condition is due to multiple repeats of a CCC expansion that leads to hypermethylation of the \textit{FMR1} gene (Xq,27fra) that prevents transcription and translation of the \textit{FMRP} protein. Affected individuals have mental retardation in association with multiple physical anomalies including large testes. Eighty percent to 95% of adolescents or adults with fragile X syndrome have testicular volume greater than 30 mL with an average of 45 mL, although the 95th percentile for the syndrome is 70 mL. In most cases the enlargement begins at 8 to 9 years of age, prior to the appearance of pubic hair, although some prepubertal children already have a testicular volume greater than 4 mL.

The enlarged testes are due to increased interstitial volume and excessive connective tissue, including increased peri-tubular collagen fibers, rather than to increase in the seminiferous tubules. Testicular biopsy has demonstrated normal Leydig and Sertoli cells, normal to slightly decreased spermatogenic cells, and an increase in testicular interstitial fluid. Although there may be subtle elevation of serum gonadotropins that might be part of the etiology of macro-orchidism, affected males are fertile, although most are not sexually active. Other associated anomalies include increased birth weight, high forehead, large ears, prognathism, pale irises, and an increased head circumference.

Macro-orchidism without androgenization is a rare manifestation of the McCune-Albright syndrome. Macro-orchidism is an occasional finding in prepubertal boys with long-standing primary hypothyroidism. This form of testicular enlargement appears to result from increased FSH secretion independent of a pubertal increase in LH secretion or a pubertal LH response to LHRH (see above). Testicular adrenal rests in congenital adrenal hyperplasia (see Chapter 22) and a lymphoma can cause bilateral macro-orchidism. It was a feature of severe aromatase deficiency in a young male adult and in men with an FSH-secreting pituitary macroadenoma. Bilateral megalotestis (testicular volume 26 mL) in adults can occur as a normal variant. One may speculate that some instances of bilateral macro-orchidism are due to a heterozygous constitutive activating mutation of the FSH receptor.
Disorders of Sexual Differentiation with Both Virilization and Feminization at Puberty

Virilization as well as feminization at puberty may occur in a phenotypic female who has a 46,XY karyotype in certain types of male pseudohermaphroditism (see Chapter 22). 17-HSD type 3 deficiency (a testosterone biosynthetic defect) and incomplete forms of androgen resistance (resulting from defects in the androgen receptor) may occur in this manner; however, ambiguous genitalia are usually noted early in life in these conditions. True hermaphrodites with ovarian and testicular tissue may undergo both virilization and feminization at puberty.

Chapter 25 - Endocrinology and Aging

Steven W. J. Lamberts

The average length of human life is currently 75 to 78 years and may increase to 85 years during the coming ten years, but it is not clear whether these additional years will be satisfactory. Most data indicate a modest gain in the number of healthy years lived but a far greater increase in years of compromised physical, mental, and social function. The number of days with restricted activity and admissions to hospitals and nursing homes increases sharply after 70 years of age. The U.S. National Health Interview Survey indicated that more than 25 million aging people suffer from physical impairment and the number of persons requiring assistance with the activities of daily living increases from 14% at ages 65 to 75 years to 45% in people older than age 85 years.
AGING AND PHYSICAL FRAILTY

Throughout adult life, all physiologic functions start to decline gradually. There is a diminished capacity for cellular protein synthesis, a decline in immune function, an increase in fat mass, a loss of muscle mass and strength, and a decrease in bone mineral density. Most older adults die of atherosclerosis, cancer, or dementia, but in an increasing number of the “healthy” oldest old, loss of muscle strength is the limiting factor that determines their chances of an independent life until death.

Age-related disability is characterized by generalized weakness, impaired mobility and balance, and poor endurance. In the oldest old, this state is termed physical frailty, defined as “a state of reduced physiological reserves associated with increased susceptibility to disability.” Clinical correlates of physical frailty include falls, fractures, impairment in activities of daily living, and loss of independence. Falls contribute to 40% of admissions to nursing homes.

Loss of muscle strength is an important factor in the development of frailty. Muscle weakness can be caused by aging of muscle fibers and their innervation, osteoarthritis, and chronic debilitating diseases. A sedentary lifestyle, decreased physical activity, and disuse, however, are also important determinants of the decline in muscle strength.

In a study of 100 frail nursing home residents (average age, 87 years), lower extremity muscle mass and strength were closely related. Supervised resistance exercise training (45 minutes three times a week for 10 weeks) doubled muscle strength and significantly increased gait velocity and stair-climbing power. This finding demonstrates that frailty in the elderly population is not an irreversible effect of aging and disease but can be influenced and perhaps even prevented. Further, in nondisabled elderly persons living in the community, objective measures of lower extremity function are highly predictive of subsequent disability. Prevention of frailty can be achieved only by working (training). However, exercise is difficult to implement in the daily routine of the aging population, and the number of dropouts from exercise programs is very high.

Part of the aging process involving body composition (i.e., loss of muscle [strength] and bone, increase in fat mass) might also be related to changes in the endocrine system. Current knowledge has shed light on the effects of long-term hormonal replacement therapy on body composition as well as on atherosclerosis, cancer formation, and cognitive function.
THE ENDOCRINOLOGY OF AGING

The two most important clinical changes in endocrine activity during aging involve the pancreas and the thyroid gland.

Approximately 40% of individuals aged 65 to 74 years and 50% of those older than 80 years have impaired glucose tolerance or diabetes mellitus, and in nearly 50% of elderly adults with diabetes the disease is undiagnosed. These adults are at risk for development of secondary, mainly macrovascular, complications at an accelerated rate. Pancreatic, insulin receptor, and postreceptor changes associated with aging are critical components of the endocrinology of aging. Apart from decreased (relative) insulin secretion by the beta cells, peripheral insulin resistance related to poor diet, physical inactivity, increased abdominal fat mass, and decreased lean body mass contributes to the deterioration of glucose metabolism. Dietary management, exercise, oral hypoglycemic agents, and insulin are the four components of treatment for these patients, whose medical care is costly and intensive.

Age-related thyroid dysfunction is also common. Lowered plasma thyroxine (T₄) and increased thyrotropin concentrations occur in 5% to 10% of elderly women. These abnormalities are mainly caused by autonomy and are thus an expression of age-associated disease rather than a consequence of the aging process. Normal aging is accompanied by a slight decrease in pituitary thyrotropin release but especially by decreased peripheral degradation of T₄, which results in a gradual age-dependent decline in serum triiodothyronine (T₃) concentrations without changes in T₄ levels. This slight decrease in plasma T₃ concentrations occurs largely within the broad normal range of the healthy elderly population and has not been convincingly related to functional changes during the aging process. At present, the question of whether healthy aging subjects might benefit from T₃ replacement therapy remains unresolved.

Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

The second hormonal system demonstrating age-related changes is adrenopause, a term that describes the gradual decline in circulating levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS). Adrenal secretion of DHEA gradually decreases over time, while corticocortropin secretion, which is physiologically linked to plasma cortisol levels, remains largely unchanged. The decline in DHEA and DHEAS levels in both sexes, therefore, contrasts with the maintenance of plasma cortisol levels and seems to be caused by a selective decrease in the number of functional zona reticularis cells in the adrenal cortex instead of being regulated by a central (hypothalamic) pacemaker of aging.

THE SECONDARY SYSTEMS OF AGING

1. The course of serum insulin-like growth factor (IGF-I) concentrations occurs largely 6 months after the initiation of menopause, serum LH and FSH levels increase sharply. Right, The adrenocortical cells responsible for the production of dehydroepiandrosterone (DHEA) decrease in activity (adrenopause) without clinically evident changes in corticosterone (adrenocorticoctropic hormone, ACTH) and cortisol secretion. There is no central pacemaker in the hypothalamus or higher brain areas (or both) that is hypothalamic or higher brain areas (or both) is hypothesized; which together with changes in the peripheral organs (the ovaries, testicles, and adrenal cortex) regulates the aging process of these endocrine axes.

2. Changes in the activity of the hypothalamic-pituitary-gonadal axis in men are slower and more subtle. During aging, a gradual decline in serum total and free testosterone levels occurs. Changes in the activity of the hypothalamic-pituitary-gonadal axis in men are slower and more subtle. During aging, a gradual decline in serum total and free testosterone levels occurs. Changes in the activity of the hypothalamic-pituitary-gonadal axis in men are slower and more subtle. During aging, a gradual decline in serum total and free testosterone levels occurs. The most dramatic and rapidly occurring change in women around age 50 years is menopause, characterized by a decrease in testicular Leydig cell numbers and their secretory capacity as well as by a decrease in estradiol. Estradiol production during the reproductive years is cycling estradiol production during the reproductive years is replaced by very low, constant estradiol levels. For many years, the prevailing view was that menopause resulted from exhaustion of ovarian follicles. An alternative perspective is that age-related changes in the central nervous system and the hypothalamic-pituitary-ovarian unit initiate the menopausal transition. The evidence that both the ovary and the brain are key pacemakers in menopause is compelling.

3. Changes in insulin sensitivity and thyroid function that occur in the aging population are frequently of clinical importance and recognized and treated as diseases. Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

4. The two most important clinical changes in endocrine activity during aging involve the pancreas and the thyroid gland.

5. Approximately 40% of individuals aged 65 to 74 years and 50% of those older than 80 years have impaired glucose tolerance or diabetes mellitus, and in nearly 50% of elderly adults with diabetes the disease is undiagnosed. These adults are at risk for development of secondary, mainly macrovascular, complications at an accelerated rate. Pancreatic, insulin receptor, and postreceptor changes associated with aging are critical components of the endocrinology of aging. Apart from decreased (relative) insulin secretion by the beta cells, peripheral insulin resistance related to poor diet, physical inactivity, increased abdominal fat mass, and decreased lean body mass contributes to the deterioration of glucose metabolism. Dietary management, exercise, oral hypoglycemic agents, and insulin are the four components of treatment for these patients, whose medical care is costly and intensive.

6. Age-related thyroid dysfunction is also common. Lowered plasma thyroxine (T₄) and increased thyrotropin concentrations occur in 5% to 10% of elderly women. These abnormalities are mainly caused by autonomy and are thus an expression of age-associated disease rather than a consequence of the aging process. Normal aging is accompanied by a slight decrease in pituitary thyrotropin release but especially by decreased peripheral degradation of T₄, which results in a gradual age-dependent decline in serum triiodothyronine (T₃) concentrations without changes in T₄ levels. This slight decrease in plasma T₃ concentrations occurs largely within the broad normal range of the healthy elderly population and has not been convincingly related to functional changes during the aging process. At present, the question of whether healthy aging subjects might benefit from T₃ replacement therapy remains unresolved.

7. Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

8. The most dramatic and rapidly occurring change in women around age 50 years is menopause, characterized by a decrease in testicular Leydig cell numbers and their secretory capacity as well as by a decrease in estradiol. Estradiol production during the reproductive years is cycling estradiol production during the reproductive years is replaced by very low, constant estradiol levels. For many years, the prevailing view was that menopause resulted from exhaustion of ovarian follicles. An alternative perspective is that age-related changes in the central nervous system and the hypothalamic-pituitary-ovarian unit initiate the menopausal transition. The evidence that both the ovary and the brain are key pacemakers in menopause is compelling.

9. Changes in insulin sensitivity and thyroid function that occur in the aging population are frequently of clinical importance and recognized and treated as diseases. Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

10. The two most important clinical changes in endocrine activity during aging involve the pancreas and the thyroid gland.

11. Approximately 40% of individuals aged 65 to 74 years and 50% of those older than 80 years have impaired glucose tolerance or diabetes mellitus, and in nearly 50% of elderly adults with diabetes the disease is undiagnosed. These adults are at risk for development of secondary, mainly macrovascular, complications at an accelerated rate. Pancreatic, insulin receptor, and postreceptor changes associated with aging are critical components of the endocrinology of aging. Apart from decreased (relative) insulin secretion by the beta cells, peripheral insulin resistance related to poor diet, physical inactivity, increased abdominal fat mass, and decreased lean body mass contributes to the deterioration of glucose metabolism. Dietary management, exercise, oral hypoglycemic agents, and insulin are the four components of treatment for these patients, whose medical care is costly and intensive.

12. Age-related thyroid dysfunction is also common. Lowered plasma thyroxine (T₄) and increased thyrotropin concentrations occur in 5% to 10% of elderly women. These abnormalities are mainly caused by autonomy and are thus an expression of age-associated disease rather than a consequence of the aging process. Normal aging is accompanied by a slight decrease in pituitary thyrotropin release but especially by decreased peripheral degradation of T₄, which results in a gradual age-dependent decline in serum triiodothyronine (T₃) concentrations without changes in T₄ levels. This slight decrease in plasma T₃ concentrations occurs largely within the broad normal range of the healthy elderly population and has not been convincingly related to functional changes during the aging process. At present, the question of whether healthy aging subjects might benefit from T₃ replacement therapy remains unresolved.

13. Changes in insulin sensitivity and thyroid function that occur in the aging population are frequently of clinical importance and recognized and treated as diseases. Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

14. The most dramatic and rapidly occurring change in women around age 50 years is menopause, characterized by a decrease in testicular Leydig cell numbers and their secretory capacity as well as by a decrease in estradiol. Estradiol production during the reproductive years is cycling estradiol production during the reproductive years is replaced by very low, constant estradiol levels. For many years, the prevailing view was that menopause resulted from exhaustion of ovarian follicles. An alternative perspective is that age-related changes in the central nervous system and the hypothalamic-pituitary-ovarian unit initiate the menopausal transition. The evidence that both the ovary and the brain are key pacemakers in menopause is compelling.

15. Changes in insulin sensitivity and thyroid function that occur in the aging population are frequently of clinical importance and recognized and treated as diseases. Changes in the hormone levels of normal women (Fig. 25-1) and men (Fig. 25-2) during aging. Note the difference in the distribution of ages in the different panels.

16. The second hormonal system demonstrating age-related changes is adrenopause, a term that describes the gradual decline in circulating levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS). Adrenal secretion of DHEA gradually decreases over time, while corticocortropin secretion, which is physiologically linked to plasma cortisol levels, remains largely unchanged. The decline in DHEA and DHEAS levels in both sexes, therefore, contrasts with the maintenance of plasma cortisol levels and seems to be caused by a selective decrease in the number of functional zona reticularis cells in the adrenal cortex instead of being regulated by a central (hypothalamic) pacemaker of aging.

17. The third endocrine system that gradually declines in activity during aging is the growth hormone (GH)insulin-like growth factor (IGF-I) system.

A number of limitations and assumptions must be considered when interpreting this table. The duration of the use and dose regimens of $E_2 + P$ varied considerably between studies included in the meta-analysis (duration, 210 years). It was assumed that the addition of progestagen to the estrogen regimen would increase the risk for breast cancer from 1.35 to 1.80. 

$E_2 + P$, estrogen plus progestagen.

*The estimated lifetime probabilities of developing the conditions mentioned have been derived from mortality and incidence data from the 1987 Vital Statistics of the United States. The relative risks are the best estimates of the relative risk for developing each condition in long-term hormone users compared with nonusers. These estimates were derived from a model of the risks and benefits of hormone therapy developed by Grady et al. 

MENOPAUSE

Menopause is the permanent cessation of menstruation resulting from the loss of ovarian follicular function and is diagnosed retrospectively after 12 months of amenorrhea.

In most women, vasomotor reactions, depressed mood, and urogenital complaints accompany this period of estrogen decline. In the subsequent years, the loss of estrogens is followed by a high incidence of cardiovascular disease, loss of bone mass, and cognitive impairment. The average age of menopause (51.4 years) has not changed over time and seems to be largely determined by genetic factors.

The use of hormone replacement therapy (HRT), consisting of estrogen or estrogen plus progestagen, can alleviate the symptoms of menopause (perimenopausal use), but long-term use of HRT (5 to 10 years or more) may also be advantageous in preventing cardiovascular disease, bone loss, and cognitive impairment.

Perimenopausal Use of Hormone Replacement Therapy

Typical symptoms that result from the sudden decrease in estrogen production around menopause are menstrual cycle disorders, vasomotor changes (hot flushes, night sweats), and urogenital complications (atrophic vaginal irritation and dryness, dyspareunia, atrophic urethral epithelium leading to micturition disorders). Additional symptoms are irritability, mood swings, joint pain, and sleep disturbances. Frequency, severity, onset, and duration of symptoms vary widely between individuals and between ethnic groups. About 75% of women in Western societies experience so few troublesome symptoms during the menopausal transition that HRT is not needed or requested.

HRT rapidly alleviates the symptoms of menopause. Hot flushes and vasomotor instability as well as symptoms of urogenital atrophy rapidly disappear upon the start of HRT.
Long-Term Hormone Replacement Therapy

Because life expectancy is increasing, the time a woman spends after menopause constitutes more than one third of her life. Long-term use of HRT (5 to 10 years) seems to have advantages with regard to the prevention of the three chronic disorders most common in the elderly: (1) cardiovascular diseases, (2) osteoporosis, and (3) dementia. There are, however, also important adverse effects of long-term estrogen-progestagen replacement therapy after menopause. The most compelling problem is the increased incidence of breast cancer. \(^\text{26} 29 30 33\) The excess risk increased by 8% for each year of combined hormone use and by 1% for each year of estrogen-only use. Thus, risk of breast cancer would be predicted to increase by approximately 80% after 10 years of estrogen-progestagen use.

Lifetime probabilities of disease occurrence for a 50-year-old white woman entering menopause without or with subsequent HRT are presented in Table 25-1. \(^\text{27} 28\)

Coronary Heart Disease and Stroke

Nearly every observational study has demonstrated a decreased risk of heart disease in women who ever used estrogen. Meta-analyses of 25 published studies of women who used estrogen and 7 studies that separately assessed estrogen plus progestagen treatment found summary relative risks of 0.70 and 0.66, respectively, for coronary heart disease among women. \(^\text{34} 35\) The apparent benefit is largely limited to current or recent estrogen use. HRT does not play a role in secondary prevention: progression of coronary atherosclerosis in women with established disease was not influenced. \(^\text{36} 37\) HRT was not consistently associated with a reduced risk of stroke. \(^\text{38}\)

The mechanism of cardiosprotection remains uncertain but probably involves multiple actions. Estrogen is an antioxidant and calcium blocker and induces beneficial effects on concentrations of serum low-density lipoprotein (LDL) cholesterol (lowering) and high-density lipoprotein (HDL) cholesterol (increasing). Added progestagen attenuates these estradiol-mediated effects experimentally, but epidemiologically there is no convincing evidence for a decreased effect of combined therapy in comparison with estrogen alone in the primary prevention of coronary disease. \(^\text{39} 40\)

Bone Loss

Osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to increased bone fragility and, therefore, to fracture susceptibility. The lifetime risk of fractures in 50-year-old white women is 30% to 40% (see Table 25-1). \(^\text{41}\)

The efficacy of HRT on the main sites of osteoporotic fractures has been documented in case-control and cohort studies but only in a few prospective controlled trials. \(^\text{42} 43\) Current use of HRT, especially long-term use, is associated with a reduction in the risk of hip fractures by about 30% and of spine fractures by about 50%. Most osteoporotic fractures occur after age 65. Long-term use is necessary to decrease the incidence of fractures substantially. After HRT is stopped, bone loss resumes within a year and bone turnover increases to the levels observed in untreated women within 3 to 6 months, which probably accounts for the lack of fracture protection in past users. \(^\text{44}\)

Estrogen reduces bone turnover and increases bone density in postmenopausal women in part because it improves calcium homeostasis. The addition of calcium potentiates the effect of estrogen on bone mass. The further addition of androgens (low-dose testosterone) or an antiresorptive drug (bisphosphonates) may further increase bone formation in women most at risk for fractures.

Dementia

A number of experimental studies indicate that estrogens may directly influence the brain by a number of mechanisms, including activation of the cholinergic system, inhibition of oxidative stress and neuronal apoptosis, and an increase in synaptic plasticity. Estrogen may also, through its effects on the cardiovascular system, reduce the risk of vascular dementia. \(^\text{45}\)

Several studies have suggested that HRT improves cognition, prevents development of dementia, and decreases the severity of dementia, but other studies have not shown this benefit of estrogen use. \(^\text{46} 47\)

It is now well recognized that cognition improves in perimenopausal women using HRT. However, most studies suggest that this improvement occurs because menopausal symptoms are alleviated and that there is no clear beneficial effect of HRT on cognition in asymptomatic women. \(^\text{48}\)

Ten observational studies have measured the effect of postmenopausal estrogen use on the risk of development of dementia. A meta-analysis of these studies suggested a 29% decreased risk of dementia among estrogen users. \(^\text{49} 50\) However, results of eight small uncontrolled trials of estrogen use in women with dementia or Alzheimer's disease did not demonstrate a clear benefit for cognition. \(^\text{51}\)

Given the limited data, no definite conclusions can be reached about the effect of HRT in reducing cognitive decline and dementia in older women. Although the data available are promising, HRT is not currently recommended for the prevention or treatment of dementia. \(^\text{52} 53\)

Other Benefits

HRT is associated with slightly longer overall survival. Apart from the clear, rapidly occurring effect on menopausal symptoms, no improvement in quality of life was observed in asymptomatic older women receiving HRT.

Breast and Endometrial Cancer

Late menopause has long been known to be associated with an increased risk, and early menopause with a reduced risk, of breast cancer. This observation is consistent with the idea that prolonged exposure to endogenous estrogen is an adverse risk factor. For every 1-year increase in age at menopause, there is about a 3% increase in the risk of breast cancer. \(^\text{54} 55\)

Most studies have found no increased risk of breast cancer in women who had ever used estrogen, usually for less than 2 years in the perimenopausal period. The relative risk increase for breast cancer in HRT users seems largely confined to current or recent use.

A meta-analysis of more than 50 studies clearly demonstrated that the risk of breast cancer increases with long-term estrogen use. \(^\text{56} 57\) Among women who used estrogen for 5 years or longer (median use, 11 years), the summary relative risk for breast cancer was 1.35. Among 1000 women who used HRT continuously for 10 years starting at age 50 years, it was estimated that there would be an additional six breast cancers, raising the incidence from a background of 45 cases to 51 cases. However, these data mainly refer to the use of estrogens only. In the Breast Cancer Detection Demonstration Project, in which 46,000 women participated, the estrogen-progestagen regimens were associated with greater increases in breast cancer risk compared with estrogen alone. \(^\text{58}\) The excess risk increased by 8% for each year of combined hormone use and by 1% for each year of estrogen-only use. Thus, risk of breast cancer would be predicted to increase by approximately 80% after 10 years of estrogen-progestagen use. \(^\text{59} 60\)
An association between endometrial cancer and estrogen use was observed many years ago. Ten years of unopposed estrogen use increases the risk for endometrial cancer 10-fold.\textsuperscript{26} For this reason, the HRT regimens were supplemented with progestagens, which almost completely prevented this excess risk for endometrial cancer.

Other Risks

HRT doubles a woman's risk of needing gallbladder surgery. It also doubles the risk of deep vein thrombosis and pulmonary embolism; however, the absolute risk is low, about 3 cases per 10,000 treated women per year.
Hormone Replacement Regimens

As described by Barrett-Connor,[27] presently advised doses of estrogen were designed to prevent bone loss, and progestagen regimens were proposed to prevent endometrial cancer. The advice, however, has not been based on studies of a wide range of doses. Several estrogen and progestagen preparations are available for HRT (Table 25-2). Components of available preparations vary in their effects on different target tissues. Commercial preparations differ in their clinical effects by design, and individual women differ in their responses. HRT can be administered orally, transdermally, topically, intranasally, or as subcutaneous implants.

Estrogen has distinct route-dependent effects on somatotropic action. Oral estrogens probably lower serum IGF-I concentrations through impairment of hepatic IGF-I production. This effect does not occur after transdermal estrogen administration. Increasing evidence suggests that transdermally administered estrogen thus has more beneficial effects on protein metabolism and body composition.

Prevention of endometrial hyperplasia and cancer induction by estrogen depends on both dose and duration of progestagen use. Uterine protection requires 12 days of cyclic progestagens or combined continuous regimens. The former causes scheduled bleeding and the latter causes unpredictable spotting or bleeding, which usually resolves within 9 months.[28][42]

Initially after the start of HRT, side effects, including mastalgia, bloating, bleeding, premenstrual tension, and depression, can occur. To prevent these side effects but also to increase compliance, it is generally recommended that the patient start with half the estrogen dose.

Data indicate a close relationship between endogenous circulating estrogen levels and bone loss, bone mineral density, and fractures.[44] Women with detectable serum estradiol concentrations (8 to 92 pmol/L; 5 to 25 pg/mL) had higher bone mineral density, significantly less bone loss, and a lower risk for subsequent hip fractures than women with undetectable estradiol levels. These findings suggest that much lower estrogen doses might be sufficient to maintain bone than those indicated in Table 25-2.
Indications for Hormone Replacement Therapy

Perimenopausal or menopausal HRT is strongly indicated for women having premature menopause, women with clinically important symptoms of the menopausal transition, and women entering menopause with osteoporosis.

The concept that long-term HRT after menopause is an effective risk reduction strategy for coronary heart disease, fractures, and cognitive decline has to be balanced against the increased risk of breast cancer. The decision to start long-term HRT should be based on an individual's risk factors, attitude toward hormonal treatment, and knowledge of its risks and benefits. Individualization of the treatment decision is mandatory. Both knowledge and education influence the decision to start HRT; in a Swedish study, only 24% of women 54 years of age but 72% of female general practitioners and 88% of female gynecologists were receiving estrogen-progestagen replacement therapy. \[45\]
Selective Estrogen Receptor Modulators

A new development in the search for optimal hormone replacement therapy during menopause came from observations that tamoxifen has variable antiestrogenic and estrogenic actions in different tissues. Tamoxifen suppresses the growth of estrogen receptor-positive breast cancer cells. Long-term treatment of menopausal patients with breast cancer with tamoxifen also lowered the incidence of new (contralateral) breast cancer by 40%. In addition, the number of cardiovascular incidents decreased by 70%, and the age-related decrease in bone mineral density was partially prevented.

These initially puzzling observations were explained by the fact that tamoxifen and other compounds such as raloxifene have selective estrogen receptormodulating effects, exerts antiestrogenic actions on normal and cancerous breast tissue but agonistic actions on bone, lipids, and the blood vessel walls. These effects of tamoxifen and raloxifene may be explained by differential stabilization of the conformation of the estrogen receptor but might also be related to the activation of different estrogen receptor forms, in which the form is the classical estrogen receptor, whereas a form mediates the vascular and bone effects of estrogens.

Raloxifene is the second selective estrogen receptor modulator (SERM) available for clinical use in menopausal women. It demonstrates estrogen agonist activity on bone and lipid metabolism and has estrogen antagonist activity in uterine and breast tissue. The 60-mg dose is currently approved for the prevention and treatment of postmenopausal osteoporosis.

The efficacy and safety of raloxifene for the prevention of osteoporosis in postmenopausal women were proved in a study that demonstrated a 2.5% increase in bone mineral density in the lumbar spine and hip in a group of postmenopausal nonosteoporotic women treated with raloxifene for 2 years. A significant reduction of vertebral fracture risk by raloxifene was subsequently demonstrated. A total of 7705 postmenopausal women with existing osteoporosis were studied. After 36 months, bone mineral density at the hip and spine increased in the women treated with 60 mg of raloxifene by 2.1% and 2.6%, respectively, compared with those receiving placebo. At 36 months, 7.4% of women had at least one new vertebral fracture, including 10.1% of women receiving placebo and 6.6% of those receiving raloxifene at 60 mg/day. Compared with the placebo group, those receiving 60 mg of raloxifene had a relative risk for fracture of 0.7 (P < .001). Forty-six subjects needed raloxifene at 60 mg for 3 years to prevent one vertebral fracture in menopausal women without an existing fracture; for those with an existing fracture, 16 subjects required treatment.

Raloxifene has effects on lipids similar to those of estrogen, except for a relatively small effect on high-density lipoprotein cholesterol and no significant effect on triglycerides. Data on cardiovascular event rates and on cognitive function are not yet available.

Raloxifene, in contrast to tamoxifen and estrogen, does not stimulate endometrial thickness or vaginal bleeding. With regard to side effects, raloxifene causes an increased incidence of leg cramps and hot flashes.

A most promising effect of raloxifene is its chemoprotective action against breast cancer. Cummings and colleagues reported the effects in 7705 postmenopausal women (mean age, 66.5 years) with osteoporosis. Statistical significance of the difference between the groups was P < .001. To prevent one case of breast cancer, 126 women would need to be treated. Raloxifene decreased the risk of estrogen receptorpositive breast cancer by 90% but did not affect the risk of estrogen receptornegative invasive breast cancer. This important study demonstrated that among postmenopausal women with osteoporosis, the risk of invasive breast cancer was decreased by 76% during 3 years of treatment with raloxifene (Fig. 25-3).

Figure 25-3 Effect of raloxifene administration (60 to 120 mg/day) on the cumulative incidence of breast cancer in 7705 postmenopausal women (mean age, 66.5 years) with osteoporosis. Statistical significance of the difference between the groups was P < .001. (From Cummings SR, Eckert S, Krueger KA, et al. The effect of raloxifene on risk of breast cancer in postmenopausal women: results from the MORE randomized trial. Multiple Outcomes of Raloxifene Evaluation. JAMA 1999; 281:21892197.)
Hormone Replacement Therapy, Selective Estrogen Receptor Modulators, or No Treatment?

The issue of hormonal intervention for postmenopausal women is controversial, and many aspects remain unresolved. The idea that HRT is a global risk reduction strategy is being reevaluated. Although the general clinical benefits of HRT in the short term during and after the menopausal transition are clear, the balance of the beneficial effects of long-term HRT after menopause versus negative effects, especially on breast cancer incidence, remains worrisome.

Currently, a vast armamentarium of pharmacologic treatments to reduce cardiovascular and bone risks is available; these include cholesterol-lowering statins, -blockers, SERMs, and bisphosphonates. An optimal choice of these different lifestyle drugs for menopausal women requires individualization of the treatment decision. Coronary artery disease, for example, is a complex disorder, resulting from an interaction of genetic predisposition and environmental factors. Risk factor modification (diet, smoking, physical activity) should be advised. Primary prevention of coronary artery disease with HRT seems effective; more effective for existing atherosclerosis are lipid-lowering drugs, aspirin, nitrates, and -blockers.

For women with existing osteoporosis, HRT is very effective. However, SERMs and bisphosphonates come close in their fracture-reducing effects. Recognition of an increased risk for breast cancer in menopausal women is an important consideration in the choice of SERMs. If the impressive preventive effect of raloxifene on breast cancer is confirmed to last much longer than 3 years, chemoprevention of breast cancer will probably become a major consideration in the pharmacologic choice for risk reduction in the long-term preventive treatment of postmenopausal women.
ANDROPAUSE

Role of Testosterone during Aging

Age-associated hypogonadism does not develop as clearly in men at andropause as in women at menopause. The key difference is the gradual, often subtle change in androgen levels in men versus the precipitate fall of estrogen production in women. It is generally agreed that as men age, there is a decline in serum total testosterone concentration that begins after the age of 40 years. In cross-sectional studies, the annual decline in total and free testosterone is 0.4% and 1.2%, respectively. The higher decline in free testosterone levels is related to the increase in sex hormone-binding globulin (SHBG) levels with age.

It remains unclear whether the well-known biologic changes occurring during aging in men (e.g., reduced sexual activity, muscle mass and strength, and skeletal mineralization) are causally related to these changes in testosterone bioactivity (andropause).

In a group of more than 400 independently living elderly men (mean age, 78 years; range, 73 to 94 years), Beld and colleagues observed a positive association between total and free serum testosterone concentrations and muscle strength as well as an inverse relationship with fat mass. Low bioavailable testosterone was associated with a depressed mood in a population-based study of 856 men aged 50 to 89 years.
Testosterone Replacement Therapy

Many persuasive reports in the literature demonstrate that testosterone replacement in men of all ages (young, adult, and old) with clear clinical and biochemical hypogonadism instantly reverses vasomotor activity (flushes and sweats); improves libido, sexual activity, and mood; increases muscle mass, strength, and bone mineralization; prevents fractures; decreases fat mass; and decreases fatigue and poor concentration. Also, the treatment of normal adult men with supraphysiologic doses of testosterone, especially when combined with resistance exercise training, increased fat-free mass and muscle mass and strength.

Most studies reporting the results of androgen therapy in older men were small, short-term, noncontrolled, and without uniform end points. The results of a large randomized study in healthy elderly men have now been published and seem representative for effects expected of androgen therapy. Ninety-six men (mean age 73 years) wore a testosterone patch on their scrotum (6 mg of testosterone per 24 hours) or a placebo patch for 36 months. Mean serum testosterone concentrations in the men treated with testosterone increased from 12.7 ± 2.9 nmol/L (367 ± 7.9 ng/dL) before treatment to 21.7 ± 8.6 nmol/L (625 ± 249 ng/dL; P < .001) at 6 months of treatment and remained at that level for the duration of the study. The decrease in fat mass (3.0 ± 0.5 kg) in the testosterone-treated men during the 36 months of treatment was significantly different from the decrease (0.7 ± 0.5 kg) in the placebo-treated men (P < .001). The increase in lean mass (1.9 ± 0.3 kg) in the testosterone-treated men was significantly different from that in the placebo-treated men (0.2 ± 0.2 kg; P < .001).

Changes in knee extension and flexion strength, hand grip, walking speed, and other parameters of muscle strength and function were not significantly different in the two groups. Bone mineral density in the lumbar spine increased in both the testosterone-treated (4.2% ± 0.8%) and placebo-treated (2.5% ± 0.8%) groups, but mean changes did not differ between groups (see Fig. 25-4). However, the lower the pretreatment serum testosterone concentration, the greater the effects of testosterone treatment on lumbar spine bone density after 36 months (P = .02). A minimal effect (0.9 ± 1.0%) of testosterone treatment on bone mineral density was observed in men with a pretreatment serum testosterone concentration of 13.9 nmol/L (400 ng/dL), but an increase of 5.9% ± 2.2% was found in men with a pretreatment testosterone concentration of 6.9 nmol/L (200 ng/dL).

The subjective perception of physical function decreased significantly during the 36 months of treatment in the placebo-treated group (P < .001) but not in the testosterone-treated group. Interestingly, the effect of testosterone treatment on the perception of physical functioning varied inversely with the pretreatment serum testosterone concentration (P < .01). There was no significant difference between the two treatment groups with regard to the subjective perception of energy or sexual functions.

With regard to the potential adverse effects of testosterone treatment in healthy elderly men, again the study by Snyder and colleagues seems representative. The mean serum prostate-specific antigen (PSA) concentration did not change during the 36 months of treatment in the placebo-treated group but increased by a relatively small but statistically significant (P < .001) amount by 6 months of treatment in the testosterone-treated group and remained relatively stable for the remainder of the study. The urine flow rate, volume of urine in the bladder after voiding, and number of clinically significant prostate events during the 3 years of the study were similar in the two groups. Hemoglobin and hematocrit did not change in the placebo-treated group during treatment, but both increased significantly (P < .001) in the testosterone-treated group within 6 months and remained relatively stable for the remainder of the study. Three men treated with testosterone developed persistent erythrocytosis (hemoglobin > 17.5 g/dL; hematocrit > 52%) during treatment.

Other androgen replacement studies in older men have demonstrated that lipid profiles are not adversely affected by this therapy, but the incidence of cardiovascular events in healthy elderly men who receive androgens for extended periods has not been studied. Numerous studies of large populations of healthy men have shown a marked rise in the incidence of impotence to over 50% in men 60 to 70 years old. Although this increased rate occurs in the same age group who show a clear decline in serum (free) testosterone levels, no causal relationships have been demonstrated. In most instances, testosterone replacement therapy in elderly men is not effective for the treatment of loss of libido or impotence in individuals with serum testosterone concentrations within the normal range in age-matched subjects. Other factors, such as atherosclerosis, alcohol consumption, smoking, and the quality of personal relationships, seem to be more important.

This result suggests that there is a threshold level of testosterone in the low normal range below which libido and sexual function are impaired and above which there is no further enhancement of response.

Summarizing the available literature, the indiscriminate (preventive) treatment of healthy elderly men with testosterone at a dose that increases serum testosterone concentrations to those observed in 20- to 30-year-olds has limited anabolic effects on body composition (a slight decrease in fat mass and a slight increase in muscle mass). No beneficial effects on muscle strength or physical performance are observed.

Detailed analyses of a number of studies of elderly men selected on the basis of low pretreatment serum testosterone concentrations indicated a beneficial effect of testosterone replacement therapy on muscle strength, bone mineral density, mood, and (subjective) aspects of the quality of life. This introduces the question of how to select elderly men who might benefit from testosterone treatment.

There is great interindividual variation in serum testosterone concentrations among healthy men. In adulthood, the biochemical definition of male hypogonadism is generally accepted if serum total testosterone is below 10.4 to 12.1 nmol/L (300 to 500 ng/dL), depending on the population studied. Of healthy men between the ages of 60 to 80 years, 20% demonstrated a serum testosterone concentration below 10.4 nmol/L (300 ng/dL). In the same study, non-SHBG testosterone levels were below the lower limit for young men (<1.6 nmol/L) in over 60% of these men.

An important question is how to define true hypogonadism in elderly men. Because many signs and symptoms of hypogonadism coincide with those observed during the normal aging process, no good single measure of clinically significant hypogonadism is available. In a discussion of testosterone replacement in older men, it was suggested that the biochemical diagnosis of hypogonadism seems certain if the serum total testosterone concentration is less than 7.0 nmol/L (200 ng/dL).
Serum total testosterone levels in a group of healthy young (n = 58; aged 21 to 35 years) and older (n = 96; aged 60 to 80 years) men. Mean ± standard deviation. Serum total testosterone is 18.2 ± 4.2 nmol/L (525 ± 122 ng/dL) for the young men and 14.5 ± 4.5 nmol/L (420 ± 12.9 ng/dL) for the older men. (From Tenover JS. Androgen administration to aging men. Endocrinol Metab Clin North Am 1994; 23:877-892.)

ng/dL). This cutoff remains arbitrary and does not answer the question of whether healthy elderly men with testosterone levels between 7.0 and 10.4 nmol/L are hypogonadal or whether such men would benefit from replacement therapy with testosterone. Also, it has been demonstrated that intercurrent diseases frequently result in a transient, sharp drop in serum testosterone concentrations, whereas frail, elderly men in general tend to have testosterone levels 10% to 15% lower than those of healthy, age-matched control subjects.

When a serum testosterone concentration is found to be below 7.0 nmol/L (200 ng/dL), an additional evaluation with measurements of serum gonadotropins and prolactin is mandatory in order to exclude pituitary pathology.
Conclusions

Testosterone at supraphysiologic doses, when administered to eugonadal men, increases muscle mass and strength. Replacement therapy directed at restoring serum testosterone in healthy elderly men to levels observed between the ages of 30 and 50 years lowers fat mass and increases lean mass to a limited extent without a beneficial effect on muscle strength and physical performance. It remains uncertain whether testosterone replacement produces clinically meaningful improvements in muscle function without significant adverse effects in frail older men or in elderly men with serum testosterone concentrations between 7.0 and 11.4 nmol/L.

If one decides to start testosterone replacement, the major goal of therapy is to return testosterone levels to values as close to "physiologic" levels in age-matched controls as possible. The dose should thus be titrated according to serum levels. Considerations concerning the choice of testosterone preparation as well as the route of administration (oral, injectable, implantable, or transdermal) are discussed in Chapter 8.

At present, the duration of testosterone administration is uncertain. Control of prostate size, PSA levels, and hematocrit is mandatory. The identification of elderly men who might benefit most from testosterone treatment remains uncertain, and the risks to the prostate and possible effects on the process of atherosclerosis require further study. The development of androgenic compounds with variable biologic action in different organs (selective androgen receptor modulation) is currently being pursued.
ADRENOPAUSE

Role of Dehydroepiandrosterone during Aging

Humans are unique among primates and rodents because the human adrenal cortex secretes large amounts of the steroid precursor DHEA and its sulfate derivative DHEAS. Serum DHEAS concentrations in adult men and women are 100 to 500 times higher than those of testosterone and 1000 to 10,000 times higher than those of estradiol. In normal subjects, serum concentrations of DHEA and its sulfate are highest in the third decade of life, after which the concentrations of both gradually decrease, so that by the age of 70 to 80 years, the values are about 20% of peak values in men and 30% of peak values in women (see Fig. 25-2).

DHEA and DHEAS seem to be inactive precursors that are transformed within human tissues by a complicated network of enzymes into androgens or estrogens, or both (Fig. 25-6). The key enzymes are aromatase, steroid sulfatase, 3-hydroxysteroid dehydrogenases (3-HSD-1, -2), and at least seven organ-specific 17-hydroxysteroid dehydrogenases (17-HSD-1 to -7). Labrie and colleagues introduced the term intracrinology to describe this synthesis of active steroids in peripheral target tissues in which the action is exerted in the same cells in which synthesis takes place, without release into the extracellular space and general circulation.

In postmenopausal women, nearly 100% of sex steroids are synthesized in peripheral tissues from precursors of adrenal origin except for a small contribution from ovarian or adrenal testosterone and androstenedione. Thus, in postmenopausal women, virtually all active sex steroids are made in target tissues by an intracrine mechanism. In elderly men, the intracrine production of androgens is also important; less than 50% of the androgen supply is derived from testicular production.

The high secretion rate of adrenal precursor sex steroids in men and women differs from that in laboratory animal models, in which the secretion of sex steroids occurs exclusively in the gonads. In rats and mice, long-term administration of DHEA prevented obesity, diabetes mellitus, cancer, and heart disease and enhanced immune function.

These experimental animal data have been used to argue that DHEA administration in adult or elderly individuals prolongs life span and might be an “elixir of youth.” Supportive data in humans are few, however, and highly controversial. Epidemiologic studies indeed point to a mild cardioprotective effect of higher DHEAS levels in both men and women. Functional parameters of activities of daily living in men older than 90 years were lowest in those with the lowest serum DHEAS concentrations, and in healthy elderly individuals there was an association between the ratio of cortisol to DHEAS levels and cognitive impairment.
Dehydroepiandrosterone Replacement Therapy

Several randomized placebo-controlled studies demonstrated that oral administration of DHEA was beneficial. Three months of daily treatment with 50 mg of DHEA in 20 healthy adults, most of whom were not elderly, increased serum DHEA and DHEAS concentrations to young adult levels, increased androgen and IGF-I concentrations, and induced a remarkable increase in perceived physical and psychological well-being in both sexes without an effect on libido. In a subsequent study, treatment with 100 mg of DHEA for 6 months in eight adult men and eight adult women increased lean body mass in both sexes but increased muscle strength only in the men. A number of shorter, well-controlled trials with DHEA subsequently did not demonstrate a clinically significant effect on the parameters just mentioned.

After 280 healthy elderly women and men, aged 60 to 79 years, were given DHEA at 50 mg or placebo orally daily for 1 year in a randomized trial, no adverse effects were noted. A significant increase in most parameters related to libido was observed in older women. Improved skin status, including hydration, epidermal thickness, serum production, and pigmentation, was also noted, particularly in women. In women older than 70 years, bone turnover slightly improved as a result of a decrease in osteoclast activity.

A physiologic functional role of DHEA in women has been ascertained in a careful double-blind study. In women with adrenal insufficiency, DHEA administration (50 mg/day) normalized serum concentrations of DHEA, DHEAS, androstenedione, and testosterone. DHEA significantly improved overall well-being as well as scores for depression and anxiety, the frequency of sexual thoughts, sexual interest, and satisfaction with both mental and physical aspects of sexuality.
Conclusions

No prospective long-term randomized studies of DHEA administration have been carried out in frail elderly people or in the elderly individuals with the lowest serum DHEA and DHEAS concentrations. DHEAS is a universal precursor for the peripheral local production and action of estrogens and androgens in elderly people. The data suggest that serum estradiol concentrations (which might be a surrogate marker for tissue concentrations) and serum luteinizing hormone concentrations (which reflect serum androgen and estrogen activity) demonstrate important positive relations with bone mineral density, quality of life, cognitive decline, and degree of atherosclerosis.

The addition of DHEA (50 mg) to the existing large pool of DHEA and DHEAS in unselected elderly individuals has limited clinical effects, especially in elderly women. It is not known whether the increase in sex steroid levels induced by long-term DHEA administration is safe with regard to development of ovarian, prostate, or other types of steroid-dependent cancers. DHEA is currently widely used in the United States as an unapproved treatment against aging. With the scientific verdict still out, without further confirmation of the reported beneficial actions of DHEA in humans, and without a better understanding of its potential risks, it is premature to recommend the routine use of DHEA for delaying or preventing the physiologic consequences of aging.
SOMATOPAUSE

Role of Growth Hormone and Insulin-like Growth Factor I during Aging

Elderly men and women secrete GH less frequently and at lower amplitude than do young people. In fact, GH secretion declines approximately 14% per decade in normal individuals. In parallel, serum levels of IGF-I (see Fig. 25-2) are 20% to 80% lower in healthy elderly individuals than in healthy young adults. The concept that this decline in GH and IGF-I secretion contributes to the decline of functional capacity in elderly people (somatopause) is mainly derived from studies in which GH replacement therapy in GH-deficient adults was shown to increase muscle mass, muscle strength, bone mass, and the quality of life. A beneficial effect on the lipid profile and an important decrease in fat mass were also observed in these patients. As in hypogonadal individuals, adult GH deficiency can thus be considered a model of normal aging because a number of catabolic processes that are central in the biology of aging can be reversed by GH replacement.

Several studies of the relationship between body composition and functional capacity and serum IGF-I concentrations demonstrated contradictory results. In a study of healthy individuals of a broad age range, an association was observed between the maximum aerobic capacity and circulating IGF-I levels. However, no relationship with IGF-I was demonstrated in a group of highly active older people when grip strength, physical performance, and cognitive state were measured.
Growth Hormone Replacement Therapy

Rudman and colleagues, after a ground-breaking randomized controlled trial in healthy men 61 to 81 years old with serum IGF-I concentrations in the lower third for their age, reported in 1990 that GH treatment (30 µg/kg three times weekly for 6 months) restored the men's IGF-I levels to "normal." In the treatment group, lean body mass rose by 8.8% and lumbar vertebral density increased by 1.6%. The magnitudes of these initial changes were equivalent to a reversal of the age-related changes by 10 to 20 years. However, during continuation of this study to 12 months, the significant positive effect on bone mineral density at any site was lost.

In the subsequent years, it became clear that GH administration in healthy elderly individuals frequently caused acute adverse effects such as carpal tunnel syndrome, gynecomastia, fluid retention, and hyperglycemia, which were severe enough for an appreciable number of individuals to drop out of these studies. The most disappointing aspect, however, was that no positive effects of GH administration were observed on muscle strength, maximal oxygen consumption, or functional capacity. (In contrast, when GH was administered in combination with resistance exercise training, a significant positive effect on muscle mass and muscle strength was recorded that did not differ from that seen with placebo treatment, which suggests that GH does not add to the beneficial effects of exercise.)

A representative example of a well-controlled study of GH administration in unselected elderly men is given in Table 25-3.

Earlier studies demonstrated that pharmacologic doses of GH prevent the autocannibalistic effects of acute diseases on muscle mass. This finding prompted us to carry out a randomized, placebo-controlled trial of 6 weeks of GH administration in elderly individuals with an acute hip fracture. Our preliminary results indicate that in patients older than 75 years, GH administration causes an earlier return to independent living after the fracture. Comparable studies are being done in several countries, and confirmation is needed before GH can gain a place in the treatment of acute catabolic states in frail elderly people.

Other components in the regulation of the GH-IGF-I axis

are effective in activating GH and IGF-I secretion. Long-acting derivatives of the hypothalamic peptide growth hormonereleasing hormone (GHRH), given twice daily subcutaneously for 14 days to healthy 70-year-old men, increased GH and IGF-I levels to those encountered in 35-year-olds. These studies suggest that somatopause is driven primarily by the hypothalamus and that pituitary somatotropes retain their capacity to synthesize and secrete high levels of GH.

GH-releasing peptides (GHRPs) are oligopeptides with even more powerful GH-releasing effects. They were originally developed by design. Their effects on GH secretion are mediated through endogenous specific receptors. Nonpeptide analogues (e.g., MK-677 and L-692,429) have powerful GH-releasing effects, restoring IGF-I secretion in older adults to levels typical of young adults. Long-term oral administration of MK-677 to healthy elderly individuals increased lean body mass but not muscle strength. If proven to be GH-specific, these orally active GHRP derivatives might be important alternatives to subcutaneously administered GH for studies of the reversal of somatopause, prevention of frailty, and reversal of acute catabolism.

The long-term safety of activating GH and IGF-I levels in older people has become a concern because of reports of an association between serum IGF-I concentrations and cancer risk. Individuals with high IGF-I levels (or low IGF-binding protein 3 levels) within the broad normal range have an increased risk of prostate, colon, and breast cancer. These epidemiologic studies, together with experimental data, suggest that the IGF-I system is involved in tumor development and progression. However, no causal relationship between IGF-I levels and cancer risk has yet been established, and possible medical intervention directed at increasing IGF-I bioactivity in elderly people will in most instances be given toward the end of life, presumably not allowing enough time to affect tumor development or progression.
Conclusions

During the aging process, GHIGF-I axis activity declines. It is unclear whether changes in body composition and functional capacity are directly related. GH administration in older adults causes an increase in lean body mass and an appreciable loss of fat mass. However, the very limited ability of GH treatment to improve muscle strength and functional capacity in elderly people, despite restoration of circulating IGF-I concentrations to young adult levels, limits its application. Furthermore, most dose regimens of GH cause appreciable adverse effects, and long-term safety with regard to tumor development and progression remains uncertain. GHRP and its orally active analogues are capable of restoring GH and IGF-I levels in the elderly population.

In the near future, clinical trials with such orally active molecules in frail elderly people or in elderly individuals with clearly lowered IGF-I levels, or both, should be able to delineate the precise role of the GHIGF-I axis in the aging process. In such trials, much emphasis must be given to safety aspects. At present, there is insufficient evidence to recommend medical intervention in the GHIGF-I axis to rejuvenate healthy elderly people. Only elderly patients with GH deficiency caused by organic diseases, such as pituitary adenomas, clearly benefit from GH replacement therapy.
THE CONCEPT OF SUCCESSFUL AGING

There is considerable variation in the effects of aging on healthy individuals, with some people exhibiting greater and others evidencing few or no age-related alterations in physiologic functions. It has been suggested that it might be useful to distinguish between usual and successful patterns of aging. Genetic factors, lifestyle, and societal investments in a safe and healthful environment are important aspects of successful aging.

Traditionally, the aging process, including the development of physical frailty toward the end of life, has been considered physiologic and unavoidable. It has recently become evident, however, that it might not be necessary to accept the grim stereotype of aging as an unalterable process of decline and loss. As life expectancy rises further in the coming decades, the overarching goal should be "an increase in years of healthy life with a full range of functional capacity at each stage of life." Such a compression of morbidity can be achieved by adapting lifestyle measures, but a number of aspects of the aging process of the endocrine system invite the development of routine medical intervention programs offering long-term replacement therapy with one or more hormones in order to delay the aging process and to allow humans to live for a longer period in a relatively intact state.

Intracellular magnesium, like phosphate, is necessary for a wide range of cellular functions. It is an essential cofactor in enzymatic reactions, including most of the gradient, is unknown, although some evidence for regulated channels has been obtained.

The concentration of which is approximately 5 mM. The intracellular cytosolic free magnesium concentration is approximately 0.5 mM—that is, 1000-fold higher than that of phosphate or other anions, and 55% is present as the free ion.

Magnesium is the fourth most abundant cation in the body. Roughly half is found in bone and half in muscle and other soft tissues. As much as half of the magnesium that disorders of phosphate homeostasis associated with severe depletion of intracellular phosphate lead to profound and global impairment of organ function.

Roles of the mineral ions
Calcium (Ca) and phosphorus (P) are the principal constituents of bone, and together they constitute 65% of its weight. Bone, in turn, contains nearly all of the calcium and phosphorus and over half of the magnesium (Mg) in the human body. Although quantitatively minor in amount, each of these ions in the extracellular fluid and within cells plays a crucial role in normal physiologic processes.

Ninety-nine percent of total body calcium resides in bone, mainly albumin and globulins. The ionized calcium concentration in serum is approximately 1.2 mM (5 mg/dL), and it is this fraction that is biologically active and that is tightly controlled by hormonal mechanisms. Because intracellular cytosolic free calcium concentrations typically are in the range of only 100 nM, a very large chemical gradient (i.e., 10,000:1), augmented by the large negative electrical potential, favors calcium entry into cells through calcium channels. This gradient is maintained by the limited conductance of resting calcium channels and by the energy-dependent extrusion of calcium into the extracellular fluid via high-affinity Ca\(^{2+}\)-ATPases and low-affinity sodium-calcium (Na\(^{+}\)-Ca\(^{2+}\) ) exchangers.

Phosphate is more widely distributed to nonosseous tissues than is calcium. Eighty-five percent of body phosphate is in the mineral phase of bone, and the remainder is located in inorganic or organic form throughout the extracellular and intracellular compartments. In human serum, inorganic phosphate (P\(_{i}\) ) is present at a concentration of approximately 1 mM and exists almost entirely in ionized form as either H\(_2\)PO\(_4\)\(^-\) or HPO\(_4\)\(^{2-}\). Only 12% of serum phosphate is protein-bound, and an additional small fraction is looselycomplexed with calcium, magnesium, and other cations. Intracellular free phosphate concentrations are generally comparable to those in the extracellular fluid (i.e., 1 to 2 mM), although the inside-negative electrical potential of the cell creates a significant energy requirement for translocation of phosphate into cells. This process generally is accomplished through sodium-phosphate cotransport driven by the transmembrane sodium gradient. A number of sodium-phosphate cotransporters have been cloned; various cells and tissues employ different species of such transporters with distinctive regulatory characteristics.

Organic phosphate is a key component of virtually all classes of structural, informational, and effector molecules that are essential for normal genetic, development, and physiologic processes. Phosphate is an integral constituent of nucleic acids; phospholipids; complex carbohydrates; glycolytic intermediates; structural, signaling, and enzymatic phosphoproteins; and nucleotide cofactors for enzymes and G proteins. Of particular importance are the high-energy phosphate ester bonds present in molecules such as adenosine triphosphate (ATP), diphosphoglycerate, and creatine phosphate that store chemical energy. Phosphate plays a particularly prominent role as the key substrate or recognition site in numerous kinase and phosphatase regulatory cascades. Cytosolic phosphate also directly regulates a number of crucial intracellular reactions, including those involved in glucose transport, lactate production, and synthesis of ATP. In light of these diverse roles, it is not surprising that disorders of phosphate homeostasis associated with severe depletion of intracellular phosphate lead to profound and global impairment of organ function.

Magnesium is the fourth most abundant cation in the body. Roughly half is found in bone and half in muscle and other soft tissues. As much as half of the magnesium in bone is not sequestered in the mineral phase but is freely exchangeable with ions in the extracellular fluid and therefore may serve as a buffer against changes in extracellular magnesium concentration. Less than 1% of all magnesium in the body is present in the extracellular fluid, where the magnesium concentration is approximately 0.5 mM. The concentration of magnesium in serum normally is 0.7 to 1.0 mM, of which roughly a third is protein bound, and an additional small fraction is loosely complexed with calcium, magnesium, and other cations. Intracellular free phosphate concentrations are generally comparable to those in the extracellular fluid (i.e., 1 to 2 mM), although the inside-negative electrical potential of the cell creates a significant energy requirement for translocation of phosphate into cells. This process generally is accomplished through sodium-phosphate cotransport driven by the transmembrane sodium gradient. A number of sodium-phosphate cotransporters have been cloned; various cells and tissues employ different species of such transporters with distinctive regulatory characteristics.

Magnesium is the fourth most abundant cation in the body. Roughly half is found in bone and half in muscle and other soft tissues. As much as half of the magnesium in bone is not sequestered in the mineral phase but is freely exchangeable with ions in the extracellular fluid and therefore may serve as a buffer against changes in extracellular magnesium concentration. Less than 1% of all magnesium in the body is present in the extracellular fluid, where the magnesium concentration is approximately 0.5 mM. The concentration of magnesium in serum normally is 0.7 to 1.0 mM, of which roughly a third is protein bound, and 15% is loosely complexed with phosphate or other anions, and 55% is present as the free ion. Over 95% of intracellular magnesium is bound to other molecules, most notably ATP, the concentration of which is 5 mM. The intracellular cytosolic free magnesium concentration is approximately 0.5 mM, which is 1000-fold higher than that of calcium and is maintained by an active sodium-magnesium antiporter. The mechanism whereby magnesium enters cells, presumably down a favorable electrochemical gradient, is unknown, although some evidence for regulated channels has been obtained.

Intracellular magnesium, like phosphate, is necessary for a wide range of cellular functions. It is an essential cofactor in enzymatic reactions, including most of the same glycolytic, kinase, and phosphatase pathways that also involve phosphate. Magnesium serves to directly stabilize the structures of a variety of macromolecules
and complexes, including deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and ribosomes; is a key activator of the many ATPase-coupled ion transporters; and plays a direct role in mitochondrial oxidative metabolism. As a result, magnesium is critical for energy metabolism and the maintenance of a normal intracellular environment. Extracellular magnesium is crucial for normal neuromuscular excitability and nerve conduction, and many of the clinical consequences of magnesium deficiency or excess reflect abnormalities in this sphere.

The importance of the mineral ions for normal cellular physiology as well as skeletal integrity is reflected in the powerful endocrine control mechanisms that have evolved to maintain their extracellular concentrations within relatively narrow limits. The following topics describe the structures, secretory controls, actions, and interactions of parathyroid hormone, calcitonin, and 1,25-dihydroxyvitamin D (1,25(OH)\(_2\) D\(_3\) or calcitriol) the major hormones involved in mineral ion homeostasis. Subsequent topics cover the wide variety of clinical disorders that accompany abnormalities in this hormonal network.
PARATHYROID HORMONE

Parathyroid hormone (PTH) is the peptide hormone that controls the minute-to-minute level of ionized calcium in the blood and extracellular fluids. PTH binds to cell surface receptors in bone and kidney, thereby triggering responses that increase blood calcium. PTH also increases renal synthesis of 1,25(OH)₂D₃, the hormonally active form of vitamin D, which then acts on the intestine to augment absorption of dietary calcium, in addition to promoting calcium fluxes into blood from bone and kidney. The resulting increase in blood calcium (and in 1,25(OH)₂D₃) feeds back on the parathyroid glands to decrease the secretion of PTH. The parathyroid glands, bones, kidney, and gut are thus the crucial organs that participate in PTH-mediated calcium homeostasis.

Parathyroid Gland Biology

Parathyroid chief cells have three properties vital to their homeostatic function:

1. They rapidly secrete stored hormone in response to changes in blood calcium.
2. They can synthesize, process, and store large amounts of PTH in a regulated manner.
3. They replicate when chronically stimulated.

These functional attributes allow for short-term, intermediate-term, and long-term adaptation, respectively, to changes in calcium availability.

Parathyroid Hormone Biosynthesis

PTH, a protein of 84 amino acids, is synthesized as a larger precursor, pre-proparathyroid hormone (pre-pro-PTH). Figure 26-3 illustrates the reported pre-pro-PTH sequences. These pre-pro-PTH sequences share a 25-residue "pre" or signal sequence and a 6-residue "pro" sequence. The signal sequence, along with the short pro sequence, functions to direct the protein into the secretory pathway (Fig. 26-4). During transit across the membrane of the endoplasmic reticulum, the signal sequence is cleaved off and rapidly degraded. The importance of the signal sequence for normal secretion of PTH is illustrated by the hypoparathyroidism inherited in families carrying mutations in the signal sequence of pre-pro-PTH.

The role of the short pro sequence is not completely understood; it may help the signal sequence work efficiently and ensure accurate cleavage of the precursor. After cleavage of the pro sequence, the mature PTH(184) is concentrated in secretory vesicles and granules. One morphologically distinct subtype of granule contains both PTH and the proteases cathepsin B and cathepsin H. This co-localization of proteases and PTH in secretory granules probably explains the observation that a portion of the PTH secreted from parathyroid glands consists of carboxy-terminal PTH fragments. No amino-terminal fragments of PTH are secreted. Although the possible functions of carboxy-terminal fragments of PTH are still poorly characterized, these fragments do not activate the PTH/PTHrP receptor (see later). Thus, the intracellular fragmentation of PTH probably represents an inactivating pathway. The intracellular degradation of newly synthesized PTH provides an important regulatory mechanism. Under conditions of hypercalcemia, the secretion of PTH is substantially decreased, and most of what is secreted consists of carboxy-terminal fragments.

Parathyroid Hormone Secretion

Although catecholamines, magnesium, and other stimuli can affect PTH secretion, the major regulator of PTH secretion is the concentration of ionized calcium in blood. Increased serum ionized calcium leads to a decrease in PTH secretion. The shape of the dose-response curve is sigmoid. Properties of the parathyroid cell determine the conformation of the sigmoid curve but do not alone determine the point on the curve that represents a physiologic steady state for an individual. This point, usually between the mid-point and the bottom of the curve, is determined by how vigorously target organs respond to PTH. Figure 26-5C (solid line) shows how an individual's calcium level rises in response to increases in PTH; the parathyroid gland's sigmoid curve is the dotted line. In the steady state, an individual's blood levels of PTH and calcium represent the intersection of the two lines.

The sigmoid curve reveals several important physiologic properties of the parathyroid gland. The minimal secretory...
For decades it has been known that phosphate elevation stimulates PTH secretion, although the mechanism by which it elevates PTH is uncertain; differing experimental paradigms suggest regulation at the levels of gene transcription, post-translational processing of peptide, and mRNA stability, and mRNA translation. A recent study has shown that acute hypocalcemia in rats leads, within an hour, to an increase in PTH messenger RNA (mRNA).

Calcium also regulates the biosynthesis of PTH. In vivo 1,25(OH) \_2 \text{D}_3 suppression of transcription does not occur when 1,25(OH) \_2 \text{D}_3 level of intracellular calcium despite fluctuations in extracellular calcium. The parathyroid cell is exceptional, in that modest changes in extracellular calcium lead to the calcium-sensing receptor gene also have the expected defects in parathyroid calcium sensing. Whereas activating mutations cause familial hypoparathyroidism with hypercalcemia. Inactivating mutations cause familial hypocalciuric hypercalcemia (FHH), a disease of defective calcium sensing (see later on), whereas activating mutations cause familial hyperparathyroidism with hypercalcemia. Furthermore, mice genetically engineered to have only one functioning copy of the calcium-sensing receptor gene also have the expected defects in parathyroid calcium sensing. Of importance, calcimimetic compounds that activate the cloned calcium-sensing receptor have been shown to inhibit PTH secretion in humans and may prove useful in the treatment of primary and secondary hyperparathyroidism in the future.

The signaling properties of the calcium-sensing receptor explain one of the most unusual features of the parathyroid cell. Most cells maintain a constant and very low level of intracellular calcium despite fluctuations in extracellular calcium. The parathyroid cell is exceptional, in that modest changes in extracellular calcium lead to corresponding changes in intracellular calcium. When calcium activates the cell surface calcium-sensing receptor, intracellular calcium rises because of release of calcium from intracellular stores and opening of plasma membrane calcium channels. This increase in intracellular calcium then leads to a decrease in PTH secretion by mechanisms that remain to be clarified.

The calcium-sensing receptor is expressed widely. Expression in the renal tubules and calcitonin-producing cells of the thyroid contributes to calcium homeostasis, whereas expression in organs such as the brain points to multiple roles for calcium signaling. The observation that the calcium-sensing receptor also responds to certain amino acids suggests that the expression of the calcium-sensing receptor in the gut and other sites may facilitate the assimilation of multiple nutrients.

The minute-to-minute regulation of PTH blood levels can be explained by the two mechanisms already discussedregulation of PTH secretion by the calcium-sensing receptor and amplification of this regulation by intracellular degradation of stored hormone. Over a longer time frame, the parathyroid cell regulates the expression of the PTH gene as well.

Although 1,25(OH) \_2 \text{D}_3, the active form of vitamin D, has no direct effect on PTH secretion, it dramatically suppresses PTH gene transcription. This suppression of transcription does not occur when 1,25(OH) \_2 \text{D}_3 is administered to chronically hypocalcemic animals, however, perhaps because hypocalcemia leads to a fall in parathyroid vitamin D receptors or because hypocalcemia increases the expression of calreticulin in the parathyroid. The capability of hypocalcemia to override the effects of high levels of 1,25(OH) \_2 \text{D}_3 represents an important defense, because it provides a way to make large amounts of PTH and 1,25(OH) \_2 \text{D}_3 at the same time, when both are needed.

Calcium also regulates the biosynthesis of PTH. In vivo studies show that acute hypocalcemia in rats leads, within an hour, to an increase in PTH messenger RNA (mRNA). In contrast, hypercalcemia leads to little or no change in PTH mRNA. Thus, under normal conditions, the inhibition by calcium of PTH biosynthesis already is nearly maximal, just as it is for PTH secretion. When the parathyroid gland is poised to respond to a fall in calcium much more readily than to a rise. The mechanism for the increase in PTH mRNA in response to hypocalcemia is uncertain; differing experimental paradigms suggest regulation at the levels of gene transcription, mRNA stability, and mRNA translation.

For decades it has been known that phosphate elevation stimulates PTH secretion, largely by lowering blood calcium and 1,25(OH) \_2 \text{D}_3 levels. More recently, a series of studies in vitro and in vivo have demonstrated that phosphate can increase PTH secretion directly, independent of effects on blood calcium and 1,25(OH) \_2 \text{D}_3. Phosphate increases PTH secretion acutely only after a delay and probably works largely through regulation of PTH mRNA levels. The direct effects of phosphate may be important at very high and very low levels, although these effects may be important in the setting of renal failure.
The regulation of the PTH gene has particular clinical relevance in patients with renal failure. Hypocalcemia, low levels of 1,25(OH)₂D₃, hyperphosphatemia, and, possibly, uremic toxins disrupt normal calcium homeostasis in this setting. Therapy with 1,25(OH)₂D₃ and calcium increases calcium absorption and also inhibits PTH synthesis by direct effects on the parathyroid gland. Prevention of hyperphosphatemia avoids the direct and indirect actions of phosphate to stimulate PTH secretion.

Regulation of Parathyroid Cell Number

Parathyroid cells divide during the growth of young animals but replicate little in adulthood. Parathyroid cell number can dramatically increase, however, in the setting of hypocalcemia, low levels of 1,25(OH)₂D₃, hyperphosphatemia, or uremia and during neoplastic growth.

Calcium, acting through the parathyroid calcium-sensing receptor, restrains parathyroid proliferation. This effect has been demonstrated clinically in patients who lack both copies of the calcium-sensing receptor gene. These neonates exhibit severe primary hyperparathyroidism with large, diffusely hyperplastic glands that presumably have developed because of insufficient activation of the parathyroid calcium-sensing receptor by extracellular calcium. Furthermore, administration of the calcimimetic compound NPS R-568, which activates the calcium-sensing receptor directly, prevents parathyroid cell proliferation in experimental uremia.

The role of 1,25(OH)₂D₃, independent of blood calcium, in regulating parathyroid cell proliferation is less well established than that of calcium. That 1,25(OH)₂D₃ can dramatically affect parathyroid cell number has been shown in vivo in many settings, but such studies cannot rigorously eliminate effects of transient changes in blood calcium. The suppression of proliferation of cultured parathyroid cells by 1,25(OH)₂D₃ certainly suggests that 1,25(OH)₂D₃ can directly inhibit parathyroid cell replication. Nevertheless, modest changes in 1,25(OH)₂D₃ have no effect on parathyroid cell proliferation in vivo, and calcium alone can prevent parathyroid cell hyperplasia in mice engineered to lack vitamin D receptors. Thus, the importance of regulation of parathyroid cell number by 1,25(OH)₂D₃ in vivo has not been established.

Although the ability to increase parathyroid cell number in response to physiologic challenge represents an important defense against hypocalcemia, it is a slow response that is not easily reversible. When the need for an increased number of parathyroid cells disappears (e.g., after renal transplantation for uremia), persistent hyperparathyroidism can cause vexing clinical problems for months and years thereafter. The mechanisms for decreasing parathyroid cell number, if they exist, are poorly understood. Apoptosis of normal parathyroid cells in response to experimental manipulation has not been demonstrated.
Parathyroid Gland Development

Genes involved in making parathyroid cells during development may also regulate PTH synthesis and parathyroid cell number throughout life; thus, an understanding of parathyroid cell development may have broad clinical implications. Although the genetic mechanisms used to generate parathyroid chief cells during development are largely unknown, the importance of four specific genes has become clear. Studies of gene knockout mice have shown that the hoxa3 and pax9 transcription factors are needed to form parathyroid glands as well as many other pharyngeal pouch derivatives, such as the thymus. People with mutations in the gene encoding the transcription factor GATA3 exhibit a syndrome of hypoparathyroidism, sensorineural deafness, and renal anomalies when only one copy of the gene is mutated. Furthermore, mice or humans missing the gcm2 and GCMB genes, respectively, have no parathyroid glands. In both species, the deletion of gcm2 or GCMB (the human equivalent) is very specific for controlling parathyroid development because no abnormalities in other tissues have been noted. Mice, which have only two parathyroid glands normally, still make PTH in a small number of cells in the thymus after gcm2 gene ablation and secrete this PTH into the circulation. A human patient without GCMB had no detectable circulating PTH at birth and low levels of PTH several years later.
Peripheral Metabolism of Parathyroid Hormone

The earliest radioimmunoassays for PTH demonstrated that the molecular forms of PTH in the circulation differ from those in the parathyroid gland. Characterization of the metabolism of PTH and its fragments has clarified the origins and significance of immunoreactive PTH molecules in the blood stream. As noted previously, both PTH(184) and carboxy-terminal fragments of PTH are secreted from the parathyroid gland; the ratio of inactive PTH to active PTH secretion increases with increasing blood calcium. Secreted intact PTH(184) is extensively metabolized by liver (70%) and kidney (20%) and disappears from the circulation with a half-life of 2 minutes. This rapid peripheral metabolism of PTH is unaffected by widely varying levels of blood calcium or 1,25(OH)\(_2\)D\(_3\). Less than 1% of the secreted hormone finds its way to PTH receptors on physiologic target organs. These features of PTH metabolism ensure that the blood level of PTH is determined principally by the activity of the parathyroid glands and that the PTH level can respond rapidly to small changes in the rate of secretion of the hormone.

In the liver, a small amount of PTH binds to physiologically relevant PTH receptors but most of the intact PTH is cleaved, initially after residues 33 and 36, probably by cathepsins. In the kidney, a small amount of intact PTH binds to physiologic PTH receptors, but most of the intact PTH is filtered at the glomerulus and subsequently bound by a large, membrane-bound luminal protein, megalin; this binding leads to internalization and degradation of PTH by the tubules. Carboxy-terminal fragments are also cleared efficiently by glomerular filtration. In fact, the kidney is the only known site of clearance of carboxy-terminal PTH fragments; these fragments thus accumulate dramatically when the glomerular filtration rate (GFR) falls. Even in the presence of normal renal function, the half-life of carboxy-terminal fragments of PTH exceeds that of PTH(184) by several-fold. Consequently, the concentration of carboxy-terminal fragments in the circulation exceeds that of intact PTH, even though intact PTH usually is the major form of PTH secreted from the parathyroid gland.

Careful analysis of PTH fragments using high-performance liquid chromatography (HPLC) and immunologic methods have revealed almost full-length PTH fragments missing the first several amino acids of the hormone, but containing most or all of the remaining hormone sequence. These still incompletely characterized fragments are both secreted from the parathyroid gland and generated by peripheral metabolism of the hormone. Because they are missing the amino-terminal portion of PTH, they cannot stimulate cyclic adenosine monophosphate (cAMP) production by the PTH/parathyroid hormone-related protein (PTHrP) receptor, and except in renal failure, they circulate in small amounts. Nevertheless, the possible biologic activity of these and other PTH fragments, possibly through novel receptors, remains an unsettled issue. Experiments with PTH(784) suggest that such extended carboxyl fragments may exert potent effects in vivo, antagonistic to those of intact PTH.

---

Actions of Parathyroid Hormone

Actions on the Kidney
Stimulation of Calcium Reabsorption

Almost all of the calcium in the initial glomerular filtrate is reabsorbed by the renal tubules. Sixty-five percent is reabsorbed by the proximal convoluted and straight tubules via a passive, paracellular route. Changes in the transepithelial voltage gradient, determined largely by the rate of sodium reabsorption, control the rate of calcium transport in the proximal tubule; PTH does little to affect calcium flux in this region. The remaining calcium is largely reabsorbed more distally20% of the initial filtrate in the cortical thick ascending limb (cTAL) of Henle's loop and 10% in the distal convoluted and connecting tubules. In the cTAL, calcium reabsorption also is mainly passive and paracellular, although some transcellular, active calcium transport may occur as well.

Efficient paracellular and magnesium movement requires expression of a unique tight junction protein, paracellin-1; mutant paracellin-1 genes underlie a rare renal calcium- and magnesium-wasting disorder. Because paracellular calcium transport in the cTAL is driven by the lumen-positive transepithelial voltage gradient that is established by active Na-K-CaCl\textsubscript{2} reabsorption, calcium reabsorption there is strongly inhibited by loop diuretics such as furosemide. The calcium-sensing receptor, initially characterized in the parathyroid, also is expressed in the cTAL. When activated by high blood calcium or magnesium, this receptor inhibits Na-K-CaCl\textsubscript{2} reabsorption in the cTAL. Consequently, renal concentrating capacity and calcium reabsorption are inhibited as well. This inhibition provides a parathyroid-independent mechanism for controlling renal calcium handling in direct response to changes in blood calcium concentration.

Although PTH modestly stimulates paracellular calcium reabsorption in the cTAL, the primary site for hormonal regulation of renal calcium reabsorption is the distal nephron, which normally reabsorbs nearly all of the remaining 10% of filtered calcium by a unique transcellular active transport mechanism. As depicted in the figure, this process is driven by a transepithelial voltage gradient that is generated by the

\]

Inhibition of Phosphate Transport

Phosphate reabsorption occurs mainly in the proximal renal tubules, which reclaim roughly 80% of the filtered load. Some additional phosphate (8% to 10%) is reabsorbed in the distal tubule (but not in Henle's loop), leaving about 10% to 12% for excretion in the urine. The normal overall fractional tubular reabsorption of phosphate (TRP), therefore, is about 88%, although a more reliable measure of renal phosphate handling is the phosphate threshold (TmP/GFR), which can be derived from the TRP through the use of a nomogram (Fig. 26-8) based on studies of experimental phosphate infusions in healthy persons and in patients with a variety of diseases that affect phosphate excretion.

\[
\text{Figure 26-8} \quad \text{Nomogram for determining renal threshold phosphate concentration (TmP/GFR) from the plasma phosphate concentration and the fractional reabsorption of filtered phosphate (TRP) or fractional excretion of filtered phosphate (1TRP, or C_{\text{urea}}/C_{\text{creatinine}}}). \quad \text{Because the blood level of phosphate influences the renal handling of phosphate, the renal threshold phosphate concentration best separates normal from abnormal renal phosphate handling. C_{\text{ur}}: clearance; creat, creatinine; GFR, glomerular filtration rate; TRP, tubular resorption of phosphate. (From Walton RJ, Bijvoet OLM: Nomogram of derivation of renal threshold phosphate concentration. Lancet 1979; 2:309710.}
\]

Dietary intake of phosphate also reciprocally regulates the expression and activity of NaP\textsubscript{2} cotransporters and thus the proximal tubular absorption of phosphate by a mechanism that is independent of PTH. Dietary deprivation of phosphate, for example, leads to a stimulation of phosphate reabsorption that can override the effects of PTH on the proximal tubule. Although not yet demonstrated experimentally, a likely candidate to mediate this effect of dietary phosphate is the putative hormone "phosphatonin," excessive action of which is implicated in the humoral hypophosphatemic syndromes X-linked hypophosphatemic rickets and oncogenic

\[
\text{Figure 26-7} \quad \text{Effects of parathyroid hormone (PTH) on distal tubular calcium transport. PTH acts to increase chloride flux through channels in the basolateral membrane. As indicated, this increase leads to calcium influx through apical calcium channels. PTH also increases basolateral Ca\textsuperscript{2+}-Na\textsuperscript{+} exchange. The apical Na\textsuperscript{+}/Ca\textsuperscript{2+} cotransporter allows chloride to enter the cell and is the target of thiazide diuretics. Cl\textsuperscript{-}, intracellular chloride. (Adapted from Friedman PA, Giesek FA: Calcium transport in renal epithelial cells. Am J Physiol 1993; 264:F181F198.)}
\]

increases this conductance (2) by increasing the transmembrane voltage gradient (i.e., by hyperpolarizing the cell), probably by increasing chloride exit through basolateral channel (1).

A similar hyperpolarizing effect is exerted by thiazide-type diuretics, which reduce intracellular chloride (by inhibiting apical sodium chloride [NaCl] transporters) and thereby also open apical calcium channels, increasing calcium entry. To protect the low physiologic level of cytosolic free calcium from the relatively large amounts of incoming calcium, these cells express the calcium-binding protein calbindin-D28K, which avidly binds calcium at the apical membrane and transports it to the basolateral membrane, where it is then ejected via active processes involving sodium-calcium exchange and an ATP-driven calcium pump. Expression of calbindin-D28K is increased by PTH directly and also indirectly, via increased synthesis of 1,25(OH)\textsubscript{2}D\textsubscript{3}.

\[

\]

Because paracellular cation transport in the cTAL is driven by the lumen-positive transepithelial voltage gradient determined largely by the rate of sodium reabsorption, the rate of distal tubular calcium reabsorption is increased by PTH, the total amount of calcium in the final urine is likely to be high, because of the high initial filtered load.
Osteomalacia (see "Disorders of Phosphate Metabolism," later).

Other Renal Effects of Parathyroid Hormone

PTH stimulates the synthesis of 1,25(OH)2D3 in the proximal tubule by rapidly inducing transcription of the 25-hydroxyvitamin D 25(OH)D3, 1-hydroxylase gene, an effect that can be overridden by hypercalcemia or by the action of 1,25(OH)2D3. 12 PTH inhibits proximal tubular transcription of the 25(OH)D3-24-hydroxylase gene and antagonizes the up-regulation of 24-hydroxylase activity by 1,25(OH)2D3. 12 (see "Vitamin D Metabolism"). PTH inhibits proximal tubular sodium, water, and bicarbonate reabsorption, 12 mainly via inhibition of the apical amiloride-sensitive Na+-H+ exchanger (NHE3) and the basolateral Na+-K+-ATPase. 12 PTH also stimulates proximal tubular gluconeogenesis 12 and acts directly on glomerular podocytes to decrease both single-nephron and whole-kidney GFR. 12

**Actions of Parathyroid Hormone on Bone**

The actions of PTH on bone are complicated because PTH acts on a number of cell types both directly and indirectly. PTH increases both bone formation and bone resorption. With regard to calcium homeostasis, the effect of PTH on bone resorption is dominant; continuous administration of PTH leads to a net release of calcium from bone. But the straightforward net effect of PTH on calcium homeostasis belies the highly variable effects of the hormone on bone, which depend on the type of bone (trabecular or cortical), the particular target cell type, and the pattern of PTH administration.

**Figure 26-9** illustrates the cells of the osteoblast lineage (see also Chapter 27). Osteoblasts are derived from multipotent mesenchymal stem cells that can differentiate into chondrocytes, adipocytes, osteoblasts, and probably other cell types. 12 Within the osteoblast lineage, committed osteoprogenitor cells divide, become preosteoblastic stromal cells (which can divide further), and then become osteoblasts. Osteoblasts no longer divide and are cuboidal cells found on the bone surface actively laying down new bone. When these cells become surrounded by bone, they become stellate osteocytes. If, instead, osteoblasts stop synthesizing matrix and remain on the bone surface, they flatten out as bone lining cells. Not all preosteoblasts and osteoblasts mature; a variable number die by apoptotic, programmed cell death. 12

Receptors for PTH are found on preosteoblasts, osteoblasts, lining cells, and osteocytes. PTH changes the osteoblast lineage cell population by stimulating cell proliferation 12 by decreasing apoptosis of preosteoblasts and osteoblasts, thereby increasing the number of osteocytes; and perhaps by converting inactive lining cells to osteoblasts. 12 When added to cells in culture, PTH stops preosteoblastic cells from becoming mature osteoblasts. 12 Furthermore, PTH changes the activity of mature osteoblasts by a variety of mechanisms. When PTH is added to isolated osteoblasts in vitro, the osteoblasts decrease their synthesis of collagen I and other matrix proteins and, at least in part by steering the essential transcription factor core-binding factor-1 (CBFA1) toward proteosomal destruction. 12 In vivo, however, the most obvious effects of PTH are to increase bone formation, probably by indirect actions such as stimulation of synthesis of insulin-like growth factor I (IGF1) and other growth factors by osteoblast lineage cells. This action of PTH can be mimicked in vivo by intermittent administration of PTH to osteoblasts in organ culture 12 or as dispersed cells. 12

Surprisingly, osteoblasts, the bone-resorbing cells derived from hematopoietic precursors, have no PTH receptors. Instead, preosteoblasts and osteoblasts signal to osteoclast precursors to cause them to fuse and form mature osteoclasts and signal to those osteoclasts to allow them to resorb bone and to avoid apoptosis. 12, 26-10 Two osteoblast surface proteins, macrophage colony-stimulating factor (M-CSF) and RANK ligand (RANKL), are essential for stimulation of osteoclast differentiation and osteoclastogenesis. 12, 26-10 RANKL is essential for the activation of mature osteoclasts. The growth factor M-CSF (or CSF1), is expressed both as a secreted protein and as a cell surface protein; the production of both forms is stimulated by PTH. 12 RANKL also

**Figure 26-9** Osteoblast lineage. All precursors of osteoblasts can proliferate; osteoblasts are transformed to osteocytes and lining cells without further proliferation. Some data suggest that lining cells may revert to osteoblast function after parathyroid hormone stimulation. At each stage in the lineage, apoptotic cell death is probably an alternative fate.

named osteoprotegerin ligand (OPGL), osteoclast-differentiating factor (ODF), and TRANCEs a membrane-bound member of the tumor necrosis factor (TNF) family; its synthesis is also increased by PTH. RANKL binds to its receptor, RANK, a member of the TNF receptor family. RANK is found on both osteoclast precursors and on mature osteoclasts. The binding of RANKL to RANK can be blocked by osteoprotegerin (OPG), another member of the TNF receptor family. OPG (also called OCIF and TR1) circulates and is also secreted by cells of the osteoclastic lineage. PTH decreases the synthesis and secretion of OPG from these cells. 12 Thus, PTH, by increasing RANK and decreasing OPG locally in bone, serves to increase bone resorption.

Because PTH can both increase bone formation and increase resorption, the net effect of PTH on bone mass varies from one part of bone to another and also varies dramatically according to whether PTH is administered continuously or intermittently. Intermittent administration of low doses of PTH causes dramatic net increase in trabecular bone mass

**Figure 26-10** Stromal cell control of osteoclastogenesis and osteoclast activity. Parathyroid hormone (PTH) acts on PTH/PTH-related protein (PTHrP) receptors on precursors of osteoblasts to increase the production of macrophage colony-stimulating factor (M-CSF) and RANK ligand and to decrease the production of osteoprotegerin (OPG). M-CSF and RANK ligand stimulate the production of osteoclasts and increase the activity of mature osteoclasts by binding to the receptor RANK. OPG blocks the interaction of RANK ligand and RANK.

with little effect on cortical bone in humans. Continuous administration of PTH, in contrast, leads to a decrease in cortical bone mass; the net effect of PTH on trabecular bone depends on the dose. In mild hyperparathyroidism, there is little net effect of PTH on trabecular bone and a decrease in cortical bone. In all of these settings, the rate of bone formation is increased; the varying rate of osteoclastic resorption determines the net effect of PTH on bone mass.

**Molecular Basis of Parathyroid Hormone Action**

Ever since the discovery that PTH stimulates the secretion of cAMP into the urine, 12 PTH has been thought to act by triggering a cascade of intracellular second messengers. This guiding hypothesis, in its current form, postulates that all of the actions of PTH result from the binding of the hormone to a receptor on the plasma membrane of target tissues. This receptor is a member of a large family of G protein-linked receptors that span the plasma membrane seven times (Fig. 26-11). The binding of hormone on the outside of the membrane causes conformational changes in the receptor molecule that activate the receptor’s ability to release guanosine diphosphate (GDP) from the subunit of a G protein bound to the receptor. The G protein then binds guanosine triphosphate (GTP) in place of GDP. The GTP-binding subunit of the G protein then separates from the subunits, and the separate subunits of the G protein then modulate the activity of enzymes and channels. The activity of these enzymes and channels then affects proteins further downstream, eventually leading to the physiologic responses of bone and kidney cells.

**Parathyroid Hormone and Parathyroid Hormone-related Receptors**

DNA encoding a PTH/PTHrP receptor has been isolated from rat, opossum, human, pig, Xenopus (toad), and zebrafish cells and tissues. 12 The receptor mediates actions of both PTH and PTHrP. The predicted amino acid sequence of the receptor and direct mapping of inserted epitopes suggest that the receptor spans the plasma membrane seven times, but the sequence does not closely resemble the sequences of most known G protein-linked receptors. Instead, it is a member of a distinct subfamily of closely related receptors. Most of these
receptors bind peptides of 30 to 40 amino acids in length. Known members of the family act as receptors for the secretin family of peptides (secretin, vasoactive intestinal peptide (VIP), glucagon, glucagon-like peptide, growth hormone-releasing hormone, pituitary adenylate cyclase-activating peptide, gastric inhibitory peptide), corticotropin-releasing hormone, calcitonin, and insulin diuretic hormones related to corticotropin-releasing hormone. The PTH/PTHrP receptor most closely resembles receptors of the secretin group. The gene encoding the PTH/PTHrP receptor has a complicated structure, with 13 introns interrupting the coding sequence. 

In the mouse, an upstream promoter is used primarily in kidney and to some extent in liver; a downstream promoter is used in all tissues that express the gene, including bone. The human promoter uses the same start sites, but the kidney-specific promoter is much less active in humans, and a third, distinct start site is used in many tissues.

The cloned PTH/PTHrP receptor binds amino-terminal fragments of PTH and PTHrP with equal affinity. The receptor is expressed at high levels in kidney and in osteoblasts of bone but is also expressed in a wide variety of tissues, such as smooth muscle, brain, and a variety of fetal tissues, which are thought to be target tissues more for PTHrP than for PTH. In response to binding of PTH or PTHrP, the receptor activates several G proteins, including G\textsubscript{i}, G\textsubscript{q}, and its close relatives, G\textsubscript{s}, and perhaps other G proteins.

The PTH/PTHrP receptor probably mediates many of the actions of both PTH and PTHrP. The ligand-binding and signaling properties of the receptor, the pattern of expression of the receptor, and the consequences of mutation of the receptor sequence (see later) are persuasive evidence in this regard. Nevertheless, the scheme of PTH action illustrated in Figure 26-11 should be considered a simplified outline. It is unlikely that all of the actions of PTH can be explained by interactions with the cloned PTH/PTHrP receptor: Fragments of PTH that seem not to bind the receptor may be biologically active; some cells respond to PTH in ways not mimicked by the cloned receptor. Furthermore, the carboxyl-terminal portion of PTH(184) binds a cell surface protein distinct from the PTH/PTHrP receptor.

A second PTH receptor, which can be activated by PTH but not by PTHrP, called the PTH2 receptor (PTH2R), has been cloned. This receptor is expressed in multiple tissues, including brain, vascular endothelium and smooth muscle, endocrine cells of the gastrointestinal tract, and sperm. Expression is not seen in osteoblasts or renal tubules, however. Although PTH activates human PTH2R well, PTH only poorly activates the rat PTH2R. Furthermore, a novel ligand called TIP39 has been characterized and shown to be a potent activator of PTH2R. TIP39 bears only a weak resemblance to PTH or PTHrP and is likely to be a physiologically relevant activator of that receptor. The functional role of the PTH2R is unknown; this receptor may well not mediate actions of PTH in vivo. The two cloned PTHRs, as well as distinct receptors for fragments of PTHrP (see later), probably are part of a complex network of ligands and receptors.

Functional implications of Parathyroid Hormone Structure

Amino-terminal fragments of PTH as short as PTH(134) have potency at least as great as that of the full-length PTH(184). Several discrete portions of the PTH(134) peptide interact with the receptor. The first several residues of PTH are particularly important for triggering the conformational change in the receptor that results in activation of G\textsubscript{i} and adenylate cyclase. Sequence responsible for transmembrane activation of G\textsubscript{i} make up most of the first 13 residues of PTH(134); it is these residues that are highly conserved between PTH and PTHrP. At high concentrations, PTH(114) by itself can activate the PTH/PTHrP receptor. This activation domain interacts with the receptor's transmembrane domains and extracellular loops. When the first nine residues of PTH are covalently linked to the receptor's transmembrane domains and extracellular loops, they can activate the receptor. An analogue of PTH(114) can trigger G\textsubscript{i} activation, thus activating phospholipase C. These data, plus the observation that a PTH analogue modified at position 1 selectively loses its ability to activate phospholipase C, demonstrate that the amino-terminal portion of PTH is essential for activation of both G\textsubscript{i} and G\textsubscript{q}. More distal regions of PTH(134) can activate protein kinase C and can raise intracellular calcium levels by mechanisms that have not been fully clarified.

The more carboxy-terminal portions of PTH(134) contribute importantly to the specificity and tight binding of PTH to the PTH/PTHrP receptor, at least partly through interactions with the receptor's amino-terminal transmembrane domain. A variety of studies of genetically altered receptors and biochemical studies using photoactivated crosslinks between PTH and the receptor have reinforced each other and show that the carboxy-terminal portion of PTH makes multiple contacts with the amino-terminal extension of the receptor and with its extracellular loops.

Studies of the structure of PTH by nuclear magnetic resonance spectroscopy suggest that the activation domain and the carboxy-terminal domain are discrete entities dominated by helices separated by a flexible loop of variable size, depending on the hydrophobicity of the solvent. In the crystal structure of human PTH(134), the flexible loop is entirely replaced with helical structure. Taken together, these studies suggest that the carboxy-terminal portion of PTH makes multiple contacts with the receptor that allow high-affinity binding and position the amino-terminal portion of PTH to activate the receptor through contacts with transmembrane domains and associated loops.
Activation of Second Messengers

Precisely how binding of PTH to the extracellular domains of the PTH/PTHrP receptor leads to activation of G proteins is not understood. The crystal structure of rhodopsin, another member of the seven-transmembrane receptor family, as well as the behavior of certain mutant PTH/PTHrP receptors, suggest that the seven transmembrane domains of the PTH/PTHrP receptors form a ring, with the seventh transmembrane domain adjacent to the first and second domains. Presumably, binding of PTH to several different regions of the receptor changes the relationships of the transmembrane domains such that the receptor’s three intracellular loops and carboxy-terminal tail interact with G proteins in an altered way.

Receptors with certain point mutations in the second, sixth, and seventh transmembrane domains can activate Gs even without stimulation by hormone. These mutant receptors were discovered by analyzing the PTH/PTHrP receptors in patients with Jansen’s metaphyseal chondrodystrophy. Patients with this disorder have signs of parathyroid overactivity (hypercalcemia, hypophosphatemia, high levels of 1,25(OH)₂D₃, and urinary cAMP) but low PTH and PTHrP levels. The mutations must change the conformation of the intracellular face of the receptor in a way that resembles the effect of binding of PTH to the normal receptor. The observation that inappropriate activation of the PTH/PTHrP receptor in Jansen’s chondrodystrophy leads to all of the metabolic abnormalities found in primary hyperparathyroidism is one of the most persuasive pieces of evidence that the cloned PTH/PTHrP receptor does, in fact, mediate the actions of PTH in bone and kidney in vivo.

Second Messengers and Distal Effects of Parathyroid Hormone

The activation of multiple G proteins by PTH raises questions about the individual roles of each second messenger and their possible interactions. The importance of cAMP as a mediator of the physiologic actions of PTH has been demonstrated by studies in vivo and in vitro. Furthermore, patients with pseudohypoparathyroidism type I, who cannot increase urinary cAMP levels in response to PTH, show clear renal resistance to PTH (see later).

Phospholipase C, with concomitant activation of protein kinase C and synthesis of IP₃, may mediate physiologic actions of PTH as well, such as inhibition of sodium-phosphate cotransport and stimulation of the renal 25(OH)D₁-hydroxylase. Some actions of PTH may require activation of both adenylate cyclase and phospholipase C for optimal activity.

Target Cell Responsiveness to Parathyroid Hormone

Physiologic responses to PTH depend not only on the concentration of PTH in blood but also on the responsiveness of target cells to PTH. This responsiveness can be modified by previous exposure to PTH or by exposure to a variety of other hormones and paracrine factors. Responsiveness can be changed by alterations at virtually every step in the cellular response to PTH.

Major regulators of PTH/PTHrP receptor gene expression include, not surprisingly, PTH and 1,25(OH)₂D₃, both of which can decrease PTH/PTHrP receptor mRNA in certain target cells. In some settings, PTH decreases the amount of immunoreactive and functional receptor on the cell surface without changing the levels of PTH/PTHrP mRNA. This decrease reflects ligand-induced internalization and degradation of receptors. Internalization of receptor is stimulated by PTH binding and is modulated by sequences found in the membrane-proximal portion of the receptor's cytoplasmic tail. The precise mechanism of PTH-induced internalization of the PTH/PTHrP receptor is not fully understood and may vary in different cellular contexts. Even without change in receptor number, previous exposure to PTH leads to inefficient triggering of G proteins (desensitization).
PARATHYROID HORMONE-RELATED PROTEIN

Parathyroid hormonelated protein (PTHrP) was discovered because the secretion of PTHrP by a wide variety of tumors contributes to the humoral hypercalcemia of malignancy. For this reason, the initial studies of PTHrP in humans and animals stressed the PTH-like structure and properties of the molecule. Subsequent studies soon showed, however, that PTHrP, unlike PTH, is made by a wide variety of tissues, in which it acts locally in ways that may have little relevance to the control of blood calcium.

Gene and Protein Structure

PTHrP sequences from human, rat, mouse, dog, bovine species, chicken, fugu, and sea bream have been cloned\(^1\)\(^2\)\(^3\)\(^4\) (Fig. 26-14). In humans, alternative RNA splicing yields transcripts that encode three distinct proteins of 139, 141, and 173 residues that differ only after residue 139.

Inspection of these sequences suggests that PTHrP has several functionally distinct domains. Eight or nine of the first 13 residues of PTHrP are identical to those in known mammalian PTH sequences. These sequences encompass the known "activation" domain of PTH (see earlier) and are instrumental in the ability of PTHrP to activate PTH/PTHrP receptors. The conserved histidine at position 5 of all PTHrP molecules, which differs from the hydrophobic residue found at the corresponding position of all PTHs, allows PTHrP to activate the PTH/PTHrP receptor but not the PTH2 receptor.\(^5\)\(^6\)\(^7\)

The sequences in PTHrP(1434) are also highly conserved. Although these sequences little resemble the corresponding region of PTH, they can displace PTH from the PTH/PTHrP receptor. Studies of the secondary and tertiary structures of PTHrP(134) and PTH(137) suggest that they have similar structures dominated by helices connected by a flexible hinge.\(^8\)\(^9\)\(^10\)

The remaining portion of the PTHrP molecule bears no resemblance to corresponding sequences in PTH. Nevertheless, residues 35 to 111 of PTHrP are strikingly well conserved, with only nine residues differing between mammalian and chicken PTHrP sequences. This sequence conservation is considerably greater than that found in the carboxyl-terminal portion of PTH, suggesting that this region of PTHrP has unique and important functions. After residue 111, the PTHrP sequences vary considerably from species to species.

Interspersed within the PTHrP sequences are multiple sites containing one or several basic residues that might serve as post-translational cleavage sites (see Fig. 26-14). Extensive analysis of PTHrP fragments in tumors, cell lines, and transfected cells has shown that several of these sites are, in fact, functional cleavage signals.\(^11\) PTHrP is cleaved after the arginine at residue 37; this cleavage, followed by carboxypeptidase cleavage, generates a PTH-like PTHrP(136) fragment as well as the fragments PTHrP(3894) amide, PTHrP(3895), and PTHrP(38101). More carboxy-terminal fragments of PTHrP have been detected in cells as well.

In the blood of patients with humoral hypercalcemia of malignancy, multiple immunoreactive species of PTHrP have been found that may well correspond to the fragments of PTHrP in cells and tissue culture media, although precise characterization of these various immunoreactive species is incomplete (see later).\(^12\)\(^13\)\(^14\)\(^15\)

\(^{1,2,3,4}\) Full-length PTHrP may well not circulate, since an amino-terminal specific immunoaffinity column was unable to extract carboxy-terminal immunoreactivity from the serum of patients with malignant hypercalcemia.
Functions of Parathyroid HormoneRelated Protein

The first actions of PTHrP to be defined were the PTH-like actions associated with the humoral hypercalcemia of malignancy. In this pathologic entity, PTHrP acts as a hormone; it is secreted from the tumor into the blood stream and then acts on bone and kidney to raise calcium levels (see "Hypercalcemia of Malignancy" later). Whether or not PTHrP circulates at high enough levels in normal adults to contribute to normal calcium homeostasis is an unanswered question. With metastases of breast cancer to bone, locally produced PTHrP can raise serum calcium without necessarily raising blood levels of PTHrP.

Growing evidence suggests that PTHrP acts as a calciotropic hormone during fetal life and in lactation. PTHrP secreted from the fetal parathyroid gland stimulates transport of calcium across the placenta in sheep. PTH, in contrast, has no effect on placental calcium transport. Furthermore, fetal mice missing the PTHrP gene transport 45Ca across the placenta inefficiently. This action of PTHrP requires only the mid-region of PTHrP and probably involves a receptor distinct from the PTH/PTHrP receptor.

The second possible setting for humoral actions of PTHrP is lactation. Secretion of PTHrP from the breast into the blood stream may influence the movement of calcium from maternal bone into breast milk. PTHrP, therefore, probably contributes to the dramatic but largely reversible bone loss during lactation, which is only minimally affected by calcium supplementation. An exaggeration of this lactational role of PTHrP may explain the rare presentation of hypercalcemia and high PTHrP levels in pregnant and lactating women. Large amounts of PTHrP are also secreted into breast milk, although the role of PTHrP in milk is unknown.

Most of the actions of PTHrP are likely to be paracrine or autocrine. PTHrP is synthesized at one time or another during fetal life in virtually every tissue. Its role in the development of fetal bone has been demonstrated through the striking abnormalities found in genetically engineered mice missing the PTHrP gene. These abnormalities suggest that PTHrP normally keeps chondrocytes proliferating in orderly columns, thereby delaying chondrocyte differentiation. The role of PTHrP in many other fetal tissues may analogously involve regulation of proliferation and differentiation. The widespread expression of the PTHrP in fetal life probably underlies the expression of PTHrP in a wide variety of malignancies. As is often the case in malignancy, the expression of PTHrP represents the reinitiation of a fetal pattern of gene expression.

PTHrP is synthesized by many adult tissues. In tissues such as skin, hair, and breast, it is likely that PTHrP regulates cell proliferation and differentiation. PTHrP is also synthesized in response to stretch in the smooth muscle of blood vessels and of the gastrointestinal tract, uterus, and bladder and acts in an autocrine fashion to relax the smooth muscle. PTHrP is also widely expressed in neurons of the central nervous system; its function in the brain is unknown, but it may protect neurons from excitotoxicity by decreasing flux through voltage-gated calcium channels; an analogous mechanism may explain the role of PTHrP in smooth muscle relaxation.

Many of the actions of PTHrP are mediated by the PTH/PTHrP receptor. Others, such as the activation of placental calcium transport, are probably mediated by a distinct receptor, and other actions on bone cells probably involve yet another receptor responsive to more distal portions of PTHrP. Increasing evidence suggests, furthermore, that some actions of PTHrP involve direct nuclear actions of PTHrP. Thus, both PTH and PTHrP are likely to use multiple mechanisms to stimulate cells.
CALCITONIN

Calcitonin has an important role in regulating blood calcium in fish and a demonstrable role in rodents; however, the importance of calcitonin in human calcium homeostasis remains uncertain.

The existence of a second calcium-regulating hormone, in addition to PTH, was first demonstrated during perfusion studies of the thyroid and parathyroid glands of dogs. High-level calcium perfusion resulted in a rapid decrease in plasma calcium, even more rapid than after parathyroidectomy. This effect suggested that calcium had stimulated the secretion of a hormone that lowered blood calcium. It was subsequently demonstrated that this missing hormone, named calcitonin for its role in regulating the "tone" or level of calcium, was elaborated by the thyroid gland, not the parathyroids. Calcitonin is found in the nonfollicular cells of the thyroid, called C cells, which originate from the neural crest. In fish, the location of the C cells in discrete organs led to the rapid isolation of calcitonin from these ultimobranchial bodies in dogfish, salmon, and several other species. The identification of the glandular origin of calcitonin enabled the isolation of sufficient quantities of calcitonin for sequence analysis and studies of its structure and biologic function.

Synthesis and Secretion

Calcitonin consists of a 32-amino-acid polypeptide with an intrachain disulfide bond provided by the cysteines at positions 1 and 7. These two cysteine residues, along with the carboxy-terminal proline-amide and six additional residues are the only amino acids conserved among the calcitonins isolated from various species. The disulfide linkage and prolineamide residues are important for the function of the molecule, although biologically active analogues lacking disulfide bonds have been developed.

Of interest, fish calcitonin is more potent in mammals than is the mammalian hormone. The mature peptide is derived from the middle of a 136-amino-acid precursor. The human calcitonin gene, located on the short arm of chromosome 11, contains six exons that are alternatively spliced in a tissue-specific manner to yield the mRNAs encoding calcitonin or calcitonin gene-related peptide (CGRP). The mRNA encoding calcitonin is derived by splicing together the first four exons and represents over 95% of mature transcripts in the thyroid C cells. The splicing of the first three exons to exons 5 and 6 results in an mRNA that encodes the 37-amino-acid -CGRP. The mRNA encoding -CGRP is expressed in multiple tissues and is the only mature transcript of the calcitonin gene detected in neural tissue. A second CGRP gene encodes the closely related -CGRP. In humans, the predicted sequence of the mature peptide differs from that of -CGRP by only three amino acids.

The synthesis and secretion of calcitonin are tightly regulated. Studies in a porcine model reveal a linear relationship between the secretion of calcitonin and ambient calcium levels. Cell culture studies using calcium ionophores and calcium channel blockers demonstrate that the calcium ion concentration within the C cell determines this secretion rate.

The calcium-sensing receptor cloned from parathyroid cells is also expressed in C cells and contributes to the regulation of calcitonin secretion. Other calcitonin secretagogues include glucocorticoids, CGRP, glucagon, enteroglucagon, gastrin, pentagastrin, pancreozymin, and -adrenergic agents. The physiologic role of the gastrointestinal hormones in regulating calcitonin remains unclear; however, they have been postulated to play a role in the regulation of postprandial hypercalcemia. The secretion of calcitonin is inhibited by somatostatin, which is also secreted by the thyroidal C cells. In vivo studies have demonstrated that 1,25(OH)_2 D_3 decreases calcitonin mRNA levels by a transcriptional mechanism.

Calcitonin, when administered acutely, decreases tubular resorption of calcium and impairs osteoclast-mediated bone resorption by a direct action on osteoclasts. In rodents, calcitonin is known to play a role in the regulation of postprandial hypercalcemia. Studies in calcitonin knockout mice reveal a doubling of bone formation rate in the absence of hormone, accompanied by resistance to ovariectomy-induced bone loss. The physiologic role of calcitonin in humans, however, remains elusive. The effect of calcitonin on bone density was examined in patients with long-term hypercalcitoninemia secondary to medullary carcinoma of the thyroid gland (MCT) and in patients with subtotal thyroidectomy resulting in lack of calcitonin secretory reserve. Bone density at the lumbar spine and distal radius were not influenced by the abnormal calcitonin levels. Furthermore, no physiologic abnormalities have been reported with long-term, high-dose administration of exogenous calcitonin.

Many of the effects of calcitonin are mediated by a G protein-coupled cell surface receptor in the PTH/secretin receptor family. The mRNA encoding this receptor has been found in multiple tissues, including kidney, brain, and osteoclasts. The coupling of this receptor to different G proteins results in the activation of either adenylate cyclase or phospholipase C; in some settings, this effect is cell cycledependent. Glycosylation of the receptor is important for both binding and signal transduction. Several isoforms of the calcitonin receptor have been described, but the functional significance of these various isoforms is not known.
Calcitonin Family: Calcitonin Gene-Related Peptide, Amylin, and Adrenomedullin

CGRP, amylin, and adrenomedullin all have been shown to have high-affinity binding sites, and displacement studies suggest that several receptor subtypes are present. However, cloning of specific receptors for these ligands proved difficult because the functional receptors consist of heterodimers between G protein-coupled receptors and single transmembrane proteins of the RAMP (receptor activity-modifying protein) family. Interaction of the calcitonin receptor-like receptor, a relative of the calcitonin receptor, with RAMP1 results in a CGRP receptor, whereas RAMP2 and RAMP3 interactions with the same calcitonin receptor-like receptor generate adrenomedullin receptors. Interaction of RAMP1 with the calcitonin receptor creates an amylin receptor.

CGRP is thought to act as a neurotransmitter and vasodilator rather than as a hormone. In support of this hypothesis, mice lacking -CGRP have an increase in mean arterial pressure. Immunohistochemical studies of CGRP in the brain and peripheral nervous system suggest that this neuropeptide also plays an important role in sensory and integrative motor functions.

Amylin is highly homologous to CGRP and calcitonin. The striking presence of amylin in the pancreas of patients with type 2 diabetes mellitus suggests an etiologic role for this peptide in this disorder.

Adrenomedullin has vasodilatory effects similar to those of CGRP. In addition to activating CGRP receptors, adrenomedullin binds to specific receptors in the vascular system. The physiologic roles of amylin and adrenomedullin and the functional correlates of their receptor interactions have not yet been clarified.
Calcitonin in Human Disease

Calcitonin is secreted by several endocrine malignancies and can therefore serve as a tumor marker. Basal and pentagastrin-stimulated calcitonin levels have been used to identify and follow persons at risk for, or affected by, medullary carcinoma of the thyroid gland (see Chapter 13), although abnormal basal and stimulated levels may be observed in patients on chronic hemodialysis. Calcitonin may also be ectopically secreted by other tumors, including insulinomas, VIPomas, and lung cancers. Severely ill patients, including those with burn inhalation injury, toxic shock syndrome, and pancreatitis, also may have elevated calcitonin levels.
Therapeutic Uses

The observation that calcitonin inhibits osteoclastic bone resorption has led to its therapeutic use for the treatment of several disorders associated with excess bone resorption, including osteoporosis and Paget's disease (see Chapter 27). Calcitonin has also been shown to have an analgesic effect in the treatment of vertebral crush fractures, osteolytic metastases, and phantom limb.
VITAMIN D

Metabolism of Vitamin D

Vitamin D is not a true vitamin, since nutritional supplementation is not required in humans who have adequate sun exposure. When the skin is exposed to ultraviolet radiation,

the cutaneous precursor of vitamin D, 7-dehydrocholesterol, undergoes photochemical cleavage of the carbon bond between carbons 9 and 10 of the steroid ring (Fig. 26-17). The resultant product, previtamin D, is thermally labile and over a period of 48 hours undergoes a temperature-dependent molecular rearrangement that results in the production of vitamin D. Alternatively, this thermally labile product can isomerize to two biologically inert products, lumisterol and tachysterol. This alternative photoisomerization prevents production of excessive amounts of vitamin D with prolonged sun exposure. The degree of skin pigmentation, which increases in response to solar exposure, also regulates the conversion of 7-dehydrocholesterol to vitamin D by blocking the penetration of ultraviolet rays.

The alternative source of vitamin D is dietary. The elderly, the institutionalized, and those living in northern climates probably obtain most of their vitamin D from dietary sources. However, with increasing avoidance of sun exposure by the general population, ensuring adequate dietary intake of vitamin D has become important for the population at large. Vitamin D deficiency is prevalent and has been shown to contribute significantly to osteopenia and fracture risk. The major dietary sources of vitamin D are fortified dairy products, although the lack of monitoring of this supplementation results in marked variation in the amount of vitamin D provided. Other dietary sources include egg yolks, fish oils, and fortified cereal products. Vitamin D provided by plant sources is in the form of vitamin D₃, whereas that provided by animal sources is in the form of vitamin D₂ (see Fig. 26-17). These two forms have equivalent biologic potencies and are activated equally efficiently by the hydroxylases in humans.

Vitamin D is absorbed into the lymphatics and enters the circulation bound primarily to vitamin D-binding protein, although a fraction of vitamin D circulates bound to albumin. The human vitamin D-binding protein is an α-globulin, with a molecular mass of approximately 52 kDa, that is synthesized in the liver. The protein has a high affinity for 25(OH)D but also binds vitamin D and 1,25(OH)₂D₃. Approximately 88% of 25(OH)D circulates bound to the vitamin D-binding protein, 0.03% is free, and the rest circulates bound to albumin. In contrast, 85% of the circulating 1,25(OH)₂D₃ binds to the vitamin D-binding protein, 0.4% is free, and the rest binds to albumin. Mice lacking vitamin D-binding protein have increased susceptibility to 1,25(OH)₂D₃ toxicity as well as to dietary vitamin D deficiency. Thus, the role of vitamin D-binding protein is to maintain a serum reservoir and to modulate the activity of vitamin D metabolites. Recent studies in megalin-null mice suggest that vitamin D-binding protein is filtered by the glomerulus and reabsorbed by a megalin-dependent pathway in the proximal renal tubule. Further investigations are required to determine the importance of this pathway in vitamin D metabolism and homeostasis.

In the liver, vitamin D undergoes 25-hydroxylation by a cytochrome P450 enzyme present in the mitochondria and microsomes. The half-life of 25(OH)D is approximately 2 to 3 weeks. The 25-hydroxylation of vitamin D is not tightly regulated; therefore, the blood levels of 25(OH)D reflect the amount of vitamin D entering the circulation. When levels of vitamin D-binding protein are low, such as in nephrotic syndrome, circulating levels of 25(OH)D are also reduced. The half-life of 25(OH)D is shortened by increases in levels of its active metabolite, 1,25(OH)₂D₃.

The final step in the production of the active hormone is the renal 1-hydroxylation of 25(OH)D to 1,25(OH)₂D₃. The half-life of this hormone is approximately 6 to 8 hours. Like the 25-hydroxylase, the 1-hydroxylase in the renal proximal convoluted tubule is a cytochrome P450 mixed-function oxidase. Unlike the 25-hydroxylase, however, 1-hydroxylation is tightly regulated. PTH and hypophosphatemia are the major inducers of this microsomal enzyme, whereas calcium and the enzyme's product, 1,25(OH)₂D₃, repress it in animal models and in vitro studies. Other hormones such as estrogen, calcitonin, growth hormone, and prolactin increase 1-hydroxylase activity; however, the clinical importance of these observations has not been established. Ketoconazole has been shown to decrease levels of 1,25(OH)₂D₃ in a dose-dependent manner, presumably by interfering with 1-hydroxylase activity.

Figure 26-18 Relative potency of analogues of 1,25(OH)₂D₃. (1,25-Dihydroxyvitamin D₃) in competitive binding to vitamin D receptors of chick intestinal mucosa. Slopes are plotted for (left to right): 1,25(OH)₂D₃, 1,25-dihydroxyvitamin D₃, 1,24R,25(OH)₂D₃, 1-deoxy-1,25(OH)₂D₃, 3-deoxy-1,25(OH)₂D₃, 3-deoxo-1,24,25(OH)₃D₃, 25-hydroxy-5,6-trans-D₃, 25-hydroxy-5,6-cis-D₃, 25-hydroxyvitamin D₃, 25-OH-D₃, 25(OH)-24R,25(OH)₂D₃, 24,25(OH)₂D₃, 24,25(OH)₂D₃, 24,25(OH)₂D₃, 3-deoxo-1,25(OH)₂D₃, 3-deoxy-1,24,25(OH)₃D₃, 3-deoxy-1,25(OH)₂D₃, 3-deoxy-1,24,25(OH)₃D₃, 3-deoxy-1,24,25(OH)₃D₃. Vitamin D₃, D₃; DHT, dihydrotestosterone. (From Prosall D-A, Okamura WH, Norman AW. Structural requirements for the interaction of 1,25-(OH)₃vitamin D₃ with its chick intestinal receptor. J Biol Chem 1975, 250:836388.)

1-Hydroxylase is also found in keratinocytes, the trophoblastic layer of the placenta, some lymphomas and granulomata, including sarcoid granulomata. In malignant and granulomatous tissue, the 1-hydroxylase gene that is expressed is identical to that expressed in the kidney, but the gene is not regulated by PTH, phosphate, calcium, or vitamin D metabolites in these cells. Activation of macrophages with interferon, however, increases the expression of the 1-hydroxylase, whereas treatment of sarcoïdosis-associated hypercalcemia with glucocorticoids, ketoconazole, or chloroquine lowers serum 1,25(OH)₂D₃ levels.

25-Hydroxyvitamin D and 1,25(OH)₂D₃ can also be hydroxylated by the vitamin D 24-hydroxylase that is present in most tissues, including kidney, cartilage, and intestine. 1,25-Dihydroxyvitamin D₃ increases the activity of the 24-hydroxylase, thereby inducing its own metabolism. The 24-hydroxylated vitamin D metabolites, 24,25(OH)₂D₃ and 1,24,25(OH)₃D₃, are not thought to play major biologic roles other than inactivation of 1,25(OH)₂D₃. Mice null for the 24-hydroxylase gene demonstrate hypercalcemia, hypercalciuria, and nephrocalcinosis owing to lethal vitamin D toxicity. Although 24,25(OH)₂D₃ has been shown to have unique actions in a number of biologic systems, no unique receptor for this metabolite has been identified, and the physiologic role of 24,25(OH)₂D₃ is unclear.

Figure 26-17 Vitamin D precursors and alternative reaction products. The numbering system for vitamin D carbons and the distinct structures of vitamin D₃ (ergocalciferol) and D₂ (cholecalciferol) are noted, as is the structure of dihydrocholsterol, a synthetic product not produced in vivo. Note that the 3-hydroxy group of dihydrocholesterol is in a pseudo-1-hydroxy configuration. This may explain the relatively high potency of dihydrocholesterol in conditions associated with low 1-hydroxylase activity.
1,25-Dihydroxyvitamin D₃ is also metabolized to several inactive products by 23- or 26-hydroxylation and side chain oxidation and cleavage. This side chain cleavage, resulting in the formation of calcitroic acid, occurs in the liver and intestine, whereas inactivation of 1,25(OH)₂D₃ in a wide variety of target tissues occurs by 24-hydroxylation. In addition, polar metabolites of 1,25(OH)₂D₃ are excreted in the bile. Some of these metabolites are deconjugated in the intestine and reabsorbed into the enterohepatic circulation.
1,25-Dihydroxyvitamin D₂ exerts its biologic functions by binding to a nuclear receptor, which then regulates transcription of DNA into RNA. Among the other nuclear receptors, the vitamin D receptor most closely resembles the retinoid acid, triiodothyronine, and retinoid-X receptors. The affinity of the receptor for 1,25(OH)₂D₃ is approximately three orders of magnitude higher than that for other vitamin D metabolites. Although 25(OH)D₃ is less potent on a molar basis, its concentration in the serum is approximately three times higher than that of 1,25(OH)₂D₃ [Fig. 26-18]; however, its free concentration is only twice that of 1,25(OH)₂D₃. Therefore, under normal circumstances it is unlikely that 25(OH)D₃ contributes importantly to calcium homeostasis.

Because the affinity of the vitamin D-binding protein for 25(OH)D is greater than for 1,25(OH)₂D₃, in states of vitamin D intoxication, the free levels of 1,25(OH)₂D₃ increase, because 25(OH)D displaces it from the vitamin D binding protein. 25-Hydroxyvitamin D, therefore, may play a role in the clinical syndrome of vitamin D intoxication both by its direct biologic effects, when present at toxic levels, and by increasing free levels of 1,25(OH)₂D₃.

The vitamin D receptor acts by forming a heterodimer with the retinoid-X receptor, binding to DNA elements, and recruiting coactivators in a ligand-dependent fashion. These coactivators link the receptor complex to the basal transcription apparatus, thereby regulating transcription of target genes. In most cases, the up-regulatory response elements for vitamin D contain hexameric repeats separated by three bases. However, vitamin D also promotes the DNA-protein interactions of other transcription factors, such as SP1 and NF-κB, in genes lacking classical response elements, by uncertain mechanisms. The mechanism of transcriptional repression by vitamin D are varied. For example, VDR-RXR heterodimers repress the 1-hydroxylase gene by binding to and blocking the function of another transcription factor, whereas interaction of the vitamin D receptor with the Kᵣ antigen, acting as a transcription factor, is required for transcriptional repression of the human PTHRP gene.

Glucocorticoids have been shown to decrease the expression of the vitamin D receptor gene in osteosarcoma cell lines, whereas 1,25(OH)₂D₃ increases its expression in many cells. In the renal proximal convoluted tubule, however, 1,25(OH)₂D₃ decreases the levels of vitamin D receptors. This decrease has been postulated to lead to decreased activation of the renal 24-hydroxylase by 1,25(OH)₂D₃, thereby protecting the newly synthesized 1,25(OH)₂D₃ from local inactivation.

1,25-Dihydroxyvitamin D₂ also has some biologic effects that occur too rapidly for transcriptional mechanisms to be implicated. These nongenomic actions, including the rapid increase in intracellular calcium, activation of phospholipase C, and opening of calcium channels, are observed in several cell types within minutes of exposure to 1,25(OH)₂D₃. Additional data supporting the hypothesis that nongenomic actions are not dependent on the classical receptor include the identification of specific binding sites for 1,25(OH)₂D₃ on the antiluminal surface of intestinal cells and a disparity between the affinity of the various vitamin D analogues for the nuclear receptor and their potency in these nongenomic actions. Evidently, at least one of the nongenomic actions of vitamin D is available for the nucleus in association with the vitamin D receptor depends on the presence of an intact intracellular receptor, because this effect is not observed in cells derived from patients with vitamin D receptor mutations. The physiologic importance of the nongenomic actions of vitamin D metabolites has not yet been established.

The vitamin D receptor is expressed in most tissues and regulates cellular differentiation and function in many cell types. Nevertheless, the most dramatic physiologic effect of vitamin D acting through the vitamin D receptor, involves regulation of intestinal calcium transport. This effect is most clearly demonstrated by the phenotype of patients and mice with mutant vitamin D receptors (vitamin D-dependent rickets type 2). Dramatic abnormalities in bone mineralization can be reversed by bypassing the defect in intestinal calcium absorption.

Intestinal Calcium Absorption

Under normal dietary conditions, calcium intake is in the range of 700 to 900 mg daily. Approximately 30% to 35% of this calcium is absorbed; however, losses from intestinal secretion of calcium lead to a net daily uptake of only approximately 200 mg. Although vitamin D is the major hormonal determinant of intestinal calcium absorption, the bioavailability of mineral ions in the intestinal lumen may be affected by a number of local factors and dietary constituents. Absorption of calcium and magnesium is impaired by bile salt deficiency, unabsorbed free fatty acids in steatorrheic states, and high dietary content of fiber or phytate. Gastric acid is needed to promote dissociation of calcium from anionic components of food or therapeutic preparations of calcium salts. Administration of calcium salts with meals, especially in patients with achlorhydria, and use of divided doses or more soluble salts, such as calcium citrate, are commonly employed strategies to increase calcium bioavailability.

Calcium is thought to be absorbed by three pathways: (1) the transcellular route, (2) vesicular calcium transport, and (3) paracellular transport. The first two pathways are dependent on 1,25(OH)₂D₃. Although the necessity of vitamin D for paracellular calcium absorption remains controversial, substantial evidence exists that the hormone enhances this pathway as well. The vesicular pathway is thought to involve the nongenomic actions of 1,25(OH)₂D₃. However, this rapid transport (transcalcehia) is observed only in vitamin D-deplete animals. The relative contribution of vesicular calcium transport to intestinal calcium absorption and the specific mediators of this transport have not yet been clarified.

The most extensively studied mechanism of intestinal calcium absorption involves the transcellular route. This pathway is thought to involve three steps: (1) entry of calcium into the enterocyte, (2) transport across the cell, and (3) extrusion across the basolateral membrane.

A number of brush border proteins, including the intestinal membrane calcium-binding protein, brush border alkaline phosphatase, and low-affinity Ca²⁺-Mg²⁺-ATPase, are induced by 1,25(OH)₂D₃. The activity of these proteins correlates with active calcium transport; however, a causal relationship remains to be established. Two calcium channels, CaT₁ and EcaC with six membrane-spanning domains and significant homology to the capsacin receptor, are expressed in the duodenum and jejunum and have been implicated as important regulators of calcium entry into the enteroocyte. Upon entering the enteroocyte, calcium binds to components of the brush border complex subjacent to the plasma membrane. Calmodulin is redistributed to the brush border in response to 1,25(OH)₂D₃.
and may play a role in this process, as may the 1,25(OH)₂D₃-inducible calcium binding protein calbindin 9K.

**Transcellular Transport**

The best-studied effect of vitamin D on the enterocyte is the induction of synthesis of the intestinal calcium-binding protein calbindin 9K. This protein has an EF hand structure that permits the binding of two calcium ions per molecule. The affinity of calbindin for calcium is approximately four times that of the brush border calcium-binding components; thus, calcium is preferentially transferred to calbindin. Calbindin serves to buffer the intracellular free calcium concentration during calcium absorption. It associates with microtubules and may play a role in the transport of calcium across the enterocyte. Organelles such as the mitochondria, Golgi, and endoplasmic reticulum also serve as reservoirs for intracellular calcium.

**Exit from the Enterocyte**

The transport of calcium across the antiluminal surface of the enterocyte, the final process involved in intestinal calcium absorption, is dependent on 1,25(OH)₂D₃. The main mechanism of calcium extrusion is the 1,25(OH)₂D₃-inducible ATP-dependent Ca²⁺ pump. The affinity of the pump for calcium is approximately 2.5 times that of calbindin. With high calcium intake, a 1,25(OH)₂D₃-independent Na⁺–Ca²⁺ exchanger may play a role in the transfer of calcium across the basolateral membrane as well.

**Actions on the Parathyroid Gland**

1,25-Dihydroxyvitamin D₃ has been shown to regulate gene transcription and cell proliferation in the parathyroid glands. The hormone also inhibits the proliferation of dispersed parathyroid cells in culture, although the relative contribution of calcium and 1,25(OH)₂D₃ in the regulation of parathyroid cell proliferation in vivo has not been established. Normocalcemic mice lacking functional vitamin D receptors have normal serum PTH levels and normal-size parathyroid glands, demonstrating that the genomic actions of 1,25(OH)₂D₃ are not essential for parathyroid cellular homeostasis. 1,25-Dihydroxyvitamin D₃, however, decreases the transcription of the PTH gene both in vivo and in vitro. This action has been exploited in the use of 1,25(OH)₂D₃ in the treatment of the secondary hyperparathyroidism associated with chronic renal failure (see "Parathyroid Hormone Biosynthesis" earlier and "Vitamin D Deficiency" later).

**Actions on Bone**

The effects of 1,25(OH)₂D₃ on bone are numerous. 1,25-Dihydroxyvitamin D₃ is a major transcriptional regulator of the two most abundant bone matrix proteins: it represses the synthesis of type I collagen and induces the synthesis of osteocalcin. 1,25-Dihydroxyvitamin D₃ promotes the differentiation of osteoclasts from monocyte-macrophage stem cell precursors in vitro, and it also increases osteoclastic bone resorption in high doses in vivo, by stimulating production of osteoclast-differentiating factor (ODF, i.e., RANK ligand) by osteoblasts. Despite the multiple effects of 1,25(OH)₂D₃ on the biology of bone in vitro, results of in vivo studies in 1,25(OH)₂D₃-deficient rats and in mice lacking functional vitamin D receptors suggest that the major osseous consequences of hormone and receptor deficiency can be reversed when mineral ion homeostasis is normalized. In addition, parietal calcium infusions have been shown to heal the osteomalacic lesions in children with mutant vitamin D receptors. These observations suggest that the major role of 1,25(OH)₂D₃ in bone is to provide the proper microenvironment for bone mineralization through stimulation of the intestinal absorption of calcium and phosphate.

**Other Actions of Vitamin D**

The effects of 1,25(OH)₂D₃ on phosphate transport are less well studied than those on calcium transport; however, vitamin D promotes the already efficient intestinal phosphate absorption.

One of the striking clinical features of profound vitamin D deficiency that remains unexplained is the severe proximal myopathy. Muscle cells express vitamin D receptors, and 1,25(OH)₂D₃ has nongenomic effects on muscle. Furthermore, 1,25(OH)₂D₃ increases amino acid uptake and alters phospholipid metabolism in vitro in muscle cells. Vitamin D administration has been shown to increase the concentration of troponin C, a calcium-binding protein that plays a role in excitation coupling and increases the rate of uptake of calcium by the sarcoplasmic reticulum. However, little is known regarding the direct role of vitamin D in normal muscle physiology. The myopathy that accompanies vitamin D deficiency is characterized by normal creatine kinase levels, a myopathic electromyogram, and biopsy findings of loss of myofibrils, fatty infiltration, and interstitial fibrosis. The myopathy resolves within days to weeks of vitamin D replacement and is not related to normalization of mineral ion homeostasis.

**Vitamin D Analogues**

The recognition that 1,25(OH)₂D₃ promotes cellular differentiation and inhibits cellular proliferation has led to efforts directed at producing new analogues that retain these effects but do not cause hypercalcemia. Several analogues have been shown to have antiproliferative effects on normal cells as well as on malignant cells in vitro and in xenografts in immunosuppressed mice. In addition, analogues of vitamin D have been shown to synergize with cyclosporine in preventing rejection of transplanted pancreatic islet cells in a murine model. One analogue, 22-oxacalcitriol, suppresses PTH synthesis and secretion in rats at doses that stimulate intestinal calcium absorption less than that caused by 1,25(OH)₂D₃. This finding suggests that such analogues may be useful in preventing and treating hyperparathyroidism. The antiproliferative effects of vitamin D have been exploited clinically in the treatment of psoriasis. Although analogues with reduced calcemic activity are predominantly used, hypercalcemic crisis after excessive topical use of such compounds can occur.

The physiologic processes underlying the differential biologic effects of these analogues are not completely understood. Altered affinity for the vitamin D binding protein, metabolism by target tissues, and effects on recruitment of coactivators by the vitamin D receptor may contribute to the unique properties of vitamin D analogues.
CALCIUM AND PHOSPHATE HOMEOSTASIS

The cytosolic concentrations of intracellular calcium, phosphorus, and magnesium differ markedly, as reviewed previously, and their physiologic roles within cells are diverse and largely unrelated (see Fig. 26-1). In contrast, the concentrations of these mineral ions in extracellular fluid are quite comparable (i.e., 1 to 2 mM), and it is here that they exert important interactions, both with cells and with one another, that are critical for bone mineralization, neuromuscular function, and normal mineral ion homeostasis. Extracellular calcium and phosphate, in particular, exist so close to the limits of their mutual solubility that stringent regulation of their concentrations is required to avoid diffuse precipitation of calcium phosphate crystals in tissues.

Serum concentrations and total body balances of the mineral ions are maintained within narrow limits by powerful, interactive homeostatic mechanisms. PTH and 1,25(OH)\textsubscript{2}D\textsubscript{3} regulate mineral ion levels, mineral ion levels regulate PTH and 1,25(OH)\textsubscript{2}D\textsubscript{3} secretion, and both hormones regulate the production of each other. Calcium-sensing receptors in the parathyroid glands control PTH secretion by monitoring the blood concentration of ionized calcium, whereas those in the kidney act to adjust tubular calcium reabsorption, independent of PTH or 1,25(OH)\textsubscript{2}D\textsubscript{3}. The operation of these homeostatic mechanisms can easily be appreciated by considering specific examples of how the organism adapts to changes in calcium loads (Fig. 26-20).

Dietary calcium restriction, for example, is followed by an increase in the efficiency of intestinal calcium absorption. This increased efficiency results from a sequence of homeostatic responses in which lowered blood ionized calcium activates secretion of PTH, PTH augments synthesis of 1,25(OH)\textsubscript{2}D\textsubscript{3} by the proximal tubules of the kidney, and 1,25(OH)\textsubscript{2}D\textsubscript{3} then acts directly upon enterocytes to increase active transcellular transport of calcium. Enhanced intestinal calcium absorption is quantitatively the most important response to calcium deprivation, but a series of other homeostatic events also occur that limit the impact of this stress. Renal tubular calcium reabsorption is increased by PTH, an effect that is enhanced by increased 1,25(OH)\textsubscript{2}D\textsubscript{3}-stimulated expression of calbindin-D\textsubscript{28K} in the distal tubules. Calcium reabsorption is also enhanced directly by any tendency to hypercalcemia, which is detected by calcium-sensing receptors in Henle’s loop (and possibly also in the distal nephron) that control transepithelial calcium movements independent of PTH or 1,25(OH)\textsubscript{2}D\textsubscript{3}.

The impact of dietary calcium deprivation is reduced by approximately 15% through release of calcium from bone in response to PTH and 1,25(OH)\textsubscript{2}D\textsubscript{3}. The concomitant increase in net bone resorption causes release of phosphate as well as calcium into the extracellular fluid. Intestinal phosphate absorption also is increased by 1,25(OH)\textsubscript{2}D\textsubscript{3}. These phosphate loads are problematic, in that phosphate directly lowers ionized calcium in extracellular fluid, suppresses renal synthesis of 1,25(OH)\textsubscript{2}D\textsubscript{3}, and directly inhibits bone resorption. These potentially negative effects of phosphate are obviated by the powerful phosphaturic action of PTH.

Finally, the possibility of unrestrained secretion of PTH, leading to excessive bone resorption and severe hypophosphatemia, is prevented by the effects of calcium on PTH secretion and by the direct suppressive effect of 1,25(OH)\textsubscript{2}D\textsubscript{3} on the synthesis of PTH and of PTH receptors. As a result of these homeostatic responses, calcium-deprived people maintain near-normal serum calcium and phosphate concentrations but display increased intestinal calcium absorption, increased bone resorption and progressive osteopenia, increased renal tubular calcium reabsorption, decreased renal tubular phosphate reabsorption, low urinary calcium excretion, elevated urinary phosphate excretion, and high serum concentrations of PTH and 1,25(OH)\textsubscript{2}D\textsubscript{3}.

Calcium loads induce an opposite series of adaptations: parathyroid suppression, inhibition of renal 1,25(OH)\textsubscript{2}D\textsubscript{3} synthesis, decreased intestinal active transport of calcium, increased renal excretion of calcium and decreased renal excretion of phosphate (secondary to functional hypoparathyroidism), and a decrease in bone resorption sufficient to allow positive skeletal calcium balance. The decline in intestinal calcium absorption is the major safeguard against calcium overload, although this mechanism may be overridden with extraordinarily high intakes of calcium because of the persistence of the passive, non-vitamin D-dependent mode of calcium absorption. Moreover, nonenteral sources of calcium, such as intravenous calcium infusion or excessive net bone resorption (as from immobiliation or malignancy), may readily overwhelm the limited homeostatic adaptations that remain once suppressed intestinal calcium absorption is bypassed. In such situations, the kidney rather than the intestine becomes the principal defense against hypercalcemia, and calcium homeostasis becomes critically dependent on adequate renal function. If renal function is impaired in these settings, as frequently occurs clinically, severe hypercalcemia and pathologic calcium deposition in extraskeletal sites may ensue.
LABORATORY ASSESSMENT OF MINERAL METABOLISM

Parathyroid Hormone

The major challenges in the measurement of blood PTH have been the low levels of circulating PTH and the presence of inactive PTH fragments in far greater abundance than for the intact, biologically active PTH molecule. The measurement of inactive fragments would not be a concern if the ratio of inactive to active PTH molecules remained constant. However, this ratio does change in response to changes in GFR and in parathyroid gland secretory activity (see “Parathyroid Hormone Secretion” and “Peripheral Metabolism of Parathyroid Hormone” earlier). Consequently, radioimmunoassays of PTH have suffered from lack of sensitivity and from the inability to measure the biologically active hormone directly.

For these reasons, two-site assays that require the presence of amino-terminal and carboxy-terminal sequences of full-length PTH(1-84) on the same molecule have generally replaced older radioimmunoassays. It is reassuring that for all assays of this type, the normal ranges for blood PTH are very similar. The assays are sensitive enough to detect PTH in all normal persons. The assays have demonstrated modest circadian variation in PTH levels and some pulsatility in PTH secretion, but these variations have not interfered with the diagnostic usefulness of randomly drawn PTH measurements. Some studies have reported modest increases of PTH levels with age, although others have not. Unlike older radioimmunoassays, the two-site assays demonstrate virtually no overlap in PTH levels between patients with primary hyperparathyroidism and those with nonparathyroid hypercalcemia (Fig. 26-21). Because this distinction represents the most important challenge in the clinical setting, the use of the two-site assay has dramatically facilitated the clinician’s task.

This straightforward picture has been complicated by the realization that many two-site assays do detect small amounts of PTH fragments that are large but do not extend to the hormone’s amino-terminus. These fragments accumulate in significant amounts in patients with renal failure. The clinical importance of the detection of large fragments of PTH by most two-site assays is unknown.
Parathyroid HormoneRelated Protein

The measurement of PTHrP in serum presents a series of challenges that have made the development of clinically useful assays for PTHrP more difficult than for PTH assays. The concentration of PTHrP in the blood stream, even in some patients with PTHrP-mediated malignant hypercalcemia, is not high, and the molecular definition of circulating, biologically active fragments is incomplete. Despite these problems, several groups of investigators have developed assays for PTHrP that can be helpful in the evaluation of a subset of hypercalcemic patients. Radioimmunoassays for amino-terminal portions of PTHrP and two-site assays for amino-terminal and mid-region PTHrP separate healthy persons and patients with nonmalignant hypercalcemia from most patients with the humoral hypercalcemia of malignancy. When measured with the most recently developed assays, PTHrP levels are elevated in almost all patients with malignant hypercalcemia without bone metastases and in most patients with hypercalcemia and bone metastases.

In occasional patients, the PTHrP assay has helped distinguish an occult malignancy from other causes of nonPTH-dependent hypercalcemia. Nevertheless, because the diagnosis of malignancy as the cause of hypercalcemia is usually clinically obvious, and the PTH assay can be used to diagnose primary hyperparathyroidism, the role of PTHrP assays in clinical practice is likely to be limited. Further improvement in assay sensitivity and further understanding of the normal functions of circulating PTHrP fragments may lead to changes in this assessment.
Calcitonin

Several assays for measuring serum calcitonin are commercially available. The measurements are based on single-antibody or double-antibody radioimmunoassays or enzyme immunoassays, several of which are sufficiently sensitive to detect calcitonin deficiency. The calcitonin monomer is thought to be the biologically active molecule; therefore, some investigators believe that extraction of the multimeric forms before radioimmunoassay provides a more sensitive and specific measurement of serum calcitonin levels. However, the double-antibody radioimmunoassay is thought by others to provide the same information with less sample manipulation. The only clinical use of the calcitonin assay is as a tumor marker, primarily in medullary carcinoma of the thyroid.
Vitamin D Metabolites

The currently used radioligand assays for determining the levels of vitamin D metabolites require fractionation and extraction of the hormone from serum proteins by HPLC or silica cartridges. These assays are sufficiently sensitive to detect subnormal values. Because the assays measure both protein-bound and unbound vitamin D metabolites, results may not always reflect the levels of biologically relevant ("free") metabolites. This limitation may lead to misleading results in patients with nephrotic syndrome and vitamin D intoxication.

The levels of 25(OH)D correlate better with the clinical signs and symptoms of vitamin D deficiency than do the levels of 1,25(OH)₂D₃. Because the 25-hydroxylation of vitamin D is not tightly regulated, measurements of 25(OH)D more accurately reflect body stores of vitamin D. Measurement of this metabolite should therefore be performed when vitamin D deficiency is suspected.

Measurements of 1,25(OH)₂D₃ should be reserved for cases when excessive or impaired 1-hydroxylation is suspected. High 1,25(OH)₂D₃ levels can be seen in sarcoidosis, lymphomas, Williams’ syndrome, and intoxication with 1-hydroxylated metabolites (see “Hypercalcemic Disorders”). Impaired 1-hydroxylation can contribute to the hypocalcemia occurring in patients with renal dysfunction, oncogenic osteomalacia, and hereditary defects of vitamin D metabolism (see “Hypocalcemic Disorders”).
The clinical spectrum of primary hyperparathyroidism was changed dramatically in the early 1970s by the introduction of routine multichannel serum chemistry.

Modern Primary Hyperparathyroidism

The bone disease osteitis fibrosa cystica was first described by von Recklinghausen in 1891, but the etiologic link between this disease and parathyroid neoplasms was not established until 1925, when Mandl observed clinical responses to removal of a parathyroid adenoma from a young man with severe bone disease. In early clinical descriptions of primary hyperparathyroidism, the disease emerged as a distinctly uncommon disorder with significant morbidity and mortality, in which nearly all affected patients had radiographically significant or symptomatic skeletal or renal involvement, or both.

CLINICAL DISORDERS

HYPERCALCEMIC DISORDERS

Parathyroid-Dependent Hypercalcemia

It is useful to delineate two categories of hypercalcemia: (1) that associated with dysfunction of the parathyroid cell and (2) that in which hypercalcemia occurs despite appropriate parathyroid suppression. This distinction is particularly useful clinically, because it emphasizes the centrality of the PTH assay in the diagnostic approach to the hypercalcemic patient. Abnormal parathyroid glands are associated with hypercalcemia in three settings: (1) primary hyperparathyroidism, (2) familial hypocalciuric hypercalcemia (FHH), and (3) lithium-induced hypercalcemia.

Primary Hyperparathyroidism

In primary hyperparathyroidism, a primary abnormality of parathyroid tissue leads to inappropriate secretion of PTH. (In contrast, increased secretion of PTH that is an appropriate response to hypocalcemia is called secondary hyperparathyroidism.) The inappropriately high serum concentration of PTH in primary hyperparathyroidism, in turn, sustains excessive renal calcium reabsorption, phosphaturia, and 1,25(OH)₂D₃ synthesis as well as increased bone resorption. These actions of PTH produce the characteristic biochemical phenotypic features of hypercalcemia and hypophosphatemia, loss of cortical bone, hypercalciuria, and the various clinical sequelae of chronic hypercalcemia. Primary hyperparathyroidism results most often in 75% to 80% of the cases from the occurrence of one or more adenomas in previously normal parathyroid glands, although in 20% of the cases, diffuse hyperplasia of all parathyroid glands may be present or, rarely, parathyroid carcinoma may be found (less than 1% to 2%).

Rafai et al.

Classical Primary Hyperparathyroidism

The skeletal involvement in "classical" primary hyperparathyroidism reflects a striking and generalized increase in osteoclastic bone resorption, which is accompanied by fibrovascular marrow replacement and increased osteoblastic activity. The radiographic appearance (Fig. 26-23) features generalized demineralization of bone, with coarsening of the trabecular pattern (due to osteoclastic resorption of the smaller trabeculae); characteristic subperiosteal resorption, often most evident in the phalanges of the hands, which gives an irregular, serrated appearance to the outer, subperiosteal cortex and may progress to extensive cortical resorption; bone cysts, usually multiple, which contain a brownish serous or mucoid fluid, tend to occur in the central medullary portions of the shafts of the metacarpals, ribs, or pelvis, and may expand into and disrupt the overlying cortex; osteolastomas, or "brown tumors," composed of numerous multinucleated osteoclasts ("giant cells") admixed with stromal cells and matrix, which are found most often in trabecular portions of the jaw, long bones, and ribs; and pathologic fractures.

The skull may exhibit a finely mottled, "salt-and-pepper" radiographic appearance, with loss of definition of the inner and outer cortices. Dental radiographs typically show erosion or disappearance of the lamina dura due to subperiosteal resorption, often with extension into the adjacent mandibular bone. The erosion and demineralization of cortical bone may lead to radiographic disappearance of some bones, most notably the tufts of the distal phalanges of the hands, the inferolateral cortex of the distal third of the clavicles, the distal ulna, the inferior margin of the femoral neck and pubis, and the medial aspect of the proximal tibia. The clinical correlates of these changes may include achon bone pain and tenderness, "bowing" of the shoulders, kyphosis and loss of height, and collapse of lateral ribs and pelvis with "pigeon breast" and triradiate deformities, respectively.

The renal manifestations of classical severe primary hyperparathyroidism include recurrent calcium nephrolithiasis, nephrocalcinosis, and renal functional abnormalities that range from impaired function to end-stage renal failure. Associated signs and symptoms include recurrent flank pain, polyuria, and polydipsia. No unique features of the stone disease in primary hyperparathyroidism serve to distinguish it from that associated with other, more common causes of kidney stones. The stone disease more often may be recurrent and severe, and in some patients, the stones may be composed entirely of calcium phosphate, instead of the pure oxalate or mixtures of oxalate and phosphate more commonly encountered in other disorders. In patients diagnosed before 1965, the frequency with which nephrolithiasis complicated primary hyperparathyroidism was as high as 60% to 80% (the frequency is currently less than 25%), yet in studies of unselected patients conducted throughout the past 50 years, primary hyperparathyroidism has accounted for fewer than 5% of all calcium kidney stones.

Nephrocalcinosis refers to the presence of bilateral, extensive but minute calcifications that are evident on plain abdominal radiographs, usually in the renal pyramids and medullary regions, and that correlate with the presence of deposits of calcium in the epithelium of the renal tubules. In classical severe primary hyperparathyroidism, nephrocalcinosis was observed with roughly one-third the frequency of symptomatic stone disease, although it may occur in the absence of stones.

Other clinical features that have been reported in association with classical severe primary hyperparathyroidism are conjunctival calcifications, band keratopathy, hypertension (50%), gastrointestinal signs and symptoms (anorexia, nausea, vomiting, constipation, or abdominal pain), peptic ulcer disease, and acute or chronic pancreatitis. The issue of whether primary hyperparathyroidism increases the risk for peptic ulcer disease and pancreatitis remains controversial. Although hyperparathyroidism is associated with a higher risk of hypertension, successful parathyroidectomy has not been shown to correct the hypertension.

Signs and symptoms in primary hyperparathyroidism may result from the involvement of bone (fracture, bone pain) or kidneys (renal colic, renal failure), peptic ulcer disease, and acute or chronic pancreatitis.

The renal manifestations of classical severe primary hyperparathyroidism include recurrent calcium nephrolithiasis, nephrocalcinosis, and renal functional abnormalities that range from impaired function to end-stage renal failure. Associated signs and symptoms include recurrent flank pain, polyuria, and polydipsia. No unique features of the stone disease in primary hyperparathyroidism serve to distinguish it from that associated with other, more common causes of kidney stones. The stone disease more often may be recurrent and severe, and in some patients, the stones may be composed entirely of calcium phosphate, instead of the pure oxalate or mixtures of oxalate and phosphate more commonly encountered in other disorders. In patients diagnosed before 1965, the frequency with which nephrolithiasis complicated primary hyperparathyroidism was as high as 60% to 80% (the frequency is currently less than 25%), yet in studies of unselected patients conducted throughout the past 50 years, primary hyperparathyroidism has accounted for fewer than 5% of all calcium kidney stones.

Nephrocalcinosis refers to the presence of bilateral, extensive but minute calcifications that are evident on plain abdominal radiographs, usually in the renal pyramids and medullary regions, and that correlate with the presence of deposits of calcium in the epithelium of the renal tubules. In classical severe primary hyperparathyroidism, nephrocalcinosis was observed with roughly one-third the frequency of symptomatic stone disease, although it may occur in the absence of stones.

Other clinical features that have been reported in association with classical severe primary hyperparathyroidism are conjunctival calcifications, band keratopathy, hypertension (50%), gastrointestinal signs and symptoms (anorexia, nausea, vomiting, constipation, or abdominal pain), peptic ulcer disease, and acute or chronic pancreatitis. The issue of whether primary hyperparathyroidism increases the risk for peptic ulcer disease and pancreatitis remains controversial. Although hyperparathyroidism is associated with a higher risk of hypertension, successful parathyroidectomy has not been shown to correct the hypertension.

Signs and symptoms in primary hyperparathyroidism may result from the involvement of bone (fracture, bone pain) or kidneys (renal colic, renal failure), peptic ulcer disease, pancreatitis, or hypercalcemia per se (weakness, apathy, depression, polyuria, constipation, coma). The presence and severity of neuropsychiatric symptoms, in particular, correlate poorly with the serum calcium concentration, although few patients with severe hypercalcemia are entirely asymptomatic. Elderly persons are most likely to exhibit such symptoms. A peculiar neuromuscular syndrome, first described in 1949 but rarely encountered now, includes symmetrical proximal weakness and gait disturbance, with muscle atrophy, characteristic electromyographic abnormalities, generalized hyperreflexia, and tongue fasciculations.

Modern Primary Hyperparathyroidism

The clinical spectrum of primary hyperparathyroidism was changed dramatically in the early 1970s by the introduction of routine multichannel serum chemistry.
screening, which unearthed a large population of patients with previously unsuspected asymptomatic disease. In Rochester, Minnesota, for example, the annual incidence of the disease increased abruptly from 0.15 to 1.12 per 1000 persons between the prescreening era (1965/1974) and 1975, the year after routine screening was introduced. The peak incidence occurs in the sixth decade of life, and the disease rarely is encountered in patients younger than 15 years of age. It is two to three times more common in women, who are slightly older than men at diagnosis.

Annual incidence rates, widely reported to be 0.1 to 0.3 per 1000 persons in the wake of this surge of ascertainment in Europe and the United States, appear to have declined substantially in the past decade to levels as low as 0.04 per 1000. This decrease may represent a true decline in disease incidence or may simply be the residual effect of "sweeping" the population of prevalent subclinical disease over the past three decades.

Ascertainment of mild or asymptomatic disease may decline even further in the future because of prevalent economic disincentives to routine serum chemistry screening in the primary care setting. On the other hand, insistence upon overt hypercalcemia or hypernatremia as a diagnostic criterion may underestimate the true incidence of the disease. For example, when serum calcium and immunoreactive PTH (iPTH) were measured in a large population of Swedish women undergoing routine mammography screening, the prevalence of asymptomatic or suspected primary hyperparathyroidism, defined by criteria that included the combination of high-normal serum calcium plus elevated or high-normal iPTH, was 2.1%. Two thirds of these women (72 of 109) were normocalcemic (10.0 to 10.4 mg/dL), yet bone density was reduced in the group as a whole, and the disease was confirmed in 98% of the 61 who underwent surgery.

It is not surprising, given that primary hyperparathyroidism now usually is diagnosed incidentally, that few patients are found to have overt signs or symptoms of the classical disease and thus are considered to be "asymptomatic." For example, only 2% of patients with primary hyperparathyroidism residing in Olmsted County, Minnesota, and only 17% of 121 patients studied at an academic referral center in New York City had classical disease symptoms. In most of these, the relevant symptom was urolithiasis. Many clinicians argue, however, that most patients regarded as having "asymptomatic" primary hyperparathyroidism and only minimally elevated serum calcium actually suffer from various neuropsychiatric or other symptoms that may abate following curative surgery. However, these symptoms, which include fatigability, weakness, forgetfulness, depression, somatization, polydipsia, polyuria, and bone and joint pain, are common in otherwise normal persons.

The difficulties in designing appropriately controlled studies to determine whether these symptoms can be confidently ascribed to the parathyroid disorder are well described. Although as yet unresolved, this is a critical issue, as the advent of less invasive operative approaches and concerns regarding fracture, cancer, and mortality risk have lowered the threshold for consideration of surgery in many patients with the disease (see later on). Throughout this chapter, "asymptomatic primary hyperparathyroidism" refers to patients who lack signs or symptoms of the classical disease, whether or not they experience any of the subtle symptoms mentioned previously.

The natural history of untreated asymptomatic primary hyperparathyroidism, as currently detected, remains incompletely understood. Few patients seem to progress from this state of health, as measured by severe elevations of serum or urinary calcium, appearance of renal dysfunction or nephrocalcinosis, or worsening osteopenia, over many years of observation. On the other hand, an excess risk of mortality, mainly from cardiovascular disease, has been noted during extended follow-up of large cohorts of patients with chronic hypercalcemia (and presumed primary hyperparathyroidism) identified by population health screening in Sweden, and similar observations have been made during extended follow-up of postsurgical patients with hyperparathyroidism. Associations of hypertension, hyperuricemia, and glucose intolerance with primary hyperparathyroidism have been implicated, together with hypercalcemia per se, as contributors to this elevated risk. Abnormal cardiac calcification and left ventricular hypertrophy (reversible after successful parathyroidectomy) have been reported in primary hyperparathyroidism as well. Increased cardiovascular mortality may be a feature only of severe hyperparathyroidism, as it was restricted to patients with serum calcium values in the highest quartile in the Olmsted County study, which otherwise showed an overall decreased risk of death. A 40% excess risk of malignancy also was reported among 4163 Swedish patients who had undergone surgery more than a year earlier for (presumably symptomatic) primary hyperparathyroidism. It has been argued that these increased risks for mortality and malignancy, even if confirmed, may apply only to persons with primary hyperparathyroidism that is more severe than the "asymptomatic" version typically encountered today.

Abnormalities of bone in modern, mild primary hyperparathyroidism are far subtler than those associated with the classical disease. Histologically, the rate at which new bone remodeling cycles are activated is increased. Because the phase of remodelling before calcium deposition is so much longer than the initial resorptive phase, such an increase in remodeling rate inevitably increases the effective volume of the remodeling space and thus the porosity of bone. Depending on the rate and extent of the accompanying increase in osteoblastic activity and the resulting local balance between net bone formation and resorption, mineralized bone volume may decrease further, remain stable, or even increase (despite an increased remodeling space). For reasons not yet understood, the balance achieved between increased resorption and formation of bone in primary hyperparathyroidism depends not only on the severity of the hyperparathyroidism but also on skeletal location. Thus, net resorption of endosteal bone may predominate in cortical bone sites, whereas net apposition of mineral may occur in trabecular bone (Fig. 26-24).

In mild primary hyperparathyroidism, osteopenia generally is not evident radiographically, although bone mineral density may be reduced, particularly at sites of predominantly cortical bone such as the mid-radius, by as much as 10% to 20%. The mass of trabecular or cancellous bone, as represented in the vertebral bodies, is preferentially preserved and often is normal. A curious finding is that the reduced cortical bone density at the forearm is not improved by successful parathyroidectomy, whereas density at trabecular bonerich sites such as the hip and spine may increase by 10% to 15% over several years postoperatively.

The critical issue of whether fracture risk is increased in patients with primary hyperparathyroidism was addressed by a retrospective analysis of fracture incidence within a cohort of 407 residents of Rochester, Minnesota, who were diagnosed with the disease between 1965 and 1992. Compared with the expected age-adjusted and sex-adjusted rates of incident fractures in that community, the relative risk among persons with hyperparathyroidism was significantly elevated for fractures of the vertebrae (3.2-fold), distal forearm (2.2-fold), and ribs (2.7-fold), although not for fractures of the hip (1.4-fold). Overall risk of fracture at any site was significantly increased as well (1.3-fold) and was as high in persons in whom primary hyperparathyroidism was diagnosed incidentally (following the institution of automated chemistry screening in 1974) as in those in whom the disorder was diagnosed before that time. These results are consistent with those of several previous studies involving smaller cohorts of patients and, absent data from an appropriately controlled prospective study, strongly support the conclusion that patients with primary hyperparathyroidism should be considered to be at increased risk for fracture. This presumably is true of those with both symptomatic

Kidney stones now are reported in only 10% to 25% of patients with primary hyperparathyroidism, although some degree of renal dysfunction, either a significant reduction in creatinine clearance or impaired concentrating or acidifying ability, may be found in up to a third of those with asymptomatic disease. As with the reduction in cortical bone mineral density, these renal abnormalities are not progressive in a majority of affected patients. The association of kidney stones with primary hyperparathyroidism generally is viewed as an indication for parathyroidectomy, however, because successful surgery usually prevents further symptomatic stone disease. Yet it is not possible at present to confidently predict, from biochemical measurements in blood or urine, which asymptomatic patients with primary hyperparathyroidism will go on to develop new stone disease. Stone formers are more likely to be hypercalcicuric than not, but less than one third of hypercalcicuric

[Image 26-24: Iliac crest biopsy specimens from a patient with primary hyperparathyroidism (left) and a normal control (right), viewed by scanning electron microscopy. Note the thin cortices and contrasting preservation of trabecular bone in the patient. (From Stein M, Silverberg SJ, Shane E, et al: The histomorphometry of bone in primary hyperparathyroidism: preservation of cancellous bone structure. J Clin Endocrinol Metab 1990; 70:930938.)]
patients with hyperparathyroidism actually develop stones. As noted later on, however, marked hypercalcemia (calcium levels of >400 mg/day) generally is viewed as an indication for surgery in otherwise asymptomatic patients.

Etiology and Pathogenesis

Parathyroid adenomas are caused by mutations in the DNA of parathyroid cells; these mutations confer a proliferative or survival advantage for affected cells over their normal neighbors. As a consequence of this advantage, the descendants of one particular parathyroid cell, a clone of cells, undergo clonal expansion to produce an adenoma.

Multiple chromosomal regions are missing in the parathyroid cells of individual parathyroid adenomas. These genetic deletions probably reflect the deletion of tumor suppressor genes. These chromosomal loci include portions of chromosome 1p-pter (in 40% of adenomas), 6q (in 32% of adenomas), 15q (in 30% of adenomas), and 11q (in 25% to 30% of adenomas). Many of the 11q deletions are associated, in the undeleted chromosome 11, with mutations in the gene encoding the tumor-suppressor factor menin, the gene mutated in multiple endocrine neoplasia type 1 (MEN 1). Thus, this gene is also involved commonly in somatic mutations in patients with sporadic parathyroid adenomas. The widespread presence of somatic mutations in sporadic parathyroid adenomas, which are detectable only because large numbers of cells in any one tumor contain the same deletion, constitutes the strongest evidence that parathyroid adenomas are clonal expansions of mutant cells.

One parathyroid proto-oncogene, the PRAD 1 or cyclin D1 gene, has been identified. This gene was discovered at the breakpoint of an inversion on chromosome 11 in a parathyroid adenoma. This inversion led to the juxtaposition of the PTH gene's regulatory region and the DNA encoding cyclin D1. As a consequence, the cyclin D1 gene was overexpressed. Cyclin D1 is an important regulator of the transition from the G1 phase of the cell cycle (which follows mitosis) to the S phase (associated with DNA synthesis) and is mutated or amplified in a wide variety of malignancies. Cyclin D1 is overexpressed in about 20% of parathyroid adenomas, though cyclin D1 gene rearrangements have been documented in only 5% of adenomas. Portions of chromosomes 16p and 19p are amplified in a subset of parathyroid adenomas; presumably, the amplified regions contain uncharacterized proto-oncogenes.

As expected for a disease caused by mutations in DNA, parathyroid adenomas occur more frequently in patients who underwent neck irradiation decades earlier, with greater radiation exposure leading to higher risk. Most patients have no definite history of exposure to specific mutagens, however. An intriguing clue that abnormalities of vitamin D physiology may predispose to primary hyperparathyroidism comes from the observation that patients with parathyroid adenomas are more likely than others to inherit a particular allele of the vitamin D receptor gene. These patients have tumors with particularly low levels of mRNA encoding the vitamin D receptor.

The cause of sporadic primary parathyroid hyperplasia is unknown. The known stimulus for parathyroid cell proliferation-low levels of blood calcium or 1,25(OH)2D3—is not present in this disease. Presumably, some other stimulus outside the parathyroid glands or a genetic abnormality present in all four parathyroid glands leads to inappropriating the transient factor menin, the gene mutated in multiple endocrine neoplasia type 1 (MEN 1). As noted later on, however, marked hypercalcemia (calcium levels of >400 mg/day) generally is viewed as an indication for surgery in otherwise asymptomatic patients.

An increase in cell number is not the only abnormality in primary hyperparathyroidism. The ability of the normal parathyroid cell to suppress PTH secretion in response to hypercalcemia might be expected to protect the individual from sustained hypercalcemia, even if the number of parathyroid cells increased moderately. Unfortunately, parathyroid cells from adenomas respond to changes in extracellular calcium with smaller than normal increases in intracellular calcium, and the amount of calcium-sensing receptor protein on the cell surface is reduced.

Inherited Primary Hyperparathyroidism

Although uncommon, inherited forms of primary hyperparathyroidism are clinically important for several reasons. The management of the parathyroid tumors found in familial parathyroid syndromes often differs from that of sporadic primary hyperparathyroidism. Furthermore, extra-parathyroidal manifestations of inherited syndromes may need treatment, and awareness of familial clustering should prompt systematic family screening.

MEN 1 is caused by inactivating mutations in the tumor suppressor gene encoding menin. Menin is a ubiquitously expressed transcription factor. Although MEN 1 includes tumors of the parathyroid, anterior pituitary, and pancreatic islets, the parathyroid tumors are far more prevalent than the others; 95% of affected patients eventually develop hyperparathyroidism. Most of the parathyroid tumors harbor mutations in both copies of the menin gene; one mutation is inherited and the second occurs in the parathyroid cell whose progeny form the tumor.

The onset of hypercalcemia occurs in the second and third decades of life, though occasional patients present in the first decade. Hypercalcemia never presents at birth or in infancy. The disease involves all four parathyroid glands, although the involvement can be asymmetrical and apparently asynchronous. Apart from the
common complicating feature is that hypercalcemia can dramatically increase the gastrin levels and symptomatology of patients who also have gastrinomas.

Treatment of the parathyroid disease in this setting can greatly simplify the management of the gastric hyperacidity. After parathyroid surgery, hypoparathyroidism and recurrent hyperparathyroidism are more common than in other forms of hyperparathyroidism. The timing and type of surgery are therefore more complicated issues in inherited primary hyperparathyroidism. Most authorities agree that parathyroid disease recurs eventually, if fewer than three glands are removed. Some surgeons prefer subtotal parathyroidectomy, whereas others prefer total parathyroidectomy with forearm implantation of a small amount of parathyroid tissue.

Parathyroid disease is usually late and infrequent (5% to 20%) occurrence in MEN 2a, a disease defined by the clustering of medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism. In some families, hyperparathyroidism is more common; however, these families have the same mutations in the RET gene that are found in families without frequent hyperparathyroidism. Both parathyroid hyperplasia and adenoma have been noted at surgery. Because asymptomatic parathyroid hyperplasia has been noted at the time of thyroid surgery, a progression from hyperplasia to adenoma in MEN 2a has been suggested. The approach to diagnosis and treatment of hyperparathyroidism is similar to that in sporadic primary hyperparathyroidism, but hyperplasia is more frequently the underlying disorder. The pathogenesis of the hyperparathyroidism is uncertain, but the RET gene, mutated in virtually all cases of MEN 2a, is expressed in parathyroid cells, so abnormal net expression in parathyroid cells may directly cause parathyroid tumorigenesis. Hyperparathyroidism does not occur in MEN 2b, the variant associated with mucosal neuromas.

Several other distinct autosomal dominant syndromes of primary hyperparathyroidism have been characterized. Patients with hereditary isolated primary hyperparathyroidism present with parathyroid tumors that can be multiple and occasionally are malignant. No other endocrine glands are abnormal in affected families, and the disease maps to neither the MEN 1 nor MEN 2a locus. Patients with hereditary hyperparathyroidism jaw tumor syndrome present with parathyroid adenomas that are usually cystic and with fibrous jaw tumors that are unrelated to the hyperparathyroidism. Parathyroid cancer, Wilms’ tumor, and polycystic renal disease also have occurred in affected families. This syndrome maps to chromosome 1q21-q31. Occasional families with apparently isolated familial hyperparathyroidism have inherited mutations in the MEN 1 gene, but most such families do not.

Management of Primary Hyperparathyroidism

The strategy for management of primary hyperparathyroidism has evolved in parallel with the changing presentation of the disease. The only opportunity for permanent cure is surgical removal of the abnormal gland(s), an approach that clearly was appropriate for virtually all patients in whom the classical, severe form of the disease was diagnosed four to five decades ago and which still is the treatment of choice for those patients who do present with recurrent kidney stones, nephrocalcinosis, clinically overt bone disease, or severe hypercalcemia. In contrast, the choice of surgical versus medical management for patients with asymptomatic primary hyperparathyroidism remains an open and hotly debated question. Investigators who favor surgery point to the expected improvement in bone mineral density (at the hip and spine) and reversibility of left ventricular hypertrophy following successful surgical intervention; evidence of increased risk for fracture, cardiovascular mortality, malignancy, and neuropsychiatric symptoms associated with primary hyperparathyroidism; and the recent successful development of effective minimally invasive surgical procedures (see later on).

Investigators who favor an observational approach emphasize the evidence for lack of disease progression in most asymptomatic patients; the small but finite risk of surgical failure and postoperative complications; the probability that excess mortality and cancer risks documented in patients with relatively severe disease may not apply to those with mild, asymptomatic primary hyperparathyroidism; the difficulty in assigning vague neuropsychiatric symptoms to the parathyroid disorder; the lack of evidence (or negative evidence) that patients with hypertension or possibly increased risk of cancer, fracture, or cardiovascular mortality, or who already have such disease, are benefited by successful parathyroidectomy; and the availability of sensitive techniques for monitoring disease status in nonoperated patients.

Unfortunately, no prospective studies have compared outcomes in patients with asymptomatic primary hyperparathyroidism randomly assigned to surgery with those in patients assigned to medical management. Furthermore, no large trials of differing strategies in medical management of the disease have been conducted. Surgical series generally reflect outcomes in patients prescreened to receive interventional treatment; thus, results may not be readily extrapolated to those with mild, asymptomatic disease. Evidence that the true incidence of the disease may be declining, and that economic forces may increasingly limit detection to more symptomatic cases of the disease, may indicate that yet another change in the clinical character of the disease is in the offing. For all of these reasons, opinion in this area is rapidly evolving, and all recommendations thus should be considered provisional.

One set of such provisional recommendations was issued by a National Institutes of Health (NIH)-sponsored Consensus Development Conference held in 1990. The major conclusion of the Conference group was that although surgery always should be considered an appropriate option, many patients with asymptomatic primary hyperparathyroidism can be safely monitored without surgery. These patients were defined as those who lacked “significant bone, renal, gastrointestinal, or neuropsychiatric symptoms typical of primary hyperparathyroidism” and who also did not meet the other criteria listed in Table 26-1. Such patients account for at least 50% of persons who currently present with primary hyperparathyroidism.

In other Consensus Conference recommendations, surgery may be preferable if the patient desires surgery even when asymptomatic, if the probability of consistent monitoring seems low, if concomitant illness seems likely to complicate management or obscure significant disease progression, or if the patient is relatively young (under 50 years of age). These recommendations reflect the absence of reliable information about the natural history of the disease over many decades of follow-up, as well as the cumulative cost of medical monitoring, which begins to exceed that of surgery by 5 to 10 years. Conversely, age alone is not a contraindication to parathyroidectomy, as the procedure has been accomplished with excellent results, with a perioperative mortality of 1% to 3%, in large numbers of appropriately selected patients older than 75 years of age. Because hypertension is not thought to be a feature of mild primary hyperparathyroidism, and because hypertension generally is not corrected by parathyroidectomy, hypertension is not viewed as an indication for surgery.

Although the Consensus Conference recommendations provide a useful framework for decision making, supporting data from large clinical trials are lacking. In a series of 52 asymptomatic patients selected for nonoperative management mainly on the basis of the Consensus Conference criteria and whose course was followed for 10 years, approximately 25% developed one or more new indications for surgery (Table 26-1). Patients who do not meet the Consensus Conference criteria for surgery may nevertheless experience the same postsurgical increase in bone density as occurs in those who do. Some investigators have emphasized that evidence of baseline vertebral osteopenia, an unusual finding in primary hyperparathyroidism, should be added to the original Consensus Conference criteria for surgery (see Table 26-1) and that surgery also should be considered for menopausal women who exhibit vertebral bone loss in the setting of primary hyperparathyroidism. A common dilemma is the inability to ascertain whether vague but troublesome symptoms such as fatigue, lethargy, weakness (without objective muscle weakness), or depression are due to hyperparathyroidism and thus qualify as "significant" in the context of the decision regarding surgery. Most clinicians do not routinely recommend parathyroidectomy on the basis of such symptoms alone, although dramatic responses to surgery are occasionally seen. With the availability of improved, minimally invasive surgical approaches, the threshold for considering surgery for patients who are significantly disabled by such symptoms clearly is lower now than in the past. Some authorities have advocated, in selected cases, a limited trial of medical therapy to reduce serum calcium (i.e., strict dietary calcium restriction, estrogen, oral phosphate, or bisphosphonate; see later), thereby attempting to predict the symptomatic response to surgical cure. The severity of such symptoms generally cannot be shown to correlate with serum calcium concentration, however, and may be related to other factors, such as blood PTH concentration.

Medical Monitoring of Primary Hyperparathyroidism

The NIH Consensus Conference recommended that patients be followed carefully, at least semiannually initially and at longer intervals if stable, for appearance of symptoms; appearance of adverse effects on blood pressure and serum or urinary calcium or creatinine; review of annual abdominal radiographs; and serial determination of bone mineral density at 1- or 2-year intervals. The most appropriate bone densitometric site was considered to be one that reflects changes in cortical bone (i.e., distal forearm or total body), although the importance of monitoring vertebral bone density, as well, has been emphasized more recently.

Patients undergoing nonoperative medical management must be cautioned to maintain adequate hydration, to avoid diuretics and prolonged immobilization, and to seek prompt medical attention in the event of illnesses accompanied by significant vomiting or diarrhea. Dietary calcium probably should not exceed the recommended daily allowance (RDA) of 800 mg/day, even though short-term studies in highly selected patients with elevated serum 1,25(OH)₂D₃ levels have demonstrated that a high-calcium diet may reduce serum 1,25(OH)₂D₃ and PTH, albeit at the expense of a mild increase in serum and urinary calcium.

Estrogen therapy may be a consideration in postmenopausal women with mild primary hyperparathyroidism or in those who are symptomatic but yet refuse or cannot safely undergo surgery. Estrogens may reduce serum calcium and phosphorus, and urinary calcium and hydroxyproline, and histologic evidence of bone resorption in women with primary hyperparathyroidism, although serum PTH remains elevated and serum 1,25(OH)₂D₃ increases, owing mainly to increased concentrations of the vitamin D binding protein. Progestins may exert similar effects on serum calcium and may slow bone loss in elderly women with primary hyperparathyroidism, but concern over their adverse effects on blood lipids have limited use of these agents in this population. Selective estrogen receptor modulators such as tamoxifen or raloxifene may prove useful in postmenopausal women with osteopenia due to primary hyperparathyroidism, but a beneficial effect has not yet been shown.

Oral phosphate therapy has been advocated for use in occasional patients with primary hyperparathyroidism who have failed or refused surgery and who may have recurrent calcium kidney stones or other serious symptoms. Phosphate in this setting may act by inhibiting both renal synthesis of 1,25(OH)₂D₃ and osteoclastic bone resorption, by promoting precipitation of calcium into bone and soft tissues, and, in the gut, by binding intraluminal calcium and impairing its absorption. Oral phosphate does reduce serum and urinary calcium as well as serum 1,25(OH)₂D₃, but it increases serum PTH, and the long-term effect on bone is unknown.

Bisphosphonates have been employed successfully in the urgent therapy of hypercalcemia due to primary hyperparathyroidism, but their use in chronic management of mild primary hyperparathyroidism has been limited by several adverse effects, including stimulation of PTH secretion and a lowering of the renal phosphate threshold, which aggravates hypophosphatemia and may augment renal 1,25(OH)₂D₃ synthesis. Although not yet available for routine clinical use, calcimimetic drugs capable of binding to and activating the parathyroid calcium-sensing receptor are in development and may offer a new avenue for control of hyperparathyroidism.

Surgical Treatment of Primary Hyperparathyroidism

Parathyroidectomy is a safe and highly effective approach to definitive treatment of primary hyperparathyroidism. The most serious potential complications of parathyroid surgery—cord palsy and permanent hypoparathyroidism—occur after less than 1% and 4%, respectively, of procedures performed by highly skilled surgeons, although the rates for these complications can be much higher with less experienced operators. Such complications occur most often in patients who require subtotal parathyroid resection for hyperplasia or resection of carcinoma. The surgical cure rate for primary hyperparathyroidism in the best hands is at least 95%. Apart from operator inexperience, the usual cause of initial surgical failure is the presence of either unrecognized (often very asymmetrical) parathyroid hyperplasia or ectopic parathyroid tissue (i.e., intrathyroidal, undescended, retroesophageal, or mediatinal glands). Patients who do not meet the Consensus Conference criteria for surgery may nevertheless experience the same postsurgical increase in bone density as occurs in those who do.
usually arises in unresected hyperplastic glands, but rarely it may be due to parathyroid carcinoma, to a second adenoma, or to a multicentric or military "parathyromatosis" engendered by inadvertent local seeding of parathyroid tissue into the neck during previous parathyroid surgery. Until recently, there was broad agreement that the best approach is a bilateral neck exploration in which all four parathyroids are identified and all enlarged glands removed. With this procedure, preoperative parathyroid localization studies before initial cervical exploration are superfluous, as the positive predictive value of even the best technique (technetium Tc 99m sestamibi scanning) falls well short of the success rate of experienced surgeons unaided by previous imaging. Some surgeons prefer to biopsy all identified glands, even though this approach risks a 20% to 40% incidence of transient postoperative hypocalcemia, whereas others report excellent results without routine biopsy of nonenlarged glands. In the event that one gland is not identified after extensive exploration, ipsilateral thyroid lobectomy commonly is performed, as the frequency of intrathyroidal parathyroid glands is approximately 5%.

With the advent of preoperative technetium Tc 99m sestamibi scanning, which can accurately localize 80% to 90% of the single adenomas that account for 75% to 85% of cases, there has been renewed interest in performance of directed unilateral explorations, which reduce operative and recovery room time, minimize the number of frozen section required, are associated with significantly fewer postoperative complications, and can more readily be performed using minimally invasive techniques (including local anesthesia and intravenous sedation) that enable same-day discharge. Sestamibi scanning also can identify the occasional medistinal adenoma and thereby direct the surgery away from neck exploration. On the other hand, because the sensitivity of sestamibi scanning ranges from 75% to 90% and the technique is least reliable in the presence of multiglandular disease (hyperplasia or double adenomas), the test may falsely localize an adenoma or miss the presence of bilateral disease in 10% to 20% of patients. To reduce this failure rate, which is unacceptably high in comparison with that of bilateral exploration, supplemental preoperative ultrasonic imaging (with or without needle biopsy) has been employed, and rapid intraoperative PTH assays have been developed to verify successful excision.

Because the half-life of intact PTH in blood is very short (<2 minutes), a decline of 50% or more from baseline within 10 minutes or so can signal successful removal of all hyperfunctioning parathyroid tissue. This approach has worked well in patients with single adenomas but can be misleading in those with multiglandular disease unless strict criteria for cure are applied (i.e., >70% decline in plasma calcium at 20 minutes). No surgical series has analyzed a sufficient number of patients with hyperparathyroidism to permit rigorous definition of the role of intraoperative PTH measurements.

Another adjunct to minimally invasive parathyroidectomy has been the use of a hand-held gamma probe intraoperatively, both to map the location of abnormal glands and to verify their removal, following immediate preoperative imaging technetium Tc 99m using sestamibi. The challenging logistics of arranging the sequence of injection, imaging, and surgery necessary for success with this technique have limited its use to a few specialized centers, however.

At present, preoperative imaging enables consideration of a minimally invasive unilateral parathyroidectomy in approximately 70% of those patients thought preoperatively to have sporadic primary hyperparathyroidism due to a solitary adenoma. The ultimate dominant of this approach will depend on the balance between advantages (reduced operative and recovery time, fewer ancillary procedures, and lower hospital charge) and disadvantages (the added costs of the imaging and intraoperative PTH assays and the possibly greater demands for surgical skill and experience). Alternatively, successful application of minimally invasive techniques to bilateral explorations has begun. In one center, for example, 97% of patients with primary hyperparathyroidism currently undergo bilateral exploration under local anesthesia, with completion of the procedure in less than 1 hour and discharge to home within 6 hours.

In patients found or suspected to have multiglandular hyperplasia, several different approaches have been recommended, including removal of all but approximately 30 to 50 mg of parathyroid tissue ("3/g-land parathyroidectomy"), removal of all enlarged glands (but at least two) with biopsy of the remaining normal-sized glands, and total resection of all parathyroid tissue from the neck followed by autotransplantation of gland fragments to the forearm, with cryopreservation of remaining tissue. A concerted effort is made to search for a possible fifth gland, and any unresected (or transplanted) parathyroid tissue is marked with clips or sutures to facilitate identification in the event that reoperation becomes necessary. Great care must be taken by both the surgeon and the pathologist to describe the origin of, and label, all resected putative parathyroid tissue, particularly in parathyroid hyperplasia, as one of the most common handicaps facing the surgeon, should a subsequent operation become necessary, is inadequate knowledge of the original surgical findings and pathology. In contrast to initial cervical exploration, preoperative localization should be attempted routinely in those few patients who require reoperation for failed surgery, and intraoperative PTH determinations may be helpful in guiding the surgeon during these often difficult procedures.

The incidence of parathyroid carcinoma in primary hyperparathyroidism is less than 1%, but this possibility should be strongly considered in patients with unusually severe hyperparathyroidism, a palpable neck mass, hoarseness, evidence of local invasion at surgery, or recurrent hypercalcemia (see later on). Even so, parathyroid carcinoma rarely is suspected preoperatively and often eludes diagnosis at the time of initial surgery. When the disease is recognized, vigorous attempts should be made to remove all of the tumor on bloc. The incidence of local recurrence approaches 50%, however, and distant metastases, particularly to lung, may be heralded by recurrent, severe hyperparathyroidism.

The immediate postoperative management of parathyroidectomy focuses on establishing the success of the surgery and monitoring the patient closely for symptomatic hypercalcemia and for uncommon but potentially serious acute complications such as bleeding, vocal cord paralysis, or laryngospasm. After successful resection of a parathyroid adenoma, serum intact PTH levels decline rapidly, often to undetectable concentrations, with a disappearance half-time of about 2 minutes, whereas serum calcium typically reaches a nadir between 24 and 36 hours. Serum PTH returns to the normal range within 30 hours, although measurements of the parathyroid secretory response to hypercalcemia suggest that it does not fully normalize for at least several weeks.

In the past, patients generally were maintained on a low-calcium diet until normalization of serum calcium was clearly documented, ampules of injectable calcium and other seizure precautions were maintained at the bedside, serum calcium was measured at least every 12 hours until the patient was stable, and symptomatic hypercalcemia was promptly treated with calcium, either intravenously (90-mg bolus, 50 to 100 mg/hour) or oral (1.5 to 3.0 g/day). This approach is no longer appropriate for most patients, who are discharged less than 24 hours after surgery. Instead, oral calcium supplements routinely are provided as soon as oral intake is re-established, and moderate doses of 1.25(OH)2 D3 (0.5 to 1.0 µg daily) are added in those with large adenomas and severe hyperparathyroidism or in whom alkaline phosphatase had been elevated preoperatively.That is, patients in whom an impressive calcium requirement can be anticipated, often for many weeks postoperatively, as they remineralize their skeletons. This Hungry bone syndrome is associated with hypocalcemia, hypophosphatemia, and low urinary calcium excretion.

Serum calcium should be checked at intervals of several days initially to guide adjustment of calcium and vitamin D therapy as needed to achieve a stable result. In patients in whom hypercalcemia persists for more than several days, serum PTH should be measured to exclude the possibility of postoperative hyperparathyroidism. In view of evidence that bone mineral density continues to increase for at least a year after successful parathyroidectomy, it is expected that calcium and vitamin D supplementation for at least that long.

The approach to patients with persistent or recurrent hyperparathyroidism is informed by the recognition that parathyroid hyperplasia or carcinoma, ectopic or supernumerary parathyroid tissue, and postoperative hyperparathyroidism and other complications of further surgery all are more common in this population. The first issue to address is whether surgery is indicated. When a presumed adenoma is not identified initially, the original indications for surgery generally still exist, although some patients may not be suitable candidates for more extensive surgery, such as a median sternotomy, because of concurrent

![Image](https://via.placeholder.com/150)
medical illness. Patients with parathyroid hyperplasia have experienced significant clinical improvement even after incomplete parathyroidectomy, although those with MEN 1 are likely to experience further progression of their disease. As noted previously, preoperative localization studies, although unnecessary for initial neck exploration, are justified for patients in whom a first operation failed to effect a cure. Since the disease has recurred uncommonly and with technetium Tc 99m sestamibi offers the highest sensitivity and accuracy, although other studies (ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI)) may provide additional or confirmatory information. Sestamibi does localize to thyroid nodules, which may accompany parathyroid disease in 20% to 40% of patients, although it tends to wash out of thyroid tissue much more rapidly than from parathyroids. Technetium Tc 99m sestamibi can be combined with 131I scanning to improve distinction of parathyroids from thyroid nodules or with single photon emission CT (SPECT) imaging to achieve accuracy in localization not possible with planar imaging. Sestamibi scanning may fail to reveal small glands or to demonstrate multiple abnormal glands in cases of parathyroid hyperplasia, the most common cause of persistent postoperative hyperparathyroidism.

More invasive techniques have been employed as well, including angiography and selective venous sampling for measurement of PTH, although the sensitivity of these procedures for detection of residual abnormal parathyroid glands is only 50% to 65%. Angiography does offer the opportunity to attempt angioablation of any identified tissue, although this procedure is not routinely successful, and when all other parathyroid tissue has been previously removed, it precludes the opportunity to avoid hyperparathyroidism by autotransplantation of parathyroid fragments at surgery. Ultrasound- or CT-guided fine-needle aspiration of suspected parathyroid tissue may be used to obtain cytologic or immunohistochemical confirmation prior to surgery. Intraoperative ultrasonography has been useful in some cases to locate cervical or intrathyroidal glands. Success with video-assisted thoracoscopic resection of documented mediastinal lesions offers a less invasive alternative to median sternotomy for this relatively common cause of persistent hyperparathyroidism.

The need for these procedures depends on the expertise of the original surgeon and the surgeon's confidence that the neck was adequately explored initially. For example, at reoperation at one center, more than half of the missed hyperplastic parathyroid glands in those cases previously explored by a highly experienced parathyroid surgeon were found in the mediastinum or another ectopic location, whereas more than 90% of those referred by less experienced surgeons were discovered in a normal anatomic location in the neck.

After successful surgery for primary hyperparathyroidism, bone mass generally improves by as much as 5% to 10% in the first year at sites rich in trabecular bone (spine, femoral neck) but does not improve at cortical bone sites (distal radius). Bone density increases at trabecular bone sites may continue for several years, to as much as 12% to 15% after 10 years, although normal bone mineral density may not be achieved. This improvement, which is most apparent in patients with the greatest preoperative reductions in bone mass, may be related in part to rapid remodeling of the previously enlarged portion of bone undergoing remodeling but the continued improvement over years suggests a more sustained increase in bone formation and total bone volume, as well.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH), also appropriately called familial benign hypercalcemia, is, in most families, a disorder of autosomal dominant inheritance. The mutations, which cause complete or partial loss of function of the calcium-sensing receptor, lead to a shift in the parathyroid cell's set-point for calcium. As a consequence, higher than normal levels of blood calcium are needed to suppress PTH secretion. Furthermore, abnormal function of the calcium-sensing receptor in the renal thick ascending limb leads to increased, PTH-independent calcium reabsorption and consequent hypercalcemia.

The presence of a normal sensing receptor gene with the abnormal one usually leads to a very mild clinical disorder, although the receptor functions as a dimer, and certain mutations can worsen the function of the normal allele. Rare patients who inherit mutant calcium-sensing receptor genes from both parents present at birth with severe, life-threatening, primary hyperparathyroidism and almost always require immediate parathyroid surgery. In another genetic variation, a familial form of calcium-sensing receptor-dependent hypercalcemia has been described in association with other autoimmune disorders such as Hashimoto's thyroiditis and celiac sprue, in which autoantibodies directed against the sensor apparently antagonize calcium recognition by the parathyroids and renal tubules.

FH is manifested at birth by hypercalcemia. Although some controversy exists, most observers note that the condition is asymptomatic and that apparent symptoms represent ascertainment bias. Possible exceptions include the occurrence of chondrocalcinosis and perhaps pancreatitis. The blood calcium level is usually less than 12 mg/dL but can be higher. Phosphate measurements are low, as in primary hyperparathyroidism. Blood magnesium levels are high normal or slightly elevated.

When patients present as adults, the distinction from mild primary hyperparathyroidism can be difficult. The distinction between FH and primary hyperparathyroidism is a crucial one, however. Young patients with primary hyperparathyroidism are usually treated surgically and cured. In contrast, hyperparathyroidism always recurs after surgery for FHH, unless the patient is rendered hypoparathyroid by the removal of all parathyroid tissue. Therefore, surgery is contraindicated as therapy for FHH, except in the very rare patient with severe, symptomatic hypercalcemia. No blood or urine measurements are completely reliable for distinguishing between the two conditions, though the ratio of calcium clearance to creatinine clearance distinguishes most patients with FHH from those with primary hyperparathyroidism. The most helpful diagnostic information is the presence of hypercalcemia in an infant relative; such early hypercalcemia does not occur in MEN 1. Furthermore, a past history of clearly normal blood calcium, considerably lower than current measurements, makes FHH unlikely, if no other reason for a change in blood calcium exists.

Lithium Toxicity

Treatment of bipolar affective disorders with lithium commonly leads to mild, persistent increases in blood calcium occasionally out of the normal range, in affected persons. After several years of therapy, clear elevations of PTH levels and modest increases in parathyroid gland size, detected by ultrasonography, often occur. Usually, when lithium therapy is stopped, the blood calcium and PTH normalize within several months. Uncommonly, substantial hypercalcemia and clear hyperparathyroidism ensue. At surgery, parathyroid hyperplasia and, occasionally, parathyroid adenomas have been found.

The management of patients with mild, lithium-induced hypercalcemia is somewhat complicated. Like patients with mild primary hyperparathyroidism, patients taking lithium usually tolerate mild hypercalcemia without obvious symptoms. These patients can be monitored with protocols similar to those for patients with asymptomatic primary hyperparathyroidism. Close attention must be paid to urine concentrating ability in these patients, however, because the nephrogenic diabetes insipidus associated with lithium therapy can lead to dehydration and sudden worsening of hypercalcemia. Substantial hypercalcemia should lead to withdrawal of lithium therapy, if possible, with substitution of newer psychopharmacologic agents. If hypercalcemia persists after withdrawal of lithium, decisions about surgery follow the
same guidelines as those for patients with primary hyperparathyroidism.

Lithium increases the set-point for PTH secretion when it is added to isolated parathyroid cells in vitro. The set-point for PTH secretion in vivo is shifted to the right in patients who have received lithium for several years as well. A corresponding shift in the concentration of extracellular calcium needed to raise intracellular calcium levels suggests that lithium interferes with the action of the parathyroid calcium-sensing receptor, perhaps by interfering with inositol phosphate metabolism.
Parathyroid-Independent Hypercalcemia

In parathyroid-independent hypercalcemia, PTH secretion is appropriately suppressed. PTH levels, measured using two-site assays, are invariably lower than 25 pg/mL and are usually lower than normal or undetectable. Most affected patients have malignant hypercalcemia, although parathyroid-independent hypercalcemia occurs in a number of other settings as well.

Hypercalcemia of Malignancy

The diagnosis of malignant hypercalcemia is seldom a subtle one. Most malignancies produce hypercalcemia only when they are far advanced; the diagnosis becomes evident after routine studies, guided by the history and physical examination. Patients with malignant hypercalcemia usually die a month or two after hypercalcemia is discovered. Patients present with the classic signs and symptoms of hypercalcemia: confusion, polydypsia, polyuria, constipation, nausea, and vomiting. Perhaps because of the acuteness of the hypercalcemia and the elderly patient population involved, dramatic changes in mental status, culminating in coma, are relatively common. The diagnosis can be missed because the manifestations often overlap those of the underlying malignancy and because low blood albumin may lead to an apparently normal total blood calcium, despite an elevated blood ionized calcium. Even though the overall prognosis is grim, the diagnosis of malignant hypercalcemia is important to make.

Treatment is usually simple and effective in the short term; such treatment can importantly reverse the patient’s symptoms for several weeks, and even provide time for a fundamental attack on the underlying tumor, if it is treatable. Only effective treatment of the underlying neoplasm can significantly influence the long-term prognosis for patients with malignant hypercalcemia.

Although mechanisms in a given patient may be multiple, it is still useful to distinguish hypercalcemia associated with local involvement of bone from that caused by humoral mechanisms. In all cases, resorption of bone plays a pivotal role in the pathogenesis.

Local Osteolytic Hypercalcemia

Hypercalcemia resulting from tumors invading bone occurs most clearly in multiple myeloma and some patients with breast cancer. There is little evidence that the tumor cells themselves resorb bone. Instead, active osteoclasts found near the tumor cells are thought to be the proximate mediators of bone resorption. Myeloma cells and marrow cells associated with myeloma cells secrete numerous cytokines capable of stimulating bone resorption, including lymphotoxin (tumor necrosis factor-) and interleukins 1 and 6 (IL-1 and IL-6). RANKL is also found on the surface of myeloma cells and therefore may stimulate the production and activity of osteoclasts, just as RANKL on the surface of osteoblast-like cells can. In patients with myeloma, treatment with intermittent intravenous pamidronate (a bisphosphonate) inhibits this resorption and reduces the incidence of bone pain, fracture, and hypercalcemia.

The pathogenesis of hypercalcemia in breast cancer is not completely understood. Extensive metastases to bone are detected in most patients with hypercalcemia and breast cancer; this finding suggests that factors produced in bone by the metastatic tumor cells may be important. Breast cancer cells make a host of cytokines capable of resorbing bone. The role of tumor-produced PTHrP may be particularly important. A majority of breast cancer patients with hypercalcemia have elevated levels of PTHrP. Circulating PTHrP, as well as PTHrP produced in bone by metastatic tumor cells, may generate the hypercalcemia. Primary breast tumors that stain for PTHrP are more likely to result in bone metastases than are those that do not stain for PTHrP. This PTHrP may be instrumental in the establishment of lytic metastases. Animal models indicate that transforming growth factor- (TGF-), released from bone matrix by PTHrP-stimulated osteoclastic resorption, may further augment PTHrP secretion by the tumor cells. The latter may be further promoted by estrogen, which may explain the occasional occurrence of hypercalcemia following institution of estrogen or tamoxifen therapy in this disease.

Humoral Hypercalcemia of Malignancy

Albright, in 1941, was the first to propose that a PTH-like humoral factor caused the hypercalcemia in patients with malignancy but few or no bone metastases. Four decades later biochemical analysis demonstrated that such patients have high blood calcium levels, low blood phosphate levels, and high urinary cAMP levels like those found in primary hyperparathyroidism, but no elevation in PTH levels. The stimulation of cAMP production was used as an assay to eventually purify PTHrP from human tumors associated with the humoral hypercalcemia of malignancy. Animal models indicate that transforming growth factor- (TGF-), released from bone matrix by PTHrP-stimulated osteoclastic resorption, may further augment PTHrP secretion by the tumor cells. The latter may be further promoted by estrogen, which may explain the occasional occurrence of hypercalcemia following institution of estrogen or tamoxifen therapy in this disease.

The evidence that PTHrP mediates the humoral hypercalcemia of malignancy in most patients is substantial. As noted previously, PTHrP binds to the PTH/PTHrP receptor and mimics all of the actions of amino-terminal fragments of PTH. Blood levels of PTHrP are elevated in most patients with solid tumors and hypercalcemia.
Vitamin D Intoxication

Because the synthesis of 1,25(OH)₂D₃ is so tightly regulated, extremely large doses of vitamin D, on the order of 100,000 units per day, are required to cause hypercalcemia. Such doses are available in the United States only by prescription; therefore, most cases of vitamin D intoxication are iatrogenic. Occasionally, inadvertent ingestion occurs. Patients present with nausea, vomiting, weakness, and altered level of consciousness. Hypercalcemia can be severe and prolonged, because of the storage of vitamin D in fat. As expected, PTH levels are suppressed, and levels of 25(OH)D, which are poorly regulated and reflect levels of ingested vitamin D, are dramatically elevated. In contrast, the levels of 1,25(OH)₂D₃ are only modestly elevated or can be normal or even low. The modest changes in 1,25(OH)₂D₃ levels result from the down-regulation of the renal 1-hydroxylase by low levels of PTH and high levels of phosphate, calcium, and 1,25(OH)₂D₃ itself. The cause of the hypercalcemia, when it occurs in the face of normal levels of 1,25(OH)₂D₃, is uncertain but may reflect the direct action of 25(OH)D and possibly other vitamin D metabolites, which are capable of binding the 1,25(OH)₂D₃ receptor weakly. Also, the weaker vitamin D metabolites may displace 1,25(OH)₂D₃ from the circulating D-binding protein and increase the concentration of active, free 1,25(OH)₂D₃.

The hypercalcemia of vitamin D intoxication results both from increased intestinal absorption of calcium and from the direct effect of 1,25(OH)₂D₃ to increase resorption of bone. In severe cases, therefore, glucocorticoid therapy, which competes the action of 1,25(OH)₂D₃ on both bone and intestine, should be added to the therapeutic regimen of hydration and omission of dietary calcium.

Sarcoidosis and Other Granulomatous Diseases

Sarcoidosis may be associated with hypercalcemia and, even more commonly, hypercalcuria. Hypercalcemic patients have high levels of 1,25(OH)₂D₃; the high level of 1,25(OH)₂D₃ probably causes the hypercalcemia, although overproduction of bone-resorbing cytokines and PTHrP may contribute in some patients. As expected in 1,25(OH)₂D₃-dependent hypercalcemia, intestinal absorption of calcium is increased and PTH levels are suppressed. Furthermore, the hypercalcemia and high levels of 1,25(OH)₂D₃ fall upon treatment with glucocorticoids. The unregulated synthesis of 1,25(OH)₂D₃ found even in an anephric patient occurs not in the kidney but rather in the sarcoid granulomas. Removal of a large amount of granulomatous tissue can reverse hypercalcemia. Furthermore, isolated sarcoid macrophages can synthesize 1,25(OH)₂D₃ from 25(OH)D, as can normal macrophages stimulated with interferon. Such macrophages express the gene encoding the identical 25(OH)D 1-hydroxylase found in the kidney.

The unregulated synthesis of 1,25(OH)₂D₃ by activated macrophages explains many of the findings in sarcoid patients. These patients have unusual sensitivity to vitamin D and can become hypercalcemic in response to ultraviolet radiation or oral vitamin D intake. Abnormalities in calcium metabolism are usually found only in patients with active disease and large, clinically obvious total-body burdens of granulomas. Nevertheless, hypercalcemia can present in patients without obvious pulmonary disease. Furthermore, subtle abnormalities of vitamin D metabolism can be demonstrated even in patients with mildly active sarcoidosis. For example, patients without elevated levels of angiotensin-converting enzyme in their blood have normal levels of 1,25(OH)₂D₃, but these levels do not fall normally in response to an oral calcium challenge.

Hypercalcemia is also associated with other granulomatous diseases, such as tuberculosis, fungal infections, and berylliosis and has been reported in Wegener's granulomatosis, in acquired immunodeficiency syndrome (AIDS)-related Pneumocystis carinii infection, and even in association with extensive granulomatous foreign body reactions.

Hyperthyroidism

Hypercalcemia can result from thyrotoxicosis. Blood calcium levels seldom exceed 11mg/dL, but mild elevations are found in a quarter of patients. Patients have low PTH levels, low 1,25(OH)₂D₃ levels, and hypercalcuria. Hypercalcemia is caused by a direct action of thyroid hormone to stimulate bone resorption.

Beta-adrenergic blocking agents can reverse the hypercalcemia.

Vitamin A Intoxication

Excess ingestion of vitamin A (retinol) results in a syndrome of dry skin, pruritus, headache from pseudotumor cerebri, bone pain, and, occasionally, hypercalcemia. Hypercalcemia occurs only with the ingestion of 10 times the RDA (5000 IU/day). The identical syndrome can result from ingestion of the vitamin A derivatives all-trans-retinoic acid [Accutane] and tretinoin (all-trans-retinoic acid [Retin-A]), used to treat acne. Bones can show characteristic periosteal calcification on radiographs. The hypercalcemia is probably caused by the action of retinoids to directly stimulate bone resorption. The diagnosis is made by the association of a history of excess ingestion of retinoids with the characteristic syndrome and abnormal results of liver function tests; elevated vitamin A levels confirm the diagnosis. Treatment involves hydration and, if necessary, glucocorticoids.

Adrenal Insufficiency

Hypercalcemia occurs in the setting of adrenal insufficiency. Blood calcium is elevated partly as a result of hemoconcentration and increased albumin levels, and even in association with extensive granulomatous foreign body reactions.

Thiazide Diuretics

Thiazide diuretics do not cause hypercalcemia by themselves, but can exacerbate the hypercalcemia of primary hyperparathyroidism. The mechanism of the hypercalcemia may involve the action of thiazide diuretics to increase distal tubular calcium reabsorption. Thiazides block sodium chloride cotransport into these cells (see Figs. 28-26-7). The fall in intracellular chloride hyperpolarizes the cell, thereby increasing calcium influx through voltage-sensitive channels. Decreased renal clearance of calcium alone would be expected to raise blood calcium in the normal human only transiently because the transient hypercalcemia would be expected to suppress PTH secretion and lead to return of the blood calcium to normal.

As predicted by this model, thiazide administration leads to chronic hypercalcemia only in patients with abnormal parathyroid physiology. In primary hyperparathyroidism, thiazide administration exacerbates the hypercalcemia, and in hypoparathyroidism, thiazide administration facilitates the maintenance of normocalcemia when given in conjunction with 1,25(OH)₂D₃ and calcium.

Milk-Alkali Syndrome

The triad of hypercalcemia, metabolic alkalosis, and renal failure can be the consequence of massive ingestion of calcium and absorbable alkali. This syndrome was first described when milk and sodium bicarbonate were used in large amounts to treat peptic ulcer disease. With the change in ulcer treatment to nonabsorbable antacids and suppression of acid secretion, milk-alkali syndrome became rare. In the last several years, however, the increased use of calcium carbonate to treat dyspepsia and osteoporosis has led to the reappearance of milk-alkali syndrome. In most cases, a history of ingestion of several grams per day of calcium in the form of calcium carbonate can be elicited. The pathogenesis of the syndrome is not understood in detail but may well involve a vicious circle in which alkalosis decreases renal calcium clearance and hypercalcemia helps maintain alkalosis. Nephrocalcinosis, nephrogenic diabetes insipidus, decrease in GFR associated with hypercalcemia, and hypovolemia from vomiting all lead to renal failure, which can be severe. PTH levels, measured with currently available two-site assays, are invariably low in hypercalcemic patients as are levels of 1,25(OH)₂D₃. After clearance of the calcium by hydration or dialysis, if necessary, renal function generally returns to normal, unless the disorder has been severe and long-standing.
Immobilization

Immobilization can lead to bone resorption sufficient to cause hypercalcemia. The immobilization is usually caused by spinal cord injury or extensive casting after fractures. Hypercalcemia of immobilization occurs predominantly in the young or in patients with other reasons for a high rate of bone turnover, such as Paget’s disease or extensive fractures. Hypercalcuria and substantial bone loss are more common than hypercalcemia is. After spinal cord injury, the hypercalcuria is maximal at 4 months and can persist for more than a year. T T PTH and 1,25(OH)₂D₃ levels are suppressed T T T T ; bone biopsies show increased resorption and decreased formation of bone. T T T The combination of calcitonin and bisphosphonates T T T T or simply bisphosphonates alone T T T T have been used to reverse the hypercalcemia and hypercalciuria of spinal cord injury.

Renal Failure

Following rhabdomyolysis, during the oliguric phase of acute renal failure, severe hypocalcemia can result from acute hyperphosphatemia and calcium deposition in muscle. T T PTH levels are high. In the diuretic phase that follows, hypercalcemia can occur. The hypercalcemia results from the high 1,25(OH)₂D₃ levels observed in some patients and from mobilization of the calcium deposits. T T

In chronic renal failure, hypercalcemia can result from tertiary hyperparathyroidism or may appear during therapy of aplastic bone disease associated with low PTH levels and sometimes with aluminum toxicity. T T

Williams’ Syndrome

Williams’ syndrome is a developmental disorder in which supravalvular aortic stenosis is associated with elfin facies and mental retardation. T T T T Hypercalcemia can occur transiently in the first four years of life. Affected hypercalcemic infants have been found to have increased intestinal absorption of calcium and associated elevations of 1,25(OH)₂D₃ that fall to normal as the blood calcium normalizes. T T Levels of 25(OH)D are normal. The hypercalcemia can generally be controlled by dietary manipulation.

Molecular analysis has clarified the origin of the connective tissue component of Williams’ syndrome. T T T T Isolated supravalvular aortic stenosis is associated with deletion or translocation of the distal portion of the elastin gene. Williams’ syndrome, with more protean connective tissue abnormalities and mental retardation, is associated with large deletions that include the elastin gene and a gene encoding the protein kinase LIM-kinase 1. T T It is possible that the subgroup of patients with infantile hypercalcemia have deletion of another gene near the elastin locus. This possible genetic heterogeneity may explain the conflicting literature, which has found no consistent abnormality of calcium metabolism in normocalcemic patients with Williams’ syndrome. T T

Jansen’s Metaphyseal Chondrodysplasia

Jansen’s metaphyseal chondrodysplasia is a rare disease in which affected persons present in childhood with short stature and hypercalcemia. T T (Fig. 26-29) Blood chemistry studies suggest hyperparathyroidism, with high calcium, low normal phosphate, high 1,25(OH)₂D₃, high alkaline phosphatase, and high urinary hydroxyproline, but PTH levels are suppressed. T T A generalized defect in endochondral bone formation results from abnormally organized chondrocytes in growth plates. Metaphyses appear disordered and rachitic on radiographs. The bones may show signs of osteitis fibrosa cystica. Constitutive activation of the PTH/PTHrP receptor, caused by point mutations in the transmembrane domains of the receptor, explains the findings in this disorder. T T T T T T The abnormalities on serum chemistry studies result from PTH-like actions of the receptor in bone and kidney. T T T T T T The growth plate disorder results from PTHrP-like actions of the receptor on the growth plate.
Approach to the Hypercalcemic Patient

The diagnostic approach to the hypercalcemic patient is strongly influenced by the clinical setting and the knowledge that primary hyperparathyroidism is at least twice as common as all other causes combined (Table 26-2). These considerations are particularly significant in the patient who seems otherwise well and in whom the hypercalcemia is detected incidentally or is mild, stable, or known to be of long duration (i.e., years). Among outpatients referred to endocrinologists for evaluation of hypercalcemia, for example, more than 90% are found to have primary hyperparathyroidism. In ill or hospitalized patients, malignant disease is the cause in more than 50% of cases. The differential diagnosis is seldom complicated, however, because malignant hypercalcemia usually presents in the context of advanced, clinically obvious disease.

Because hypercalcemia usually is first detected as an elevation of total serum calcium, it is important to distinguish hemoconcentration or rare instances of calcium-binding paraproteinemia from a true increase in serum ionized calcium (Fig. 26-30). The presence of hypercalcemia should be confirmed by direct measurement of ionized calcium, and total calcium should be repeated, together with albumin, globulin, electrolytes, blood urea nitrogen (BUN), creatinine, and phosphate. Especially when hypercalcemia is mild, it is prudent to repeat the serum total or ionized calcium measurement at least twice, preferably with the patient fasting and without venous occlusion, before proceeding with more costly studies directed at discovering its etiology.

A careful history and physical examination, combined with efforts to assess chronicity by seeking previous results of routine multichannel serum chemistry determinations, most often points to the likely diagnosis. Serum phosphate often is low in hyperparathyroidism; however, because phosphate is often low in PTHrP-secreting malignancies as well, the presence of hypophosphatemia is not helpful in distinguishing these possibilities. When serum phosphate levels are normal or high despite correction of dehydration, the possibility of PTH- or PTHrP-independent hypercalcemia should be considered more strongly, however. Elevations in serum chloride and alkaline phosphatase, often observed in primary hyperparathyroidism, cannot be reliably employed in the differential diagnosis of hypercalcemia.

Important elements of the medical history of hypercalcemic patients include inquiries about kidney stones or fractures, weight loss, back or bone pain, fatigue or weakness, cough or dyspnea, ulcer disease, or pancreatitis; ingestion of vitamins, calcium preparations, lithium, or thiazides; dates of most recent mammograms and chest radiographs; and a family history of hypercalcemia, kidney stones, ulcer disease, endocrinopathy, or tumors of the head or neck. Because malignancy is a common cause of hypercalcemia and may occur concomitantly with primary hyperparathyroidism, clinical findings strongly suggestive of malignancy should be acted on by proceeding directly to a search for an underlying tumor, regardless of serum PTH levels.

The single most important test in the differential diagnosis of hypercalcemia is the measurement of serum PTH, preferably in a two-site assay specific for the intact, biologically active molecule (see Fig. 26-21). A consistently elevated serum PTH

level in the presence of true hypercalcemia is always abnormal and almost always indicates the presence of primary hyperparathyroidism. The exceptions are FHH, autonomous parathyroid secretion complicating secondary hyperparathyroidism (*tertiary* hyperparathyroidism), ongoing lithium therapy in some patients, and, very rarely, ectopic PTH secretion by a malignant neoplasm.

Diagnosis of primary hyperparathyroidism is complicated, however, by the fact that some patients fail to exhibit both hypercalcemia and elevated iPTH. In up to 10% of patients with hypercalcemia and primary hyperparathyroidism, PTH levels may fall within the (high) normal range with current PTH assays. Such PTH levels are inappropriate in the face of hypercalcemia, however, and support the diagnosis of PTH-dependent hypercalcemia. In fact, many such patients will demonstrate frankly elevated serum PTH if retested, especially if dietary calcium is restricted beforehand. As noted previously, some may present with serum calcium in the high-normal range (>10.0 mg/dL), together with an elevated or high-normal PTH. This abnormality may be discovered incidentally in an otherwise asymptomatic person or in the course of evaluating recurrent urolithiasis or osteopenia. Patients with persistently high-normal serum calcium and high-normal iPTH should be retested at intervals and, meanwhile, given a provisional diagnosis of hyperparathyroidism and evaluated accordingly.

In patients with PTH-dependent hypercalcemia (Fig. 26-31), calcium and creatinine should be measured in a 24-hour urine collection and a simultaneous serum sample to measure total urinary calcium output (mg/day) and the clearance ratio of urinary and serum calcium and creatinine (i.e., UCa/Cr x SCr/Cr). A daily calcium excretion of less than 100 mg per day, or a clearance ratio less than 0.01, should prompt consideration of familial hypocalciuric hypercalcemia, especially in patients younger than 40 years of age, those with high-normal PTH levels, and those with a family history of hypercalcemia. A urinary calcium excretion of greater than 4 mg/kg per day or a clearance ratio greater than 0.02 effectively excludes FHH. If FHH, serum phosphate is normal or slightly low, serum magnesium may be slightly high, and serum

1,25(OH)2D3 is normal or low (unlike in primary hyperparathyroidism).

A definite diagnosis of FHH, as in the MEN syndromes, may be provided by confirming the presence of mutations in the relevant genes, although such studies are not invariably informative (presumably because of mutations in introns and other unchecked regions) and usually are unnecessary. The identification of RET gene mutations is now an essential part of the management of families with MEN 2, because this information most effectively guides the decision for preventive thyroidectomy to prevent medullary cancer of the thyroid. In contrast, the identification of MENIN gene mutations has not yet led to any effective preventive strategies; thus, genetic analysis may be useful only for genetic counseling in families with MEN 1. Even for this purpose, the incomplete ascertainment of mutations limits the effectiveness of such analysis.

In patients with suspected lithium-induced hyperparathyroidism, a trial off lithium, if feasible clinically, may confirm the diagnosis or indicate the presence of persistent primary hyperparathyroidism. Patients with primary hyperparathyroidism should undergo bone densitometry, preferably at both cortical bone and trabecular bonerich sites (i.e., forearm and hip or lumbar spine, respectively) to assist in the decision about surgery. Those younger than 40 years of age or who have a family history of hypercalcemia (or other MEN manifestations) should be evaluated for these syndromes as well. Patients who do not meet criteria for parathyroidectomy should be followed medically, as should those with FHH.

A low or undetectable serum PTH level signifies the presence of nonparathyroid hypercalcemia and should prompt a detailed evaluation for malignancy or other causes of PTH-independent hypercalcemia (see Table 26-2). Breast and lung cancers alone account for over 50% of all malignancy-associated hypercalcemias. Mammography, chest radiography with or without CT, abdominal CT, and serum and urinary immuno-electrophoresis are among the more useful tests for detecting the cause of nonparathyroid hypercalcemia. Although humoral mechanisms, especially secretion of PTHrP, are implicated in the pathogenesis of most cancer-associated hypercalcemias, bone metastases are common, particularly in breast cancer. Technetium

99m bone scanning, therefore, generally is useful for detecting this syndrome and identifying bones vulnerable to fracture. The utility of serum PTHrP measurements probably is limited to the unusual situation in which serum PTH is suppressed but an underlying malignancy cannot readily be demonstrated.

In the absence of evident malignancy, unusual causes of hypercalcemia should be sought. Vitamin D and vitamin A intoxication can be excluded by measurement of serum 25(OH)D and retinoids, respectively. Elevated 1,25(OH)2D3 and hypercalcemia may occur in several settings, including sarcoidosis and other granulomatous diseases, B-cell and T-cell lymphomas (including AIDS-associated lymphomas) and, uncommonly, in epithelial neoplasms such as lung cancer. Very rarely, patients with severe idiopathic hypercalcemia and excessive absorption of dietary calcium may manifest mild, dietary-dependent hypercalcemia. Overtreatment of hyperparathyroidism or other conditions with oral 1,25(OH)2D3 or topical use of analogues of the active metabolite in psoriasis should be obvious from the history. Because hypercalcemia and hypercalciuria are observed in up to 10% and 30%, respectively, of patients with thyrotoxicosis, measurement of serum thyroid-stimulating hormone (TSH) may be helpful, especially in older patients who may be less overtly symptomatic. Adrenal insufficiency and pheochromocytoma usually are accompanied by characteristic clinical features, but a definite diagnosis may be sought with appropriate studies. Granulomatous diseases are among the more common disorders that underlie initially unexplained hypercalcemia.
Therapy of Severe Hypercalcemia

Causes of Severe Hypercalcemia

The need for urgent therapy of acute, severe hypercalcemia, usually defined as a serum calcium concentration greater than 14 mg/dL (3.5 mM), is unusual. This is because most patients with hypercalcemia have primary hyperparathyroidism, in which hypercalcemia is typically chronic and mild. Episodes of acute, severe hypercalcemia may occur occasionally in primary hyperparathyroidism (“parathyroid crisis”), usually in patients with large parathyroid adenomas and very high PTH levels. The severe hypercalcemia appears in the setting of dehydration due to diarrheal illness, protracted vomiting or diuretic therapy, recovery from major surgery, immobilization, ingestion of large amounts of oral calcium salts, or parathyroid carcinoma.

Most often, acute, severe hypercalcemia is encountered in patients with underlying malignancy, in whom accelerated bone resorption dramatically increases the filtered load of calcium. The ensuing profound hypercalcemia impairs renal tubular sodium reabsorption, which induces progressive extracellular volume depletion, reduces GFR, impairs renal calcium clearance, and further aggravates the hypercalcemia. In many such patients, elevated circulating levels of PTH and PTHrP compound the problem by mimicking the action of PTH to enhance distal tubular calcium reabsorption.

Clinical Features of Severe Hypercalcemia

The indications for urgent therapy of hypercalcemia usually relate more to the presence of clinical symptoms of hypercalcemia than to the absolute level of serum calcium, although few clinicians would hesitate to treat patients in whom total serum calcium exceeded 14 mg/dL (3.5 mM). Many patients with previously mild hypercalcemia become symptomatic when serum calcium concentrations exceed 12 mg/dL (3.0 mM). It is important to remember that hypoalbuminemia may mask significant elevations of ionized calcium. The most common symptoms of severe hypercalcemia are referable to disturbances of nervous system and gastrointestinal function—fatigue, weakness, lethargy, confusion, coma (rarely), anorexia, nausea, abdominal pain (rarely due to pancreatitis), and constipation. Polyuria, nocturia, and polydypsia are present also.

Bone pain is often present but is usually due to underlying metastatic disease. Cardiac arrhythmias may occur, particularly bradyarrhythmias or heart block, and digitalis toxicity may be potentiated. Patients who suffer a fatal outcome from acute severe hypercalcemia may manifest coma, hypotension, acute pancreatitis, acute renal failure, widespread soft tissue calcification, heart failure, or venous thrombosis, particularly of the renal veins.

Management of Severe Hypercalcemia

The first decision to be made in the management of acute, severe hypercalcemia is whether or not to treat the problem at all. The question of definitive treatment may become an issue for the patient with an incurable, widely disseminated malignancy, when all other approaches to controlling the neoplasm have been exhausted, and the patient has chosen not to have complications treated. Otherwise, as noted previously, patients with serum calcium levels above 14 mg/dL ordinarily should receive aggressive treatment. Treatment most often entails rehydration and administration of a bisphosphonate intravenously. Calcitonin can be useful as a temporary measure early in therapy. Gallium nitrate, plicamycin, and intravenous phosphate are infrequently used, because of toxicity.

Volume Repletion

When treatment is indicated, the first priority is to correct the extracellular volume depletion that is invariably present, usually by infusing isotonic saline at a rate of 2 to 4 liters/day. The aggressiveness with which the individual patient is rehydrated must be considered in relation to both the patient's volume status and the risk of precipitating or aggravating congestive heart failure or asosites. Diuretics, particularly thiazides, should be discontinued. The conventional use of furosemide or other potent "loop" diuretics to promote calciuresis may exacerbate extracellular volume depletion if used early in the course of treatment. In light of the current availability of highly effective alternatives for the therapy of hypercalcemia, such drugs probably are best avoided, except when vigorous rehydration fails to improve severe hypercalcemia or may precipitate congestive heart failure. In any case, prolonged use of saline-induced calciuresis without the early introduction of an effective anti-resorptive agent is ill advised and ultimately futile.

Bisphosphonates

Several drugs are available for specific therapy of acute hypercalcemia (Table 26-3). Each of these agents inhibits osteoclastic bone resorption, although their relative efficacy and toxicity vary substantially. The antiresorptive drug of first choice in most situations is an intravenous bisphosphonate. Of the two currently available in the United States, pamidronate more reliably normalizes serum calcium and frequently does so following even a single intravenous infusion, although the dose can be repeated in refractory cases. The drug is generally well tolerated, although local pain or swelling at the infusion site, low-grade fever 1 or 2 days after the infusion, transient lymphopenia, and mild hypophosphatemia or hypomagnesemia may occur in a significant fraction of patients. Serum calcium concentration usually declines rapidly following administration of 60 to 90 mg, reaching the normal range within 2 to 3 days in over 80% of cases and occasionally falling below normal at its nadir. The duration of the response to pamidronate varies dramatically ranging from a week or so to several months and cannot be predicted in an individual patient.

Calcitonin

Calcitonin, which directly inhibits osteoclast function, is frequently used with other antiresorptive agents to achieve more rapid control of severe hypercalcemia. Calcitonin rarely produces a decline in serum calcium of more than 2 mg/dL, and its efficacy typically is limited to a few days at most, possibly because of receptor

</table>
down-regulation in target cells of bone and kidney. Its major advantages are a more rapid onset of action (by several hours) and its potential to augment renal calcium excretion directly. Calcitonin is also unique in that it may produce a significant analgesic effect in many patients with fracture or metastatic bone disease. Calcitonin is generally well tolerated, although transient nausea, vomiting, abdominal cramps, flushing, and local skin reactions may occur.

**Gallium Nitrate**

Gallium nitrate can normalize serum calcium within 5 to 7 days in most patients given the recommended 5-day infusion of 200 mg/m²/day, but it is rarely used because of significant nephrotoxicity and other adverse effects such as hypotension, nausea, vomiting, hypophosphatemia, and anemia and is not currently available in the United States.

**Plicamycin**

Plicamycin (formerly mithramycin), an antiresorptive drug that for many years was considered the first-line agent for treatment of severe hypercalcemia, can cause a broad range of significant hepatic, renal, and hematologic toxic effects and offers no practical or theoretical advantage over bisphosphonates. The drug is no longer used for this purpose.

**Phosphate**

Intravenous phosphate infusion was employed in the past to control hypercalcemia in patients with concomitant hypophosphatemia, but the mechanism of action, which may partly depend on direct inhibition of osteoclasts, almost certainly involves also generalized precipitation of calcium phosphate salts in soft tissues, notably kidneys, pancreas, heart, lungs, stomach, and vessels. For this reason, and also because intravenous phosphate administration may produce severe, life-threatening hypocalcemia or hypotension, this therapy can no longer be considered standard for severe hypercalcemia. Oral phosphate, in doses up to 2000 mg daily, has been advocated for therapy of hypercalcemia in hypophosphatemic patients with normal renal function, but its efficacy is limited, it is not appropriate for urgent therapy of severe hypercalcemia, and its use is accompanied by frequent nausea, abdominal cramps, and diarrhea.

**Other Approaches**

Other strategies for control of severe hypercalcemia may be applicable in specific circumstances. High-dose glucocorticoids, for example, may be very helpful in vitamin D intoxication, in granulomatous diseases such as sarcoidosis, and with hematologic malignancies known or likely to be glucocorticoid-responsive. Because the effects of antiresorptive agents are somewhat delayed (i.e., days) and acute reduction of serum calcium during the first 12 to 24 hours depends mainly on inducing calciuresis through adequate rehydration, peritoneal or, better, hemodialysis may be required early in the management of life-threatening hypercalcemia. In this case, it is desirable to employ low- or zero-calcium dialysate.
HYPOCALCEMIC DISORDERS

Clinical Presentation

The predominant clinical symptoms and signs of hypocalcemia are those of neuromuscular irritability, including perioral paresthesias, tingling of the fingers and toes, and spontaneous or latent tetany. Tetany can be elicited by percussion of the facial nerve below the zygoma, resulting in ipsilateral contractions of the facial muscle (Chvostek’s sign) or by 3 minutes of occlusive pressure with a blood pressure cuff resulting in carpal spasm, which, on occasion, can be very painful (Trousseau’s sign) (Fig. 26-32). The usefulness of these signs in diagnosing hypocalcemia and in following therapeutic responses cannot be overemphasized.

Electrocardiographic abnormalities also result from hypocalcemia, including prolonged QT intervals and marked QRS and ST segment changes that may mimic acute myocardial infarction or conduction abnormalities. Ventricular arrhythmias are a rare complication of hypocalcemia, although congestive heart failure, corrected by normalization of serum calcium, has been reported.

In profound hypocalcemia or during acute falls in serum calcium, grand mal seizures or laryngospasm also may be observed. Chronic hypocalcemia is associated with milder symptoms and signs of neuromuscular irritability and may even be asymptomatic. Long-standing hypocalcemia associated with hyperphosphatemia (observed with PTH deficiency or resistance) may lead to calcification of the basal ganglia and occasional extrapyramidal disorders. In addition, mineral ion deposits in the lens may lead to cataract formation.

Chronic hypocalcemia, particularly when associated with hypophosphatemia, as in vitamin D deficiency, is associated with growth plate abnormalities in children (rickets) and defects in the mineralization of new bone (osteomalacia) (see Chapter 27). Severe symptomatic hypocalcemia constitutes an emergency that requires immediate attention to prevent seizures and death from laryngospasm or cardiac causes.

Total calcium in serum includes both the free (biologically active) and protein-bound components; the major binding protein is albumin (see "Roles of the Mineral Ions"). Therefore, measurements of total calcium cannot be interpreted without concurrent measurement of albumin. Studies of hypoalbuminemic patients with cirrhosis have led to a formula for correction of total calcium based on concurrent albumin levels (a decrease in calcium of 0.8 mg/dL for every 1 g/dL decrease in albumin). No formula has proved accurate, however, for assessment of calcium concentration in acutely ill patients. This difficulty probably relates to the variety of factors that may increase protein binding and decrease the fraction of total calcium present as the free ion, including alkalosis, elevated circulating free fatty acids, and lipid infusions. Consequently, ionized calcium should be measured when the diagnosis of hypocalcemia is considered in the setting of acute illness or severe hypoalbuminemia.

Chronic hypocalcemia is most often due to deficiency of PTH or 1,25(OH)₂D₃ or to resistance to the biologic effects of these calcium-regulating hormones (Table 26-4).
Parathyroid-Related Disorders

Hypocalcemia associated with parathyroid dysfunction can be differentiated from other causes of hypocalcemia by routine laboratory tests. Serum calcium is low owing to lack of PTH-mediated bone resorption and urinary calcium reabsorption. Serum phosphate is increased owing to impaired renal clearance. Serum 1,25(OH)₂D₃ is low because PTH and hypophosphatemia stimulate the renal 25(OH)D₁-hydroxylase. Consequently, 1,25(OH)₂D₃-mediated intestinal calcium absorption is markedly decreased, further exacerbating the hypocalcemia. PTH levels measured using sensitive two-site PTH assays (see Fig. 26-21) are usually low or undetectable but may be inappropriately normal if some degree of PTH production is preserved. Elevated levels of PTH are found in syndromes associated with resistance to the biologic effects of PTH.

Congenital or Inherited Parathyroid Disorders

Several rare syndromes associated with congenital or inherited hypoparathyroidism appear sporadically, or in a variety of inheritance patterns suggesting multiple causes. Mutation of a transcription factor called glial cell missing (GCM)b (6p23), which is expressed in the PTH-secreting cells of the developing parathyroids, is a cause of familial hypoparathyroidism in humans and mice. Though as yet uncloned, the gene responsible

for X-linked recessive hypoparathyroidism has been linked to Xq26.7-q27. DiGeorge's syndrome occurs sporadically and is associated with an embryologic defect in the formation of the third, fourth, and fifth branchial pouches, resulting in the absence of parathyroid glands. DiGeorge's syndrome is often associated with other congenital abnormalities in a syndrome referred to by the acronym CATCH 22 (cardiac defect, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, and 22q11 deletions). Microdeletion of 22q11.21q11.23 and a t(2;22)(q14;q11) balanced translocation suggest that a gene at chromosome 22q11 may be pathogenic in this syndrome. Hypoparathyroidism also has been reported in two patients with a 22q11 deletion. In a number of cases of DiGeorge's and velocardiofacial syndromes, there is a recognizable abnormality at 22q11; rather, terminal 10p deletions or interstitial 10p13/10p14 deletions have been identified, suggesting that two loci may be critical for development of branchial pouch structures. Terminal deletions of 10p accompanied by hypoparathyroidism can be further subdivided into DiGeorge critical region II (10p13.14) and a more telomeric region (10p14.10pter) wherein mutation of the transcription factor GATA3 causes the syndrome of hypoparathyroidism, sensorineural deafness, and renal anomaly (HDR).

DiGeorge's syndrome may in fact be a neurocraniopathy, because ablation of the premigratory cephalic neural crest in chick embryos produces the same phenotype. The contribution of homeobox genes to parathyroid development and their potential relationship to DiGeorge's syndrome also have been demonstrated by the absence of thymic and parathyroid tissue, accompanied by cardiac and craniofacial abnormalities, in mice lacking the homeobox gene hoxa11. Familial hypoparathyroidism is seen in conjunction with mucocutaneous candidiasis, Addison's disease, and other immune disorders in autosomal recessive autoimmune polyglandular syndrome type I (see Chapter 37). Hypoparathyroidism may also be observed in association with mitochondrial myopathies such as mitochondrial trifunctional protein deficiency and the Kearns-Sayre syndrome. With other inherited forms of hypoparathyroidism, the disorder may be observed as an isolated defect, or affected patients may present with other features such as lymphedema, dysmorphism, hearing impairment, and renal and cardiac abnormalities.

Abnormalities in the Parathyroid Hormone Gene

Specific defects have been found in the PTH gene in a small number of kindreds affected by congenital hypoparathyroidism. These defects include point mutations in the signal peptide and in an intron border, leading to aberrant splicing. No abnormalities in the sequences encoding PTH(1-84) have been discovered in familial hypoparathyroidism.

Destruction of the Parathyroid Glands

The most common cause of chronic hypocalcemia is post-surgical hypoparathyroidism. This problem may occur after removal of all parathyroid tissue during thyroidec- tomy and radical neck dissection for malignancies, or after inadvertent interruption of the blood supply to the parathyroid glands during head and neck surgery. Transient hypoparathyroidism, attributed to chronic suppression of the remaining normal glands, is common after parathyre idec-tomy; permanent hypoparathyroidism may occur after vascular or surgical injury or inadvertent removal of all parathyroid tissue. Rarely, transient hypoparathyroidism may follow spontaneous infarction of autonomou s tissue in primary hyperparathyroidism. Hypoparathyroidism is a rare complication of radioactive iodine ablation of the thyroid gland for Graves' disease. Hypoparathyroidism also can occur as a result of infiltrative diseases of the parathyroids. This association is seen in diseases of iron overload such as hemochromatosis and in patients with thalassemia major who have received numerous transfusions. Copper deposition in Wilson's disease may also cause parathyroid dysfunction. Metastatic disease to the parathyroid glands is a rare cause of hypoparathyroidism, presumably because of the need for four-gland involvement before significant hypoparathyroidism is observed.

Impaired PTH Secretion

Impaired secretion of PTH from the parathyroid glands can lead to functional hypoparathyroidism. This problem is commonly seen in profound hypomagnesemia, in which target organ resistance to PTH can also occur. Both of these abnormalities are reversible on magnesium repletion (see "Disorders of Magnesium Metabolism"). Copper deposition in Wilson's disease may also cause hypoparathyroidism. Chronic respiratory alkalosis leads to hyperphosphatemia and decreased ionized calcium levels accompanied by impaired renal calcium resorption and inappropriately normal PTH levels. This biochemical phenotype suggests both an abnormality of PTH secretion and renal resistance to PTH.

Activating mutations in the calcium-sensing receptor cause autosomal dominant hypocalcemia (ADH) associated with inappropriately normal PTH levels. The clinical syndrome is variable; patients present with hypocalcemia and seizures, whereas their affected relatives may be only subsequently diagnosed with asymptomatic hypocalcemia. Unlike in patients with inactivating mutations of the calcium sensor, homozgyously affected persons do not appear to have a more severe phenotype. The presence of hypercalculia in these patients makes medical management uniquely challenging.

Treatment with vitamin D metabolites often results in a marked increase in renal calcium excretion, associated with renal calcification and resultant renal impairment. On the basis of these observations, it has been suggested that asymptomatic persons be left untreated and that the goal of therapy in patients with symptomatic hypocalcemia be solely to relieve symptoms, not to achieve normocalcemia.

Pseudohypoparathyroidism

The idiopathic and inherited forms of PTH resistance are referred to as pseudohypoparathyroidism (PHP). The first cases of documented PTH resistance were
described by Albright in 1942. The patients were hypocalcemic and hyperphosphatemic and also exhibited a number of clinical features including short stature, round face, foreshortened fourth metacarpals, obesity, and subcutaneous calcifications (Fig. 26-33 and Fig. 26-34). These are the characteristics of the disorder now called Albright’s hereditary osteodystrophy (AHO).

PTH administration to affected patients failed to provoke a phosphate diuresis or an increase in serum calcium. It was subsequently demonstrated that hypocalcemic patients with features of AHO had elevated PTH levels and that PTH infusions failed to stimulate renal production of cAMP. Failure of stimulation of cAMP production suggested a defect in the PTH receptor or in its cAMP-mediated signal transduction. The measurement of cAMP in the urine following an infusion of synthetic PTH(1-34) is now used to establish the diagnosis of PTH resistance.

The variable presence of AHO and renal resistance to PTH in PHP has led to the subclassification of pseudohypoparathyroidism (Table 26-5). Type Ia is characterized by AHO and diminished Gs activity (approximately 50% of normal). The diminished Gs activity has been demonstrated in several tissues and cells, including kidney, fibroblasts, transformed lymphocytes, platelets, and erythrocytes. Decreased amounts of Gs mRNA (50%) are present in fibroblasts of many patients with PHP Ia, and inactivating mutations in the Gs gene have been identified in several kindreds.

Impaired mentation is seen in approximately half of the patients with PHP Ia and appears to be related to the Gs deficiency rather than to chronic hypocalcemia, because patients with other forms of PHP and hypocalcemia have normal mentation. The Gs deficiency in PHP Ia may be associated not only with PTH resistance but also with resistance to other hormones such as TSH, glucagon, and gonadotropins, resulting in thyroidal and gonadal dysfunction. Paradoxically, two unrelated males with both PHP Ia and gonadotropin-independent precocious puberty have been described. The Gs point mutation found in these patients is thought to lead to a protein that is unstable at 37°C and, therefore, to confer renal resistance to PTH. At the lower temperature of the testes, however, the protein is not degraded. In this setting, the stable but mutated protein is constitutively active and stimulates the Leydig cell, in a manner similar to the skeletal effects of the Gs gene.

Patients with PHP type Ib and gonadotropin-independent precocious puberty have been described. The Gs gene from their fathers, they exhibit pseudo-PHP; when they inherit the mutant Gs gene from their mothers, they exhibit PHP. This pattern, in which the phenotype depends on the parent of origin, is termed genetic imprinting; mice with targeted ablation of the Gs gene (GNAS1) also display such imprinting.

The observation of a phenotype in a heterozygous "loss of function" mutation in Gs is in contrast to the findings in mice with targeted deletions of the other G genes (G2, G13), in which a phenotype is observed only in the homozygous state. The fact that the GNAS1 gene is imprinted has partly resolved the dilemma of this dominant phenotype. Notably, mice with targeted ablation of one GNAS1 gene fail to express mRNA in the renal cortex when

AHO, Albright’s hereditary osteodystrophy; cAMP, cyclic adenosine monophosphate; PO4, phosphate.

the mutant gene is inherited from the mother but have normal expression in the cortex when the mutant gene is inherited from the father. No such imprinting pattern is seen in the inner medulla; this finding correlates with demonstration of PTH but not vasopressin resistance in the mice (and patients).

Patients with PHP type Ib present with hypocalcemia and high PTH levels, and PTH infusions fail to increase urinary cAMP production. However, this disorder is not accompanied by any of the clinical features of AHO, nor is it associated with abnormal Gs levels in fibroblasts. Renal resistance to PTH is the only consistent feature of type Ib; therefore, several investigators have postulated that this syndrome is due to an isolated abnormality of the PTH receptor. However, a search for mutations in the coding exons of the receptor gene failed to reveal a functional receptor abnormality. The target organ manifestations of PHP Ib are variable, with some affected persons demonstrating PTH overactivity in bone and PTH resistance in kidney. Cultured osteoblast-like cells from a patient with this disorder demonstrated normal cAMP responsiveness to PTH, despite the lack of renal responsiveness.

The locus responsible for PHP Ib has been found to reside on chromosome 20q13.3, the same region that contains the GNAS1 gene, encoding Gs. The disease is inherited with the imprinting characteristic of PHP Ia, but mapping studies suggest that the disease mutations are close to but distinct from the Gs-coding region; furthermore, some kindreds have no abnormalities in Gs exonic sequences. In contrast, in one family, a 3-base-pair deletion in the Gs gene was found in three brothers with the syndrome of PHP Ib and in their unaffected mother. In vitro studies demonstrated that this mutation prevented coupling of Gs to the PTH/PTHrP

![Figure 26-33](Image) Daughter (left) and mother (right) with pseudohypoparathyroidism and Albright’s hereditary osteodystrophy.

receptor, but not to the TSH or LH receptors. The mutations in a large majority of patients, which do not involve the \( G_s \)-coding region, remain to be defined.

Several patients with AHO and PTH resistance have been found to have normal \( G_s \) activity; the disorder in this subgroup has been designated PHP Ic. Biochemical characterization in one case revealed a significant decrease in the manganese-stimulated adenylate cyclase activity in fibroblast membranes of the affected person, raising the possibility that a second defect in the cAMP pathway may lead to the phenotype of PHP Ic. In a more recently analyzed patient with PHP Ic, a small deletion in the \( G_s \) gene blocked activation by receptors but did not change \( G_s \) activity in the usual in vitro assays.

A second bone disorder distinct from AHO has been associated with \( G_s \) gene mutations that are paternally inherited. These patients have progressive osseous heteroplasia, a disabling disorder associated with ossification of skin, muscle, and other connective tissue.

In PHP II, PTH infusions increase urinary cAMP normally; however, PTH does not elicit a phosphaturic response. In this syndrome, as in PHP Ib, signs of AHO or resistance to other hormones are lacking, but unlike in PHP Ib, the disorder is not familial in origin. The age at onset of this disorder is variable, ranging from infancy to senescence, suggesting that it is an acquired defect or that the biochemical phenotype may be unmasked by intercurrent abnormalities. A subset of patients with myotonic dystrophy display the biochemical features of PHP II, the degree of PTH resistance correlating with the degree of expansion of the pathogenetic CTG repeats in the myotonin protein kinase gene. A similar biochemical phenotype can also be observed in vitamin D deficiency, and some authors have suggested that PHP II is a manifestation of vitamin D deficiency rather than a distinct clinical entity.

Minagawa and colleagues reported on cases of three neonates with no signs of rickets and with normal levels of vitamin D who presented with transient PHP II that resolved at about 6 months of age. These workers postulated that PTH responsiveness is subject to maturation during fetal and neonatal development. PHP II, therefore, seems to reflect a heterogeneous clinical disorder associated with defects in PTH responsiveness distal to cAMP generation or involving a separate signal transduction pathway.

The resistance to PTH in PHP has not been documented in bone cells; rather, several patients with PHP Ib have been reported to have skeletal changes consistent with hyperparathyroidism. Patients with PHP have lower bone density than that in normal persons and hypoparathyroid patients. Basal urinary hydroxyproline excretion in patients with PHP is twice that in hyperparathyroid patients, and they have similar increases in response to parathyroid extract. Because the markers of bone turnover in patients with PHP are not as high as those in hyperparathyroid patients with similar or lower PTH levels, it has been postulated by some authors that the PTH resistance in bone is relative. However, normal cAMP response has been documented in osteoblasts isolated from patients with PHP Ia and PHP Ib. This finding suggests that the hypocalemia in PHP is not secondary to skeletal resistance but is a consequence of the renal resistance to PTH that results in both increased urinary calcium losses and impaired 25(OH)D \( \rightarrow \) hydroxylation. The lack of activation of vitamin D results in diminished intestinal calcium absorption and osteomalacia, both of which further exacerbate the hypocalemia. Deficiency of 1,25(OH)\(_2\)D \( \rightarrow \) and the resultant hypocalemia can, in turn, impair the phosphaturic responses to PTH but not the urinary cAMP responses to PTH; therefore, it is imperative that studies to confirm the diagnosis of PHP II be performed in normocalcemic patients who have normal vitamin D status.
Hypocalcemia secondary to vitamin D deficiency or resistance to the biologic effects of 1,25(OH)\textsubscript{2}D\textsubscript{3} is easily differentiated from the hypocalcemia of hyperparathyroidism by routine clinical and laboratory evaluation. The primary cause of hypocalcemia in vitamin D deficiency is decreased intestinal absorption of calcium. In the setting of normal renal function, the hypocalcemia of vitamin D deficiency, unlike that of hypoparathyroidism, is accompanied by hypophosphatemia and increased renal phosphate clearance. This increase in phosphate clearance is a direct result of compensatory (secondary) hyperparathyroidism. The hyperparathyroidism is a consequence of the hypocalcemic stimulus to PTH secretion and the stimulation of PTH gene expression and parathyroid cell proliferation caused by hypocalcemia (see “Parathyroid Hormone Biosynthesis” earlier). Therefore, measurement of serum phosphate and PTH are very useful in distinguishing these disorders from hyperparathyroidism. The secondary hyperparathyroidism results in increased calcium mobilization from the skeleton, increased renal reabsorption of calcium, and increased renal 1-hydroxylation of 25(OH)D. In severe vitamin D deficiency, the increased levels of PTH no longer lead to increased bone resorption, perhaps because osteoclasts appear not to resorb unmineralized osteoid.

In profound vitamin D deficiency, the level of 1.25(OH)\textsubscript{2}D\textsubscript{3} is usually low; in moderate vitamin D deficiency, the stimulation of the renal 1-hydroxylase by PTH can result in a normal or even elevated 1.25(OH)\textsubscript{2}D\textsubscript{3} level. These high levels of 1.25(OH)\textsubscript{2}D\textsubscript{3} reflect the action of PTH on the renal 1-hydroxylase. The ineffectiveness of the high levels of total 1.25(OH)\textsubscript{2}D\textsubscript{3} to normalize serum calcium may be explained by increased binding of this metabolite to vitamin D-binding protein when the levels of 25(OH)D are very low.

**Vitamin D Deficiency**

Because the two sources of vitamin D are the diet and cutaneous synthesis after ultraviolet radiation, lack of solar radiation and decreased intake or impaired absorption of vitamin D can lead to vitamin D deficiency. As the population has become increasingly educated about the risks of skin cancer from solar radiation, the avoidance of long periods of intense sun exposure, coupled with the use of high-SPF (sun protection factor) sun blocks, has resulted in increased reliance on dietary sources of vitamin D. The RDA for vitamin D is 200 IU; however, in the absence of solar exposure, this recommendation is two to three times lower than that required to prevent vitamin D deficiency.

Vitamin D is present in many food sources, both vegetable and animal. In addition, many prepared foods, especially cereals, are fortified with vitamin D. Although dairy products have been fortified with vitamin D as well, the actual amount of vitamin D provided does not correlate well with the purported content. The vitamin D derived from vegetable sources is vitamin D\textsubscript{3}, and that from animal sources is vitamin D\textsubscript{2}. These two forms of vitamin D are metabolized identically and have equivalent biologic potency in humans. Both forms have been used to fortify foods.

Early vitamin D deficiency can be detected when the serum level of 25(OH)D falls below 15 ng/dL, because this level has been shown to be associated with the development of secondary hyperparathyroidism. Although elderly, homebound individuals are at high risk, several studies have demonstrated that vitamin D deficiency is prevalent in the general population (reviewed in reference 618). The clinical relevance of this vitamin D deficiency has been confirmed by a study demonstrating that vitamin D administration (800 IU/day) to an ambulatory elderly population decreases serum PTH levels as well as the incidence of hip fracture.

Malabsorption also remains an important cause of vitamin D deficiency in all age groups. Because vitamin D is a fat-soluble vitamin, its absorption is dependent on emulsification by bile acids. Any cause of fat malabsorption or short bowel syndrome can result in vitamin D deficiency; therefore, malabsorption should be ruled out in patients with low 25(OH)D levels (<8 ng/dL).

**Accelerated Loss of Vitamin D**

25-Hydroxyvitamin D and 1,25(OH)\textsubscript{2}D\textsubscript{3} are secreted with bile salts and undergo enterohepatic circulation; therefore, intestinal disease may also result in vitamin D deficiency owing to excessive losses. Increased metabolism of vitamin D, leading to low blood levels of 25(OH)D, is seen in individuals given anticonvulsant medications and antituberculous therapy. Phenobarbital, primidone, phenytoin, rifampin, and glutethimide have all been reported to accelerate the hepatic inactivation of vitamin D.

**Impaired 25-Hydroxylation of Vitamin D**

The vitamin D that is absorbed undergoes 25-hydroxylation in the liver; therefore, severe hepatic parenchymal damage can result in 25(OH)D deficiency. Clinically, severe vitamin D deficiency secondary to liver disease is rare, because the degree of hepatic destruction necessary to impair 25-hydroxylation is incompatible with long-term survival. However, isoniazid has been shown to decrease the 25-hydroxylation of vitamin D. Two kindreds have been described in whom the clinical and biochemical presentations and therapeutic responses suggest an inherited 25-hydroxylation defect.

**Impaired 1-Hydroxylation of 25-Hydroxyvitamin D**

The clinical relevance of this vitamin D deficiency has been confirmed by a study demonstrating that vitamin D administration (800 IU/day) to an ambulatory elderly population decreases serum PTH levels as well as the incidence of hip fracture.

The metabolic consequences of chronic renal failure on the parathyroid glands and the skeleton are complex (see Chapter 27). Impaired renal 1-hydroxylation leads to decreased intestinal absorption of calcium, resulting in hypocalcemia. The diminished phosphate clearance associated with renal failure leads to elevated levels of blood phosphate; this change, in turn, lowers levels of calcium and 1,25(OH)\textsubscript{2}D\textsubscript{3}. The resultant secondary hyperparathyroidism increases release of calcium and phosphate from bone; however, because of the renal insufficiency, PTH does not have a phosphaturic effect. As a result, the increased serum phosphate rises further.

Oral phosphate binders are used to lower blood phosphate. Calcium-containing antacids are now used as oral phosphate binders, in preference to the more toxic aluminum-containing antacids (see Chapter 27). Calcium administration also attenuates the hypocalcemic stimulus to parathyroid secretion. 1,25-Dihydroxyvitamin D\textsubscript{3} therapy is crucial for the absorption of this calcium and should be instituted early in the course of renal failure (when the creatinine clearance falls below 30 to 40 mL/min) to avoid the development of secondary hyperparathyroidism, with careful monitoring to avoid hypercalcemia. Once secondary hyperparathyroidism has developed, pharmacologic doses of 1,25(OH)\textsubscript{2}D\textsubscript{3} delivered intravenously or orally may be required to suppress PTH gene transcription and parathyroid cellular proliferation.
of malignancies whose proliferation is inhibited by pharmacologic doses of 1,25(OH)\(_2\)D\(_3\).

Decreased levels of 1,25(OH)\(_2\)D\(_3\) may also be observed in patients taking ketoconazole\(^{61}\) and in those with oncogenic osteomalacia\(^{28}\) (see Chapter 27).

A rare heritable defect of vitamin D activation has been described in several kindreds. Biochemically, vitamin D-dependent rickets type I (VDDR I) is characterized by hypocalcemia and secondary hyperparathyroidism. The only feature that differentiates this disorder from dietary vitamin D deficiency is the presence of normal or elevated levels of vitamin D and 25(OH)D accompanied by low levels of 1,25(OH)\(_2\)D\(_3\).\(^{62,63}\) The disease is inherited in an autosomal recessive fashion; those affected present in infancy with rickets, osteomalacia, and seizures. Cloning of the 1-hydroxylase gene has confirmed that mutation of this gene constitutes the molecular basis for the disorder.\(^{64,65,66}\) and as expected, physiologic replacement doses of 1-hydroxylated metabolites of vitamin D result in clinical remission.\(^{67,68}\)

**Target Organ Resistance to 1,25-Dihydroxyvitamin D**

A second rare inherited disorder characterized by resistance to the biologic actions of 1,25(OH)\(_2\)D\(_3\) has been described in several kindreds. This disorder, referred to as vitamin D-dependent rickets type II (VDDR II), is also characterized by autosomal recessive inheritance. Its biochemical presentation, with hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism, resembles that of vitamin D deficiency, but it is accompanied by elevated levels of 1,25(OH)\(_2\)D\(_3\). The molecular basis for this disease is mutation of the vitamin D receptor gene (VDR), resulting in impaired target organ responsiveness. Most of the mutations that have been described involve the DNA binding domain of the receptor.\(^{69,70,71,72,73}\) These mutations result in a decreased affinity of the receptor for its response elements on target genes,\(^{74,75}\) leading to impaired regulation of these genes. Mutations in the hormone-binding domain\(^{76}\) of the receptor have also been described in kindreds with VDDR II.

The clinical presentation of VDDR II is variable; however, most patients present in infancy with rickets, hypophosphatemia, and seizures, although presentation in late adolescence has also been described.\(^{77}\) Alopecia totalis, developing in the first 2 years of life, is present in some kindreds.\(^{78}\) The finding of alopecia in mice with VDR mutations\(^{79,80}\) confirms the association of alopecia with disruption of the vitamin D receptor gene.

Because of the target organ resistance to the active metabolite of vitamin D, there is no ideal treatment for VDDR II. Pharmacologic doses of vitamin D, 25(OH)D, 24,25(OH)\(_2\)D, and 1,25(OH)\(_2\)D\(_3\) have been administered in an attempt to overcome this target organ resistance.\(^{81,82,83}\) with variable effects. In those patients in whom the hypocalcemia and osteomalacia are resistant to such therapeutic interventions, parenteral calcium infusions have been used to heal osteomalacic lesions.\(^{84}\) Studies in VDR-ablated mice have demonstrated that maintenance of normal mineral ion homeostasis prevents all of the complications of VDR ablation except alopecia.\(^{85,86}\)

On the basis of these observations, patients with VDR mutations should receive early and aggressive treatment to prevent skeletal abnormalities and parathyroid hyperplasia. Lifelong therapy is usually required, although spontaneous remissions off therapy have been described.\(^{87,88,89,90}\) The pathophysiology of the spontaneous remissions is not well understood, because the underlying genetic defect remains. It is likely that these "remissions" reflect compensated calcium homeostasis that obtains once the needs of the growing skeleton are met. In support of this hypothesis is a report of a relapse in a pregnant woman, followed by a remission post partum.\(^{91}\)

Phenytoin causes target organ resistance to the biologic effects of 1,25(OH)\(_2\)D\(_3\), in addition to its acceleration of the hepatic catabolism of vitamin D metabolites. Phenytoin has been shown to impair intestinal calcium absorption in vivo in rats\(^{92}\) and to impair PTH- and 1,25(OH)\(_2\)D\(_3\)-mediated bone resorption in vitro. Combination chemotherapy with 5-fluorouracil and low-dose leucovorin has been reported to cause hypocalcemia in 65% of patients, associated with an acute decrease in plasma 1,25(OH)\(_2\)D\(_3\) levels.\(^{93}\)
Other Causes of Hypocalcemia

Excessive Deposition into the Skeleton

Excessive deposition of calcium into the skeleton can occur in association with osteoblastic metastases, with chondrosarcomas, 93 or in the hungry bone syndrome. This syndrome is characterized by prolonged hypocalcemia, hypocalcinuria, and hypophosphatemia following parathyroidectomy for primary hyperparathyroidism (see "Primary Hyperparathyroidism" earlier). It is a consequence of remineralization of a skeleton that has been subjected to the bone-resorbing effects of PTH over a prolonged period. Hungry bone syndrome can also be observed after treatment of other diseases that are associated with excessive bone resorption. It has been described following radioactive iodine treatment for Graves’ disease. 113

Chelation

Decreases in ionized calcium have been reported with foscarnet, a pyrophosphate analogue that is used as an antiviral agent. 29 This effect may be secondary to complex formation between ionized calcium and the drug.

Hyperphosphatemia, due to phosphate administration or rapid destruction of soft tissue (e.g., with rhabdomyolysis or chemotherapy of hematologic malignancies), may produce profound hypocalcemia by directly complexing and precipitating calcium in bone or soft tissues, by inhibiting bone resorption, and by blocking renal synthesis of 1,25(OH)2 D3 (see "Hyperphosphatemia" later).

Massive infusions of citrated blood products may cause hypocalcemia, presumably because citrate complexes calcium in the recipient's plasma. 29 Large doses of ethylenediaminetetraacetic acid (EDTA)-containing radiographic contrast dyes have also been reported to cause hypocalcemia. Hypocalcemia, due to formation of complexes of calcium and fluoride, has been reported with hydrofluoric acid burns 159 and ingestion. 159

Neonatal Hypocalcemia

Neonatal hypocalcemia is seen in infants of hyperparathyroid mothers and of diabetic mothers, in premature infants, and in infants with birth asphyxia. The cause of hypocalcemia in infants of diabetic mothers is probably multifactorial. Prematurity per se does not account for the higher incidence. 106 The response of premature infants and infants of diabetic mothers to exogenous PTH suggests that functional hypoparathyroidism may account in part for the increased hypocalcemia in these two populations. 113, 116 The hypocalcemia in infants of hyperparathyroid mothers is presumably secondary to the maternal hypercalcemia, which in turn suppresses fetal parathyroid function. 159

Human Immunodeficiency Virus Infection

Hypocalcemia is 6 times more prevalent in human immunodeficiency virus (HIV)-infected patients than in the general population. 110 Although hypocalcemia is often a consequence of antiretroviral and antibiotic or antifungal therapy, vitamin D deficiency and hypomagnesemia are also common in patients with AIDS. Impaired parathyroid responsiveness to hypocalcemia has also been documented.

Critical Illness

Hypocalcemia is commonly seen in critically ill patients and is thought to be a reflection of parathyroid gland suppression, failure to activate vitamin D, calcium chelation or sequestration, and hypomagnesemia. However, one study has demonstrated an increased basal level and secretory response of PTH to lowering serum calcium in both septic and nonseptic intensive care unit (ICU) patients. 29 A correlation between cytokine levels and hypocalcemia was noted in this and other studies, suggesting that these inflammatory agents may play a role in redistribution of calcium to the intracellular or other pools.

Severe acute pancreatitis is often associated with hypocalcemia, and this association is a negative prognostic indicator. The hypocalcemia occurs shortly after the onset of the pancreatitis and is associated with an increase in PTH levels, suggesting that parathyroid function is normal. It has long been thought that this hypocalcemia is secondary to deposition of calcium "soaps" consisting of calcium and fatty acids. Supporting this hypothesis, studies in a patient with a pancreatic fistula demonstrated hypocalcemia (calcium concentration of 4.3 mg/dL).

* Molecular weight (MW) shown is for the usual chemical form, including water molecules (e.g., MgSO₄· 7 H₂O).

Other formulations exist. Those shown are among those approved in the United States. Phosphate preparations contain buffered mixtures of monobasic (H₂PO₄⁻) and dibasic (HPO₄²⁻) ions; the phosphorus content therefore is specified in millimoles. Oral phosphates contain 7 mEq sodium and potassium per capsule (sodium/potassium form) or 14 mEq potassium/capsule (potassium form). Parenteral solutions typically contain 4 mEq of sodium or potassium per mL.

in the setting of high levels of calcium (26 mg/dL) and fatty acids in ascitic fluid. Subsequent studies in a rat model supported this finding and demonstrated that oleate has a high binding capacity for calcium. However, other investigations in a porcine model of experimental pancreatitis have demonstrated that hypocalcemia does not occur if the animals are subjected to thyroidectomy before the induction of pancreatitis. This finding suggests a role for calcitonin in the development of hypocalcemia with acute pancreatitis, although several clinical studies have documented normal calcitonin levels in hypocalcemic persons with pancreatitis. Severe hypocalcemia with hypercalcitoninemia and hypophosphatemia has been reported in patients with the toxic shock syndrome or sepsis and in critically ill patients. As in acute pancreatitis, this hypocalcemia is usually accompanied by increases in serum levels of PTH, and the degree of hypocalcemia is a negative prognostic indicator. The mechanism of hypocalcemia in these patients is likely to be heterogeneous and has not been clearly defined.
hours with close monitoring of calcium levels. In hypocalcemia associated with hypomagnesemia, magnesium replacement also is required. Magnesium should be given intravenously. 100 mEq infused over 24 hours in the acute setting. Because most of the parenteral magnesium is excreted in the urine, oral magnesium oxide should be instituted as soon as possible for repletion of body stores. Special caution and use of reduced doses are necessary in administering magnesium to patients in renal failure (see “Disorders of Magnesium Metabolism” later).

The treatment of hypocalcemia should be directed at the underlying disorder. In all cases, replacement with exogenous calcium (1 to 3 g of elemental calcium daily) should be instituted. Calcium carbonate is the least expensive formulation but requires acidification for efficient absorption. This requirement becomes important in patients with achlorhydria and those in whom gastric acid production is being suppressed with pharmacologic agents. Notable in this respect is the acid-buffering capacity of calcium carbonate. Because of this, it is recommended that patients take their calcium carbonate supplements in divided doses of 1 g or less. In such cases, the calcium should be taken with food or citrus drinks to promote maximal absorption.

In cases of vitamin D deficiency or resistance, the metabolite of vitamin D chosen depends on the underlying disorder. If impaired renal 1-hydroxylation is present, such as in renal failure, hyperparathyroidism (or PTH resistance), or the vitamin D-dependent rickets syndromes, metabolites that do not require this modification should be administered (calciotrol 0.25 to 1 µg per day or dihydrotachysterol 0.2 to 1 mg/day). If decreased intake or increased losses are the problem, vitamin D should be administered and the treatment directed at the underlying disorder. Initial repletion of stores can be undertaken with 50,000 IU of vitamin D daily for 2 to 3 weeks, followed by weekly or bimonthly administration until the underlying problem has been corrected.

In patients with resistance to vitamin D, such as those receiving phenytoin, high doses (50,000 IU one to three times weekly) should be used as maintenance therapy. In other patients, once treatment of the underlying disorder and repletion of body stores have been addressed, two multivitamins (800 IU) should provide sufficient maintenance therapy. In cases of severe malabsorption, vitamin D can be administered parenterally (in intravenous hyperalimentation formulations or as intramuscular injections of as much as 500,000 IU every 6 months).

Patients should be monitored closely both to assess response to therapy and to prevent therapeutic complications. Serum calcium should be monitored frequently (daily with profound hypocalcemia, weekly with moderate hypocalcemia) for the first month of therapy. Concomitant with resolution of hypocalcemia, the serum PTH level should decline as the secondary hyperparathyroidism resolves. Measurement of serum PTH and assessment of 24-hour urinary calcium excretion should be performed within 2 to 4 weeks of institution of therapy. The urinary calcium measurement reflects the effect of therapy on the patient’s ability to absorb calcium. In addition, it provides important information on which to base therapeutic modifications to avoid nephrolithiasis.

Once normalization of serum and urinary calcium and a decrease in PTH levels are observed, a transition from aggressive replacement therapy to maintenance therapy should be undertaken to prevent hypercalcemia and nephro lithiasis. These same parameters should be monitored 1 and 3 months after a dosage change to assess the effect of the therapeutic intervention. Monitoring of alkaline phosphatase levels can also be performed at this time. Alkaline phosphatase levels may actually increase soon after treatment is started because of healing of the osteomalacic lesions; however, by 3 to 4 months after institution of therapy, a clear downward trend should be observed. Alkaline phosphatase and PTH values may remain elevated for 6 to 12 months after institution of therapy; persistence of elevated values should not be a cause for alarm, provided that levels are declining and that the other parameters suggest that therapy is effective.

The treatment of hyperparathyroidism is similar to that of vitamin D deficiency, with the exception that these patients have impaired renal 1-hydroxylation of 25(OH)D and therefore require treatment with 1-hydroxylated metabolites. PTH has been used experimentally for the treatment of hyperparathyroidism but is not approved for therapy. Further work is needed to determine the role of this expensive parenteral therapy. Oral calcium and 1-hydroxylated vitamin D metabolites, therefore, remain the mainstay of therapy. Monitoring of serum and urinary calcium levels should be performed as in the treatment of vitamin D deficiency. Therapy in these patients is lifelong; accordingly, careful monitoring is required to avoid renal or hypercalcemic complications. The aim of therapy should be to maintain serum calcium in the low-normal range without causing frank hypercalcuria. Because PTH plays an important role in renal calcium reabsorption, difficulties are often encountered attaining these therapeutic goals. In such cases, renal calcium losses can be minimized by the addition of a thiazide diuretic to the treatment regimen.

One of the frustrations often encountered in treating patients with hyperparathyroidism is the fluctuating response to a seemingly stable therapeutic regimen. Episodes of hypercalcemia are occasionally observed without any discernible cause. Because of this, serum calcium should be monitored every 3 months to permit temporary withdrawal of 1,25(OH)2D3 should a hypercalcemic trend be observed. Fortunately, the half-life of this metabolite is short, so that discontinuation for a few days to a week with resumption of a lower dose is usually efficacious.

All patients receiving vitamin D metabolites and calcium need to be aware of potential therapeutic complications. The mild symptoms of hypercalcemia must be emphasized to the patient. It is essential that these patients be aware that their calcium level should be monitored more frequently during intercurrent illnesses that may affect calcium absorption or hydration status, to prevent the development of hypocalcemia or severe hypercalcemia.
DISORDERS OF PHOSPHATE METABOLISM

Hyperphosphatemia

The kidney exerts dominant control over the serum concentration of phosphate by adjusting the rate of tubular phosphate reabsorption, mainly in response to changes in the serum concentration of PTH. At near-normal daily loads of filtered phosphate, the capacity of the kidney to excrete phosphate is not easily exceeded. Consequently, when hyperphosphatemia occurs, it is generally in the setting of significantly impaired renal function, hypoparathyroidism, or a greatly increased flux of phosphate into the extracellular fluid, or some combination of these factors (Table 26-7).

The most common cause of hyperphosphatemia is acute or chronic renal failure in which GFR is so reduced that the usual daily load of phosphate cannot be excreted at a normal level of serum phosphate, despite maximal inhibition of phosphate reabsorption in the remaining functional nephrons. In hypoparathyroidism (or pseudohypoparathyroidism), serum phosphate levels may rise to levels as high as 6 to 8 mg/dL, owing to loss of the tonic inhibitory effect of PTH on phosphate reabsorption. The hyperphosphatemia of hypoparathyroidism is only partly due to the absence of PTH per se. Hypocalcemia may further impair phosphate clearance in this setting, and correction of hypocalcemia by treatment with vitamin D metabolites and oral calcium may reduce serum phosphate, for example, even though PTH levels remain low, a response attributed to a direct renal tubular phosphaturic effect of the raised serum calcium level.

Other circumstances in which renal tubular phosphate excretion is decreased, in the absence of renal failure, include (1) acromegaly, or heparin, and (3) tumoral calcinosis. Tumoral calcinosis is an unusual disorder of unknown cause that appears frequently to have a genetic basis consistent with autosomal recessive inheritance, although dominant transmission also has been reported. Affected patients may display focal hyperostosis, large, lobulated perilobular ectopic calcifications, especially around shoulders or hips; hyperphosphatemia due to increased renal tubular reabsorption of phosphate; increased serum 1,25(OH)2D3 levels and intestinal hyperabsorption of calcium; and increased intestinal calcium absorption, consistent with the elevated serum 1,25(OH)2D3 concentration. The disorder may present in childhood or adulthood, is more common in blacks, and is lifelong, with a tendency for the tumoral calcifications to progress at affected sites.

Tumoral calcinosis appears to result from a primary overproduction of 1,25(OH)2D3, although unlike in idiopathic hypercalciuria, urinary calcium usually is not high, in a response attributed to a direct renal tubular phosphaturic effect of the raised serum calcium level.

Other circumstances in which renal tubular phosphate excretion is decreased, in the absence of renal failure, include (1) acromegaly, or heparin, and (3) tumoral calcinosis. Tumoral calcinosis is an unusual disorder of unknown cause that appears frequently to have a genetic basis consistent with autosomal recessive inheritance, although dominant transmission also has been reported. Affected patients may display focal hyperostosis, large, lobulated perilobular ectopic calcifications, especially around shoulders or hips; hyperphosphatemia due to increased renal tubular reabsorption of phosphate; increased serum 1,25(OH)2D3 levels and intestinal hyperabsorption of calcium; and increased intestinal calcium absorption, consistent with the elevated serum 1,25(OH)2D3 concentration. The disorder may present in childhood or adulthood, is more common in blacks, and is lifelong, with a tendency for the tumoral calcifications to progress at affected sites.

Hyperphosphatemia may result from overly rapid administration of therapeutic phosphate preparations, especially if renal function is compromised, or from rapid shifts of phosphate out of cells, most often provoked by mechanical or metabolic injury. Most cases of hyperphosphatemia associated with intestinal phosphate loads have involved children who received phosphate-containing laxatives or enemas. Hyperphosphatemia due to cytolytic release of intracellular phosphate can be quite dramatic, with serum phosphate concentrations of 20 mg/dL or greater. This problem was described initially as a complication of rapid-induction chemotherapy for certain hematologic malignancies, although it also may occur from cellular injury associated with trauma, hyperthermia, overwhelming infection, hemolysis, rhabdomyolysis, or metabolic acidosis.

Most often, hyperphosphatemia is mild and asymptomatic, although chronic hyperphosphatemia is an important factor in the development of secondary hyperparathyroidism in progressive renal failure. The clinical manifestations of acute, severe hyperphosphatemia are related mainly to those of the accompanying hypocalcemia, caused by formation of insoluble calcium phosphate precipitates. Thus, tetany, muscle cramps, paresthesias, and seizures may occur, compounded by
other metabolic disturbances (hyperkalemia, acidosis, hyperuricemia) that frequently coexist. Generalized precipitation of calcium phosphate into soft tissues may produce renal failure.

Therapeutic options for hyperphosphatemia are limited. Volume expansion may be helpful to improve GFR in acute syndromes. Identification and removal of any exogenous sources of phosphate are important, and phosphate-binding aluminum hydroxide antacids may be useful in limiting intestinal phosphate absorption and chelating phosphate secreted into the intestine. Hemodialysis is the most effective approach and should be considered early in severe hyperphosphatemia, especially in the tumor lysis syndrome and particularly if symptomatic hypocalcemia cannot be adequately treated for fear of inducing widespread soft tissue calcification.
Hypophosphatemia

Etiology

Hypophosphatemia may result from one or more of three general mechanisms: increased urinary losses due to decreased net renal tubular phosphate reabsorption; rapid shifts of phosphate from extracellular fluid into the intracellular space or the mineral phase of bone; or, rarely, severe and selective deprivation of dietary phosphate, as may occur with chronic ingestion of large amounts of nonabsorbable aluminum-containing antacids. Fasting or starvation does not lead directly to hypophosphatemia, apparently because phosphate is mobilized from catabolized bone and soft tissue in amounts sufficient to maintain serum phosphate, even during prolonged caloric deprivation. Starvation does induce phosphate deficiency and therefore predisposes the affected person to subsequent hypophosphatemia.

Chronic hypophosphatemia usually can be traced to ongoing renal phosphate wasting. Elevation of serum PTH for any reason (other than renal failure), as in primary hyperparathyroidism or secondary hyperparathyroidism due to vitamin D or calcium deficiency, results in inhibition of tubular phosphate reabsorption and fasting hypophosphatemia. Phosphate clearance also is increased by PTHrP in patients with humoral hypercalcemia of malignancy.

As noted previously, hypercalcemia exerts a direct phosphaturic effect on the renal tubules that is most evident in hypoparathyroid persons but that also may contribute to the hypophosphatemia in primary hyperparathyroidism. Nevertheless, in severely hypercalcemic patients, hypophosphatemia may be masked acutely by accompanying dehydration and reduced GFR. When severe hypocalcemia and hypomagnesemia coexist, selective correction of hypomagnesemia may provoke hypophosphatemia.

as hypocalcemia persists and PTH secretion increases.

Renal phosphate clearance may be increased in a variety of conditions that do not involve increases in PTH or PTHrP. These conditions include the proximal tubular dysfunction associated with Fanconi's syndrome, severe hypokalemia or hypomagnesemia, acute metabolic alkalosis induced by bicarbonate infusion, and exposure to certain drugs or toxins (see Table 26-7). Excessive phosphaturia also may occur in patients with idiopathic hypercalcemia or primary hyperaldosteronism, with severe glycosuria in poorly controlled diabetes, following renal transplantation, and in Rey's syndrome.

Two syndromes familial X-linked hypophosphatemic rickets (XLH) and oncogenic osteomalacia result from renal tubular phosphate wasting that appears to be driven by humoral mechanisms. Involvement of a humoral mediator is clear-cut in oncogenic osteomalacia, as the syndrome resolves following extirpation of the responsible neoplasm. The renal lesion in XLH is still not well characterized by studies in a relevant animal model. Both syndromes include renal tubular phosphate wasting, impaired renal synthesis of 1,25(OH)₂D₃, borderline hypocalcemia, hypocalcuria, and rickets or osteomalacia. Serum PTH generally is normal or only slightly elevated, and 1,25(OH)₂D₃ is inappropriately normal. The bone disease dominates the clinical picture (see Chapter 27).

Rapid egress of extracellular phosphate into cells is the cause of hypophosphatemia that develops acutely during administration of intravenous glucose, insulin therapy for hyperglycemia, or administration of catecholamines (pressors or bronchodilators) or in profound respiratory alkalosis or leukemic blast crisis. Hypophosphatemia in these situations is more pronounced when the underlying phosphate depletion, as in hyperparathyroidism or vitamin D deficiency, or following prolonged malnutrition or with alcoholism or glycosuria. Accelerated uptake of phosphate into cells, principally into muscle and bone, is particularly likely in postsurgical or trauma patients, in whom it may be promoted by high levels of circulating catecholamines and exacerbated by concurrent respiratory alkalosis, fever, volume expansion, sepsis, and hypokalemia. Similar mechanisms may pertain in nonsurgical illnesses such as acute myocardial infarction. Hypophosphatemia complicating administration of hematopoietic growth factors such as erythropoietin or G-CSF is due to the high demand for new intracellular phosphate imposed by rapid cellular proliferation in the bone marrow.

Clinical Features

The clinical significance of hypophosphatemia has been the subject of some controversy and probably depends on the presence and severity of underlying phosphate depletion. Unfortunately, the status of the total-body phosphorus pool is reflected only indirectly by the concentration of phosphate in the extracellular fluid, which contains less than 5% of body phosphorus. Thus, although serum phosphate concentrations generally are used to characterize hypophosphatemia as severe (<11.5 mg/dL, or <0.30.5 mM), moderate (1.52.2 mg/dL, or 0.50.7 mM), or mild (2.23.0 mg/dL, or 0.751.0 mM), the serum phosphate level may be normal or even high (depending on renal function) in the presence of profound intracellular phosphate deficiency. Conversely, it may be low when intracellular phosphate is relatively normal, as following a sudden movement of extracellular phosphate into cells.

The prevalence of severe hypophosphatemia among hospitalized patients is less than 1%, whereas mild or moderate hypophosphatemia may be detected in 2% to 5% of patients. Hypophosphatemia is recognized most often in critically ill patients, alcoholics or other malnourished individuals, diabetics, and those with acute infectious or pulmonary disorders.

The clinical manifestations of severe hypophosphatemia are protean. Among the most common are various neuromuscular symptoms, ranging from progressive lethargy, muscle weakness, and paresthesias to paralysis, coma, and even death, depending on the severity of the phosphate deficiency. Confusion, profound weakness, paralysis, seizures, and other major sequelae generally are limited to patients with serum phosphate concentrations below 0.8 to 1.0 mg/dL.

Biochemical evidence of muscle injury is observed within 1 or 2 days in over a third of patients whose serum phosphate concentrations falls to less than 2 mg/dL. Overt rhabdomyolysis also may occur, especially in the setting of chronic alcoholism with underlying malnutrition and phosphate depletion. However, by the time this problem is recognized, the serum phosphate often has been raised by the large amounts of cellular phosphate released from damaged muscle.

Reversible respiratory failure due to respiratory muscle weakness may preclude successful weaning from ventilatory support. Left ventricular dysfunction, heart failure, and ventricular arrhythmias may result from profound hypophosphatemia but may not be significant if serum phosphate is greater than 1.5 mg/dL. In one study, correction of moderate hypophosphatemia (phosphate level of <2 mg/dL) in patients with septic shock led to a significant increase in blood pressure as well as improvement of left ventricular function and arterial pH. Hematologic sequelae of severe hypophosphatemia include hemolyis, platelet dysfunction with bleeding, and impaired leukocyte function (phagocytosis and killing). Erythrocytes demonstrate increased fragility, altered membrane composition, rigidity, and microspherocytosis; and reduced levels of ATP and 2,3-diphosphoglycerate (2,3-DPG). The reduction in erythrocyte 2,3-DPG impairs oxyhemoglobin dissociation, thereby potentially reducing oxygen delivery to tissues. This problem, together with accelerated hemolysis, may provoke a substantial increase in cardiac output. The blockade in cellular glycolysis becomes demonstrable at levels of serum phosphate between 1 and 2 mg/dL. Glucose intolerance and insulin resistance also have been demonstrable in affected patients.

Treatment

Hypophosphatemia appears most often in acutely or critically ill persons. Accordingly, it is often difficult to discern whether hypophosphatemia is responsible for features of the multiple organ dysfunction commonly encountered in this population. For example, although depression of intracellular high-energy organophosphates has been demonstrated during treatment of diabetic ketoacidosis, and phosphate repletion leads to more rapid recovery of erythrocyte 2,3-DPG concentrations, opinion is divided as to whether phosphate therapy in this setting hastens recovery, prevents complications, or reduces mortality. Nevertheless, because severe hypophosphatemia has been associated in a variety of clinical settings, with serious neuromuscular, cardiovascular, and hematologic dysfunction that is at least partially reversible with phosphate repletion, most authorities now agree that a relatively low threshold for treatment should be adopted.

The decision to correct hypophosphatemia urgently should be guided by the estimated severity of the cellular phosphate deficit, the presence of signs or symptoms suggestive of phosphate depletion, and the overall clinical status of the patient. The presence of renal insufficiency (a risk for iatrogenic hyperphosphatemia), concomitant administration of intravenous glucose (alone or as a component of hyperalimentation solutions), and the potential for aggravating coexistent hypocalcemia also should be considered.

Limited data are available from clinical trials to predict the appropriate dose and rate of phosphate administration. In patients without severe renal insufficiency or hypocalcemia, administration of intravenous phosphate at rates of 2 to 8 mmol/hour of elemental phosphate over 4 to 8 hours frequently corrects hypophosphatemia without provoking hyperphosphatemia or hypocalcemia. Suggested guidelines based on serum phosphate concentration are shown in Table 26-9. It is essential that serum calcium and phosphate be monitored every 6 to 12 hours during and after phosphate therapy, both to detect untoward consequences and because many patients require additional infusions for recurrent hypophosphatemia within 24 to 48 hours of apparently successful repletion. Less acute or severe hypophosphatemia should be managed with oral (or enteral) phosphate supplements if possible, generally given as a total of 1.0 to 2.0 g/day (as elemental...
phosphate) of neutral sodium or potassium phosphate in divided doses three to four times a day (see Table 26-6). In many patients, however,

oral phosphate therapy is limited by gastrointestinal symptoms such as nausea or diarrhea.
DISORDERS OF MAGNESIUM METABOLISM

The fourth most abundant extracellular cation, magnesium, like calcium, plays a critical physiologic role, particularly in neuromuscular function. The importance of intracellular magnesium in energy metabolism, as a cofactor for ATP and a wide variety of enzymes and transporters, is reflected in the fairly global clinical effects that accompany disorders of magnesium homeostasis. Hypomagnesemia and hypermagnesemia are among the most common electrolyte disturbances; one or the other of these abnormalities is observed in as many as 20% of hospitalized patients and even more frequently (i.e., in 30% to 40%) among those admitted to intensive care units.

Hypermagnesemia

Magnesium homeostasis is achieved mainly through highly efficient regulation of tubular magnesium reabsorption in the loop of Henle. As normal kidneys can readily excrete even large amounts of magnesium (i.e., 500 mEq/day), high filtered loads of magnesium rarely cause hypermagnesemia except in patients with severe acute or chronic renal failure. Increased magnesium loads in such cases may arise from ingestion of large amounts of oral magnesium salts, typically given as cathartics or antacids, or from extensive soft tissue ischemia or necrosis in patients with trauma, sepsis, cardiopulmonary arrest, burns, or shock (Table 26-10). Hypermagnesemia may result from parenteral administration of magnesium salts, as when magnesium is used to treat preeclampsia. The infants of such hypermagnesemic mothers may manifest transient hypermagnesemia as well, along with parathyroid suppression and neurobehavioral symptoms. The use of oral magnesium preparations as laxatives may lead to hypermagnesemia if absorption is increased by intestinal ileus, obstruction, or perforation.

The most prominent clinical manifestations of hypermagnesemia are vasodilatation and neuromuscular blockade, which may involve both pre- and postsynaptic inhibition of neuromuscular transmission. Signs and symptoms generally do not appear unless the serum magnesium concentration exceeds 4 mEq/L.

4 mEq/L Hypotension, often refractory to pressors and volume expansion, may be one of the earliest signs of progressive hypermagnesemia. Lethargy, nausea, and weakness, accompanied by reduction in or loss of deep tendon reflexes, may progress to stupor or coma with respiratory insufficiency or quadriparesis at serum concentrations in excess of 8 to 10 mEq/L. Gastrointestinal hypomotility or ileus is common. Facial flushing and pupillary dilatation may be observed. Hypotension may be complicated by a paradoxical relative bradycardia, and other cardiac effects may be evident, including prolongation of the PR, QRS, and QTc intervals and appearance of heart block and, ultimately, asystole as serum concentrations approach 20 mEq/L.

Hypermagnesemia also causes hypocalcemia and increased urinary calcium excretion, the result of both a direct suppression ofPTH secretion and a PTH-independent inhibition of renal tubular calcium reabsorption. Severe hypocalcemia opposes the effect of hypermagnesemia on PTH secretion, so that serum PTH typically remains within the normal range but is still inappropriate for the serum calcium level.

Successful treatment of hypermagnesemia requires identification and interruption of the source of magnesium, together with measures to increase clearance of magnesium from the extracellular fluid. Use of magnesium-free cathartics or enemas to accelerate clearance of ingested magnesium from the gastrointestinal tract, together with vigorous intravenous hydration, generally has been successful in reversing hypermagnesemia. Refractory cases, especially those in patients with advanced renal insufficiency, may require hemodialysis. Intravenous calcium (100 to 200 mg) infusions have been advocated as an effective antidote to hypermagnesemia, and there are examples in which this approach has apparently been successful, at least temporarily.
Hypomagnesemia

Hypomagnesemia may occur because of impaired intestinal absorption of magnesium or defective renal tubular reabsorption of magnesium, or a combination of these (Table 26-11). Because only 1% of the body's magnesium content is present in extracellular fluid, measurements of serum magnesium concentration typically do not adequately reflect total-body magnesium or the magnesium status of the intracellular compartment in critical tissues such as muscle. Thus, patients with deficiency of tissue magnesium may fail to manifest overt hypomagnesemia but will exhibit abnormal retention (i.e., >50% in 24 hours) of infused magnesium, a maneuver that may be employed to assess magnesium status.

Etiology

Intestinal Causes of Hypomagnesemia

Selective dietary magnesium deficiency does not occur, and it is remarkably difficult, in fact, to induce magnesium depletion experimentally by feeding magnesium-deficient diets, probably because renal magnesium conservation is so efficient. Large amounts of magnesium may be lost in chronic diarrheal states (this fluid may contain more than 10 mEq of magnesium per liter), or via intestinal fistulae or prolonged gastrointestinal drainage. More commonly, magnesium becomes trapped within fatty acid "soaps" in disorders associated with chronic malabsorption. In a rare but informative genetic syndrome

termed primary hypomagnesemia, a defect in the saturable component of intestinal magnesium absorption causes hypomagnesemia that can be partially overcome by administering large amounts of oral magnesium. 

Renal Causes of Hypomagnesemia

Renal magnesium wasting may result from a primary tubular transport defect, as occurs in Bartter's syndrome and a number of other rare inherited magnesium-wasting renal tubular disorders (see Table 26-11). Most often, however, it is attributable to an acquired abnormality in tubular magnesium reabsorption. In normal persons, magnesium reabsorption is virtually complete within several days of instituting experimental dietary magnesium deficiency, even before serum magnesium has declined substantially. Thus, the finding of more than 1 mEq/day of urinary magnesium in a frankly hypomagnesemic patient indicates a defect in renal tubular magnesium reabsorption. Acquired primary renal tubular magnesium wasting occurs in various tubulointerstitial disorders, recovery from acute tubular necrosis or obstruction, renal transplantation, various endocrinopathies, alcoholism, and exposure to certain drugs (see Table 26-11).

Hypomagnesemia or magnesium depletion due to subtotal renal reabsorption may complicate a variety of endocrinopathies, including hyperaldosteronism, hyperthyroidism, and disorders associated with hypercalcemia, hypercalciuria, or phosphate depletion. In primary hyperparathyroidism, PTH stimulates increased tubular magnesium reabsorption, but this increase is opposed by a direct tubular effect of hypercalcemia. As a result, the serum magnesium level in primary hyperparathyroidism generally is normal or only slightly reduced. In hypoparathyroidism, serum and urinary magnesium levels are low. The magnesium depletion in hypoparathyroidism is consistent with loss of both the magnesium-retaining action of PTH and the stimulatory effect of 1,25(OH)\(_2\)D on intestinal magnesium absorption.

Diabetes is among the most common medical disorders associated with hypomagnesemia. The severity of the hypomagnesemia in diabetics correlates with indices of glycosuria and poor glycemic control, which suggests that urinary losses of magnesium on the basis of glycosuria may partly explain the magnesium depletion. Rapid correction of hypoglycemia with insulin therapy causes magnesium to enter cells and may further lower the extracellular magnesium concentration during treatment.

Alcoholism is another very common clinical setting in which hypomagnesemia occurs. Magnesium depletion in alcoholism may result in part from nutritional deficiency of magnesium, overall caloric starvation and ketosis, and gastrointestinal losses due to vomiting or diarrhea, but an acute magnesium effect of alcohol ingestion probably plays the major role. This effect of alcohol is most evident when blood alcohol levels are rising and may be related to transient suppression of PTH secretion. Other factors that may contribute to hypomagnesemia in alcoholism include pancreatitis, malabsorption, secondary hyperaldosteronism, respiratory alkalosis, and elevation in plasma catecholamines, which increase intracellular sequestration of magnesium.

Numerous drugs have been identified as causes of defective renal tubular magnesium reabsorption and hypomagnesemia. These agents include diuretics of all classes (especially loop diuretics), cisplatin, pentamidine, cyclosporine, aminoglycosides, foscarnet, and amphotericin. Most often, drug-induced hypomagnesemia is mild and reversible, particularly that associated with diuretic therapy. In over half of patients undergoing cisplatin therapy, hypomagnesemia is noted within days or weeks and roughly half of those who develop the abnormality exhibit persistent hypomagnesemia many months or even years later. The median duration of hypomagnesemia in cisplatin-treated patients is about 2 months, but recovery has been observed up to 2 years after treatment. Cisplatin may induce a more generalized nephropathy and azotemic renal failure, but the magnesium wasting appears to be an isolated functional abnormality. There is some evidence that the renal magnesium-wasting syndrome can be prevented by intravenous magnesium administration (24 to 40 mEq) before or during cisplatin infusion. Such findings suggest that cisplatin may selectively impair magnesium reabsorption by binding competitively to sites or cells involved in binding and transport of magnesium.

A syndrome very similar to that seen with cisplatin therapy is observed frequently in transplant recipients who receive cyclosporin A. Cisplatin may selectively impair magnesium reabsorption by binding competitively to sites or cells involved in binding and transport of magnesium. This abnormality appears to be due mainly to impaired renal 1-hydroxylation of 25(OH)D, although tissue resistance to 1,25(OH)\(_2\)D may also play a role. The serum 1,25(OH)\(_2\)D concentration usually is low during hypomagnesemia, which may result from magnesium depletion per se, parathyroid insufficiency, or coexistent vitamin D deficiency. Deficiency of 1,25(OH)\(_2\)D is probably not the main cause of hypocalcemia in these patients, however,
because hypocalcemia can be rapidly corrected (within hours to days) by magnesium therapy alone, well in advance of any increase in the serum 1,25(OH)₂D₃ concentration.

Therapy of Hypomagnesemia

Mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts (MgCl₂, MgO, or Mg(OH)₂) usually given in divided doses totaling 40 to 60 mEq (480 to 720 mg) per day (see Table 26-6). Diarrhea sometimes occurs with larger doses but generally is not a problem. The gluconate form (supplying 58 mg of magnesium per gram) is said to cause less diarrhea. Patients with malabsorption or ongoing urinary magnesium losses may require chronic oral therapy to avoid recurrent magnesium depletion. Although intestinal magnesium absorption is severely impaired in renal failure, oral magnesium must be administered with great caution in this setting, especially in patients receiving concomitant therapy with 1,25(OH)₂D₃.

Symptomatic or severe hypomagnesemia (magnesium concentration <1 mEq/L), especially if complicated by hypocalcemia, usually signifies magnesium deficits of at least 1 to 2 mEq/kg and is best treated promptly with parenteral magnesium salts. The use of intramuscular magnesium sulfate (MgSO₄) is to be discouraged, as the injections are painful and provide relatively little magnesium (2 mL of 50% MgSO₄ supplies only 8 mEq of magnesium, as compared with typical magnesium deficits in excess of 100 mEq). Moreover, because unretracted sulfate ions also may increase urinary calcium excretion, administration of intravenous magnesium chloride or gluconate probably is the most logical approach to initial parenteral therapy for patients who also may be hypocalcemic.

In adult hypomagnesemic patients with normal renal function, rates of infusion of 2 to 4 mEq/hour (i.e., 50 to 100 mEq/day) generally are needed to maintain serum magnesium concentrations in the range of 2 to 3 mEq/L. Up to 100 mEq/day for 2 days can be safely administered without elevating serum magnesium concentration above 4 mEq/L, whereas doses of 200 mEq/day may increase serum magnesium to 4.5 to 5.5 mEq/L and thus are excessive. In patients with active seizures or other urgent indications, the infusion may be preceded by a slowly administered bolus of 10 to 20 mEq, followed by a higher rate of infusion (i.e., 10 to 15 mEq/hour) for the first 1 or 2 hours only. Patients with normal renal function can readily excrete over 400 mEq/day of magnesium in the urine without becoming hypermagnesemic, but even mild renal failure may greatly limit magnesium excretion. Therefore, doses of magnesium supplements should be reduced two- to threefold and careful serial monitoring of serum magnesium performed in patients with compromised renal function.

It is important to appreciate that a large fraction of parenterally administered magnesium may be excreted in the urine, even in patients with profound magnesium deficiency. Many such patients excrete as much as 50% to 75% of infused magnesium; in normal subjects, this fraction approaches 100%. Moreover, because equilibration of the intracellular and extracellular magnesium pools is relatively slow, it is generally necessary to continue magnesium therapy for 3 to 5 days to achieve adequate repletion of the typical deficit of 1 to 2 mEq/kg. Because serum magnesium may become normal well before tissue stores are repleted, monitoring of urinary magnesium excretion is a more reliable measure of the approach to full repletion, especially after patients are switched to oral therapy.

The need for calcium, potassium, and phosphate supplementation should be considered in the usual clinical setting of hypomagnesemia. Vitamin D deficiency also frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH)D. Use of 1,25(OH)₂D₃ is not necessary, does not hasten recovery, and may actually worsen hypomagnesemia by suppressing PTH secretion and thereby promoting renal magnesium excretion. Initial parenteral magnesium therapy in hypocalcemic patients may produce dramatic hypophosphatemia via the rapid stimulation of PTH secretion. This effect is most likely to be problematic in patients with underlying phosphate depletion (as in malabsorption, alcoholism, or diabetes), in whom it may provoke acute neuromuscular dysfunction, and may be avoided by concomitant intravenous calcium therapy.

Chapter 27 - Metabolic Bone Disease

Lawrence G. Raisz

Joseph A. Lorenzo

STRUCTURE AND FUNCTION OF THE SKELETON

The skeleton is one of the largest organ systems in the body. It consists of a large mineralized matrix and a small but highly active cellular fraction. The skeleton serves the dual functions of maintaining the structure of the body and providing a storehouse of minerals and protein. Imbalance between the structural and the storage functions of the skeleton can be important in the pathogenesis of metabolic bone disease.

Embryology and Anatomy

In the embryo, skeletal development begins with the condensation of mesenchyme into cartilage. Bone formation then occurs through one of two distinct pathways. The growth of long bones and the vertebrae involves endochondral bone formation (Fig. 27-1). The cartilage growth plate cells proliferate and then undergo hypertrophy; this is followed by partial degradation of the matrix, which then mineralizes. The cartilage is invaded by vessels, and the spicules of mineralized cartilage are covered by osteoblasts to form a cancellous or trabecular bone mass (the primary spongiosa). These structures are then resorbed and replaced by trabecular plates made up entirely of bone, termed the secondary spongiosa. This bone undergoes rapid remodeling. In the adult, it is most abundant at the ends of the long bones and in the bodies of the vertebrae.

Intramembranous bone formation occurs adjacent to the cartilage template, typically in flat bones, such as the skull, scapula, and ileum, and on the outer surfaces of long bones. Initially, relatively disorganized woven bone is formed, but this rapidly converts to more organized lamellar bone produced by oriented layers of osteoblasts. The main difference between endochondral and intramembranous bone formation is that the latter does not use calcified cartilage as a direct template for osteoblasts.

Cortical bone is the dense bone that is found, for example, in the shafts of long bones. It makes up 80% of the mass of the skeleton, determines its shape, and provides much of its strength. Modeling of cortical bone involves not only new bone formation but also resorption to alter skeletal shape (see Fig. 27-1). The wide cortex at the epiphyseal plate of long bones must be resorbed because these bones elongate to maintain the narrow tubular structure of the diaphysis.

Although remodeling begins early in cancellous bone, remodeling of cortical bone begins only after the cortex reaches a critical thickness. In smaller animals such as rodents, cortical bone can remain lamellar. In large animals and humans, lamellar cortical bone is gradually replaced through haversian remodeling to form cylindrical osteons.
Bone mineral consists of fibers of type I collagen laid down in layers that have various orientations, which may add to the strength of the matrix. The matrix contains many additional proteins, including small amounts of other collagen types that may be important in the interaction of type I collagen with noncollagen proteins. The noncollagen proteins represent about 10% of the total protein in bone and may serve to direct the formation of fibers, enhance mineralization, strengthen the attachment between cells and matrix, and provide signals for bone remodeling (Table 27-1).

The protein composition of matrix may vary particularly between woven and lamellar bone. These proteins range from the large cell-attachment proteins (e.g., thrombospondin and fibronectin) with molecular masses higher than 400 kd, to the small, vitamin K-dependent gamma-carboxylated proteins, matrix Gla protein and osteocalcin, which are 6-kd calcium-binding proteins. A number of the noncollagen proteins (e.g., biglycan, decorin, bone sialoprotein, osteopontin, and osteoadherin) are highly acidic. In addition to cell-attachment functions of matrix proteins, many noncollagen proteins represent about 10% of the total protein in bone and may serve to direct the formation of fibers, enhance mineralization, strengthen the attachment between cells and matrix, and provide signals for bone remodeling.

sequences, these proteins contain varying amounts of carbohydrate and may be termed glycoproteins or proteoglycans. Noncollagen proteins of bone are often highly phosphorylated, which enables them to bind calcium, and may regulate mineralization. The matrix is also a storehouse for growth factors and their binding proteins (see later).

### Collagen Synthesis

Type I collagen, a rigid, rodlike, insoluble molecule composed of two 1 chains and one 2 chain, consists of repeating triplets of amino acids with glycine in every third position and a high content of proline and lysine residues, which requires ascorbic acid. Collagen is initially synthesized as a soluble propeptide with large nonhelical extensions at both the COOH and NH₂ termini.プロコラーゲン also contains COOH-terminal interchain disulfide bonds that help initiate triple-helix formation. Procollagen is released into the cisternae of the rough endoplasmic reticulum, packaged in the Golgi vesicles, and secreted extracellularly. The procollagen peptides are then removed by specific peptidases.

### Chemistry of Matrix and Mineral

Bone mineral is made up of small, imperfect hydroxyapatite crystals, which contain carbonate, magnesium, sodium, and potassium. When bone forms in the presence of fluoride ions, the fluorapatite crystal is larger and less soluble than hydroxyapatite and may increase bone fragility.

---

**Figure 27-2** Synthesis and assembly of collagen fibrils. To produce mature insoluble collagen molecules, which are further stabilized by intramolecular and intermolecular cross-links. The major cross-links are formed by lysine and hydroxylysine residues that ultimately form pyridinium ring structures (see later).

**Mineralization**

Bone mineral is made up of small, imperfect hydroxyapatite crystals, which contain carbonate, magnesium, sodium, and potassium. When bone forms in the presence of fluoride ions, the fluorapatite crystal is larger and less soluble than hydroxyapatite and may increase bone fragility.
Mineralization occurs by two distinct mechanisms. The initial mineralization of calcified cartilage and woven bone probably occurs by means of matrix vesicles. These membrane-bound bodies are released from chondrocytes and osteoblasts, contain alkaline phosphatase, and can form a nidus for crystallization. In contrast, in lamellar bone, the collagen fibers are tightly packed and matrix vesicles are rarely seen. Mineralization does not occur immediately after collagen deposition, and there is a layer of 10 to 100 µm of unmineralized osteoid between the mineralization front and the osteoblast. Perhaps changes in the packing of the fibrils and in the composition of the noncollagen proteins are required for mineralization. Mineralization of collagen fibrils begins in the hole zones, where there is more room for inorganic ions to accumulate (Fig. 27-3). Mineralization requires calcium, phosphate, and alkaline phosphatase. This process is impaired in vitamin D deficiency and hypophosphatasia.
Osteoblast Differentiation and Function

Bone is formed by osteoblasts, \(^1\) which are highly differentiated cells that have many unique features (Fig. 27-4). They are initially derived from mesenchymal stem cells, which are termed inducible osteoprogenitors. \(^1\) Adult bone also contains less pluripotent bone cell precursors, or committed osteoprogenitors.

Osteoprogenitor cells (or preosteoblasts) replicate and differentiate into active osteoblasts that may exhibit varying phenotypic characteristics. \(^1\) For example, osteoblasts in early development and during repair produce woven bone, whereas more mature osteoblasts produce lamellar bone.

The distribution of noncollagen proteins in cortical and trabecular bone may also differ. The activity of osteoblasts can vary during bone formation. Some cells are tall and closely packed and produce a large amount of matrix in a small area; others are flatter and produce matrix at a slower rate over a larger area. Nevertheless, all differentiated osteoblasts share certain features. They are connected by gap junctions and contain a dense network of rough endoplasmic reticulum and a large Golgi complex. They secrete collagen and noncollagen proteins in an oriented fashion and produce more type I collagen and alkaline phosphatase than other mesenchymal cells. Some products, such as osteocalcin, are produced almost uniquely by osteoblasts; others, such as osteopontin, are produced by a limited number of cell types.

Mature osteoblasts have a finite capacity to produce matrix, and bone formation is sustained by the arrival of new populations of cells at the bone surface. After osteoblasts have completed their matrix formation, they may become embedded in the matrix as osteocytes, may undergo apoptotic cell death, or may be converted to flattened lining cells, which cover a large percentage of the surface of bone with a thin cytoplasmic layer.

The conversion of osteoblasts to osteocytes involves a reduction of, but not a complete loss of, metabolic activity. \(^1\) A critical feature is the development of an extensive network of cytoplasmic connections. The osteoblasts have multiple cell processes that are connected to underlying osteocytes through small canaliculi. After mineralization is complete, the processes persist as connections between osteocytes (Fig. 27-5). This extended syncytium is probably important in maintaining the viability of the osteocytes, which otherwise would be separated from the extracellular fluid.

Initially, osteocytes may continue to synthesize collagen and play a role in mineralization. Later, the major role of the osteocyte-osteoblast syncytium may be to sense mechanical forces. \(^1\) One hypothesis is that small strains produce fluid shear stress in the canaliculi between osteocytes. This effect may result in intracellular signaling through changes in ion channels or in the production of biologically active molecules (e.g., prostaglandins) from the phospholipid membrane.

Cells of the osteoblastic lineage are important not only in forming bone but also in initiating resorption. \(^1\) It is still not clear which cells of the osteoblast lineage activate resorption. However, the nature of the factors that osteoblast-lineage cells produce, which regulate osteoclast formation and activity, is now more clearly understood (see later). Most of the hormonal factors that stimulate bone resorption act on osteoblasts or their precursor cells. Osteoblast-lineage cells also produce factors that regulate resorption, including cytokines, prostaglandins, and growth factors. In cell culture, contact between osteoblastic cells and hematopoietic cells appears to be necessary for osteoclast formation (Fig. 27-6). Osteoblasts may also play a role in initiating bone resorption by releasing enzymes that prepare the bone surface. Hormones and local factors that stimulate bone resorption increase the production of collagenase, other metalloproteinases, and plasminogen activator by osteoblasts. These enzymes may remove the surface proteins of bone, which block the access of osteoclasts to the mineralized matrix. Osteoblasts may also influence the development and maintenance of the marrow because they are sources of growth factors, cytokines, and chemokines that may act on hematopoietic cells.
Osteoclast Differentiation and Function

Although osteoclasts are derived from hematopoietic progenitors, their relation to other hematopoietic lineages is not fully defined. Hematopoietic stem cells under the direction of granulocyte-macrophage colony-stimulating factor (GM-CSF) and colony-stimulating factor 1 (macrophage colony-stimulating factor [M-CSF]) may differentiate into either monocyte-macrophages or preosteoclasts. The latter fuse to form highly differentiated multinucleated osteoclasts that resorb bone (see Fig. 27-6). Progression through the osteoclast pathway probably involves multiple local and systemic hormones that may include 1,25-dihydroxyvitamin D (1,25(OH)₂ D), prostaglandins, and the cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF).

The nature of the osteoblast-lineage cell products, which directly regulate osteoclast formation and function, has been clarified. The principal Stimulator of osteoclast formation is a member of the TNF protein family, termed receptor activator of nuclear factor B ligand (RANKL). This protein was originally identified as a product of activated T lymphocytes but is also recognized as a critical Stimulator of osteoclastogenesis.

Production of RANKL in osteoblast-lineage cells is stimulated by essentially all agents that enhance osteoclast formation, including parathyroid hormone (PTH), 1,25(OH)₂ D, prostaglandins, and many cytokines. Mice deficient in RANKL do not form osteoclasts and have osteopetrosis. In contrast, injection of RANKL into mice stimulates osteoclast formation and bone resorption. RANKL is produced as a membrane protein. In activated T lymphocytes, however, RANKL is cleaved from the cell membrane and is released as a soluble factor. It is unclear whether similar events occur in osteoblast-lineage cells, although there is some evidence that cleavage and release of soluble RANKL occur in malignant cells that metastasize to bone.

In addition to RANKL, osteoblast-lineage cells produce an inhibitor of osteoclastogenesis, called osteoprotegerin (OPG). OPG is a soluble receptor for RANKL that binds this ligand and prevents interaction of RANKL with its bioactive receptor RANK. OPG is produced widely. In bone marrow cultures, a number of stimulators of resorption, including PTH, 1,25(OH)₂ D, and prostaglandin E₂ (PGE₂), inhibit OPG production. Hence, for these factors there is a reciprocal relationship between RANKL stimulation and OPG inhibition that causes activation of osteoclastogenesis and enhanced resorption. Mice deficient in OPG have osteoporosis, whereas mice that overexpress OPG have increased bone mass. These results, together with those for RANKL-deficient mice or mice injected with RANKL, demonstrate that osteoclast-mediated bone resorption is tightly regulated by the combined actions of RANKL and OPG.

The active receptor for RANK is RANK, a member of the TNF receptor family. Osteoclasts and their immediate precursor cells express RANK. Binding of RANKL to RANK activates a series of intracellular pathways that activate nuclear factor B and an N-terminal kinase (JNK). The TNF receptor-associated factors (TRAFs) bind RANK intracellularly and are involved in RANK responses. Mice deficient in TRAF-6, like those deficient in RANK, develop osteopetrosis. In addition to its effects on bone, the RANK-RANKL system is involved in lymphocyte function as well as breast and lymph node development. Mature osteoclasts express RANK, and treatment of these cells with RANKL inhibits programmed cell death (apoptosis) and stimulates resorptive activity.

In addition to RANKL, M-CSF is essential for osteoclast formation. Mice deficient in M-CSF have osteopetrosis and few osteoclasts. In cultures of isolated osteoclast precursor cells, both M-CSF and RANKL must be present for mature osteoclasts to form. M-CSF enhances RANK production in osteoclast precursors and inhibits apoptosis of both osteoclast precursors and mature osteoclasts. Binding of c-fms by M-CSF activates tyrosine kinase activity in the receptor, which initiates a series of intracellular events.

The formation of multinucleated osteoclast-like cells in vitro requires both hematopoietic precursors and cells of the osteoblastic lineage. In vivo or in cultures with devitalized bone, mononuclear preosteoclasts attach to the bone surface and form multinucleated osteoclasts by fusion. The accumulation of additional nuclei into osteoclasts by fusion probably continues while the cell is actively resorbing. The life span of the osteoclast is limited. As osteoclasts become inactive, they die by apoptosis. Hormones that enhance bone resorption may delay apoptosis, and inhibitors of resorption can accelerate it. The mechanisms that limit the extent of osteoclastic resorption are incompletely understood and may involve inhibition by calcium ions, which accumulate under the osteoclast resorbing surface, or by local inhibitory factors, such as transforming growth factor (TGF-β), which are released and activated during resorption.

The mature osteoclast is a unique and highly specialized cell. It usually contains 10 to 20 nuclei, but giant osteoclasts with up to 100 nuclei can be seen in Paget's disease or giant cell tumors of bone. The large size of osteoclasts is probably essential for their resorptive function, which depends on their ability to isolate a region of the bone surface from the extracellular fluid and produce a local environment that can dissolve bone mineral and degrade matrix. The resorbing apparatus consists of a central ruffled border area, which secretes hydrogen ions and proteolytic enzymes, surrounded by a clear or sealing zone that anchors the cell to the bone surface by a ring of contractile proteins linked to integrin receptors. The osteoclast may secrete adhesion proteins, such as osteopontin and bone sialoprotein, that anchor the cell to bone by binding both to mineral and to cell-surface integrins.

Acidification of the ruffled border area requires that osteoclasts have proton pumps. These pumps are similar to the vascular proton pumps that acidify intracellular organelles, but in the osteoclast they are exteriorized to increase the extracellular hydrogen ion concentration. The hydrogen ions dissociate from carbonic acid, which is synthesized by carbonic anhydrase; the bicarbonate generated by this dissociation is removed from the cell by chloride-bicarbonate exchange. Ion pumps can transport the dissolved calcium from the bone surface through the cell to the extracellular fluid.

However, calcium can also reach the extracellular fluid directly if the sealing zone is disrupted. The proteolytic enzymes produced by the osteoclast include lysosomal enzymes and metalloproteinases. Lysosomal proteases can degrade collagen at the low pH present in the ruffled border area. Cathepsin K is probably the most important of these. Metalloproteinases, which are active at neutral pH, have also been detected at the resorption site. In trabecular bone, osteoclasts characteristically resorb to a limited depth and then move laterally to produce irregular, plate-like resorption areas that are termed Howship's lacunae. In cortical remodeling, the path of directed resorption is longer, possibly because of renewal of osteoclasts from hematopoietic cells brought to the site through the haversian canal.
BONE REMODELING AND ITS REGULATION

After peak bone mass has been achieved, the cellular activity in the skeleton is largely devoted to an orderly sequence of bone resorption and formation, termed remodeling. This process produces plate-like structures on trabecular surfaces and cylindrical structures (osteons) in cortical bone called basic multicellular or basic structural units. The remodeling cycle can be divided into four steps: (1) activation, (2) resorption, (3) reversal, and (4) formation (Fig. 27-8 and Fig. 27-9).

Similar sequences are seen in trabecular and cortical remodeling. In young adults, this cycle is tightly coupled and the amount of new bone formed by osteoblasts is equal to the amount that is resorbed by osteoclasts. Postmenopausal and age-related bone loss begins when resorption increases and formation no longer keeps pace. The activation of new remodeling sites may also increase with age.

Calcitonin inhibits bone resorption by acting directly on the osteoclast but appears to play a small role in the regulation of bone turnover in adults. Bone mass is not increased in patients with medullary thyroid carcinoma, who have an excess of calcitonin production, or in athyreotic patients receiving adequate thyroid hormone replacement, who have low calcitonin levels.

Calcium-Regulating Hormones

Parathyroid Hormone

PTH acts on bone to stimulate resorption but does not act on osteoclasts in the absence of cells of the osteoblastic lineage; moreover, PTH receptors are abundant on osteoblasts but not on osteoclasts. PTH acts on osteoblasts to cause cell contraction; to induce immediate-early response genes, including c-fos and the inducible form of prostaglandin G/H synthase (cyclooxygenase); and to increase the synthesis of local mediators, including insulin-like growth factor I (IGF-I) and IL-6. High concentrations of PTH in vitro inhibit expression of type I collagen, but intermittent administration of PTH in vivo or in vitro can stimulate bone formation. PTH induces production of RANKL by cells of the osteoblast lineage and thereby increases osteoclastogenesis and the activity of osteoclasts. In some settings, PTH increases proliferation of cells of the osteoblast lineage and decreases their death by apoptosis.

Vitamin D

The hormonal form of vitamin D1,25(OH)2D3 is necessary for intestinal calcium and phosphorus absorption and, therefore, for mineralization. This form of vitamin D also has effects on the skeleton, but its physiologic role in bone remodeling is not clear. By increasing RANKL production by osteoblasts, it is a potent stimulator of osteoclast formation in cell culture, and high concentrations increase osteocalcin synthesis by osteoblasts and inhibit collagen synthesis. Lower concentrations may increase bone formation but not to the extent seen with intermittent administration of PTH.

Calcitonin

Calcitonin inhibits bone resorption by acting directly on the osteoclast but appears to play a small role in the regulation of bone turnover in adults. Bone mass is not greatly altered in patients with medullary thyroid carcinoma, who have an excess of calcitonin production, or in athyreotic patients receiving adequate thyroid hormone replacement, who have low calcitonin levels. In fact, bone turnover is increased in patients with medullary thyroid carcinoma. Nevertheless, subtle alterations in calcitonin production or response may play a role in metabolic bone disease.
Other Systemic Hormones

Growth Hormone

Deficiency and excess of growth hormone have marked effects on skeletal growth. Growth hormone increases both circulating and local levels of IGF-I, which mediates the skeletal effects of growth hormone. Both exogenous growth hormone and IGF-I increase bone remodeling. Growth hormone also stimulates cartilage growth, probably through an increase in local IGF production and direct stimulation of cartilage cell proliferation. Whether systemic IGF plays a role in skeletal growth is not known, but low levels of growth hormone receptors are present in bone cells and administration of IGF-I together with its major binding protein, IGFBP-3, can increase skeletal growth.

Glucocorticoids

Glucocorticoids exert biphasic effects on bone formation and resorption. In vivo, glucocorticoids may increase bone resorption indirectly by diminishing calcium absorption and producing secondary hyperparathyroidism. Low levels of glucocorticoids increase osteoclastic activity in organ culture, whereas high levels inhibit it, perhaps by decreasing the production of cytokines and prostaglandins. Glucocorticoids enhance differentiation of osteoblast precursors in cell culture and cause a transient increase in collagen synthesis in bones in organ culture, possibly as a result of increased sensitivity to endogenous IGF-I. However, glucocorticoids act in the long term in vitro and in vivo to inhibit bone formation, to decrease osteoblast replication and differentiation, to decrease IGF-I synthesis, and to increase osteoblast apoptosis.

Thyroid Hormones

In children, hyperthyroidism is associated with increased skeletal growth and hypothyroidism results in decreased growth. Thyroid hormones are crucial for cartilage growth and differentiation and enhance the response to growth hormone. Thyroid hormones increase bone turnover, although their effects on bone formation are less clear. Increased resorption as a result of hyperthyroidism may result in a coupled increase in bone formation, but thyroid hormone may also directly stimulate bone cell replication.

Insulin

Normal skeletal growth depends on an adequate amount of insulin. Excess insulin production by the fetuses of mothers with uncontrolled diabetes results in excessive growth of the skeleton and other tissues, and undertreated diabetes mellitus impairs skeletal growth and mineralization. In vitro, insulin at physiologic concentrations selectively stimulates osteoblastic collagen synthesis by a pretranslational mechanism. Insulin can mimic the effects of IGF-I but only at supraphysiologic levels. Insulin does not appear to affect bone resorption.

Gonadal Hormones

Both estrogens and androgens are critical for skeletal development and maintenance. Bone cells contain estrogen and androgen receptors, but it is difficult to demonstrate direct effects of gonadal steroids on bone formation or resorption in cell and organ culture. Gonadal hormones are crucial for the pubertal growth spurt, and estrogen is necessary for epiphyseal closure. Deficiency of estrogen or androgen increases bone resorption in vivo, possibly by increasing local synthesis or sensitivity to cytokines, such as IL-1, TNF, or IL-6, and to prostaglandins (see later). Androgens can increase bone formation in vivo. The effect of estrogens on bone formation is less clear. The absolute rate of bone formation is increased in estrogen deficiency states, possibly because of an increase in the activation frequency and the number of remodeling sites in bone. However, the fact that estrogen deficiency causes bone loss implies a relative deficiency in bone formation. Estrogens may also stimulate osteoblasts directly.
Local Regulators

Characterization of local regulators produced within the bone itself represents a major advance in bone biology. These local factors can be synthesized by bone cells or by adjacent hematopoietic cells and can interact both with each other and with systemic hormones. They are critical in the repair of skeletal damage and in the response to mechanical forces.

Cytokines

IL-1, IL-1, TNF-, and TNF- are potent stimulators of bone resorption and inhibitors of bone formation and may mediate bone loss after estrogen withdrawal. IL-6 increases osteoclastogenesis in cell cultures and may mediate some of the resorbing activity of PTH. IL-6 is produced by osteoblasts, and its production is stimulated by PTH, PGE$_2$, and other factors that increase resorption. IL-11, another member of the IL-6 cytokine family, also stimulates resorption. As noted previously, colony-stimulating factors are probably important in the early stages of osteoclast formation.

IL-4 and IL-13 inhibit resorption and prostaglandin synthesis in bone cells, and leukemia inhibitory factor has biphasic effects on bone formation. IL-7 stimulates B lymphopoiesis, which may be involved in osteoclastogenesis. IL-10 is an inhibitor of osteoclastogenesis and bone resorption. IL-15 and IL-17 stimulate IL-6, whereas IL-18 is inhibitory through its ability to increase production of granulocyte-macrophage colony-stimulating factor.

Interferon inhibits resorption by inhibiting osteoclast responses to RANKL. In addition to direct effects, responses to cytokines can be blocked by inhibitors, such as the IL-1 receptor antagonist and the soluble TNF receptor, or they can be enhanced by activators such as the soluble IL-6 receptor.

Transforming Growth Factor and Epidermal Growth Factor

These peptides stimulate bone resorption through the same receptor and act by both prostaglandin-dependent and prostaglandin-independent pathways. TGF- and epidermal growth factor (EGF) are potent mitogens in bone that probably act on both mesenchymal and hematopoietic precursors. TGF- is produced by neoplasms and may play a role in the increased bone resorption that occurs in certain malignancies.

Prostaglandins

Prostaglandins are potent regulators of bone cell metabolism and are synthesized by many cell types in the skeleton. Prostaglandin production in bone is regulated by the effects of local and systemic hormones and mechanical forces on the inducible cyclooxygenase (COX-2). Increased prostaglandin production may contribute to the increase in bone resorption with immobilization, the increase in bone formation with impact loading, and the changes after estrogen withdrawal. Many of the hormones, cytokines, and growth factors that stimulate bone resorption also increase prostaglandin production.

Prostaglandins have biphasic effects on bone formation. Stimulation of bone formation is seen in vivo, and inhibition of collagen synthesis occurs in osteoblast cultures. Bone cells produce PGE$_2$, PGF$_2$, prostacyclin, and lipoxygenase products (e.g., leukotriene B$_4$), which may also stimulate bone resorption.
Growth Factors

A large number of growth factors have been identified in bone, and their production by bone cells has been established by measurements of messenger ribonucleic acid (mRNA) and protein. Bone cells also produce binding proteins for growth factors, which may regulate their activity and storage in bone.

Insulin-like Growth Factors

IGFs increase bone cell replication, matrix synthesis, and bone formation. Both IGF-I and IGF-II are synthesized by bone cells and stored in bone matrix. More IGF-II is stored in human bone, but IGF-I is a more potent stimulator of osteoblasts. Binding of IGF-I and IGF-II to matrix may be mediated by specific IGF-binding proteins. Five of the six known binding proteins have been identified in bone, and these both inhibit and enhance IGF responses. Because PTH and PGE₂ increase and glucocorticoids decrease skeletal IGF-I synthesis, IGFs may mediate the effects of these hormones on bone growth. IGF-I and its binding proteins may also stimulate osteoclast formation.

Transforming Growth Factor and Bone Morphogenetic Proteins

This family of peptides has many complex actions on bone metabolism. TGF-β acts to stimulate bone formation and to inhibit bone resorption. Because it is stored in bone matrix and released in an active form by bone-resorbing hormones, it may play a role in the reversal phase of bone remodeling when resorption stops and formation starts. The bone morphogenetic proteins (BMPs), like TGF-β, stimulate mitosis and the growth of bone cells and have similar effects on other mesenchymal cells, particularly cartilage. TGF-β and BMPs accelerate the healing of bone defects in vivo.

Fibroblast Growth Factors

Acidic and basic fibroblast growth factors (FGF-1 and FGF-2, respectively) are crucial for skeletal development. FGFs inhibit collagen synthesis in cell culture but increase bone formation in vivo. FGF can stimulate bone resorption by both prostaglandin-dependent and prostaglandin-independent pathways. FGFs are heparin-binding growth factors, and this binding can influence their cellular activity and their sequestration in extracellular matrix. Mice deficient in FGF-2 have decreased bone mass.

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) was originally isolated from blood platelets and can stimulate bone formation, and it is also present in bone. The two gene products, PDGF-A and PDGF-B, form dimers. PDGF-AA is the major product of bone cells, but PDGF-BB is a more active stimulator of osteoblast replication. PDGF also stimulates bone resorption by prostaglandin-dependent and prostaglandin-independent mechanisms.
CLINICAL EVALUATION OF METABOLIC BONE DISEASE

Bone Densitometry

The most widely used procedure for measuring bone mass is dual-energy x-ray absorptiometry (DXA).\textsuperscript{64} Other methods include quantitative computed tomography (QCT), quantitative radiography, single-energy x-ray absorptiometry, and ultrasonography.\textsuperscript{65,66} The correlations among these methods are quite variable.\textsuperscript{67,68,69}

Both densitometry and ultrasound data are reported in terms of T-scores (standard deviations from the young adult norm for that instrument) or Z-scores (standard deviations from the expected value for individuals of the same sex, age, and body size). These values depend on the normative data that have been obtained for each specific instrument. Moreover, the normative data are likely to be different for different populations, not only for men and women but also for members of different racial and ethnic groups. Methods of assessing microarchitecture using magnetic resonance imaging (MRI) and QCT are being developed but are not yet available for clinical use.\textsuperscript{70}

Dual-Energy X-Ray Absorptiometry

DXA can provide accurate and reproducible values for bone mineral content (BMC) and bone mineral density (BMD) in the lumbar spine, the proximal femur, the distal radius, and the whole body. BMD is calculated from the BMC and the area of bone scanned (g/cm\textsuperscript{2}); hence, it represents areal bone density rather than true volumetric density.

DXA has many advantages. Radiation exposure is minimal (<10 mrem), and scanning time is short (5 to 20 minutes). If quality control is maintained, variability of repeated readings is less than 1% for phantom standards; less than 2% for lumbar spine, total body, and radius; and less than 3% for proximal femur.

The major disadvantages of DXA are as follows:

1. Changes with disease progression or therapy are small in relation to the variability of the measurement.\textsuperscript{71}
2. The test is moderately expensive.
3. Anteroposterior measurements of the lumbar spine in older patients are subject to errors caused by aortic calcification and osteoarthritic changes.\textsuperscript{72}

Quantitative Computed Tomography

QCT, which employs instruments available in most radiology departments, can be used to assess true bone density (g/cm\textsuperscript{3}) and to separate cancellous and cortical bone in the vertebral body. QCT has also been used to measure cortical and trabecular bone density in the appendicular skeleton. The radiation exposure (100 to 300 mrem) is larger than for DXA, and the precision and accuracy are lower but within the acceptable range. A major disadvantage may be cost, but this varies widely.

Peripheral Densitometry

A number of methods to measure bone mass and density in the appendicular skeleton have been developed that are less expensive, faster, and more portable than DXA or QCT.\textsuperscript{73} Measurement of cortical bone in the shaft of the radius and ulna and trabecular bone in the distal radius by radiography, photon absorptiometry, or CT scanning is precise and can be used to predict fracture risk in populations, but it cannot predict BMD of the spine and hip in individual patients. The advantages of ultrasonography, particularly of the calcaneus, are that (1) it does not use x-rays, (2) it is rapid and portable, and (3) it has the capability of predicting fracture risk. These measurements may be particularly useful for large-scale screening programs.
Biochemical Measurements

One of the most important advances in metabolic bone disease has been the development of more accurate biochemical measurements that can assess rates of bone formation and resorption. In population studies, these methods have been used to show that increased turnover (i.e., high rates of both resorption and formation) correlates inversely with bone mass and may predict a high rate of bone loss and an increased risk of fracture. However, markers currently available are characterized by a wide normal range and considerable variability, which limit their use in individual patients. The most common current clinical use of these assays in care of patients is to obtain a more rapid assessment of the response to antiresorptive agents, which can be detected at 3 to 6 months, before changes in BMD.
Markers of Bone Formation

Alkaline Phosphatase

Total serum alkaline phosphatase is measured to assess osteoblastic activity in Paget's disease, primary hyperparathyroidism, osteomalacia, and rickets. An immunoassay that selectively measures the bone isoenzyme may increase the usefulness of this test in osteoporosis, in which changes in osteoblastic activity are smaller. High bone-specific alkaline phosphatase values have been shown to predict bone loss and fractures.\(^8\)

Osteocalcin

Osteocalcin, a bone carboxyglutamic acid-containing protein, is one of the few proteins that are relatively specific for skeletal tissue. A fraction of the osteocalcin synthesized by osteoblasts is released into the circulation. Carboxyl-terminal cleavage of the molecule may occur after release, but both the intact and amino-terminal portions can be measured by specific immunoassays. Serum osteocalcin correlates with skeletal growth rates in childhood and puberty and is increased when bone turnover is accelerated (e.g., in hyperparathyroidism, hyperthyroidism). In Paget's disease, osteocalcin is elevated to a lesser degree than alkaline phosphatase.

Because osteocalcin production is increased by 1,25(OH)\(_2\)D, the levels may be low in osteomalacia and rickets even when alkaline phosphatase is elevated. Conversely, osteocalcin levels may be selectively reduced in patients given glucocorticoids to a greater degree than other formation markers. Undercarboxylated osteocalcin is present in vitamin K and vitamin D deficiency, increases with age, and is associated with increased fracture risk.

Procollagen Peptides

The amino-terminal and carboxyl-terminal extension peptides of procollagen (see Fig. 27-2), which are removed during processing of collagen, are released into the circulation. The N-terminal propeptide assay may be more sensitive and reliable than the C-terminal assay.\(^8\) Their measurement is an index of total-body synthesis of collagen, the bulk of which is derived from bone. Procollagen peptide levels correlate with histologic measures of bone formation. Levels of procollagen peptides are high in infants and may provide a clinically useful index of growth.
Markers of Bone Resorption

Calcium

Measurement of fasting urinary calcium excretion is convenient but shows wide variation, reflecting the net result of intestinal absorption, bone resorption, and mineralization as well as renal tubular handling of calcium. Markedly increased urinary calcium occurs with a marked increase in osteoclastic activity with little change in formation, for example, in some patients with osteolytic bone metastases.

Hydroxyproline

Collagen degradation releases hydroxyproline into the circulation in both free and peptide-bound forms. Because bone resorption is by far the largest contributor to collagen breakdown, urinary hydroxyproline excretion has been used as a measure of bone resorption. However, 80% to 90% of the released hydroxyproline is metabolized, and hydroxyproline from collagen or gelatin in the diet is excreted in urine. Therefore, the sample should be obtained after a 12-hour fast or while the patient is receiving a gelatin-free diet. The hydroxyproline assay has been most useful in conditions in which resorption is markedly increased, such as Paget's disease, hyperparathyroidism, and malignancy. Because cross-link excretion can also be used in these conditions, hydroxyproline assays are used less frequently in clinical assessment.

Collagen Cross-Links

Unlike hydroxyproline, the pyridinoline and deoxypyridinoline cross-links that stabilize collagen in the extracellular matrix (Fig. 27-11) are not metabolized but are excreted in the urine in either a free or peptide-bound form. The deoxypyridinoline cross-link is almost entirely derived from skeletal tissue and therefore is a more sensitive indicator of bone resorption than pyridinoline, which is also found in skin and other connective tissues.

Measurement of total urinary pyridinoline and particularly deoxypyridinoline by high-performance liquid chromatography (HPLC) probably provides the best measure of bone resorption but is expensive and time-consuming. Immunoassays have been developed for free pyridinoline and deoxypyridinoline as well as for peptides that include these cross-links and are released during resorption. These assays can now be carried out in serum as well as urine. Measurements correlate with bone turnover and change in response to agents that affect resorption. Hence, they are useful in assessing changes in resorption in the course of disease or in response to therapy. They may also be valuable in identifying patients with high bone turnover, who not only have low bone mass but also lose bone rapidly and are more likely to develop osteoporosis.

All of these assays have shown diurnal variation and may also be affected by meals. For urine assays, a fasting, second-voided morning urine sample is probably the most reliable.

Other Assays

Tartrate-resistant acid phosphatase is secreted by osteoclasts into serum and may be useful as a measure of bone resorption. Other collagen breakdown products, such as glycosylated hydroxylysines, may be used to assess resorption. Bone sialoprotein is a product of osteoblasts but apparently is not released during bone formation, it correlates best with other measures of bone resorption.
Bone Biopsy

Transiliac bone biopsy can provide direct information about cancellous bone volume, the density of connections between trabecular plates (connectivity), and the function of bone cells. The rate of bone formation and mineralization can be measured by this technique with the use of dynamic histomorphometry after tetracycline labeling (Fig. 27-12), but bone resorption is more difficult to assess by bone biopsy. Bone biopsy necessitates the use of a large needle with a 7- to 9-mm internal bore and the technical skill to obtain a sample that is not crushed or distorted. The sample must be processed without decalcification and stained appropriately. Unstained sections are needed in order for one to see fluorescent tetracycline labels. Special stains may be used to identify mast cells in mastocytosis or aluminum in renal osteodystrophy.

Bone biopsies are rarely indicated in the clinical care of patients with osteoporosis but may be indicated for patients with unusual skeletal lesions or for young men or women who have osteoporotic fractures with no evident secondary cause. However, therapeutic decisions can generally be made without biopsies. Biopsies may be indicated more frequently in renal osteodystrophy because the different forms of this disorder are managed differently.
Radiographs and Bone Scans

The use of radiographs and bone scans in diagnosis is covered under the discussions of specific disorders. Radiographs are very important in detecting fractures. High-resolution radiographs and CT images have also been used to assess cortical porosity.

Bone scans using technetium 99m linked to a bisphosphonate are useful in localization of bone lesions. Uptake is a function of blood flow to the region and the amount of mineralizing bone. The test does not give information about the nature of the lesion but may serve as a guide for further studies. The current systems for MRI may be used to assess bone structure. Moreover, the type of tissue in the marrow or surrounding the bone can be identified. MRI is particularly useful in the detection of small soft tissue masses or vascular lesions in bone.
OSTEOPOROSIS

Primary Osteoporosis

Definition

Osteoporosis is by far the most common metabolic bone disease. One in two white and Asian postmenopausal women and at least one in eight older men and women of other racial backgrounds are likely to have an osteoporotic fracture at some time during their lifetime (Fig. 27-13). Osteoporosis has been better defined by the Consensus Development Conference (1) as "a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk."

Currently, diagnostic categories for postmenopausal women are based on measurements of BMD (Table 27-2). These categories are clearly arbitrary but do give some indication of fracture risk. However, the risk of fracture at any given BMD increases markedly with age and can be affected by a number of other factors.

A more rational approach to diagnosis and management might be to obtain an estimate of fracture risk based on all factors in individual patients. The use of T-scores to categorize BMD measurements as indicating the presence or absence of osteoporosis is complicated by the fact that the estimation of fracture risk is both site and method specific. Despite great advances, there are still many unresolved questions in defining and diagnosing osteoporosis.

Epidemiology

Osteoporosis has been considered a disorder of postmenopausal women of Northern European descent because they have high rates of fractures. However, the frequency of osteoporotic fractures is also high in other populations and is likely to increase further as life expectancy increases. Moreover, the age-adjusted incidence of hip fractures around the world is rising, possibly related to increasing industrialization and decreasing physical activity. Most of the epidemiologic data are for hip fractures, but vertebral fractures are equally common. In one study, the lifetime risk of osteoporotic fractures of the hip, spine, or wrist after age 50 years was about 40% in women and 13% in men (Table 27-3). The temporal pattern of the increase in fracture incidence differs for the hip, spine, and wrist (Fig. 27-14). The incidence of osteoporotic fractures varies among populations, possibly because of variations in skeletal architecture and turnover and in bone mass. For example, in South Africa the incidence of hip fracture in Bantus is only a fraction of that in whites, although the Bantus have lower bone densities.

Pathogenesis

Understanding of the pathogenesis of primary osteoporosis remains largely descriptive. Decreased bone mass and increased fragility can occur because of (1) failure to achieve optimal peak bone mass, (2) bone loss caused by increased bone resorption, or (3) inadequate replacement of lost bone as a result of decreased bone formation. Moreover, an analysis of the pathogenesis of osteoporosis must take into account the heterogeneity of clinical expression.

TABLE 27-2 - Diagnostic Categories for Osteoporosis Based on Measurements of Bone Mineral Density and Bone Mineral Content

BMC, bone mineral content; BMD, bone mineral density; SD, standard deviation.

Inadequate Peak Bone Mass

Studies of twins suggest that genetic determinants are responsible for up to 85% of the variation in peak bone mass. However, genetic factors may be less important in determining fracture incidence in elderly people. Polymorphisms of candidate genes, including vitamin D and estrogen receptors, collagen, cytokines, apolipoprotein E, and growth factors, have been analyzed to assess their possible roles in determining peak bone mass, remodeling, and fracture risk. The results generally show small effects or are inconsistent. This problem may reflect the fact that it is difficult to determine the appropriate control population or that these polymorphisms may reflect effects of linked genes. Moreover, gene effects may be influenced by environmental factors.

A broader search for quantitative trait loci associated with differences in bone mass has identified a number of chromosomes that may be involved. This approach is likely to lead to the identification of a number of genes that influence the skeleton and are determinants not only of peak bone mass but also of microarchitecture and turnover. Furthermore, microarchitectural features of the skeleton, such as the length of the femoral neck, are genetically determined and can influence fracture incidence. High levels of physical activity and good calcium intake during childhood and puberty can help achieve maximal peak bone mass.
Skeletal development involves a number of systemic hormones, including glucocorticoids, growth hormone, thyroid hormones, and particularly gonadal steroids. These hormones are responsible for the initiation of the pubertal growth spurt, and a delay in puberty is associated with a decrease in peak bone mass. Estrogen plays the primary role in epiphyseal closure and the decrease in bone remodeling after puberty in both men and women. Thus, men with defects in the estrogen receptor or in the enzyme aromatase, which converts testosterone to estrogen, show failure of epiphyseal closure, low bone mass, and high turnover. These changes can be reversed by estrogen administration in patients who lack aromatase.

**Pathogenetic Factors**

Bone mass achieved during puberty is maintained throughout life, with Evidence of bone mass remaining stable for years because resorption and formation are equal. However, bone loss in women, particularly in the distal radius, may begin well before menopause. The incidence of Colles’ fractures increases in women in their 40s. In contrast, the increase in vertebral crush fractures is greatest 5 to 15 years after menopause and hip fractures show a logarithmic increase later in life. These differences indicate that rates of bone loss and changes in fragility, although related to menopause and age, vary in different sites.

Excessive bone resorption probably reflects an increased number of sites of resorption rather than an increase in the amount of bone resorbed at each site. However, prolonged osteoclastic activity may play a role, increasing the depth of each resorption cavity and causing trabecular perforation. This activity may be due to loss of estrogen and other factors that normally cause programmed cell death (apoptosis) in osteoclasts. The finding that markers of bone turnover are increased in postmenopausal women, even in older people, suggests that excessive bone resorption is the predominant cause of osteoporosis. Moreover, both increased resorption and increased formation correlate inversely with BMD and directly with fracture risk in postmenopausal women and men as well. Biopsies of both men and women show loss of connectivity of trabeculae, presumably related to excessive resorption. Yet biopsies of patients with established osteoporosis often show decreased bone formation.

**Biochemical Abnormalities**

Classically, osteoporosis is differentiated from disorders, such as osteomalacia and osteogenesis imperfecta, by the fact that there is no obvious defect in mineralization or the structure of collagen. Subtle abnormalities may occur, however. For example, a polymorphism in the collagen gene COL1A1 can result in differences in the ratio of the 1 to 2 chains, which might alter collagen strength. Differences in crystal structure and alignment have also been described. However, these may simply be the consequence of differences in turnover. The possibility that one or more of the many noncollagen proteins in bone is abnormal in osteoporosis has not been adequately explored.

**Decreased Bone Formation**

Skeletal bone mass increases during puberty and young adult life, even though the rate of resorption is high. Thus, menopausal and age-related bone loss must involve relative impairment of bone formation. With age, the amount of bone formed decreases with each bone structural unit, as evidenced by a decrease in mean wall thickness. This decrease may be due to an age-related decline in skeletal growth factors.

*Clinical diagnosed fractures.

**Local Factors**

Other systemic hormones may play a role in age-related bone loss. PTH levels increase with age. The increase is probably due to decreased dietary intake and impaired intestinal absorption of calcium, often associated with vitamin D deficiency, but estrogen deficiency may also play a role. Increased PTH can accelerate cortical bone loss. However, PTH levels in patients with vertebral fractures are not different from those in age-matched control subjects. 25(OH)D levels are often decreased in osteoporotic patients but levels of 1,25(OH)2D are not consistently altered, although some older patients with hip fractures do have low levels. Calcitonin deficiency does not appear to play a role in osteoporosis, although pharmacologic doses of calcitonin can prevent bone loss or increase bone mass in patients with high bone turnover.

Glucocorticoid excess can produce secondary osteoporosis but does not appear to play a major role in primary osteoporosis. Growth hormone secretion and circulating IGF-I decrease with age, and decreased IGF-I levels have been reported in osteoporotic patients, particularly in males. Thyroid hormone excess may exacerbate osteoporosis.
Two features of osteoporosis suggest a role for local factors in pathogenesis:

1. Systemic hormones that influence the skeleton, including estrogen and PTH, alter the production of local factors (e.g., cytokines, prostaglandins, and growth factors).
2. Differential bone loss occurs in different parts of the skeleton.

Production of IL-1, TNF-α, and IL-6 may be increased in estrogen-deficient and osteoporotic patients. However, there have been negative results in studies of the role of cytokines in osteoporosis in humans. The most striking evidence for the role of cytokines in the bone loss of estrogen deficiency comes from rodent models. The loss of bone after ovariectomy in rats can be blocked by inhibiting the activity of IL-1 and TNF-α. Ovariectomy does not cause bone loss in mice lacking the IL-1-activating receptor. PGE2 production is increased in bones from oophorectomized animals and decreased by estrogen administration. Estrogen levels decrease and PTH levels increase IL-6 production. Studies in rodent models suggest the existence of an important interaction between cytokines produced by cells in the marrow, possibly both hematopoietic and mesenchymal, and osteoblasts. These local factors act through the RANKL-RANK system, including OPG, but defects in this system have not yet been identified in osteoporotic patients.

It is likely that skeletal as well as systemic production of IGF or IGF-binding proteins plays a role in osteoporosis. TGF-β and BMPs may regulate bone remodeling, and TGF-β levels are decreased in bones from oophorectomized animals. Decreased TGF-β levels may not only impair bone formation but also increase bone resorption.

**Nutrition and Lifestyle**

Calcium deficiency and decreased physical activity in early life can lead to a lower peak bone mass and may accelerate bone loss later in life. Calcium supplementation, particularly when given with vitamin D, can slow bone loss in elderly people. Vitamin D deficiency is common in elderly persons, particularly those with disabilities.

Protein deficiency may also be associated with bone loss. Vitamin K deficiency is associated with increased hip fracture risk. There are positive correlations between body fat, lean body mass, and bone density. One mechanism of protection of bone density in overweight people may be conversion of adrenal androgens to estrogens in fat. Another pathway may be the decrease in sex hormone globulin associated with increased body mass index. Finally, increased fat and muscle mass would lead to increased impact loading and mechanical stress on bone.

**Nonskeletal Factors**

Low body weight and weight loss are important risk factors for osteoporotic fractures. This association may be due in part to nonskeletal effects, such as decreased padding of the hip and decreased muscle strength. Neuromuscular factors, such as loss of muscle strength, impaired balance, and impaired vision, are important, particularly in increasing the risk of falls that result in hip fracture.

Drugs that affect the central nervous system or that decrease vascular volume and cause postural hypotension are likely to increase this risk, particularly in older adults.

**Clinical Features**

**Vertebral Crush Fractures**

Compression fractures of the vertebrae, which occur spontaneously or with minimal trauma, are the most common manifestation of osteoporosis. The terms postmenopausal osteoporosis and type I osteoporosis have been applied to vertebral crush fractures at a younger age and mainly in women, whereas senile osteoporosis and type II osteoporosis have been used for hip fractures in older women and men. These distinctions may not be helpful clinically. The disorders certainly are not separate, because patients with any type of osteoporotic fracture are more likely to have subsequent fractures of either the spine or the hip.

The clinical course of the vertebral crush fracture syndrome varies. Some patients exhibit compression of only one vertebra, and others show collapse of multiple vertebrae. Nevertheless, the risk of additional fractures is high. Vertebrae may show extensive loss of trabecular structure before they collapse. Radiologically, fractures can vary from mild end-plate deformities or anterior wedging to complete vertebral collapse. The most frequent fractures are in the thoracic vertebrae below T6 and in the lumbar vertebrae.

Patients with vertebral crush fractures usually have back pain that leads to radiologic assessment. Pain in the lumbar or sacral area, compared with pain in the thoracic area, is less likely to be associated with vertebral compression. Height loss is a sensitive indicator of compression, but height loss can occur without fractures as a result of narrowing of vertebral discs and postural changes.

Many patients are asymptomatic, particularly those who have only anterior wedging. Anterior wedging in the upper thoracic vertebrae (T5 to T8) is common in older men and women and is not necessarily associated with severe compression fractures. Bone density measurements can help predict fracture risk in these patients. Anterior wedging may also develop early in life, probably during pubertal growth. This condition, called Scheuermann’s disease, may be transmitted as an autosomal dominant disorder.

Multiple vertebral crush fractures cause severe impairment. Kyphosis and loss of the lumbar lordosis are deforming and can exacerbate back pain. Impairment of chest wall function may reduce vital capacity. Compression of abdominal contents may be disfiguring and uncomfortable. Ultimately, impingement of the ribs on the iliac crest is another source of pain. Many patients have additional spinal abnormalities, including spondylolisthesis, intervertebral disc disease, and osteoarthritis.
particularly in the spinal facets. Osteoporosis itself rarely compresses nerve roots or the spinal cord. Although patients with severe osteoarthritides are somewhat less likely to have osteoporosis, these two common disorders commonly occur in the same patient. 164

Hip Fracture

Fractures of the proximal femur are a major cause of morbidity and mortality in older people. Most fractures are in the femoral neck or at the base of the greater trochanter and are associated with trauma, although the trauma may be minimal. The risk is influenced by factors that increase the risk of falling and by the type of fall as well as the structure of the skeleton and surrounding soft tissue. 165 The increased incidence of hip fractures with age is caused both by increased falls and by continued bone loss. Vitamin D deficiency may play a role. 166

Hip fracture is usually treated surgically, and the costs are substantial. In addition, perioperative and postoperative complications are associated with a 5% to 20% mortality rate. Many elderly patients cannot return to their previous level of activity after hip fracture and require long-term nursing home care. It is important to perform a diagnostic evaluation and to develop a prevention plan for these patients because a second hip fracture or a fragility fracture at another site is likely to occur. Unfortunately, most patients with hip fractures do not undergo evaluation or treatment to prevent progression of osteoporosis and additional fractures. 167

Colles’ Fracture

Colles’ fractures of the distal radius, which is composed largely of trabecular bone, are caused by falling on the outstretched hand. The incidence in women begins to increase after age 40 years and may be associated with premenopausal and perimenopausal bone loss 168 and with genetic factors. 169 Unlike that of vertebral and hip fractures, the incidence of Colles’ fractures in men does not increase with age. Colles’ fractures usually heal well and only occasionally result in long-term morbidity. Women with a Colles’ fracture should be assessed for so that an appropriate treatment plan can be provided.

Other Fractures

Fractures at any site, with the possible exception of the face and skull, can be associated with osteoporosis. Measurements of bone mass and further diagnostic work-up are indicated for all fractures that occur with minimal trauma.

Osteoporosis in Men

The incidence of hip and spine fractures in men increases with age and is about one third that in women. 162 Men often have vertebral deformities associated with trauma earlier in life. In men, the increase in hip fractures tends to occur later in life, and a higher proportion of men have definable secondary causes. 169 Bone histomorphometry shows increased resorption in most patients. 169

Osteoporosis in men is associated with low estrogen and high SHBG levels. 164 Abnormalities of the IGF system are also implicated. 165 A diagnostic work-up and therapeutic plan should be provided for men with fragility fractures, but this is rarely carried out in practice. Screening for osteoporosis in older men who do not have fractures has not yet been evaluated but may be justified now that preventive therapy is available.

Juvenile Osteoporosis

Juvenile osteoporosis 160 is a rare, self-limiting disease that can begin between the ages of 8 and 14 years with back pain and vertebral compression. If bone turnover is high, antiinflammatory or anti-inflammatory agents may be beneficial. 164 However, deficient bone formation may be the critical defect leading to fractures in these children. 164 A mutation in type I collagen has been reported in one family with this disorder. 164 Spontaneous remission usually occurs, and the disorder usually does not lead to permanent deformity.

139

Idiopathic Osteoporosis

Osteoporosis with no obvious secondary cause in premenopausal women or younger men is called idiopathic osteoporosis. The term is not used consistently, and patients so defined include individuals with both high and low bone turnover. 164 Some patients have a transient, self-limited condition, whereas others have a progressive and disabling disease. Idiopathic osteoporosis can be associated with nonspecific inflammatory changes, and these cases may be caused by abnormal cytokine activity. A careful evaluation, including consideration of bone biopsy, should be made to search for secondary causes.

Osteoporosis in Pregnancy

Osteoporosis in pregnancy is rare and may represent bone disease that has been present before pregnancy. Ordinarily, maternal bone loss is modest, 164 presumably because the high levels of estrogen protect the skeleton and high levels of 1,25(OH)2 D stimulate calcium absorption. Bone loss can occur, however, particularly in adolescents. 164 Lactation is associated with transient bone loss but is not a risk factor for osteoporosis. 167

Localised Osteoporosis

Immobilization is the most common cause of localized osteoporosis (see later). Transient osteoporosis of the hip has been reported in middle-aged men and in pregnancy. 162 Regional migratory osteoporosis can occur without immobilization, particularly in the lower extremities. 163 This phenomenon may be associated with local inflammation or autonomic dysfunction with vasomotor changes and hyperesthesia, a syndrome called reflex sympathetic dystrophy. 166
Secondary Osteoporosis

The division of osteoporosis into primary and secondary forms is somewhat arbitrary. For example, patients with diseases that lead to hypogonadism early in life are considered to have secondary osteoporosis, whereas osteoporosis in women with natural menopause and older men with low sex hormone levels is termed primary. Moreover, many patients have a combination of primary and secondary causes. Although most postmenopausal women and older men do not have a definable secondary cause, the few who do can be treated more effectively. Therefore, this possibility should be considered in every patient. There are many causes of secondary osteoporosis (Table 27-4), only a few of which are discussed here.

Glucocorticoid-Induced Osteoporosis

The most common form of secondary osteoporosis is that induced by exogenous glucocorticoids. Cushing's syndrome, caused by an excess of endogenous glucocorticoids, is less common but may also involve osteoporosis at presentation. Patients with rheumatoid arthritis, chronic pulmonary disease, or gastrointestinal disease who receive exogenous glucocorticoids are at additional risk because disease-associated inflammation, poor nutrition, and immobilization can worsen bone loss. Glucocorticoid-induced osteoporosis is particularly common in postmenopausal women, presumably because they also have primary osteoporosis. However, fragility fractures can occur in any patient receiving moderate to high doses of glucocorticoids. The increased fracture risk appears within a few months of initiating therapy and rapidly declines after cessation of treatment.

Glucocorticoid-induced osteoporosis is a result of both increased bone resorption and decreased bone formation. Increased
inhibition of osteoblasts, which are highly sensitive to glucocorticoids. For example, as little as 2.5 mg of prednisone given at bedtime can block the normal nocturnal rise in osteoclastion. Glucocorticoids decrease osteoblast formation and increase osteoblast and osteocyte apoptosis. Glucocorticoids also increase urinary calcium and phosphate and can inhibit gonadal hormone production by blocking gonadotropin release. Levels of testosterone are low in men receiving prednisone, 20 mg/day or more. Exogenous glucocorticoids decrease secretion of corticotropin, thereby decreasing the production of adrenal androgens, which are the major precursors for estrogen formation in postmenopausal women.

Clinically, glucocorticoid-induced osteoporosis is similar to primary osteoporosis. Initial bone loss is predominantly trabecular and is best assessed in the spine or distal radius. However, rib fractures and aspecific necrosis of the femoral or humeral heads or the vertebralae are common in glucocorticoid-induced osteoporosis, although they are rare in primary osteoporosis. Glucocorticoid-induced osteoporosis can be reversible, particularly in young patients who are cured of Cushing’s syndrome, in patients who cannot discontinue glucocorticoid therapy, early preventive therapy may be effective. Bisphosphonates and PTH prevent bone loss in patients with glucocorticoid-induced osteoporosis. Bisphosphonates also decrease fracture risk; they may act in part by suppressing osteoblast and osteocyte apoptosis.

Hypogonadism

Hypogonadism can occur in either men or women and has multiple causes. Patients with primary hypogonadism related to ovarian or testicular failure or secondary hypogonadism related to hypothalamic or pituitary disease lose bone rapidly and often have fragility fractures. The hypogonadotropic group includes patients with anorexia nervosa, athletic amenorrhea, prolactinoma, or lesions of the pituitary gland or hypothalamus, including tumors. Undernutrition and hypercortisolism may also contribute to bone loss in anorexia nervosa and athletic amenorrhea. Loss of growth hormone may play a role in the osteoporosis of pituitary tumors. Patients with prolactinomas can secrete parathyroid hormone-related protein (PTHrP), which may cause bone loss.

Drug-induced hypogonadism is increasing in frequency. The drugs implicated include long-acting progestins used for contraception in young women and gonadotropin-releasing hormone (GnRH) analogues used to block hormone production in women with endometriosis and men with prostate cancer.

Other Endocrine Causes

Hyperthyroidism can produce bone loss; however, the increase in formation in young persons is usually adequate, and, if the disease is treated early, changes in bone mass are small. Although there is no general increase in fracture risk in hyperthyroid patients, long-term thyroid hormone excess may lead to bone loss and increased risk of fractures. In individuals at risk for osteoporosis, primary hyperthyroidism may be missed or excessive amounts of exogenous thyroid hormone may be administered for many years. Osteoporosis has been seen in patients with growth hormone deficiency, acromegaly, and prolactinoma and may be caused by gonadotropin deficiency and the loss of gonadal hormones with any large pituitary tumor. Patients with insulin-dependent diabetes mellitus, especially men, often have low bone mass and diminished bone formation, but osteoporotic fractures are not a major problem. The role of noninsulin-dependent diabetes mellitus in the pathogenesis of osteoporosis is unclear. Bone loss may occur, particularly in patients who are not obese, but the data on fracture incidence are inconsistent.

Malignancy

Multiple myeloma and other lymphoproliferative malignancies can produce a clinical picture that resembles primary osteoporosis. It is particularly important to exclude myeloma in patients with rapidly progressive vertebral crush fracture syndrome. Metastases to the spine may also cause vertebral compression and should be considered in the differential diagnosis, particularly for patients with normal bone density. These lesions can usually be detected by MRI.

Other Diseases

The incidence and severity of osteoporosis are increased in patients with chronic hepatic and intestinal disorders, probably for nutritional reasons and because these patients often receive glucocorticoids or other drugs that affect the skeleton. Abnormal cytokine production may be a factor in inflammatory bowel disease. Although it was initially thought that impairment of vitamin D function in hepatic and intestinal disease would cause osteomalacia, the most common lesion in such patients is osteoporosis. Unfortunately, these patients often do not respond to vitamin D supplementation. People with severe alcoholism can also have osteoporosis; however, low intakes of ethanol may be associated with increased bone mass and a decreased fracture risk.

Mastocytosis causes both osteoporosis and osteosclerosis, and the number of mast cells may be increased in the marrow of patients with primary osteoporosis. The functional significance of the mast cells is not known, although mast cells produce heparin, which can cause bone loss. Hyperplastic anemias, such as thalassemia, can also cause bone loss, partly because of bone erosion by the marrow and partly because of hypogonadism associated with transfusion-induced hemochromatosis. Osteoporosis after organ transplantation is common and results both from the underlying disease and from the drugs used to prevent graft rejection.

Drugs

A number of drugs can produce osteoporosis. Heparin stimulates bone resorption and inhibits bone formation and can cause osteoporosis. Patients receiving anticonvulsants, including phenytoin, barbiturates, and carbamazepine, often have low bone mass. Impairment of vitamin D metabolism has been described, but most patients have osteoporosis with normal mineralization. Immunosuppressive agents, such as cyclosporine and FK506, are associated with bone loss. GnRH analogues, which decrease production of gonadal hormones, can lead to osteoporosis. Some agents used in cancer chemotherapy probably act both by inhibiting osteoclasts and by suppressing gonadal hormones.
Diagnosis

As indicated by the World Health Organization, osteoporosis can be diagnosed before fracture occurs by measuring bone density. The frequency of diagnosis, therefore, depends on the frequency, site, and timing of bone density measurements. There is no general agreement about who should be screened or when screening should be done. A suggested approach is illustrated in Figure 27-17.

Screening at menopause is recommended for women who have multiple risk factors, such as low body weight or a personal or family history of fragility fractures (appendicular or axial fractures after a fall from standing height or less). Universal screening of postmenopausal women after age 65 years has been recommended as cost-effective. Bone density should also be measured in men and premenopausal women with fragility fractures. BMD measurements may also be useful in early postmenopausal women under consideration for hormone replacement therapy. Bone density measurements not only establish the severity of bone loss but also provide a baseline for monitoring the patient’s therapeutic response. The test may also enhance health-related behavior. The subsequent work-up should be the same whether osteoporosis is diagnosed on the basis of screening or after the finding of a fragility fracture.

The history should include a detailed analysis of calcium intake and nutrition, changes in height or weight, physical activity and lifestyle, smoking history, menstrual and reproductive history, and personal or family history of fragility fractures or other metabolic or endocrine disorders that may affect the skeleton. Physical examination should include a careful height measurement, assessment of the spine, and evaluation for thyroid or adrenal disease. Radiologic assessment of fractures may be possible using DXA as well as ordinary radiographs. In addition, MRI or CT may be indicated if there are neurologic changes or if fractures are associated with normal bone density, raising the possibility of malignancy.

A minimal laboratory screen should include measurement of serum calcium, preferably as ionized calcium or with albumin to permit correction for protein-bound calcium and fasting calcium excretion (most easily measured as the calcium/creatinine ratio in the second-voided morning specimen). Appropriate tests to exclude secondary causes of osteoporosis should be based on the history and physical findings. Serum phosphorus and alkaline phosphatase are useful in ruling out hyperparathyroidism and osteomalacia. Measurements of vitamin D metabolites, urine phosphorus, and PTH are indicated if the screening test results are abnormal. Serum electrophoresis, blood count, and erythrocyte sedimentation rate can help to rule out myeloma, and thyroid function should be assessed. Laboratory studies for Cushing's syndrome are indicated in patients with suggestive clinical features. Measurements of gonadal and pituitary hormones are indicated for younger patients with osteoporosis. Gluten-sensitive enteropathy should be ruled out in patients with weight loss or frequent bowel movements.

Despite the inverse correlation between markers of bone resorption and formation and bone mass, these measurements have wide variations and cannot substitute for measurements of BMD in the diagnosis of osteoporosis. Because elevated values of both resorption and formation markers do indicate increased risk for bone loss and fractures, these measurements may become useful in determining the need for therapy, particularly if they can be made more accurate and less expensive.
Prevention and Therapy

Although it is important to relieve pain and to limit the impact of deformities in established osteoporosis, the primary goal of treatment is to prevent fractures. Therefore, prevention and therapy are considered together.

Nutrition and Calcium Supplementation

The calcium intakes recommended for prevention and treatment of osteoporosis range from 1 to 2 g/day. In children and adolescents, intakes of 1000 to 1200 mg/day are recommended. Most studies indicate that calcium supplementation slows bone loss, and there is limited evidence that calcium supplementation alone can decrease fracture risk. Moreover, low calcium intakes in the presence of low calcium absorption increase the risk of hip fractures. High calcium intakes are generally safe, although it may be worthwhile to check urinary calcium levels.

There is no clear advantage for any particular calcium formulation. Calcium carbonate is inexpensive and, when taken with meals, is usually well absorbed, even in patients with achlorhydria. Calcium citrate and other salts may be absorbed better than calcium carbonate in the fasting state. It is also worthwhile to include foods high in calcium in the diet. Patients should be informed about the calcium content of the major food sources, such as dairy products.

Vitamin D intake should be at least 400 U/day, and up to 2000 U/day is probably safe; higher levels may produce hypercalcemia or hypercalciuria. Calcium and vitamin D increase bone mass, decrease seasonal bone loss, and decrease the incidence of fractures, particularly in populations likely to have deficient intakes or limited sun exposure. Other forms of vitamin D have been used, including calcitriol (25(OH)D), calcitriol (1,25(OH)2D), and 1(OH)D, but there is no direct evidence that these are superior to ordinary vitamin D, which is less expensive. Dietary intakes of other minerals and of vitamins C and K, which are important for bone matrix synthesis, as well as protein should be adequate.

Exercise, Lifestyle, and Prevention of Falls

The role of exercise in treatment of osteoporosis has not been defined. On the basis of limited data, ¼ hour of weight-bearing exercise per day is recommended for patients who can tolerate it. Epidemiologic data suggest that lifetime leisure exercise is associated with higher BMD at the hip but may have no effect on fracture incidence. Patients are often better able to develop and maintain a suitable exercise program under the supervision of a physical therapist. Patients should also be instructed in body mechanics and posture in order to minimize musculoskeletal damage and the likelihood of falls. They should stop smoking and limit their intake of alcohol.

Medicines that cause prolonged sedation or postural hypertension should be avoided in elderly people. Older patients at high risk may be able to avoid hip fractures by wearing a hip protector. Help should be provided for coping with osteoporosis and for designing a lifestyle that maintains function and minimizes fracture risk. Excessive sodium intake should be avoided because it can increase urinary calcium excretion.

Management of Fractures

Fractures of the hip as well as other appendicular fractures are generally treated surgically. Vertebral fractures may require transient bed rest. A careful but intensive program of rehabilitation is critical in patients with fractures of the hip and spine. Pain relief for patients with vertebral crush fractures can usually be achieved with mild analgesics and local physical therapy. Calcitonin has analgesic effects and may be useful in patients with severe pain.

Surgical treatment of individual vertebral fractures by injection of methylacrylate has been used to relieve pain and expand the compressed vertebral body. Kyphoplasty employs a balloon to create a space for the resin, whereas in vertebroplasty the resin is injected directly.

Hormone Replacement Therapy

Postmenopausal women with and without osteoporosis should be informed about the benefits and risks of hormone replacement therapy. Many different regimens and forms of estrogen have been shown to slow bone loss; the choice is based on tolerance and convenience. Estrogen induces a decrease in bone resorption in postmenopausal women at all ages. Bone formation also decreases, but bone mass usually increases. Although the increase may result primarily from filling in of the remodeling space, estrogen may also have some anabolic effect, particularly in high doses. The rate of increase in bone mass tends to decrease with time.

Patients with an intact uterus should be given progestagens to prevent endometrial hyperplasia and an increased risk of endometrial cancer. Intermittent progestagen use reduces uterine bleeding. Low-dose, continuous progestagen may be more acceptable in older patients because it usually causes only transient breakthrough bleeding. Older women may respond to lower doses of estrogen, particularly if they combine calcium and vitamin D. At the lowest biochemically effective doses (0.25 mg of micronized estradiol per day), side effects of breast tenderness, menstrual bleeding, and endometrial hyperplasia have been minimal. All patients taking estrogen should have annual mammograms and should undergo appropriate evaluation if atypical uterine bleeding occurs.

The most important contraindication to the use of estrogen is breast cancer. A strong family history of breast cancer is a relative contraindication. Estrogen use is associated with a small but significant increase in breast cancer incidence. The incidence may be increased when progesterin is added. Hormone replacement therapy increases the incidence of thromboembolic disease and may exacerbate headaches or hypertension. Thus, the presence of thromboembolic disease, hypertension, or migraine headaches may also be a relative contraindication. Nevertheless, in epidemiologic studies, patients receiving hormone replacement therapy had lower mortality rates.

Data concerning the overall benefits of estrogen in prevention of cardiovascular disease and Alzheimer's disease are conflicting. Moreover, whereas prevention of bone loss has been adequately demonstrated, data on reduction of fractures are limited, in part because no large prospective trials have been completed. Although significant bone loss occurs in fewer than 15% of women taking estrogen, rapid bone loss can occur after estrogen is discontinued.

Bisphosphonates

Bisphosphonates are pyrophosphate analogues that bind to bone mineral and inhibit resorption. The first compound available for clinical use, etidronate, inhibits bone mineralization at high doses but increases bone mass without impairing mineralization when given intermittently. Second-generation bisphosphonates, such as alendronate and risedronate, do not impair mineralization at therapeutic doses and can be given continuously. Bisphosphonates bind to bone mineral and are then taken up by osteoclasts and rapidly inhibit bone resorption. The inhibitory effects on osteoclast function differ for the first-generation compounds, which lower adenosine triphosphate levels at high concentrations, and the second-generation compounds, which impair isoprenylation of proteins at low concentrations.

Alendronate and risedronate are approved for prevention and treatment of osteoporosis on the basis of evidence that they decrease bone resorption, increase bone mass in the spine and hip, and decrease the incidence of fractures. Bisphosphonates can prevent bone loss in patients receiving glucocorticoids and...
in men. There is no consensus on the duration of therapy, but continued benefit has been observed in patients treated for up to 7 years.

Bisphosphonates are poorly absorbed orally and must be taken on an empty stomach with no food or other medication. The major side effects are gastrointestinal, particularly esophageal irritation. This problem can be circumvented by using parenteral bisphosphonates. Pamidronate is available, although not approved for osteoporosis therapy, and other still more potent intravenous bisphosphonates are being developed.

Gastrointestinal side effects may also be reduced by giving bisphosphonates weekly instead of daily. Because they act by different mechanisms, bisphosphonates can be added to estrogen for patients who are responding poorly or have severe disease. However, it is not known whether combined therapy further reduces fracture risk.

Calcitonin
Calcitonin, an inhibitor of bone resorption, can increase bone mass, particularly in association with high turnover rates. Calcitonin also has some analgesic properties and may be particularly useful in patients with recent painful vertebral fractures. It is available either for subcutaneous injection or as a nasal spray. The former preparation is probably more effective but is less well tolerated, often producing gastrointestinal side effects. In a 3-year randomized trial, nasal calcitonin at 200 U/day was found to decrease fracture incidence significantly, although the effects on bone turnover and bone mass were diminished by the end of the study. Doses of 100 or 400 U/day did not significantly decrease fractures. Nasal calcitonin is less effective in increasing BMD than alendronate.

Selective Estrogen Receptor Modulators
A number of compounds have had effects similar to those of estrogen on bone, but they act as antagonists in the breast.

Tamoxifen has been shown to diminish bone loss in women with breast cancer. Another selective estrogen receptor modulator, raloxifene, has not only prevented bone loss but has also reduced the risk of fracture in osteoporotic patients. Its effects on bone turnover and mass are somewhat less than those of estrogen. Raloxifene does not stimulate the breast or uterus and may even decrease the risk of breast cancer. It reduces low-density lipoprotein levels but does not increase high-density lipoprotein. It is associated with an increased risk of thromboembolism and may produce hot flashes.

Other Therapeutic Approaches
Many years ago, PTH given intermittently in low doses was shown to increase bone mass in animals.

Parathyroid Hormone
The use of intermittent low-dose PTH in humans has produced a substantial increase in trabecular bone mass with little loss or even a gain in cortical bone in the femur and has reduced the incidence of fractures. Treatment with PTH alone or in combination with an antiresorptive agent is likely to be the most effective approach in patients who lose bone or continue to have fractures with estrogen or bisphosphonates. PTH may be particularly useful in glucocorticoid-induced osteoporosis or in patients given GnRH analogues. PTH must be given by injection, and patients must be monitored carefully for hypercalcemia and hypercalciuria.

Fluoride
Fluoride increases bone formation and has been used in the treatment of vertebral crush fractures. However, in a large prospective controlled trial of monofluorophosphate, the incidence of vertebral fractures was not decreased. A slow-release fluoride preparation was reported to decrease fractures in a smaller number of osteoporotic patients. Fluoride is not approved for treatment of osteoporosis in the United States.

Anabolic Steroids
Anabolic androgenic steroids (e.g., testosterone) and analogues (e.g., nandrolone) may increase bone as well as muscle mass. However, high doses produce unacceptable androgenic side effects in many women. Testosterone therapy is effective in hypogonadal men. Testosterone can also increase bone and muscle mass in older men, particularly those with low levels of bioavailable testosterone.

Thiazides
Thiazides can decrease urinary calcium excretion and increase bone mass in patients with hypercalciuria and may reduce cortical bone loss in normal postmenopausal women. The incidence of hip fractures may be lower in patients receiving thiazides, but the data are inconsistent. Thiazides can be combined with amiloride to minimize potassium loss. This therapy is particularly appropriate in patients with hypercalciuria and osteoporosis.
RICKETS AND OSTEOIMALACIA

Rickets and osteomalacia are disorders of the mineralization of newly synthesized organic matrix. In adults, the disorder involves only bone; in children, however, defects also occur in the growth plate and in the mineralization of cartilage, leading to characteristic deformities.

Pathogenesis

To understand the pathogenesis of rickets and osteomalacia, we should recognize that vitamin D is a prohormone that can be synthesized in the skin or supplied in the diet. Vitamin D deficiency is usually the combined result of deficient sun exposure and decreased dietary intake or intestinal malabsorption. Rickets and osteomalacia can also be caused by metabolic defects in the vitamin D hormone system, including inadequate activation in the liver and kidney and abnormalities of the vitamin D receptor (see Chapter 28). Mineralization can also be impaired when the supply or transport of mineral is inadequate in renal, intestinal, or bone cell disorders.

Nutritional and Gastrointestinal Disorders

Inadequate vitamin D intake is less common in the United States than in other countries because many foods are supplemented with this vitamin. However, the combination of inadequate sunlight or lack of the appropriate ultraviolet wavelengths, which occurs during the winter in the northern half of the United States, and failure to provide vitamin D supplements in the diet can lead to rickets in infants and osteomalacia in older persons. Individuals with darker pigmentation of the skin are more susceptible to vitamin D deficiency because they are less efficient in converting 7-dehydrocholesterol to vitamin D. For example, nutritional rickets occurs in black infants who are breast-fed without vitamin D supplementation. Adult Asian Indians in the United States and Europe have low 25(OH)D levels and are more likely to have osteomalacia. Intestinal malabsorption of fat can also cause deficiency of vitamin D and of other fat-soluble vitamins. Inability to produce adequate amounts of 25(OH)D can occur in advanced liver disease and with use of antiepileptic drugs.

Calcium deficiency rickets may differ from other forms of rickets and osteomalacia, particularly in adolescents, who may have genu valgum without end-plate deformities. In contrast, phosphate deficiency causes typical rickets. Because most foods contain phosphate, this form of rickets requires markedly unbalanced nutrition, such as can occur with prolonged intravenous feeding, removal of phosphate by dialysis with a low-phosphate solution, or use of aluminum-containing antacids, which bind phosphate in the intestine.

Renal Defects

Impairment of 1-hydroxylase can occur because of loss of renal mass or in renal tubular disorders such as the Fanconi syndrome. A hereditary deficiency of 1-hydroxylase, termed vitamin D-dependent rickets type I or pseudovitamin D deficiency, is a rare autosomal recessive disorder in which rickets develops during the first year of life. It occurs in rodents with homogenously inactivating mutations of the 1-hydroxylase gene and responds to physiologic doses of calcitriol.

Hereditary Resistance to Vitamin D

This severe form of rickets occurs in members of families who are homozygous for defects in the vitamin D receptor gene. These patients also often have alopecia. They may show a skeletal response to high doses of calcium and phosphorus, but this does not reverse the alopecia.

Familial X-Linked Hypophosphatemia

Originally termed vitamin D-resistant rickets, this syndrome is caused by a defect in phosphate transport. Although the most apparent abnormality is decreased renal tubular reabsorption of phosphate, phosphate transport may be impaired in other cells, particularly osteoblasts. Mutations in a gene (PEX) for a membrane-bound endopeptidase have been found in this disorder. This enzyme is thought to inactivate a hormone, phosphatonin, that inhibits phosphate transport. These patients may also have some impairment in 1-hydroxylase activity, and treatment involves a combination of calcitriol and phosphate. However, it is difficult to achieve normal growth rates in this disorder.

The condition exhibits genetic and phenotypic heterogeneity. Autosomal dominant and recessive as well as X-linked transmission has been described. The autosomal dominant form has been linked to a mutation in a new member of the FGF family, FGF-23; hence, FGF-23 may be the phosphatonin hormone. Although most cases are familial, some severe sporadic cases have their onset at puberty.

Oncogenic Osteomalacia

This severe form of osteomalacia may be caused by production of phosphatonin by fibrous and mesenchymal tumors.

Figure 27-19 Active osteomalacia in a patient (a sibling of the patient in Fig. 27-18) with hereditary tissue resistance to 1,25-dihydroxyvitamin D at age 18 with pseudofracture of the left tibia. (From Marx SJ, Spiegel AM, Brown EM, et al. Familial syndrome of decrease in sensitivity to 1,25-dihydroxyvitamin D. J Clin Endocrinol Metab 1978; 47:1303-1310. Copyright © 1978, by The Endocrine Society.)

that are often small and difficult to identify. These tumors express FGF-23. Removal of the tumor causes rapid reversal of the osteomalacia.

Hypophosphatasia

A rare autosomal recessive disorder, hypophosphatasia is characterized by mutations in the gene for the tissue-nonspecific (liver-bone-kidney) isoenzyme of alkaline phosphatase.
Clinical manifestations vary from death in utero related to severe deformities through infantile and childhood rickets to adult-onset osteomalacia. Premature loss of deciduous teeth and impaired dentition in adults are common. Levels of organic phosphate compounds, such as pyridoxal 5-phosphate, in plasma are increased.

Fluoride and Bisphosphonates

High doses of sodium fluoride or of first-generation bisphosphonates (e.g., etidronate) can produce osteomalacia. Anticonvulsant therapy in patients with a marginal vitamin D supply can cause osteomalacia by decreasing 25(OH)D levels.
Clinical Features

Rickets differs from osteomalacia in that it occurs before closure of the epiphyses. Enlargement of cartilage at the growth plate causes the so-called rachitic rosary at the costochondral junctions of the ribs and widening of the cartilaginous ends of the long bones. Impaired mineralization results in bowing of long bones. Radiologically, widening, cupping, and fraying of the metaphyses are seen (Fig. 27-18). Severe vitamin D deficiency causes muscle weakness, and this weakness, combined with the deformity of the chest wall, causes an increased incidence of pneumonia. The clinical expression of osteomalacia in adults varies widely. The most common deformity is bowing of the legs, and in severe cases bone pain and weakness may cause the patient to be bedridden. 

Radiographic changes include subperiosteal erosions caused by marked secondary hyperparathyroidism and a virtually pathognomonic but relatively uncommon lesion, the so-called pseudofracture (Looser’s zones or Milkman’s syndrome) of the long bones, ribs, scapulae, or public rami (Fig. 27-19). Coarsening of the trabecular pattern in the spine may be present, but it is also seen in osteoporosis.
Diagnosis

Although clinical features may point to rickets or osteomalacia, the diagnosis depends on laboratory studies. The biochemical picture can vary with different pathogenetic mechanisms and with different stages of disease. In infants with vitamin D deficiency, serum calcium may be low and the serum phosphorus concentration may be normal initially; as secondary hyperparathyroidism develops, however, calcium concentrations usually return to the low-normal range and serum phosphorus levels fall further. In advanced stages, the serum calcium concentration may fall again. This fall has been attributed to the inability of secondary hyperparathyroidism to maintain the serum calcium level when the bone surface is covered by osteoid and is resistant to attack by osteoclasts.

In adults, the characteristic picture is a low-normal or slightly decreased serum calcium level, a decreased urinary calcium level, and a low serum phosphate level. Increased alkaline phosphatase levels reflect the activity of the osteoblasts, which form unmineralized matrix. PTH levels may be markedly increased. The key diagnostic test in vitamin D deficiency is demonstration of a decreased serum 25(OH)D value. The 25(OH)D levels may also be decreased in hepatic disease or with drugs that impair 25-hydroxylation. The 1,25(OH)$_2$D levels may be normal in vitamin D deficiency, presumably because of a maximal stimulation of 1-hydroxylase by the low serum phosphorus and high PTH levels. Nevertheless, the amount of this hormone is inadequate to activate the receptors in intestine and bone. Because of the high activity of 1-hydroxylase, administration of vitamin D to these patients causes a further increase in 1,25(OH)$_2$D to supranormal levels.

The diagnosis of other forms of rickets and osteomalacia can be made by measuring vitamin D metabolite levels. For example, low values of 1,25(OH)$_2$D and normal levels of 25(OH)D suggest a defect in 1-hydroxylase that may be genetic or acquired as a result of loss of renal function or tumor-induced osteomalacia. High levels of 1,25(OH)$_2$D and normal levels of 25(OH)D are seen in patients with vitamin D receptor defects. In X-linked hypophosphatemia, serum phosphorus levels are low and levels of serum calcium and vitamin D metabolites are normal. If alkaline phosphatase levels are low, a definitive diagnosis of hypophosphatasia should be sought by measuring pyridoxal 5-phosphate; elevated levels are relatively specific for hypophosphatasia and correlate with clinical severity.

Although the diagnosis of osteomalacia can usually be made on the basis of clinical findings and laboratory studies, a bone biopsy is sometimes needed for a definitive diagnosis. The characteristic finding is markedly widened osteoid seams and impaired mineralization with diffuse or absent tetracycline labeling. The bone also shows great variation in trabecular width and resorption lacunae resulting from secondary hyperparathyroidism. A modest increase in osteoid width can occur in a high-turnover state, such as hyperparathyroidism, thyrotoxicosis, or Paget's disease; however, tetracycline labeling shows a normal mineralization front in these conditions.
Therapy

Vitamin D is effective in the treatment of nutritional and malabsorptive rickets and osteomalacia. High doses (50,000 to 100,000 U/day) may be given initially, but it is important not to overtreat patients because vitamin D is stored in the fat and excessive amounts can cause prolonged hypercalcemia and hypercalciuria. Monitoring of urinary calcium excretion is useful to determine when the vitamin D dose should be decreased. Patients with malabsorption may require large doses or parenteral vitamin D. Patients with defects in 1-hydroxylase can be treated with calcitriol. If the cause is tumor-induced osteomalacia, the treatment is to find and remove the lesion, but oral or intravenous phosphate and calcitriol can be used to heal the skeletal lesions.

Severe defects in the vitamin D receptor are most difficult to treat. Massive doses of calcium and phosphorus have been given to these patients, but normal growth is rarely achieved and alopecia persists. Intravenous calcium therapy may be necessary and is effective in restoring bone mineralization. Similarly, normal growth may not occur despite repletion of phosphorus and administration of calcitriol in patients with X-linked hypophosphatemia, although bone mineralization can be restored. Growth hormone has been used to help achieve normal height. Careful monitoring of levels of calcium, phosphorus, and vitamin D metabolites is important to prevent impairment of renal function. At present, there is no effective therapy for hypophosphatasia.
HYPERPARATHYROID BONE DISEASE

In the past, severe cases of primary hyperparathyroidism showed osteitis fibrosa cystica generalisata, manifested by generalized bone loss with increased bone resorption, including both subperiosteal and endosteal surfaces. The formation of fibrotic cystic lesions (brown tumors) in the long bones and jaw caused swelling, pathologic fractures, and bone pain. This bone disease is now rarely seen in primary hyperparathyroidism but may occur in poorly managed secondary hyperparathyroidism.

With the common forms of hyperparathyroidism, the major finding is an increased rate of remodeling in bone. Bone mass is decreased in the cortex, largely because of endosteal resorption, but trabecular bone is preserved. Bone density is low in the cortical bone of the radius, but bone density in the metaphyses and vertebrae, which represent largely trabecular bone, is normal or only moderately decreased. Patients with mild to moderate disease do not have progressive bone loss; however, when these patients are cured surgically, bone density in the spine can increase by as much as 15%, even in post-menopausal women who are at the highest risk for fracture. Bone density also increases in the radius and hip. Moreover, bone loss is attenuated in postmenopausal women with hypoparathyroidism. On the basis of these results, patients with primary hyperparathyroidism and low levels of bone density who are at risk for fractures are candidates for parathyroid surgery.
RENAL OSTEODYSTROPHY

In view of the central role of the kidney in regulating mineral metabolism, it is not surprising that patients with chronic renal failure frequently have skeletal abnormalities. In renal failure, the decreased capacity to synthesize 1,25(OH)_2 D and to excrete phosphate causes secondary hyperparathyroidism. This results from the lowering of serum calcium by phosphate, the impairment of calcium absorption in the intestine, and the loss of the feedback inhibitory effect of 1,25(OH)_2 D on PTH production. The increased secretion of PTH ultimately leads to osteitis fibrosis cystica.

Development of bone disease can be slowed or prevented by phosphate restriction or by treatment with phosphate binders and calcitriol. In the past, aluminum hydroxide was used to bind phosphate, a therapy that sometimes caused aluminum-induced adynamic bone disease. This condition is less common with the use of calcium salts to decrease phosphate absorption, but low-turnover bone disease still occurs, particularly in patients in whom secondary hyperparathyroidism has been reversed. Osteomalacia can occur in patients receiving dialysis if they have an inadequate supply of vitamin D and calcium, but this is unusual.

Renal osteodystrophy causes growth retardation and skeletal deformities in children, and both children and adults have bone pain and muscle weakness. Soft issue calcifications are particularly dangerous when they occur in blood vessels and lead to ischemia and gangrene. Calcification may be the result of a high calcium-phosphorus product and of vessel wall changes secondary to renal failure or direct effects of PTH. To prevent calcification, it is important to avoid a high serum calcium-phosphorus ion product and to minimize secondary hyperparathyroidism.

Diagnosis

The diagnosis of a specific form of renal osteodystrophy can often be made on biochemical grounds. Levels of PTH are high in patients with severe secondary hyperparathyroidism. Plasma aluminum levels may be elevated in patients with aluminum-induced osteodystrophy but do not necessarily reflect the stores in bone. Deferoxamine chelates aluminum, and this agent can be used to measure the body burden and to treat aluminum overload. The interpretation of biochemical markers of bone turnover is difficult in renal disease because their clearance may be altered.

A bone biopsy may clarify the pathogenesis of renal osteodystrophy. Using double tetracycline labeling, it is possible to determine whether mineralization is impaired. Sections that have not been decalcified show the extent of osteoid seams and resorption surfaces. Aluminum can be identified by special stains. Amyloid deposits, which consist largely of β2-microglobulin, may be seen in the bone. Amyloidosis of the bone is associated with cystic lesions but not necessarily with bone pain.
Therapy

The treatment of renal osteodystrophy can be highly successful if it is correctly focused on specific pathogenetic mechanisms. The goal should be to maintain normal serum calcium and phosphorus levels and minimize exposure to aluminum. Phosphate restriction should be instituted relatively early in renal failure, but diets low in phosphorus are difficult to achieve. Therefore, after the filtration rate is reduced below 25% of normal, it is usually necessary to administer phosphate-binding salts such as calcium carbonate, calcium acetate, or calcium citrate. The ability of citrate to increase aluminum absorption is a concern. Correction of acidosis is also important in preventing bone disease.

Early in renal failure, modest supplementation with vitamin D may be sufficient to maintain 1,25(OH)₂D levels, but eventually calcitriol itself should be administered. Low doses (0.25 to 0.5 µg/day) are well tolerated, but higher doses can lead to hypercalcemia and hypercalciuria. In severe secondary hyper-parathyroidism, low doses are often not sufficient to suppress PTH secretion and intravenous calcitriol may be used.

In some cases, parathyroidectomy may be required. Persistent hypercalcemia in patients with renal failure, intractable pruritus, extracellular calcifications, and severe skeletal lesions are all indications for surgery. However, parathyroidectomy should be avoided in patients with aluminum-induced bone disease because symptoms may be worsened. Hemodialysis patients have a high incidence of fractures of the distal forearm and ribs.

Renal transplantation corrects many of the biochemical disturbances that lead to renal osteodystrophy, but bone disease may progress. Usually, secondary hyperparathyroidism slowly resolves, but patients with persistent hypercalcemia or autonomy of the parathyroid glands (tertiary hyperparathyroidism) may require surgery. A major concern, particularly in older patients, is progressive osteoporosis; glucocorticoids and immunosuppressants worsen bone loss in these patients. Finally, osteonecrosis or avascular necrosis, particularly of the proximal femur, is common after renal transplantation.
PAGET’S DISEASE

Paget's disease may affect as many as 3% of adults older than 40 years of age; it is often asymptomatic and usually progresses slowly.

Pathogenesis

The primary abnormality in Paget's disease is the localized, uncontrolled formation of large, highly active osteoclasts. The initial lesion is an increase in bone resorption. The response to this resorption, particularly in bones that are subject to mechanical force, is an intense but chaotic increase in osteoblastic activity. The characteristic histologic appearance is of focal lesions with many giant osteoclasts and active osteoblasts. The bone that forms in the lesions is disorganized and has a mosaic pattern with loss of the usual lamellar structure. The marrow shows a pattern of fibrosis and increased vascularity.

The concept of a viral origin of Paget's disease is based on the finding of nuclear inclusion bodies in osteoclasts and the detection of viral transcripts in hematopoietic cells from patients with the disease. Several paramyxoviruses have been suggested, including measles and canine distemper virus. Expression of the measles virus nucleocapsid protein gene in osteoclast precursor cells was found to enhance the ability of these cells to form osteoclasts. However, further work is needed to establish pathogenetic links between viral sequences and production of abnormal osteoclasts in this condition. Pagetic osteoclasts differ from normal osteoclasts not only in their greater size and the presence of viral inclusions but also because they express IL-6, which may play a role in pathogenesis. Expression of resorption stimulators by osteoblast-lineage cells is probably also involved in the development of Paget's disease.

Pagetic bone often distributes in a heterogeneous pattern throughout the skeleton. In addition, when lesions appear, they remain stationary over many years. Hence, abnormalities only in osteoclast precursor cells, which are believed to circulate freely in blood, cannot explain all the pathology that is seen in this condition. A description of the pathogenetic mechanisms in Paget’s disease must elucidate how the spotty distribution of this condition develops. Some insight into this puzzle was provided by studies of bone marrow stromal cells from pagetic lesions. These cells, believed to be stationary in bone, have been shown to produce enhanced RANKL mRNA compared with marrow stromal cells from uninvolved areas in the same patient.

There may also be a genetic component in Paget's disease. As many as 15% to 30% of patients have a positive family history, and first-degree relatives of patients with Paget's disease have a sevenfold greater relative risk of having the disorder than individuals with no affected relatives. There is also ethnic and geographic clustering. The incidence is high in some areas of northern Europe, particularly in northern England, but low in Norway and Sweden. A rare related illness, familial expansile osteolysis, which is seen in young adults as a generalized increase in osteoclastic activity and bone turnover, has been found to result from an activating mutation of RANK, the receptor for RANKL.
Clinical Features

Paget's disease affects men and women almost equally, but men tend to be more symptomatic. The disease is usually not clinically apparent until age 50 to 60 years. It usually progresses slowly and does not develop in new sites. Many different bones can be affected, and the lesions can vary from single, monostotic lesions to involvement of almost the entire skeleton. The pelvis, femur, spine, skull, and tibia are most commonly involved, whereas hands and feet are rarely affected.

Paget's disease is often discovered in asymptomatic patients because of an elevated serum alkaline phosphatase measurement obtained on routine screening or because of a radiograph taken for an unrelated problem. The most common symptom is bone pain at the site of pagetic involvement. Pain also commonly occurs in adjacent joints as a result of secondary degenerative arthritis. Bowing of the legs is common (Fig. 27-21), and pathologic fractures can occur. Vertebral involvement can cause kyphosis and compression of the spinal cord. Neural changes can also result from vascular steal because of the high blood flow to the lesion. The most common consequence of Paget's disease of the skull is hearing loss, which can be both conductive and neurosensory. Extensive involvement of the base of the skull can produce basilar impression and, rarely, brain stem compression (Fig. 27-22). Facial and skull deformities and dental problems are common.

Figure 27-21 Paget's disease of the tibia. Note the bowing, marked irregularity of the anterior cortex and the flame-shaped lytic lesion of the posterior cortex. (Courtesy of Dr. Ethel S. Siris.)

The incidence of osteosarcoma is increased but is less than 1%. When osteosarcoma does occur, it is highly malignant. Most patients do not live longer than 1 to 3 years. Fibrosarcomas, chondrosarcomas, and benign giant cell tumors are also occasionally seen. The giant cell tumors, termed reparative granulomas, may represent an extension of pagetic tissue outside the skeleton. These tumors are sensitive to antipagetic therapy and may also respond to glucocorticoids.

Patients with Paget's disease may have an increased incidence of primary hyperparathyroidism. Angioid streaks are often seen in the fundus. Pseudogout, gout, and osteoarthritis occur. Patients with heart disease may show worsening of heart failure, which has been attributed to the increase in blood flow in pagetic lesions.
Diagnosis

As noted previously, the diagnosis of Paget's disease may be made by the finding of an elevated alkaline phosphatase concentration or after a routine radiograph. In older persons with deformities or bone pain, the diagnosis should be considered and a careful family history and review of the musculoskeletal system by both history and physical examination should be obtained. A bone scan should be carried out to localize possible pagetic sites. Positive scans do not necessarily indicate Paget's disease, and radiographs should be obtained to confirm that Paget's disease is the cause of the increased uptake. Rarely, pagetic sites in bone are not evident on bone scan because there is a minimal formation response in the lesion. Such pagetic lesions in the skull are termed osteoporosis circumscripta.

An audiogram should be obtained in patients with involvement of the petrous bone or in those with complaints of hearing loss. Because of the possible increased incidence of hyperparathyroidism, ionized calcium levels should be measured in the initial work-up. Monostotic Paget's disease, particularly in the vertebrae, may be difficult to distinguish from metastatic disease. In addition, some patients with vertebral disease may have impingement on the spinal canal. In these individuals, the area should be examined by CT or MRI. Bone biopsies can be useful in atypical cases. An ordinary aspiration biopsy sometimes yields the giant osteoclasts that are pathognomonic of Paget's disease. Samples of bone that show the irregular marble bone pattern can also be diagnostic.

After the initial evaluation has been completed, the patient can usually be monitored biochemically by serial measurements of total or bone-specific alkaline phosphatase and a marker of bone resorption. Urinary hydroxyproline measurements may be used, as may serum or urinary levels of type I collagen breakdown products such as C-telopeptide or N-telopeptide or measurements of pyridinolone or deoxypyridinolone in the urine. Although 24-hour urine measurements of hydroxyproline are often recommended, a morning fasting measurement avoids the dual problems of collecting a 24-hour sample and maintaining a diet free of gelatin products.
Therapy

In the past, patients with Paget’s disease were often simply observed until symptoms were clear-cut or until there was evidence of progression in critical areas of the skeleton. With the newer bisphosphonates, treatment is instituted earlier. Pamidronate is available for IV use. The recommended dose for Paget's disease is 30 mg infused over 4 hours on 3 consecutive days for a total of 90 mg. Patients with more extensive disease may require retreatment and should be evaluated by measuring levels of bone turnover markers at regular intervals. IV pamidronate is generally safe, although transient fever and a transient increase in bone pain may occur. Rare idiosyncratic reactions include uveitis.

Other bisphosphonates are given orally. Alendronate (40 mg/day for 6 months), risedronate (30 mg/day for 2 months), and tiludronate (400 mg/day for 3 months) are approved in the United States. As with pamidronate, patients may require repeated therapy with oral bisphosphonates after a drug-free period that varies with each agent (6 months for alendronate, 2 months for risedronate, and 3 months for tiludronate). Oral bisphosphonates need to be taken in a manner that minimizes the development of esophagitis or interactions with food and other therapeutics in the stomach. These treatments have largely replaced therapy with calcitonin, etidronate, or plicamycin. All of these agents act by inhibiting osteoclastic activity, and the earliest indication of therapeutic response is a drop in resorption markers followed by a decrease in formation markers.

The indications for treatment are pain that can be attributed to Paget’s disease and deformities that might produce neurologic changes or are likely to lead to fracture, such as the osteolytic flame lesion or blade of grass lesion in weight-bearing bones (see Fig. 27-20). Hearing loss may be an indication for therapy, although most patients do not show major improvement after treatment.

Patients with heart disease and extensive Paget's disease should be treated in the hope that decreased pagetic activity will improve management. With the advent of safe and effective therapy, patients with mild to moderate disease, particularly those with the potential for complications (i.e., those with lesions in weight-bearing bone, the vertebral bodies, or the base of the skull), are being treated before symptoms develop. Early treatment is logical in young patients with Paget's disease because it is hoped that therapy may prevent progression. However, proof of this hypothesis is not conclusive.

Many patients with Paget's disease have pain associated with joint damage that does not respond to antipagetic therapy. These patients may respond to anti-inflammatory drugs. If osteoarthritis is advanced, knee and hip replacement may be appropriate but biochemical remission should be obtained before surgery.

A high calcium intake may be useful in Paget's disease. Bisphosphonate therapy can lower the serum calcium level and cause secondary hyperparathyroidism, which is probably not advantageous; increased calcium intake may prevent this development. Moreover, calcium loading can produce an increase in endogenous calcitonin secretion that may have beneficial effects. It is also important to monitor serum 25(OH)D levels periodically in patients with Paget's disease who are to be treated with bisphosphonates, as osteomalacia is not uncommon in the elderly population who are at risk for this condition and low serum vitamin D levels may exacerbate the potential of bisphosphonates to cause hypocalcemia. Urinary calcium should be checked before calcium or vitamin D supplementation is given because an increase in the incidence of renal stones has been reported in pagetic patients.
Hereditary Hyperphosphatasia

Although hereditary hyperphosphatasia has been termed juvenile Paget's disease, it involves all of the skeleton and develops in infants. The serum alkaline phosphatase levels are very high. There are severe bone deformities, and the histologic appearance resembles that of Paget's disease with high bone turnover, although the osteoclasts are not enlarged. Treatment with bisphosphonates or calcitonin may be effective in reducing bone turnover and improving bone lesions. A new familial form with expansile long bone lesions has been described.
OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta, or brittle bone disease, is a heterogeneous, congenital disorder in which increased bone fragility leads to fractures and deformity. It ranges in severity from a lethal perinatal form to a mild disorder that results only in increased fractures.

Pathogenesis

Most patients with osteogenesis imperfecta have defects in the genes for type I collagen. Bones, ligaments, skin, sclerae, and teeth are affected. The incidence of osteogenesis imperfecta is estimated to be 1 in 200,000 to 500,000. The heterogeneity of the features is caused by the variety of genetic defects, although phenotypic variation occurs even with the same genetic abnormality (see Table 27-5). The more severe forms, type II and type III, involve mutations at the helical portion of the collagen molecule that prevent normal assembly and produce unstable triple helices. Point mutations in this portion of the collagen gene can be associated with mild disease (type IV).

Type I osteogenesis imperfecta differs from the other forms in that there is usually a deletion of one allele of the 1(I) procollagen gene, resulting in decreased collagen production but a normal molecular structure.

Bone biopsies show decreased cortical width and trabecular bone volume, increased turnover, and decreased bone formation in patients with type I disease. The disorder in a subgroup of patients with low turnover and ligamentous calcifications has been designated type V osteoporosis imperfecta.
Classification and Clinical Features

The classification devised by Sillence and modified by Byers is summarized in Table 27-5. In addition to the bone involvement, there may be ligament laxity, joint hypermobility, and easy bruising. Dentin formation is often abnormal, and the teeth are fragile and discolored. Blue sclerae are a variable manifestation and do not correlate with severity. Because of the thoracic deformities, patients with severe manifestations are predisposed to pulmonary infections and usually have a shortened life span. Intelligence is not affected, and individuals with marked deformities can be highly productive if appropriate conditions are provided.
Diagnosis

In patients with moderate to severe disease, the clinical features make the diagnosis relatively straightforward; in patients with the milder forms, however, the diagnosis may be missed. In children without deformities, multiple fractures are usually attributed to trauma; in infants, the presence of such fractures may lead to an accusation of parental abuse. In the absence of typical clinical features, the diagnosis can be made only biochemically. Culture of fibroblasts from skin biopsies and analysis of the collagen by gel electrophoresis can point to a defect, and the techniques of molecular biology can identify the mutation more specifically. This analysis is useful for families because specific deoxyribonucleic acid (DNA) polymorphisms may allow prenatal diagnosis if the mutation has already been identified in other affected family members.

In children and adolescents with multiple fractures but no deformity, measurements of bone density and turnover may point toward the diagnosis. In the type I disorder, both bone density and serum type I procollagen peptide levels are likely to be decreased. However, because excretion of collagen cross-links is increased in most types of osteogenesis imperfecta,
Therapy

Antiresorptive therapy with IV pamidronate has been shown to decrease fractures in children with severe osteogenesis imperfecta, even before 3 years of age. Supportive treatment is important. The Osteogenesis Imperfecta Foundation works with patients and families to improve the quality of life. Orthopedic and rehabilitation services can be helpful in dealing with deformities. Genetic counseling and prenatal diagnosis, including ultrasound examination and testing for informative DNA polymorphisms, are important for the family. Gene therapy is being explored.
Other Connective Tissue Disorders Affecting the Skeleton

Other inherited disorders of connective tissue with impairment of skeletal development or increased bone fragility include Ehlers-Danlos syndrome, Menkes' disease, lysinuric protein intolerance, and homocystinuria. In these disorders, abnormalities of collagen cross-linking can affect bone and other connective tissues. In Ehlers-Danlos syndrome the cross-linking enzyme lysyl oxidase is deficient, and in Menkes' disease copper deficiency impairs the function of the enzyme. Lysinuric protein intolerance and homocystinuria probably also impair cross-linking of collagen.
OSTEOPETROSIS

Osteopetrosis, or marble bone disease, is a heterogeneous group of disorders characterized by a generalized increase in bone density caused by defective osteoclastic bone resorption. These syndromes are part of a larger group of sclerosing bone dysplasias (see later) that vary in severity and sites of skeletal involvement. Most cases are inherited, but some are acquired.

Osteopetrotic rats and mice with specific defects in osteoclasts have been found as a result of spontaneous mutations and developed using gene knockout techniques. The op/op mouse has a genetic defect in the production of M-CSF that results in failure of osteoclast formation and can be corrected by treatment with M-CSF. Knockouts of the proto-oncogenes c-src and c-fos; of TRAF-6, a mediator of RANK action; and of the critical osteoclast protease cathepsin K also cause osteopetrosis. Similar mutations may cause human osteopetrosis, but to date only defects in the vascular proton pump and in carbonic anhydrase, which affects acidification by osteoclasts, have been identified.

Infantile Osteopetrosis

Infantile osteopetrosis is a rare, autosomal recessive disorder in which failure to resorb bone and calcified metaphyseal cartilage causes near obliteration of the marrow spaces. Extramedullary hematopoiesis occurs in the liver and spleen. The cranial nerve foramina do not form normally, causing optic atrophy and other cranial nerve defects. The bones, although dense, are brittle, and pathologic fractures can occur. The impaired function of the hematopoietic system causes death in the first decade from hemorrhage or infection. On the basis of studies in animal models in which transfer of hematopoietic tissue resulted in cure, patients have been treated with total body radiation and grafting of marrow from human leukocyte antigen-identical donors. Some of these patients have been shown to have genetic defects of subunits of the vascular-type H^+-adenosine triphosphatase that acts as a proton pump in osteoclasts, but other patients show no abnormalities in these genes.
Carbonic Anhydrase II Deficiency

Carbonic anhydrase II deficiency, a nonlethal autosomal recessive disorder, is associated with a complete deficiency of the type II carbonic anhydrase that provides carbonic acid for hydrogen ion secretion by osteoclasts and by the distal tubules. Hence, osteopetrosis is accompanied by renal tubular acidosis that may involve both distal and proximal lesions. Affected individuals are shorter than their siblings and may have calcification of the basal ganglia.
Autosomal Dominant Osteopetrosis

Two forms of autosomal dominant osteopetrosis (ADO) have been described. ADO type II is the classical Albers-Schönberg disease in which there is generalized osteosclerosis with thickening of the vertebral end plates (sandwich vertebrae) and bone within bone in the pelvis. ADO type I is characterized by generalized osteosclerosis and thickening of the cranial vault.

In ADO type I, the number of osteoclasts is reduced; in ADO type II, the osteoclasts are large but apparently nonfunctional. Interestingly, bone resorption can be stimulated by triiodothyronine in patients with both types. The term benign osteopetrosis has been used to describe these disorders, but fractures, orthopedic problems, and cranial nerve involvement do occur, particularly in ADO type II.
FIBROUS DYSPLASIA

Clinical Features

Fibrous dysplasia is characterized by expanding lesions within the bone that contain both fibroblastic and osteoblastic elements. The disorder can occur as a monostotic lesion without any associated abnormalities or in a polyostotic form, which may occur as part of the McCune-Albright syndrome, associated with functional abnormalities of one or more endocrine glands and irregular hyperpigmented macules called café-au-lait spots.

The most common endocrine manifestation is precocious puberty, particularly in girls. The molecular defect in the McCune-Albright syndrome is somatic mosaicism for an activating mutation of the Gs subunit of the nucleotide-binding regulatory protein that couples receptors to adenylyl cyclase. Similar defects have been found in bone lesions in the absence of McCune-Albright syndrome. Local production of PTHrP may also be involved in pathogenesis. The bone lesions may show increased expression of the c-fos oncogene.
Diagnosis

Monostotic fibrous dysplasia is usually diagnosed in the second or third decade of life as an expanding bone lesion that can cause fracture, deformity, or nerve entrapment. Sarcomatous degeneration can occur. In fibrous dysplasia, any skeletal site can be affected but the femur, tibia, ribs, and face are most often involved. Histologically, the lesions contain many spindle-shaped fibroblasts and islands of woven bone. Bone lesions can worsen during pregnancy, and estrogen receptors have been identified in the bone lesions of patients with McCune-Albright syndrome.
Therapy

The course of both monostotic and polyostotic fibrous dysplasia is variable. Patients who show progression, nerve compression, or pathologic fractures may require surgery. Careful assessment of the endocrine system is critical in the McCune-Albright syndrome because early intervention can prevent irreversible changes resulting from precocious puberty. The bone lesions may respond to bisphosphonate. \[356\] \[357\] Treatment with 1,25(OH)\(_2\)D may reduce PTHrP production and decrease activity of the bone lesions. \[353\]
SCLEROSING BONE DYSPLASIAS

A number of rare, congenital skeletal disorders cause irregular bone structure and varying degrees of sclerosis. Acquired osteosclerosis related to increased bone formation occurs in fluorosis and in rare cases of hepatitis C infection, and a localized form is seen in certain metastatic malignancies, particularly cancers of the prostate and breast. Osteosclerosis with increased bone formation occurs in mice overexpressing the transcription factor Fra-1.

Pyknodysostosis

Pyknodysostosis is an autosomal recessive disorder characterized by short stature, a large cranium, and small facies. Unlike patients with osteopetrosis, these patients do not demonstrate loss of the marrow cavity and are not anemic. Histologically, trabecular bone volume is increased despite an increase in the number of osteoclasts, suggesting a defect in osteoclast function. This defect has been attributed to a mutation of the cathepsin K gene.
Progressive Diaphyseal Dysplasia

Known as Camurati-Engelmann disease, progressive diaphyseal dysplasia consists of patchy thickening of the bone on both periosteal and endosteal surfaces and is associated with gait abnormalities and muscle wasting. The histologic picture is one of increased bone formation rather than decreased resorption. The disease can be inherited as an autosomal dominant disorder. The gene has been localized to chromosome 19q13, and the disorder may be due to a defect in the latency-associated peptide of TGF-1. Glucocorticoid therapy relieves bone pain and reverses the histologic abnormalities in some cases.
Endosteal Hyperostosis

The term van Buchem's disease is applied to both severe and mild forms of hyperostosis. The disorder begins in infancy, and progressive enlargement of the jaw commences at puberty. Some subjects have cranial nerve deficits caused by impingement of the foramina. This disorder may be related to sclerosteosis, in which there is also syndactyly. Subjects with both disorders are usually tall and heavy. Both disorders have been localized to chromosome 17q12-q21.
Other Disorders

Unusual disorders that affect bone structure include (1) osteopoikilosis, which is characterized by many small foci of sclerosis in cancellous bone; (2) osteopathia striata, in which there are linear striations of the ends of the long bones and associated cranial sclerosis; and (3) melorheostosis, in which patchy areas of hyperostosis affect both the cortex and the medullary canal, sometimes associated with thickening of the overlying skin. Mixed pictures involving several different forms of sclerosis have been described.

Axial osteomalacia and fibrogenesis imperfecta ossium are rare disorders characterized by a coarse and dense appearance of trabecular bone. These disorders may be forms of osteomalacia because they show defective mineralization, presumably because of a defect in the matrix produced by osteoblasts.

Pachydermoperiostosis is a disorder characterized by periostitis, sclerosis of the distal portions of the tubular bones, and thickening of the skin. It may be inherited as an autosomal recessive disorder. It is also termed primary hypertrophic osteoarthropathy and must be distinguished from the secondary hypertrophic osteoarthropathy that occurs in patients with chronic pulmonary disease.

Infantile cortical hyperostosis is characterized by overgrowth of cortical bone. The similarity of this disorder to the changes seen after prolonged infusion of PGE in neonates has suggested a possible cause, and the disorder has been treated with glucocorticoids and nonsteroidal anti-inflammatory drugs.
EXTRASKELETAL CALCIFICATION AND OSSIFICATION

Mineral deposition in soft tissues is a common consequence of tissue damage and of a local elevation of the extracellular calcium-phosphate product. Ectopic or heterotopic bone formation can occur at sites of injury or surgical trauma and may be related to the presence of an inductive protein matrix. This form of bone induction stimulated the search for BMPs. The frequency of heterotopic ossification after hip replacement or spinal cord injury can be decreased by treatment with nonsteroidal anti-inflammatory drugs that inhibit prostaglandin synthesis or by local irradiation. Extensive subcutaneous calcium deposition may be crippling in inflammatory disorders such as dermatomyositis.

The term myositis ossificans is used when bone formation occurs in traumatized muscle, but similar masses can be formed in tendon, ligaments, joint capsules, and fascia without trauma.

Tumoral Calcinosis

Primary tumoral calcinosis is an inherited disorder characterized by periarticular calcification and hyperphosphatemia. It is associated with defective phosphate transport and sometimes with excessive activity of renal 1-hydroxylase. The primary disorder must be differentiated from secondary tumoral calcinosis, which occurs in association with renal failure and with hypercalcemic disorders.

Treatment by phosphate depletion using phosphate-binding antacids or diuretics, parathyroidectomy, and dialysis has been attempted.
Fibrodysplasia Ossificans Progressiva

This rare congenital disorder is most often sporadic but can be transmitted as an autosomal dominant disorder. Characteristic short phalanges and soft tissue swelling can be detected at birth. Abnormal regulation of a BMP has been implicated, and linkage analysis has localized the abnormality to chromosome 4q27. Painful, tender lesions caused by true ectopic bone can develop in connective tissues. Progressive deformities may include scoliosis and ankylosis of the spine and rib cage. There is no known therapy.

Progressive osseous heteroplasia is another genetic disorder in which ossification occurs largely in the skin.
SKELETAL ABNORMALITIES ASSOCIATED WITH LDL RECEPTOR-RELATED PROTEIN 5 (LRP5)

Recently a gene defect was identified that produced a rare form of osteoporosis associated with ocular changes, termed the osteoporosis-pseudoglioma syndrome.\[385\] The mutation is in the LDL receptor-related protein 5 (LRP5), a receptor that interacts with the frizzled receptor to mediate signaling by members of the wnt family. In addition, studies of a remarkable family who have unusually high bone mass inherited as an autosomal dominant trait, but who are otherwise phenotypically normal, also show an abnormality in the LRP5.\[386\] In this case, the mutation appears to be one that results in activation of LRP5 and hence could enhance signaling. These new observations may indicate another important pathway in regulation of the skeleton, with relevance to the pathogenesis and/or treatment of osteoporosis.

Nephrolithiasis is a common disorder with an incidence greater than one case per 1000 patients per year. The incidence peaks in the third and fourth decades. The prevalence in industrialized nations is close to 10% and increases with age until approximately age 70 years. In general, stones may be composed of calcium oxalate, calcium phosphate, uric acid, magnesium ammonium phosphate (struvite), or cystine, or a combination thereof. A variety of pathogenetic mechanisms determine the type of stone formed.

Stones tend to localize in the renal tubules and collecting system but are also commonly found within the ureters and bladder. Nephrolithiasis rarely results in renal insufficiency or life-threatening illness but is responsible for substantial morbidity. The severe pain of renal colic can lead to frequent hospitalization, shock wave lithotripsy, or invasive surgical procedures. Insight into the mechanisms involved in stone formation can help direct appropriate therapy, which is known to decrease the incidence of stone disease and its associated morbidity.
EPIDEMIOLOGY OF STONE FORMATION

Numerous factors determine the prevalence of stones, including sex, age, race, and geographic distribution. Nephrolithiasis is more common in men than women at a ratio of 2:1 to 4:1. In the United States, blacks, Hispanic Americans, and Asian Americans are much less likely to have stones than whites. Geography also appears to influence stone formation in the United States, with a decreasing prevalence from south to north and, to some degree, from east to west.

The greater exposure to sunlight in the southeastern United States may be responsible for the increased rates of nephrolithiasis in that area. Sun exposure can lead to more concentrated urine by increasing insensible fluid losses due to sweating; in addition, it may result in intestinal calcium absorption and urinary calcium excretion by stimulating vitamin D production.

Geographic location can also influence the type of stone formed. Uric acid stones, for example, predominate in Mediterranean and Middle Eastern countries, where they constitute up to 75% of all the stones formed. In the United States, however, fewer than 10% are pure uric acid stones, and more than 70% of stones formed are composed of calcium and an associated anion. Less common are magnesium ammonium phosphate (struvite or infection) stones, which account for about 10% to 15% of stones formed, and cystine stones, which are due to an autosomal recessive disorder and constitute only about 1% of all stones formed. (Table 28-1)

---

[1][2][3][4][5][6][7][8][9]
PATHOGENESIS OF STONE FORMATION

Kidney stones form when urine becomes oversaturated with respect to the specific components of the stone. Saturation is dependent on chemical free ion activities of the stone constituents. Factors that affect chemical free ion activity include urinary ion concentration, pH, and complexing with other substances. For example, an increase in the quantity of urinary calcium or a decrease in urine volume increases the free ion activity of calcium ions in the urine. Urinary pH can also modify chemical free ion activity. A low urinary pH increases the free ion activity of uric acid ions but decreases the activity of calcium and phosphate ions. Citrate combines with calcium ions to form soluble complexes and can thereby decrease their free ion activity. When the chemical free ion activities are increased, the urine becomes oversaturated and new stones may form or established stones grow. In the setting of decreased free ion activity, urine becomes undersaturated and stones do not grow and may even dissolve. The equilibrium solubility product is the degree of chemical free ion activity of stone components in a solution in which the stone neither grows nor dissolves.

Formation of stones occurs through either homogeneous or heterogeneous nucleation:

1. Homogeneous. Progressive oversaturation can eventually result in formation of small clusters of ions; these clusters grow in size to form a permanent solid phase.

2. Heterogeneous. This category refers to crystal formation on the surface of a different crystal type or on other foreign substances, such as cells. In vivo, this type of nucleation is more common than homogeneous nucleation because crystals form at a lower level of oversaturation in the presence of a solid phase.

The crystals must then aggregate into clinically significant stones, a process that takes longer than the passage of urine through the renal tubules. For stone formation to occur before the crystals are swept away in the urine, they must adhere to the renal tubular cells in order to allow more time for growth. This anchoring of crystals to tubular cells is a process that is undergoing careful study.

An important factor in the development of kidney stones may be the absence of adequate levels or activity of crystallization inhibitors in patients with stones. Uropontin, pyrophosphate, and nephrocalcin are endogenously produced substances that have been shown to inhibit calcium crystallization. Differences in the amount or activity of inhibitors may account for the variability in stone formation among people with similar degrees of urinary oversaturation. The influence of such inhibitors on stone formation is also an area of ongoing research.

Clinically, most physicians evaluate the lithogenic potential of the urine from stone formers by measuring the rate of excretion of the principal stone-forming elements in mass per unit time (e.g., milligrams per 24 hours). It is clear, however, that the lithogenic potential of urine is better determined by the degree of oversaturation. Computer programs that calculate saturation from concentrations of various elements in the urine are now available and more accurately determine the risk of stone formation. Any calculation of mean saturation under-estimates the maximum oversaturation because of hourly variations in water and solute excretion throughout the day.
PATHOGENESIS OF IDIOPATHIC HYPERCALCIURIA

Idiopathic hypercalciuria (IH) is the most common cause of calcium-containing kidney stones. IH is defined as excessive urinary calcium excretion (hypercalciuria) in the setting of normocalcemia and in the absence of secondary causes of hypercalciuria. The disorder is familial, was initially thought to exhibit an autosomal dominant pattern of inheritance, but may be polygenic. The mechanism by which IH leads to hypercalciuria is not known. It has been postulated that IH may comprise three distinct disorders:

1. Excessive intestinal calcium absorption.
2. Decreased renal tubular calcium reabsorption.
3. Enhanced bone demineralization.

Recent observations have led many to believe that IH consists of a spectrum of these disorders, with considerable overlap among these potential mechanisms.

Calcium Homeostasis

Urinary calcium homeostasis is regulated by the gastrointestinal (GI) tract, the kidneys and bone, and the hormones parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D₃ (1,25(OH)₂ D₃). Approximately 99% of the calcium in the body is contained within the bone mineral. Daily bone resorption and bone formation, which in healthy, nonpregnant adults should be equal, allow less than 1% of bone calcium to be exchanged with that in the extracellular fluid.

Both PTH and 1,25(OH)₂ D₃, at high concentrations, stimulate release of calcium from the bone mineral through osteoclast-mediated bone resorption. Net calcium influx into the extracellular fluid is achieved principally by absorption from the GI tract, which occurs through 1,25(OH)₂ D₃-dependent and -independent mechanisms. Although PTH appears to have no direct effect on GI calcium absorption, increased levels of the hormone can stimulate production of 1,25(OH)₂ D₃, which in turn leads to enhanced absorption.

The roughly 60% of calcium in the extracellular fluid that is not protein-bound is freely filtered by the renal glomeruli. Approximately 80% to 85% of this amount is passively reabsorbed in the proximal tubule. Most of the remaining calcium is reabsorbed in the distal cortical tubules under PTH stimulation. Ultimately, these reabsorptive mechanisms result in a urinary calcium concentration that is less than 2% of the daily filtered load of calcium. Except during pregnancy and lactation, urinary calcium excretion equals intestinal calcium absorption in healthy adults.
Potential Mechanisms for Development of Idiopathic Hypercalciuria

Dysregulation of calcium flux at any of these sites may lead to hypercalciuria. For example, excessive calcium absorption by the GI tract would lead to a transient increase in the serum calcium. This increase in serum calcium would suppress secretion of PTH and 1,25(OH)\(_2\)D\(_3\), which, along with the increased filtered load of calcium to the kidneys, would result in hypercalciuria. Excessive 1,25(OH)\(_2\)D\(_3\) would have a similar effect on intestinal calcium absorption but would also result in influx of calcium into the extracellular fluid because of enhanced bone demineralization. The result would be hypercalciuria even in the setting of a low-calcium diet or an overnight fast.

If a primary defect in renal calcium reabsorption has led directly to hypercalciuria, there would be a fall in the serum calcium concentration that would stimulate production of PTH and 1,25(OH)\(_2\)D\(_3\). This production, in turn, would result in enhanced intestinal calcium absorption. With this mechanism, the renal loss of calcium would persist even with a low-calcium diet or overnight fast.

Hypercalciuria may also develop as a result of a renal defect in phosphorus reabsorption. The resultant hypophosphatemia would lead to enhanced 1,25(OH)\(_2\)D\(_3\) production, which would stimulate intestinal absorption of both phosphorus and calcium. The increased serum calcium would suppress PTH production. The increased filtered load of calcium in the setting of suppressed PTH would also lead to hypercalciuria. Enhanced bone demineralization would increase the serum calcium concentration, which in turn would suppress PTH production. The increase in the filtered load of calcium in this setting would result in hypercalciuria.

Thus, there are several potential mechanisms for hypercalciuria. Do human or animal data support one mechanism above all others? From a clinical therapeutic standpoint, is it worth differentiating among the various potential mechanisms in each patient with suspected IH?
Human Data

Larsen compiled the results of numerous calcium balance studies on patients with IH and normocalciuric control subjects and normalized the results for calcium intake. He found that intestinal calcium absorption was significantly higher in the subjects with IH.

Asplin and colleagues, also collecting data from published metabolic balance studies, compared net intestinal calcium absorption and urinary calcium excretion in hypercalciuric and normocalciuric adults. They also noted an increase in intestinal calcium absorption in subjects with IH but found that urinary excretion of calcium was increased to an even greater degree, placing many of these patients in net negative calcium balance.

Although these data confirm that enhanced intestinal absorption of calcium probably plays a role in the pathogenesis of IH, the investigators could not clarify whether this is the primary defect or is secondary to another lesion, such as a primary defect in renal handling of calcium. Others suggested that the increase in intestinal calcium absorption, in combination with excessive renal calcium excretion, indicated a more generalized defect in calcium homeostasis. Nonetheless, the finding of enhanced calcium absorption makes enhanced bone resorption an unlikely primary mechanism of IH, as the increase in serum calcium concentration resulting from bone resorption would suppress 1,25(OH)\(_2\)D\(_3\)-mediated intestinal calcium absorption.

In most published studies, patients with IH have higher serum levels of 1,25(OH)\(_2\)D\(_3\) than normocalciuric control subjects. Kaplan and colleagues determined that 1,25(OH)\(_2\)D\(_3\) levels were higher than control values in approximately one third of patients with IH and that intestinal calcium absorption was inappropriately high for the level of 1,25(OH)\(_2\)D\(_3\). These studies support either 1,25(OH)\(_2\)D\(_3\)-mediated intestinal calcium absorption or a primary defect in renal tubular calcium reabsorption as a primary mechanism for hypercalciuria in IH.

PTH levels in patients with IH have been reported as normal or slightly lower than those in controls. This finding argues against a reduction in renal tubular calcium reabsorption as the primary defect in IH because with this mechanism the hypercalciuria would lead to low serum calcium levels and stimulation of PTH secretion. This finding also does not support the hypothesis that elevated levels of PTH are the stimulus for the increased levels of serum 1,25(OH)\(_2\)D\(_3\) observed in many studies. It is, however, consistent with the other potential mechanisms for IH.

Bone mass in patients with IH has been assessed by a number of methods, including radiologic densitometry, quantitative computed tomography (CT), dual-energy x-ray absorptiometry, single-photon absorptiometry, and others. Studies of patients with IH have generally shown only a mild reduction of bone mineral density compared with values in controls. The studies were unable to reveal a unifying mechanism for the mild reduction in bone mineral density, but primary net bone resorption is unlikely because a much greater decrease in bone density would be expected in this setting. Altered 1,25(OH)\(_2\)D\(_3\) regulation would be consistent with this finding because the effects of 1,25(OH)\(_2\)D\(_3\) on bone resorption would be mitigated by the increased intestinal calcium absorption stimulated by the hormone.

Until recently, it was considered necessary to determine whether a patient with IH tended to have excessive GI calcium absorption (absorptive hypercalciuria) or excessive renal excretion (renal leak). Patients with excessive renal calcium excretion were prescribed thiazide diuretics, and those thought to have a predominantly absorptive defect were prescribed a low-calcium diet. Coe and colleagues undermined the validity of this approach in a study in which 24 patients with IH and 9 control subjects were given a low-calcium diet (2 mg/kg per day) for more than 1 week. Urine and blood tests revealed normal serum calcium levels, a mild decrease in PTH levels in the patients with IH, but no difference in 1,25(OH)\(_2\)D\(_3\) levels.

The striking finding was that whereas all the normocalciuric subjects excreted less calcium than they ingested, 16 of the 24 subjects with IH had urinary calcium excretion that exceeded their intake. Thus, most of the patients with IH receiving a low-calcium diet were in net negative calcium balance. No clear demarcation was noted between the patients who tended to excrete excessive amounts of calcium and those who did not. Instead, there was a smooth continuum of urinary calcium excretion among patients with IH that appeared not to be influenced by calcemic hormones. These findings have rendered insignificant not only the need to clinically distinguish IH mechanisms in humans but also the prescription of a low-calcium diet in any of these patients, as the result may be a dangerous reduction in bone mineral density, especially in women.
Genetic Hypercalciuric Stone-Forming Rats

To explain more fully the mechanism of IH in humans, we have developed an animal model of this disorder. Through more than 54 generations of successive inbreeding of the most hypercalciuric progeny of hypercalciuric Sprague-Dawley rats, we have established a strain of rats that excrete abnormally large amounts of urinary calcium (Fig. 28-1). As in humans, the principal mechanism for the excessive calcium excretion in these rats appears to be an increase in intestinal calcium absorption. The increased absorption appears to be mediated not by an increase in the serum level of 1,25(OH)_{2}D_{3} but by an increase in the number of intestinal vitamin D receptors.

When these hypercalciuric rats were fed a diet very low in calcium, their urinary calcium excretion remained elevated compared with that of similarly treated control rats, indicating a defect in renal calcium reabsorption or an increase in bone resorption, or both. Bone from these hypercalciuric rats released more calcium than the bone of control rats when exposed to increasing amounts of 1,25(OH)_{2}D_{3} and the administration of a bisphosphonate to rats fed a low-calcium diet significantly reduced urinary calcium excretion. In addition, a primary defect in renal calcium reabsorption was observed during clearance studies. We have shown that, besides the intestine, both the bone and kidney of the hypercalciuric rats have an increased number of vitamin D receptors.

Thus, hypercalciuric rats appear to have a systemic abnormality in calcium homeostasis; they absorb more intestinal calcium, they resorb more bone, and they do not adequately reabsorb filtered calcium. Because each one of the hypercalciuric rats forms renal stones, we have described them as genetic hypercalciuric stone-forming (GHS) rats. These studies suggest that an increased number of vitamin D receptors may be the underlying mechanism for hypercalciuria in these rats and perhaps, by analogy, in humans. Clinical studies are ongoing to determine whether patients with hypercalciuria have an increased number of vitamin D receptors.
CLINICAL PRESENTATION

Kidney stones vary in clinical presentation from asymptomatic to large, obstructing staghorn calculi that can significantly impair renal function and lead to end-stage renal disease. The severity of stone disease depends on the pathogenetic factors contributing to the rate of stone formation in addition to the stone type, size, and location. In its most classic form, nephrolithiasis is manifested as renal colic. This discomfort of abrupt onset intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency and frequency, nausea, and vomiting may be present. Stones smaller than 5 mm are likely to pass spontaneously with hydration, whereas larger stones often necessitate urologic intervention.

Certain disorders can lead to small, diffuse renal parenchymal calcifications termed nephrocalcinosis. The calcifications, usually calcium phosphate or calcium oxalate, may be present in the cortex or medulla. Among the most common causes of stone-related nephrocalcinosis are primary hyperoxaluria and medullary sponge kidney.
METABOLIC EVALUATION OF STONE FORMERS

Although it is uniformly accepted that patients with multiple stones merit a thorough investigation into the cause of nephrolithiasis, evaluation of the patient with a single stone is controversial. This is probably due to the difficulty in determining the cost-to-benefit ratio of stone evaluations and wide differences in reported rates of stone recurrence.

In 1988, the National Institutes of Health convened a consensus conference to resolve such issues related to the prevention and treatment of kidney stones. The panel determined that all patients, even those with a single stone, should undergo at least a basic evaluation in order to rule out a systemic etiologic mechanism. Patients with an increase in number or size of stones within a certain time frame (metabolically active stones), all children, all non-calcium oxalate stone formers, and those in demographic groups not typically susceptible to stone formation (nonwhites) warrant a more complete metabolic evaluation (Fig. 28-2).
THE BASIC EVALUATION (Table 28-2)

History
In addition to the medical history typically obtained from new patients, the evaluation of the stone former includes a stone history and a thorough review of diet, fluid intake, and lifestyle. Specific laboratory studies and radiographic tests are also required.

Stone History
The stone history begins with a chronology of stone events: age of incidence of first stone, size and number of stones formed, frequency of passage, stone type if known, and whether the stones occur equally in both kidneys or unilaterally. Also helpful is a report of the patient's symptoms with each episode as well as the need for and response to surgical intervention. This information imparts not only the severity of the stone disease but also clues to the origin of the patient's nephrolithiasis. For example, nephrolithiasis that begins at a young age may be attributable to an inherited metabolic disorder such as primary hyperoxaluria or cystinuria. Large staghorn calculi that are difficult to eradicate and that recur despite

</tr>
</tbody>
</table>

Frequent surgical intervention are more likely to be composed of struvite instead of calcium oxalate. Cystine stones are not crushed thoroughly with the use of lithotripsy, and alternative surgical modalities are generally required for stone removal. In patients who tend to form stones in only one kidney, the possibility of congenital abnormalities of that kidney, such as megacalix or medullary sponge kidney, should be explored.

Medical History

Systemic disorders that can contribute to nephrolithiasis are sought in the medical history. For example, any disorder that can result in hypercalcemia, such as sarcoidosis or certain malignancies, may also lead to hypercalcemia. A variety of GI disorders associated with malabsorption (e.g., sprue, Crohn's disease) can cause calcium oxalate nephrolithiasis on the basis of enteric hyperoxaluria. Patients with gout are more likely to have uric acid stones (Table 28-3 and Table 28-4).

Family History
A number of stone disorders are inherited, making the family history an important component of the basic evaluation. IH appears to be a familial disorder. Although the exact chromosomes and genes have not yet been identified, the pattern of inheritance may prove to be polygenic.

Stones arising in childhood or young adulthood can be related to autosomal recessive disorders such as cystinuria and primary oxaluria, although the latter tends to affect younger children. Cystinuria is thought to result from a genetic defect on chromosome 2, whereas the exact genetic abnormality that causes primary oxaluria remains unknown. Several inherited metabolic disorders can also cause hyperuricosuria.

Medications

Medications can contribute to stone formation in several ways. Calcium-containing antacids, for example, can increase the amount of calcium absorbed and subsequently excreted. Loop diuretics, on the other hand, can directly promote renal tubular excretion of calcium. Acetazolamide, a weak diuretic, induces a mild metabolic acidosis and alkaline urine, favorable conditions for the development of calcium phosphate stones. Other medications, such as salicylates and probenecid, are implicated in uric acid lithiasis.

Certain crystals or stones may consist completely of precipitated medication. Such medications include intravenously administered acyclovir, triamterene, and indinavir. Although oxalate is a metabolic end product of vitamin C, there has been no obvious correlation between vitamin C ingestion and calcium oxalate nephrolithiasis. Nonetheless, patients are counseled to avoid large doses of the vitamin.

Lifestyle and Diet

Occupation and lifestyle are aspects of the social history that may contribute to stone formation. Surgeons and traveling salespeople, for example, tend to minimize fluid intake in order to avoid frequent micturition throughout the day. Loss of insensible fluid can also exacerbate nephrolithiasis and may be related to employment (e.g., construction work) or hobbies (running, gardening).

The evaluation proceeds with a thorough review of the patient's diet and fluid intake. Patients are asked to review what they eat at all meals and snacks. Particular attention is paid to ingestion of foods high in sodium (fast foods, canned foods, added salt or soy sauce) and the quantity of animal protein consumed (see later). Patients are also asked to list four or five favorite foods or snacks to assess whether they may be consuming foods high in oxalate or purine as well. Many patients are erroneously counseled by physicians to avoid calcium-containing foods. Doing so not only results in bone demineralization, a grave concern in women with stones, but also appears to be associated with increased stone formation.
Physical Examination

For most patients with nephrolithiasis, physical findings are normal; in some patients, however, the findings may reveal a systemic disorder related to the stone disease. An enterocutaneous fistula, for example, may be associated with Crohn’s disease, a common cause of enteric oxaluria. A paraplegic patient with an indwelling catheter may be susceptible to frequent urinary tract infections with urease-producing organisms and consequent struvite stone formation. Hyperuricosuria and uric acid stone formation may be seen in patients with tophi related to gout.
Laboratory Tests

Although valuable information is gleaned from the history and physical examination, it is often difficult to determine the metabolic cause of a patient's nephrolithiasis without laboratory data. The urinalysis is an easy and inexpensive test that provides a great deal of information. Uric acid and calcium oxalate stones, for example, grow more favorably at an acidic pH, and a consistently high urinary pH may suggest calcium phosphate or struvite nephrolithiasis. The specific gravity, if high, may confirm suspicions of inadequate fluid intake.

Hematuria is often present in active stone disease. Microscopic examination of the urine in this case may reveal characteristic crystals. Bacteria and pyuria noted in conjunction with a high urinary pH (>6.5) are characteristic of struvite stone disease. Urine specimens for culture should be obtained in this setting. Because enough urease may be produced to form struvite stones even when colony counts are low (<50,000 colony-forming units), the microbiology laboratory should be instructed specifically to identify the organism and to check for urease despite low colony counts.

If available, qualitative cystine screening should be performed on a urine specimen. Urine turns purple-red when sodium nitroprusside is added to a specimen containing cystine at a concentration greater than 75 mg/L.

Recommended blood tests in the basic evaluation include electrolytes (sodium, potassium, chloride, bicarbonate), serum creatinine to determine the overall renal function, uric acid, calcium, and phosphorus. If the calcium level is elevated or at the upper limit of normal or if the serum phosphorus level is reduced or at the lower limit of normal, a serum intact PTH level is also determined to rule out primary hyperparathyroidism. Low serum bicarbonate levels suggest a hypocitraturic disorder such as renal tubular acidosis (RTA) or acetazolamide ingestion.
Stone Analysis

Stone analysis should be performed, whenever possible, in patients with a new history of nephrolithiasis or in patients with long-standing stone disease who note a difference in clinical presentation or in the color, shape, or texture of any stone passed. Knowing the constituents of a stone can help the physician target certain elements of the medical history and specific urine studies. In most cases, the stone must be sent to an outside laboratory for examination. X-ray diffraction crystallography and infrared spectroscopy are currently the most accurate methods available for stone analysis.\(^5\)
Radiologic Evaluation

A number of useful radiologic tests can help determine the location and extent of the stone burden and may elucidate genitourinary abnormalities contributing to stone formation. In patients with known radiopaque stones (calcium, cystine, and struvite), a plain film of the abdomen that includes a view of the kidneys, ureters, and bladder (KUB) demonstrates most stones. Radiolucent stones composed of uric acid and xanthine, however, are not visible. The intravenous pyelogram (IVP) may be superior for screening, in that it can reveal all stones as filling defects regardless of composition. Abnormalities of the genitourinary tract that can predispose to nephrolithiasis (e.g., medullary sponge kidney and caliceal abnormalities) are also evident with IVP but not with KUB films. In an acute episode of renal colic, the osmotic diuresis generated by the contrast agent administered may flush out the offending stone.

Disadvantages of IVP include additional radiation exposure, since numerous radiographs must be taken and the patient is exposed to radiographic contrast material. Administration of contrast material should be avoided in patients with contraindications to this measure, such as renal insufficiency, diabetes mellitus, and proteinuria.

Despite the advantages of IVP, non-contrast-enhanced helical (or spiral) CT is increasingly considered the diagnostic test of choice in many institutions. Helical CT has proved to be at least as sensitive and specific as IVP in detecting stones of all types in both the kidneys and ureters. In addition, it can more accurately reveal causes of flank pain and hematuria not related to stones and requires no exposure to intravenous contrast material. Radiation exposure is a disadvantage of both CT and IVP, although the exposure to patients undergoing helical CT may be triple that of IVP. Helical CT takes less time to perform, a potential advantage in an emergency department setting, but tends to be more costly.

Renal ultrasound examinations are useful when radiation exposure must be limited. In general, ultrasonography is excellent in demonstrating stones within the kidneys but may miss ureteral stones.

Once a patient is known to have a certain type of stone, specific tests may be used in follow-up. For example, a patient known to have asymptomatic calcium stones can have a KUB test 6 to 12 months later to assess for any increase in stone size or number.
THE COMPLETE EVALUATION (see Table 28-3)

The complete evaluation comprises the entire basic examination as well as a 24-hour urine collection to determine volume and levels of calcium, oxalate, citrate, sodium, urate, phosphorus, and creatinine (Table 28-6). Creatinine is used to assess the adequacy of the collection; men should excrete at least 15 to 20 mg/kg of creatinine per day, and women should excrete 10 to 15 mg/kg of creatinine per day. In patients known to have cystine stones or in whom prior urine studies have been unrevealing, cystine should also be measured.

Patients should be instructed to collect the urine on a day when they perform usual activities and have their typical fluid and dietary intake. The first morning's urine specimen is discarded, and all urine for the next 24 hours (including the next morning's specimen) is collected in the jug. The collection jug should contain preservatives for some or all of the constituents being measured. In our laboratory, all the measurements may be done with hydrochloric acid as a preservative. Certain laboratories require various preservatives for the different factors measured. Physicians should ask their laboratory how many 24-hour urine collections and which preservatives are required for the complete evaluation.

The patients who require the complete evaluation are as follows: (1) all children, (2) nonwhites (demographic groups not typically prone to nephrolithiasis), (3) noncalcium stone formers, and (4) patients with metabolically active stone disease (metabolically active stones are those that grow in size or number within 1 year).

| Table 28-6 – Optimal 24-Hour Urine Values in Patients with Nephrolithiasis |

Table 28-6 – Optimal 24-Hour Urine Values in Patients with Nephrolithiasis
NONSPECIFIC THERAPY

Most patients are given general advice about fluid and dietary modification to prevent further stone formation. These nonpharmacologic interventions, which include an increase in fluid intake as well as restriction of dietary sodium and animal protein, can reduce the incidence of stone formation, a result termed the stone clinic effect. In one study, such interventions resulted in a 60% decrease in stone recurrence over 5 years. Many patients with calcium stones are erroneously advised to restrict their calcium intake, a recommendation that is harmful not only with respect to preservation of bone mineral but also with regard to stone formation.

Augmented fluid intake to ensure a urine volume greater than 2 to 2.5 L/day has proved efficacious in reducing stone formation and continues to be a mainstay of therapy for all stone types. With an increased urine volume, the supersaturation of calcium oxalate and other crystals is significantly reduced.

Renal calcium excretion is augmented by increased sodium excretion, and hypercalciuric patients tend to have a greater calciuric response to a sodium load than control subjects. Dietary sodium restriction with the consequent decrease in urinary sodium thus reduces calcium excretion. Patients are therefore counseled to limit their daily sodium intake to 3000 mg (130 mEq) in an attempt to reduce hypercalciuria.

A moderate reduction in animal protein (1.0 mg/kg per day) is beneficial in patients with nephrolithiasis because of the multiple mechanisms by which animal protein can contribute to stone formation. A mild metabolic acidosis develops when animal proteins are metabolized. In order to buffer the excess hydrogen ions, calcium is resorbed from bone, which increases the filtered load of calcium. Metabolic acidosis also diminishes renal tubular calcium reabsorption, which further enhances the hypercalciuria. In addition, metabolism of amino acids contained in animal protein generates sulfate ions, which couple with calcium ions to form insoluble complexes.

Citrate, a base, forms soluble complexes with calcium and is beneficial in lowering calcium oxalate and calcium phosphate oversaturation and in reducing stone formation. During metabolic acidosis, citrate is reabsorbed from bone, which increases the filtered load of calcium. Metabolic acidosis also diminishes renal tubular calcium reabsorption, which further enhances the hypercalciuria. In addition, metabolism of amino acids contained in animal protein generates sulfate ions, which couple with calcium ions to form insoluble complexes.

As indicated previously, hypercalciuric patients have often been categorized as having either excessive renal calcium excretion (renal leak) or excessive absorption of calcium from the GI tract (absorptive hypercalciuria). For several reasons, these distinctions and the numerous possible subdivisions are no longer favored.

First, both human and animal studies have shown that these are probably not two distinct entities but, rather, a linked abnormality that leads to a spectrum of both excessive calcium absorption and excretion. Second, patients with enhanced intestinal calcium absorption have generally been prescribed a low-calcium diet. Although some patients may absorb an excessive amount of calcium, many patients with IH given a low-calcium diet excrete more calcium than they absorb, rendering them vulnerable to excessive bone demineralization.

Studies have demonstrated the apparently paradoxical benefits of a high-calcium diet in patients with kidney stones. Ingested calcium binds oxalate in the intestine, reducing its absorption and consequent renal excretion. It has been suggested that a diet high in calcium decreases oxalate absorption and, consequently, urinary calcium oxalate supersaturation, leading to reduced stone formation.

---
ETIOLOGY AND SPECIFIC THERAPY

The optimal therapy for patients with metabolically active stone disease is directed at the particular metabolic abnormality. Before medications for nephrolithiasis are prescribed, all patients should be treated with the nonspecific measures noted earlier.

Before therapy is initiated, it is also worth assessing the patient’s existing stone burden with a radiologic examination (KUB, IVP, spiral CT, or ultrasonography). If stones are seen, the subsequent passage of stones would not necessarily indicate therapeutic failure. The basic and complete evaluations help direct the clinician to the specific treatments discussed here.

**Calcium Stones**

Most kidney stones (70%) contain calcium (see Table 28-1). More than one third of these are composed of calcium oxalate alone, and another 7% are composed of calcium phosphate alone. The remainder are composed of a combination of calcium oxalate and either urate or calcium phosphate. The stones tend to be gray, brown, or tan and rarely grow larger than 1 to 2 cm.

The main causes of calcium stone formation are as follows:

- Hypercalciuria (excessive urinary calcium excretion)
- Hyperoxaluria (excessive oxalate excretion)
- Hyperuricosuria (excessive uric acid excretion)
- Hypocitraturia (insufficient citrate excretion)
- Renal tubular acidosis
- Congenital abnormalities of the genitourinary tract
- Certain medications

**Hypercalciuria**

Patients with persistent hypercalciuria despite increased volume intake and a low-sodium diet often benefit from a thiazide diuretic. This class of drugs is inexpensive and extremely effective at reducing urinary calcium excretion and stone formation.

In order to maximize the efficacy of thiazides, patients must consume a sodium-restricted diet. Whereas hydrochlorothiazide is more commonly used for hypertension, chlorthalidone is favored for the treatment of hypercalciuria because it has a longer half-life and requires only daily dosing. The starting dose is 25 mg and can be increased to 50 mg. In petite patients or those with low blood pressure, therapy can be initiated with 12.5 mg.

One side effect of thiazides is an increase in serum lipid levels. For patients in whom this is a concern, such as those with hypercholesterolemia or other cardiac risk factors, indapamide, 1.25 to 2.5 mg, is a good alternative because it has less effect, compared with thiazides, on serum lipids.

Hypokalemia is another common side effect of thiazide therapy. Patients should be advised to increase their dietary intake of potassium-rich foods, and the potassium level should be checked 7 to 10 days after the start of the medication. Hypokalemia can result not only in cardiac and neuromuscular problems but also in hypocitraturia, another risk factor for stone formation. The supplement of choice, therefore, is potassium with a base, such as citrate, as the accompanying anion.

Potassium citrate is available as a liquid or as a wax matrix tablet. The latter form is preferable because patients generally find the liquid unpalatable. Patients with malabsorptive disorders, however, absorb potassium citrate better in the liquid form. Potassium citrate, in the wax matrix formulation, is available as 5- and 10-mEq tablets; 20 to 40 mEq/day in single or divided doses is usually adequate supplementation. Determination of follow-up potassium and bicarbonate levels may be required for further dose adjustment. Because citrate is a base, metabolic alkalosis can result with this medication and an alternative potassium supplement (e.g., potassium chloride) may be required. If hypokalemia persists or if large doses of supplemental medication are required, the patient may benefit from the addition of a potassium-sparing diuretic. Triamterene is generally avoided because it can precipitate into stones. Amiloride, however, may be initiated at a starting dose of 5 mg or in a combination tablet with thiazide.

After at least 4 weeks of the new medication, the 24-hour urine test should be repeated to assess the efficacy of therapy in reducing calcium levels; 24-hour urinary sodium and citrate levels should also be measured. The thiazide dose may need to be increased to decrease calcium excretion to less than 3 to 4 mg/kg per day. If sodium excretion remains high in conjunction with elevated urinary calcium excretion, further dietary counseling aimed at reducing dietary sodium may be required. Additional potassium citrate may be required if urinary citrate or serum potassium levels remain low.

**Hyperoxaluria**

Oxalate is produced predominantly by endogenous metabolism of glyoxylate and, to a lesser extent, by ascorbic acid. Some urinary oxalate is derived from dietary sources, such as rhubarb, cocoa, nuts, tea, and certain leafy green vegetables. Absorbed oxalate is excreted unchanged in the urine and raises urinary supersaturation with respect to calcium oxalate. Hyperoxaluria accounts for the formation of approximately 5% of all calcium stones.

The three main causes of hyperoxaluria are:

1. Excessive oxalate ingestion (dietary oxaluria).
2. Malabsorptive GI disorders (enteric oxaluria).
3. Excessive endogenous metabolism of oxalate related to a hepatic enzyme deficiency (primary hyperoxaluria).

Since ethylene glycol (used as an antifreeze in automobiles) is metabolized to oxalate, nephrolithiasis is frequently observed in patients after ingestion of ethylene glycol.

**Dietary Oxaluria**

Dietary oxaluria results in urinary oxalate levels that are mildly elevated (40 to 60 mg/day). Patients with hyperoxaluria should be given detailed lists of high-oxalate foods to avoid (Table 28-7). In addition, calcium carbonate (500 to 650 mg per tablet, two or three tablets with each meal and snacks) may further help reduce the amount of oxalate absorbed. Alternatively, patients can be advised to drink a glass of milk with meals, especially meals that might be high in oxalate. The calcium in milk binds the dietary oxalate and helps prevent its absorption.

**Enteric Oxaluria**

Enteric oxaluria results in higher urinary oxalate levels (60 to 100 mg/day). GI malabsorptive conditions associated with normal colonic function, such as Crohn's
disease, celiac sprue, jejunoileal bypass, chronic pancreatitis, and biliary obstruction, may lead to enteric oxaluria. In these disorders, malabsorbed fatty acids bind calcium in the gut, making more free calcium available for absorption in the colon. In addition, the colonic mucosa becomes more permeable to oxalate as a result of exposure to malabsorbed bile salts.

The mainstay of treatment, whenever possible, is therapy for the underlying disorder. A gluten-free diet, for example, can significantly reduce hyperoxaluria associated with sprue; for other conditions (e.g., surgical short-bowel syndrome), no specific therapy is feasible. In such cases, reduction of malabsorption and oxalate absorption may be achieved by instituting general therapy for steatorrhea, such as a low-fat diet, cholestyramine, and medium-chain triglycerides.

As in patients with dietary oxaluria, an oxalate-restricted diet and calcium carbonate with meals should be prescribed. Because of chronic diarrhea, these patients are also at risk for low urine volumes, hypocitruria, hypokalemia, and hypomagnesemia. The acidic, concentrated urine also predisposes to development of uric acid stones. Additional fluid intake must be stressed, and potassium citrate (the liquid form is generally better absorbed in these patients) and magnesium supplementation are often prescribed. Magnesium appears to be an inhibitor of stone formation and is supplied as magnesium oxide at 400 mg by mouth twice a day or magnesium gluconate at 0.5 to 1 g by mouth three times a day.

Primary Hyperoxaluria

Primary hyperoxaluria (PH) leads to nephrolithiasis, since hepatic enzyme deficiencies in these patients lead to massive endogenous oxalate production. PH results not only in severe hyperoxaluria (80 to 300 mg/day) but also in widespread deposition of oxalate in numerous organs and tissues such as the heart, bone marrow, muscle, and renal parenchyma at a young age. Cardiomyopathy, bone marrow suppression, and renal failure may ensue. In type 1 PH, the deficient hepatic enzyme is alanine:glyoxylate aminotransferase (AGT). In type 2 PH, which is an even more uncommon disorder, patients lack α-glycerate reductase and glyoxylate reductase. Patients with type 1 PH benefit from pyridoxine (vitamin B₆) therapy, which may reduce oxalate production.

All patients with PH should be treated with measures that reduce calcium oxalate precipitation, such as large fluid supplementation, potassium citrate, magnesium, and orthophosphate. Orthophosphate is an effective inhibitor of calcium oxalate crystalization but should be avoided in patients with a glomerular filtration rate below 50 mL/minute. Patients with renal failure may benefit from renal transplantation because dialysis is not as effective as a functioning kidney in oxalate removal.

The preceding measures should be continued after transplantation to avoid rapid loss of the allograft caused by calcium oxalate deposition. Ultimately, for patients with type 1 PH, liver transplantation can supply the missing AGT and may be curative, especially if it is performed before the development of end-stage renal failure. Some patients require combined liver-kidney transplantation.

Hyperuricosuria

Calcium oxalate crystals in the urine preferentially nucleate around other types of crystals or sloughed cells (heterogeneous nucleation). Uric acid crystals frequently form the nidus or internal core of calcium oxalate stones. In fact, up to 15% of calcium stones are found in patients with hyperuricosuria. In contrast to patients with pure calcium oxalate stones, these patients typically have elevated urinary uric acid levels but normal urinary calcium and oxalate levels. They also differ from patients with pure uric acid stones in that they tend to have a higher urinary pH (>5.5).

Therapy consists of dietary purine restriction and increased fluid intake. If urinary uric acid levels remain uncontrolled with these measures, allopurinol, 100 to 300 mg/day, may be added.

Hypocitruria

Citrate combines with calcium to form a soluble complex that reduces both calcium oxalate and calcium phosphate precipitation. In some patients, hypocitruria is the principal metabolic abnormality found in the 24-hour urine collection. Risk factors for hypocitruria include high protein intake, hypokalemia, metabolic acidosis, exercise, infection, starvation, androgens, and acetazolamide. Men tend to have lower urinary citrate concentrations than women, which may be responsible for the higher incidence of stone formation in men.

Furthermore, women with nephropthiasis have lower urinary citrate concentrations than nonstone-forming women.

Along with therapy for the underlying condition, such as moderating dietary protein intake, potassium citrate is prescribed. This salt is preferable to sodium citrate because sodium excretion promotes calcium excretion. Again, potassium citrate in the wax matrix formulation is preferred to the liquid preparation because of increased palatability. Large amounts may be required (30 to 75 mEq/day) in divided doses in order to raise the urinary citrate concentration to more than 320 mg/day. Potassium and bicarbonate levels should be closely monitored, especially in patients with renal insufficiency. If metabolic alkalosis ensues, partial supplementation with potassium chloride may be necessary.

Renal Tubular Acidosis

Distal (type 1) RTA is a disorder in which distal tubular hydrogen ion excretion is impaired, resulting in a nonanion gap metabolic acidosis and a persistently alkaline urine. The acidosis leads to calcium and phosphate release from bone as well as enhanced proximal tubular reabsorption of citrate. The net result is an increased filtered load of calcium and phosphate, severe hypocitraturia, and an elevated urinary pH, all of which promote calcium phosphate precipitation. Nephrocalcinosis, or renal parenchymal calcification, is frequently seen in this setting.

Twenty-four-hour urinary citrate levels are commonly below 100 mg in patients with distal RTA. Therapy consists of potassium citrate or potassium bicarbonate supplementation in order to treat both the metabolic acidosis and hypocitraturia. Large doses of these medications are often required (1 to 2 mEq/kg per day in two or three divided doses).
Nephrocalcinosis

Nephrocalcinosis is a process in which calcium is deposited in the renal parenchyma. There are two forms:

1. **Dystrophic calcification.** Calcium deposition arises from tissue necrosis secondary to neoplasm, infarction, or infection. It may be seen in the setting of renal transplant rejection, renal cortical necrosis, chronic glomerulonephritis, ethylene glycol toxicity, acquired immunodeficiency syndrome (AIDS)–related infections, and Alport’s syndrome. In general, serum calcium and phosphorus levels are normal and calcium-phosphate deposition occurs predominantly in the renal cortex.

2. **Metastatic calcification.** Patients may have elevated serum calcium and phosphate levels or an elevated urinary pH. Calcification in this setting occurs more commonly in the renal medulla. Common causes include RTA, primary hyperparathyroidism (or any disorder resulting in elevated serum calcium levels), medullary sponge kidney, papillary necrosis, acetazolamide, amphotericin B, triamterene, and primary hyperoxaluria. Primary hyperoxaluria can result in both medullary and cortical calcifications.

Both medullary and cortical parenchymal calcifications are easily noted with ultrasonography and CT scanning, even before they can be detected on plain radiographs. Therapy consists of treating the underlying disorder whenever possible. Otherwise, measures aimed at reducing hypercalcemia, oxalosis, and hyperphosphatemia should be attempted.
Uric Acid Stones (see Table 28-4)

Although uric acid stones make up only about 5% to 10% of all calculi formed in the United States, the prevalence of uric acid lithiasis is much greater in Mediterranean countries. These stones tend to be round, smooth, and yellow-orange. Because they are radiolucent, they are not visible on plain films but can be detected by ultrasonography or CT as filling defects on IVP. Uric acid is a purine metabolite and is also found in large quantities within cells. The three main causes of uric acid stone formation are (1) low urine volume, (2) low urinary pH, and (3) elevated urinary uric acid levels.

Urine Volume and pH

Any disorder that results in low urine volume (e.g., diarrheal disorders, diaphoresis, reduced fluid intake) can contribute to uric acid lithiasis. Diarrhea and diets high in animal protein can also contribute to an acidic urinary pH. Uric acid is increasingly soluble at an alkaline urinary pH such that urine with a pH of 6.5 can contain more than five times more uric acid than urine at pH 5.3 without inducing precipitation and may actually dissolve existing stones.  

Hyperuricosuria

Hyperuricosuria may be evident in patients who ingest large quantities of dietary purine or animal protein. Foods high in purine include organ meats, shellfish, certain fish, meat extracts, yeast, gravies, and stocks (Table 28-8). Hyperuricemic disorders such as gout, myeloproliferative disorders, tumor lysis syndrome, and certain inborn errors of metabolism (e.g., glucose-6-phosphatase deficiency, Lesch-Nyhan syndrome) may also contribute to an increased urinary filtered load of uric acid. Certain medications such as salicylates and probenecid can be hyperuricosuric as well.  

Therapy for patients with uric acid stones begins with nonspecific measures such as increasing fluid intake to maintain urine volume at about 3 L/day. Patients are prescribed a low-purine diet to decrease uric acid production. Despite dietary intervention, hyperuricemia often persists, especially in patients with disorders of cellular catabolism. In this setting, allopurinol should be prescribed at a starting dose of 100 mg/day, increasing to 300 mg/day as needed. 

A diet low in animal protein is also beneficial because the

Decreased endogenous acid production raises urinary pH. Ideally, the urinary pH should be elevated to approximately 6.5 to 7.0, a level that can dissolve existing crystals and stones. A urinary pH higher than 7.0 should be avoided, however, as calcium phosphate deposition may result. Potassium citrate at doses of 30 mEq by mouth twice a day or greater may be required to raise the urinary pH sufficiently. (See "Hypercalciuria" and "Hypocitruria" on available potassium citrate preparations.) Prescription of Nitrazine paper allows patients to monitor the urinary pH at various times of day and adjust their potassium citrate intake accordingly.

Although sodium bicarbonate may effectively alkalize the urine, it should be avoided because the additional sodium excretion encourages sodium urate formation. Sodium urate in the setting of alkaline urine can serve as a nidus for calcium oxalate precipitation. If the urinary pH cannot be raised adequately despite high doses of potassium citrate or if the dose prescribed results in hyperkalemia, the carbonic anhydrase inhibitor acetazolamide may be initiated. This medication results in an alkaline urine and mild systemic metabolic acidosis, a pattern similar to that in type 1 RTA. Again, the urinary pH should be maintained at less than 7.0 in order to avoid calcium phosphate precipitation.
Struvite Stones (see Table 28-4)

Struvite stones have also been termed triple phosphate stones, magnesium ammonium phosphate stones, and infection stones. Although they make up only about 10% to 15% of all stones formed, most staghorn calculi (i.e., large stones that extend beyond a single renal calix) are composed of struvite. The propensity of these stones to grow rapidly to a large size, to recur despite therapy, and to result in significant morbidity (and potential mortality) has also led to the appellation stone cancer. Infection with urease-producing bacteria must be present for these stones to form, and therefore severe renal infections as well as sepsis and loss of renal function may develop.

In contrast to other stone types, struvite stones occur with a higher incidence in women than in men, largely because of women’s increased susceptibility to urinary tract infections. Other groups at risk for development of struvite stones because of urinary stasis or infection include elderly people and patients with neurogenic bladders, indwelling urinary catheters, spinal cord lesions, or genitourinary abnormalities. Even in the absence of stone analysis, struvite stones should be suspected in patients with large stones, an alkaline urinary pH (>7), and the presence of urease-producing bacteria in the urine. Early detection and therapy are essential to avoid great potential morbidity.

Urease-Producing Bacteria

The formation of struvite stones is dependent on the presence of both ammonium ions and an alkaline urinary pH, conditions met clinically only through the actions of urease-producing bacteria. Ammonium, magnesium, and carbonate apatite (\( \text{Ca}_10(\text{PO}_4)_6\text{CO}_3 \)) in the urine combine with phosphate, which is present in this setting in its trivalent form.

Numerous bacteria, both gram-negative and gram-positive, as well as Mycoplasma and yeast species have been implicated in urease production. Bacteria in which urease is frequently isolated include Proteus species, Haemophilus, Corynebacterium, and Ureaplasma. Escherichia coli, despite its frequent role as a urinary tract pathogen, has not been shown to produce urease. Urease production adequate to stimulate stone formation may be present despite low bacterial colony counts. For this reason, the microbiology laboratory should be asked specifically to perform bacterial identification and to determine sensitivities even with colony counts lower than 100,000 colony-forming units. If no bacteria are isolated but a urease producer is suspected, special cultures for Ureaplasma urealyticum, a mycobacterium, should be ordered.

Therapy

In order to eradicate struvite stones, early and aggressive medical and urologic management is required. Appropriate antibiotic therapy is essential but must be combined with long-term bacterial suppression and complete surgical or medical stone removal. Extracorporeal shock wave lithotripsy is often adequate for fragmentation of stones less than 2 cm in size, but percutaneous nephroscopy or a combination of the two procedures is usually required for larger stones. Antibiotics should be continued on the basis of cultures of any stone fragments retrieved. After approximately 2 weeks of antibiotic therapy, when the urine culture is sterile, the dose of antibiotic should be halved. Suppressive antibiotics should continue at this dose as long as monthly surveillance cultures remain sterile for three consecutive months. At this point, antibiotics may be discontinued as long as surveillance urine cultures are obtained monthly for 1 year.

In addition to antimicrobial therapy, medical treatment may involve urease inhibition and chemolysis. In chemolysis, the kidney is irrigated with an acidic solution through a nephrostomy tube or ureteral catheter. Although rarely used today with the advent of less invasive surgical techniques, it can still play a role in dissolution of residual stone fragments. Ten percent hemiacidrin, the solution most commonly utilized, is composed of carbonic acid, citric acid, \( \alpha \)-gluconic acid, and magnesium at a pH of 3.9. The use of chemolysis was controversial in the past because high mortality rates were reported, but with close monitoring of serum magnesium levels, intrapelvic pressures, infection, and obstruction to flow, it is now thought to be relatively safe.

Urease inhibition has been shown to retard stone growth and to prevent new stone formation. It does not decrease bacterial counts and cannot eradicate existing stones. Combined with antimicrobial therapy, it serves primarily as palliative care for patients who cannot undergo definitive surgical management. The agent most commonly used is acetohydroxamic acid (AHA). These medications require adequate renal clearance for therapeutic efficacy and are contraindicated in patients with a serum creatinine level higher than 2mg/dL (or 176 µmol/L). Renal insufficiency can increase the incidence of side effects of the medications, which are numerous and limit their use. Side effects that result in discontinuation of the drug include neurologic symptoms, GI upset, hair loss, hemolytic anemia, and rash. Fortunately, the side effects all resolve with discontinuation of the drug. AHA is also teratogenic. The starting dose of AHA is 250 mg by mouth twice a day. If it is well tolerated for about 1 month, the dose is increased to 250 mg by mouth three times a day.
Cystine Stones (see Table 28-4)

Cystinuria is an autosomal recessive disorder that results in excessive renal tubular excretion of the dibasic amino acids cystine, ornithine, lysine, and arginine. The frequency of the abnormal gene, which is found on chromosome 2, is fairly high at 0.01%. The genetic defect would probably go unnoticed were it not for the low solubility of cystine, 250 mg/L. Cystinuria should not be confused with cystinosis, a more serious and debilitating disorder that results in extensive intracellular cystine accumulation. Whereas people with no tubular defect in cystine transport excrete approximately 30 to 50 mg of cystine per day, heterozygotes excrete about 400 mg/day and homozygotes often excrete larger amounts (>600 mg/day).

Stones usually develop in patients within the second or third decade. The stones may grow to large size and can appear as staghorn calculi or multiple stones. They are radiopaque because of the sulfur content of cystine molecules. The disease should be suspected in any patient with stone onset in childhood, frequent recurrence of nephrolithiasis, and a strong family history of the disease. The presence of the classic, hexagonal cystine crystals in the urine can verify the diagnosis. As these crystals may not be evident in a dilute or alkaline urine, qualitative screening with the sodium nitroprusside test better confirms the presence of cystinuria at a concentration greater than 75 mg/L. Quantitative cystine measures with a 24-hour urine sample should follow to determine the risk of stone formation and to guide therapy.

Therapy

The aim of treatment is to lower the urinary cystine concentration below the limits of solubility (<250 mg/L). As with the treatment of other stones, nonspecific therapy plays a large role. Patients are advised to drink large quantities of fluids. A patient with a cystine excretion of 750 mg/day, for example, should ideally drink enough fluid to increase urine output to more than 3 L/day. Large quantities of milk should be avoided because dairy products and foods high in protein contain large quantities of methionine, an essential amino acid that is a precursor of cystine. Since cystine is more soluble at a higher pH, juices are encouraged, as they tend to alkalize the urine. Potassium citrate (see "Hypercalciuria" and "Hypocitraturia" for details) is also prescribed to maintain the urinary pH between 6.5 and 7.0.

Approximately 50% of cystine stones are mixed stones. Patients with cystinuria often have other metabolic defects such as hypercalciuria, hypocitraturia, and hyperuricosuria. Therefore, a complete 24-hour urine collection for all stone-forming elements is necessary to treat nephrolithiasis fully in this setting.

If the preceding measures are inadequate in controlling stone formation or if the urinary cystine concentration is too high to make adequate fluid intake practical, chelating agents may be added. D-Penicillamine is a chelating agent that reduces the cystine concentration by forming a more soluble compound with cystine. The medication is associated with numerous serious side effects that limit its use. Second-generation and third-generation chelating agents such as -mercaptopropionylglycine and bucillamine are now available that reduce the cystine concentration with fewer side effects.

Section 8 - Disorders of Carbohydrate and Lipid Metabolism

Chapter 29 - Type 2 Diabetes Mellitus

John B. Buse
Kenneth S. Polonsky
Charles F. Burant

EPIDEMIOLOGY

Type 2 diabetes is the predominant form of diabetes worldwide, accounting for 90% of cases globally. An epidemic of type 2 diabetes is under way in both developed and developing countries, although the brunt of the disorder is felt disproportionately in non-European populations as evidenced by studies in Hispanic populations, Native American and Canadian communities, Pacific and Indian Ocean island populations, and in India and Australian Aboriginal communities. In the Pacific island of Nauru, diabetes was virtually unknown 50 years ago and is now present in approximately 40% of adults. Globally, the number of people with diabetes is expected to rise from the current estimate of 150 million to 220 million in 2010 and 300 million in 2025. Alarming increases in the prevalence of diabetes have occurred in various Chinese populations. Type 2 diabetes has become one of the world's most important public health problems.

Considerable information is available on the factors that are responsible for the development of type 2 diabetes, and these are summarized in Table 29-1. Type 2 diabetes is currently thought to occur in genetically predisposed individuals who are exposed to a series of environmental influences that precipitate the onset of clinical disease. The genetic basis of type 2 diabetes is discussed in detail later in this chapter, but the syndrome consists of monogenic and polygenic forms that can be differentiated both on clinical grounds and in terms of the genes that are involved in the pathogenesis of these disorders.

Sex, age, and ethnic background are important factors in determining risk for the development of type 2 diabetes. The disorder is more common in females, and the increased prevalence in certain racial and ethnic minority groups has already been alluded to. Age is also a critical factor. Type 2 diabetes has been viewed in the past as a disorder of aging with an increasing prevalence with age. This remains true today. However, a disturbing trend has become apparent in which the prevalence of obesity and type 2 diabetes in children is rising dramatically. In the past, it was believed that the overwhelming majority of children with diabetes had type 1 diabetes, with only 1% to 2% of children considered to have type 2 or other rare forms of diabetes. Later reports suggest that as many as 8% to 45% of children with newly diagnosed diabetes have nonimmune-mediated diabetes. The majority of these children have type 2 diabetes, but other types are being increasingly identified. An idiopathic nonimmune-mediated form of diabetes has been reported particularly in the black population.

DIAGNOSTIC CRITERIA FOR DIABETES MELLITUS

The diagnosis of diabetes rests on the measurement of plasma glucose levels. The diagnostic criteria for diabetes were changed in 1997 with the most significant changes being the level of fasting plasma glucose (FPG) that is recognized as diagnostic for diabetes, which was decreased from 140 to 126 mg/dL, and the introduction of a category of impaired fasting glucose (IFG). Current criteria for the diagnosis of diabetes, impaired fasting glucose and impaired glucose tolerance (IGT), are shown in Table 29-2.

Because plasma glucose concentrations range as a continuum, the criteria are based on estimates of the threshold for the complications of diabetes. The primary end point used to evaluate the relationship between glucose levels and complications is retinopathy. The prevalence of retinopathy in comparison with FPG and 2-hour plasma glucose has been evaluated.

FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; PG, plasma glucose.

* A diagnosis of diabetes must be confirmed, on a subsequent day, by measurement of FPG, 2-hour PG, or random plasma glucose (if symptoms are present). The FPG test is greatly preferred because of ease of administration, convenience, acceptability to patients, and lower cost. Fasting is defined as no caloric intake for at least 8 hours.

Both diagnostic criteria were able to predict the presence of retinopathy and, by inference, glucose levels that are diagnostic of diabetes [Fig. 29-1]. There is also an association between FPG and 2-hour plasma glucose and risk of macrovascular and cardiovascular disease. For instance, the Paris Prospective Study showed that the incidence of fatal coronary heart disease was related to both FPG and 2-hour plasma glucose that were determined at a baseline examination. Rates of disease were markedly increased at FPG greater than 125 mg/dL (6.9 mmol/L) or 2-hour plasma glucose greater than 140 mg/dL (7.8 mmol/L).

Reproducibility of the plasma glucose concentration is an important issue in the interpretation of the results of diagnostic tests for diabetes. There is significant variation in the results of repeated tests in adults after a 2- to 6-week interval. The intraindividual coefficient of variation in one study was 6.4% for the FPG and 16.7% for the 2-hour plasma glucose value. Thus, it is essential that abnormal results be confirmed by a repeated test. Although the oral glucose tolerance test (OGTT) is an invaluable tool in research, it is not recommended for routine use in the diagnosis of diabetes. It is inconvenient for patients, and in the vast majority of cases the diagnosis can be made on the basis of either an elevated fasting glucose concentration or an elevated random glucose determination in the presence of hyperglycemic symptoms.

In general, levels of hemoglobin A1c (HbA1c) are not currently recommended for the diagnosis of diabetes. The major reasons are the lack of standardization of the assays for HbA1c, and the imperfect correlation between HbA1c and FPG and 2-hour plasma glucose. However, HbA1c remains the most effective method for monitoring the effectiveness of diabetes treatment.
SCREENING FOR TYPE 2 DIABETES

Undiagnosed type 2 diabetes is common, with an estimated lag of 5 to 7 years between the onset of diabetes and diagnosis. It is estimated that in up to 50% of affected people the disease is undiagnosed. Subjects with IGT and undiagnosed type 2 diabetes are at significantly increased risk for coronary heart disease, stroke, and peripheral vascular disease. Thus, this delay in the diagnosis of type 2 diabetes causes an increase in microvascular and macrovascular disease. In addition, affected individuals have a greater likelihood of having dyslipidemia, hypertension, and obesity. Therefore, it is important for the clinician to screen for diabetes in a cost-effective manner in subjects who demonstrate major risk factors for diabetes as summarized in Table 29-3. Recommendations for screening are summarized in Table 29-4.
PATHOGENESIS OF TYPE 2 DIABETES

The pathogenesis of type 2 diabetes is complex and involves the interaction of genetic and environmental factors. A number of environmental factors have been shown to play a critical role in the development of the disease, particularly excessive caloric intake leading to obesity and a sedentary lifestyle. The clinical presentation is also heterogeneous with a wide range in age of onset, severity of associated hyperglycemia, and degree of obesity. From a pathophysiologic standpoint, persons with type 2 diabetes consistently demonstrate three cardinal abnormalities: (1) resistance to the action of insulin in peripheral tissues, particularly muscle and fat but also liver; (2) defective insulin secretion, particularly in response to a glucose stimulus; and (3) increased glucose production by the liver.

</table>

Although the precise manner in which these genetic, environmental, and pathophysiologic factors interact to lead to the clinical onset of type 2 diabetes is not known, our understanding of these processes has increased substantially. With the exception of specific monogenic forms of the disease that may result from defects largely confined to the pathways that regulate insulin action in muscle, liver, and fat or defects in insulin secretory function in the pancreatic beta cell, there is an emerging consensus that the common forms of type 2 diabetes are polygenic in nature and are due to a combination of abnormal insulin secretion and insulin resistance. From a pathophysiologic standpoint, it is the inability of the pancreatic beta cell to adapt to the reductions in insulin sensitivity that occur over the lifetime of human subjects in response to puberty or pregnancy, a sedentary lifestyle, or overeating leading to weight gain that precipitates the onset of type 2 diabetes. An underlying genetic predisposition appears to be a critical factor in determining the frequency with which this occurs.

Genetic Factors in the Development of Type 2 Diabetes

Genetically, type 2 diabetes consists of monogenic and polygenic forms. The monogenic forms, although relatively uncommon, are nevertheless important and a number of the genes involved have been identified and characterized. The genes involved in the common polygenic form or forms of the disorder have been far more difficult to identify and characterize.

</tbody>
</table>

In the monogenic forms of diabetes, the gene involved is both necessary and sufficient to cause disease. In other words, environmental factors play little or no role in determining whether or not a genetically predisposed individual develops clinical diabetes. The monogenic forms of diabetes generally occur in young individuals, often in the first two to three decades of life, although if only mild asymptomatic elevations in blood glucose occur the diagnosis may be missed until later in life.
Mitochondrial gene mutations

- Maturity-onset diabetes of the young (MODY)
  - HNF-4 (MODY 1)
  - Glucokinase (MODY 2)
  - HNF-1 (MODY 3)
  - IPF-1 (MODY 4)
  - HNF-1 (MODY 5)
  - NeuroD1/Beta2 (MODY 6)

HNF, hepatocyte nuclear factor; IPF, insulin promoter factor; MODY, maturity-onset diabetes of the young; NeuroD1/Beta2, neurogenic differentiation 1/beta cell E-box trans-activator 2; PPAR, peroxisome proliferator-activated receptor.

The monogenic forms of diabetes are summarized in Table 29-5 and can be divided into those in which the mechanism is a defect in insulin secretion and those that involve defective responses to insulin or insulin resistance.

### Monogenic Forms of Diabetes Associated with Insulin Resistance

#### Mutations in the Insulin Receptor

More than 70 mutations have been identified in the insulin receptor gene in various insulin-resistant patients. There are at least three clinical syndromes caused by mutations in the insulin receptor gene. Type A insulin resistance is defined by the presence of insulin resistance, acanthosis nigricans, and hyperandrogenism. Patients with leprechaunism have multiple abnormalities, including intrauterine growth retardation, fasting hypoglycemia, and death within the first 2 to 3 years of life. The Rabson-Mendenhall syndrome is associated with short stature, protuberant abdomen, and abnormalities of teeth and nails; pineal hyperplasia was a characteristic in the original description of this syndrome.

These mutations may impair receptor function by a number of different mechanisms, including decreasing the number of receptors expressed on the cell surface (e.g., by decreasing the rate of receptor biosynthesis [class 1], accelerating the rate of receptor degradation [class 5], or inhibiting the transport of receptors to the plasma membrane [class 2]). The intrinsic function of the receptor may be abnormal if the affinity of insulin binding is reduced (class 3) or receptor tyrosine kinase is inactivated (class 4). The insulin resistance that is associated with insulin receptor mutations may be severe and present in the neonatal period, as with leprechaunism and the Rabson-Mendenhall syndrome, or occur in a milder form in adulthood leading to insulin-resistant diabetes with marked hyperinsulinemia, acanthosis nigricans, and hyperandrogenism.

#### Lipoatrophic Diabetes

In another monogenic form of diabetes, so-called lipoatrophic diabetes, severe insulin resistance is associated with lipoatrophy and lipodystrophy. This form of diabetes is characterized by a paucity of fat, insulin resistance, and hypertriglyceridemia. The disease has several genetic forms, including face-sparing partial lipoatrophy (the Dunnigan syndrome or the Koberling-Dunnigan syndrome), an autosomal dominant form caused by mutations in the lamin A/C gene, and congenital generalized lipodystrophy (the Seip-Berardinelli syndrome), an autosomal recessive form.

#### Mutations in Peroxisome ProliferatorActivated Receptor

It has been demonstrated that mutations in the transcription factor peroxisome proliferatoractivated receptor (PPAR) can cause type 2 diabetes of early onset. Two different heterozygous mutations were identified in the ligand-binding domain of PPAR in three subjects with severe insulin resistance. In the PPAR crystal structure, the mutations destabilize helix 12, which mediates trans-activation. Both receptor mutants showed markedly decreased transcriptional activation and inhibited the action of coexpressed wild-type PPAR in a dominant negative manner. A common amino acid polymorphism (Pro12Ala) in PPAR has been associated with type 2 diabetes. People homozygous for the Pro12 allele are more insulin resistant than those having one Ala12 allele and have a 1.25-fold increased risk of diabetes. There is also evidence for interaction between this polymorphism and fatty acids, linking this locus with diet.

### Monogenic Forms of Diabetes Associated with Defects in Insulin Secretion

#### Mutant-Insulin Syndromes

The first syndrome associated with diabetes to be characterized in terms of the clinical picture, genetic mechanisms, and clinical pathophysiology was that associated with mutant insulin or proinsulin. Persons with this disorder present clinically with a mild non-insulin-dependent form of diabetes. Affected individuals characterize themselves as having hyperinsulinemia on routine insulin assays. Increases in the concentration of insulin in association with diabetes are usually indicative of insulin resistance, but in this syndrome insulin resistance can be easily excluded because the patients respond normally to administration of exogenous insulin. Characterization of the insulin by high-performance liquid chromatography reveals that the hyperinsulinemia is due to the presence of the abnormal insulin or proinsulin and related breakdown products. The increased concentrations of insulin appear to be related to the presence of mutations in regions of the insulin molecule that are important for receptor binding, particularly the COOH terminus of the insulin B chain.

Because the liver is the major site of insulin clearance and the first-step hepatic insulin uptake and degradation are mediated by the insulin receptor, mutant forms of insulin with diminished insulin receptor binding ability are cleared more slowly from the circulation, and this reduction in insulin clearance leads to hyperinsulinemia. Alternatively, mutations in proinsulin may reduce the conversion of proinsulin to insulin, leading to accumulation of proinsulin.

Because proinsulin is cleared more slowly from the circulation than insulin, proinsulin levels increase. Proinsulin cross-reacts in most commercially available assays, and this insulin-like immunoreactivity can be characterized as related to the presence of proinsulin rather than insulin only by high-performance liquid chromatography or by the use of assays that are specific for insulin and proinsulin.

A patient with a mutation in prohormone convertase 1, one of the enzymes responsible for the conversion of proinsulin to insulin, has been described.

### Mitochondrial Diabetes

An A-to-G transition in the mitochondrial tRNALeu(UUR) gene at base pair 3243 has been shown to be associated with maternally transmitted diabetes and sensorineural hearing loss. In other subjects, this mutation is associated with diabetes and the syndrome of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS syndrome). The mitochondrial plays a key role in the regulation of insulin secretion, particularly in response to glucose. We have documented abnormal insulin secretion on at least one of a battery of tests in subjects with this mitochondrial mutation, even in subjects with normal or impaired glucose tolerance who have not developed overt diabetes.
Maturity-onset diabetes of the young (MODY) is a genetically and clinically heterogeneous group of disorders characterized by nonketotic diabetes mellitus, an autosomal dominant mode of inheritance, onset usually before 25 years of age and frequently in childhood or adolescence, and a primary defect in pancreatic beta cell function. A detailed review of MODY has been published,10 and the information contained in that review is summarized.

MODY can result from mutations in any one of at least six different genes. One of these genes encodes the glycolytic enzyme glucokinase (MODY5),11 and the other five encode transcription factors, hepatocyte nuclear factor (HNF)-4 (MODY7),12 HNF-1 (MODY3),13 insulin promoter factor-1 (IPF-1) (MODY4),14 HNF-1 (MODY5),15 and neurogenic differentiation 1/beta cell E-box trans-activator 2 (NeuroD1/BETA2) (MODY6).16 All of these genes are expressed in the insulin-producing pancreatic beta cells, and heterozygous mutations cause diabetes related to beta cell dysfunction. Abnormalities in liver and kidney function may occur in some forms of MODY, reflecting expression of the transcription factors in these tissues. Nongenetic factors that affect insulin sensitivity (infection, puberty, pregnancy, and rarely obesity) may trigger diabetes onset and affect the severity of hyperglycemia in MODY but do not play a significant role in the development of MODY.

The most common clinical presentation of MODY is a mild asymptomatic increase in blood glucose in a child, adolescent, or young adult with a prominent family history of diabetes often in successive generations, suggesting an autosomal dominant mode of inheritance. Some patients may have mild hyperglycemia for many years, whereas others have varying degrees of glucose intolerance for several years before the onset of persistent hyperglycemia.17 The diagnosis may be made only in adulthood even though the elevation in plasma glucose has been present for many years. Prospective testing indicates that in most patients the disease onset occurs in childhood or adolescence. In some patients, there may be a rapid progression to overt asymptomatic or symptomatic hyperglycemia necessitating therapy with an oral hypoglycemic drug or insulin. The presence of persistently normal plasma glucose levels in subjects with mutations in any of the known MODY genes is unusual, and the majority eventually experience diabetes (with the exception of many patients with glucokinase mutations; see later).

Although the exact prevalence of MODY is not known, current estimates suggest that MODY may account for 1% to 5% of all cases of diabetes in the United States and other industrialized countries.18 Several clinical characteristics distinguish patients with MODY from those with type 2 diabetes, including a prominent family history of diabetes in three or more generations, young age at presentation, and absence of obesity.

**Functional Effects of MODY Genes**

The identification of several genes associated with diabetes has provided a unique opportunity to characterize the pathophysiological mechanisms by which genetic mutations can lead to an increase in the plasma glucose concentration. All the susceptibility genes identified to date cause impaired insulin secretory responses to glucose, although the mechanisms differ.

**Glucokinase**

Glucokinase is expressed at its highest levels in the pancreatic beta cell and the liver. It catalyzes the transfer of phosphate from adenosine triphosphate (ATP) to glucose to generate glucose-6-phosphate (Fig. 29-2) (Figure Not Available). This reaction is the first rate-limiting step in glucose metabolism. Glucokinase functions as the glucose sensor in the beta cell by controlling the rate of entry of glucose into the glycolytic pathway (glucose phosphorylation) and its subsequent metabolism. In the liver glucokinase plays a key role in the ability to store glucose as glycogen, particularly in the postprandial state. Heterozygous mutations leading to partial deficiency of glucokinase are associated with MODY, and homozygous mutations resulting in complete deficiency of this enzyme lead to permanent neonatal diabetes mellitus. As predicted by the physiologic functions of glucokinase, the increase in plasma glucose concentrations seen in patients with this form of diabetes is due to a combination of reduced glucose-induced insulin secretion from the pancreatic beta cell and reduced glycogen storage in the liver after glucose ingestion.

**Liver-Enriched Transcription Factors: Hepatocyte Nuclear Factor-1, Hepatocyte Nuclear Factor-1, and Hepatocyte Nuclear Factor-4**

The transcription factors HNF-1, HNF-1, and HNF-4 play a key role in the tissue-specific regulation of gene expression in the liver.12 and are also expressed in other tissues including pancreatic islets, kidney, and genital tissues. HNF-1 and HNF-1 are members of the homeodomain-containing family of transcription factors, and HNF-4 is an orphan nuclear receptor.13,14 HNF-1, HNF-1, and HNF-4 make up part of an interacting network of transcription factors that function together to control gene expression during embryonic development and in adult tissues in which they are coexpressed. In the pancreatic beta cell, these transcription factors regulate the expression of the insulin gene as well as proteins involved in glucose transport and metabolism and mitochondrial metabolism, all linked to insulin secretion, and lipoprotein metabolism.15 The expression of HNF-1 is regulated at least in part by HNF-4. Persons with diabetes related to mutations in these genes have defects in insulin secretory responses to a variety of secretagogues, particularly glucose, that are present before the onset of hyperglycemia, suggesting that they represent the primary functional defect in the syndrome. Reduced glucagon responses to arginine have also been observed, suggesting that the pancreatic alpha cell is also involved in a broader pancreatic developmental abnormality.

**Insulin Promoter Factor-1**

IPF-1 is a homeodomain-containing transcription factor that was originally isolated as a transcriptional regulator of the insulin and somatostatin genes. It also plays a central role in the development of the pancreas as well as the regulation of expression of a variety of pancreatic islet genes including, besides insulin, glucokinase, islet amyloid polypeptide, and glucose transporter 2 genes. IPF-1 also appears to mediate glucose-induced stimulation of insulin gene transcription.16

**Neurogenic Differentiation 1 (NeuroD1/BETA2)**

The basic helix-loop-helix transcription factor NeuroD1/BETA2 was isolated on the basis of its ability to activate transcription of the insulin gene and is required for normal pancreatic islet development. Two patients with heterozygous mutations in NeuroD1 and diabetes have been described,16 and a third has been identified in an Icelandic population. Studies in other populations have failed to detect mutations in NeuroD1 even in subjects with a MODY phenotype. It therefore appears that mutations in NeuroD1 are a rare cause of MODY.

**Genetics of the Polygenic Forms of Type 2 Diabetes**

As alluded to earlier, the common polygenic form of type 2 diabetes has complex pathophysiology with genetic and environmental factors both playing a major role. The phenotypic manifestations of the disease are also complex, and subjects with established type 2 diabetes demonstrate abnormalities in a number of tissues that play a key role in the regulation of glucose metabolism. These include resistance to the action of insulin in muscle, fat, and liver; defects in insulin secretory responses from the pancreatic beta cell; and increases in hepatic glucose production. However, the primary defect or defects responsible for the development of the syndrome remain elusive and are likely not to be defined until more is known about the genes responsible for diabetes and the nature of the gene-environment interactions that are ultimately responsible for the development of the disorder in predisposed individuals.

Insulin resistance is present in individuals predisposed to type 2 diabetes before the onset of hyperglycemia, and this finding has been interpreted by some to indicate...
that insulin resistance is the primary abnormality that is responsible for the development of type 2 diabetes. However, defective beta cell function is also present before the onset of type 2 diabetes when IGT is present and in first-degree relatives of persons with type 2 diabetes who have completely normal plasma glucose concentrations. Thus, although there is still controversy about whether insulin resistance or abnormal insulin secretion represents the primary defect in type 2 diabetes, there is general consensus that both defects are present in essentially all subjects with the disorder, frequently from an early preclinical stage.

It is therefore evident that the identification and characterization of the genes responsible for type 2 diabetes will add an essential level to our understanding of the pathophysiology of the disorder. Unfortunately, progress in identifying these genes has been slow for reasons that are discussed in greater detail in the following.

The candidate gene approach has not been successful in identifying genes responsible for the common polygenic forms of type 2 diabetes. This approach involves identifying and then cloning genes known to be involved in pathways that regulate glucose metabolism, screening for variants in these genes, and assessing the frequency of the variants in cases and controls.

Because the candidate gene approach has not been productive in identifying the genes for the common forms of type 2 diabetes, linkage analysis has been applied. This approach involves defining regions of chromosomal DNA shared to excess by affected family members. Parents are genotyped at a particular marker, and the offspring are scored for sharing of zero, one, or two alleles inherited from their parents. Markers are genotyped in family members in the regions of polymorphic repeats called microsatellites or simple tandem repeats. Because in the case of type 2 diabetes (as well as other common polygenic human diseases), there is no prior knowledge of the gene defect, microsatellites at defined chromosomal locations are typed either in family members or in affected sibling pairs. In order to screen the whole genome, 300 to 400 microsatellites are genotyped in the study subjects at roughly 10-centimorgan intervals. This is generally adequate to define chromosomal regions sharing single gene defects. The evidence for linkage usually extends over a broad region, which may be 10 to 20 cM, and positional cloning strategies are then utilized to find the gene within this broad region.

This approach has demonstrated that genetic variation in the gene that encodes a ubiquitously expressed member of the calpain-like cysteine protease family, calpain-10 (CAPN10), is associated with increased risk for type 2 diabetes.

Until the observation was made on the grounds of genetic studies that calpains may be involved in the pathophysiology of diabetes, this possibility had not been considered. It is now critical that the role of calpains in regulating the metabolic pathways responsible for the maintenance of insulin secretion and insulin action be defined. Data available from the initial studies that have addressed these questions have begun to provide clues to the mechanisms that may be involved.

It appears that the effects of the at-risk polymorphisms are mediated by decreasing calpain-10 expression in relevant tissues. Thus, Baier and colleagues demonstrated that the polymorphism in calpain-10 that is responsible for the linkage to type 2 diabetes is associated with reduced muscle messenger ribonuclease acid (mRNA) and insulin resistance in Pima Indians, a population at extremely high risk for the development of type 2 diabetes. In order to simulate the physiologic effects of reduced calpain activity or expression, we have exposed rodent pancreatic islets or muscle strips to various calpain inhibitors for either 4 to 6 or 48 hours. The effects on pancreatic islets were dependent on the duration of the exposure. After 4 to 6 hours, inhibition of calpain activity was associated with enhanced glucose-induced insulin secretion that appeared to be mediated by effects on the secretion process itself. Exposure of mouse islets to calpain inhibitors of different structure and mechanism of action for 48 hours reversibly suppressed glucose-induced insulin secretion by 45% to 80%. Exposure of islets to other protease inhibitors (cathepsin B and proteasome) did not result in similar effects. The 48-hour incubation with calpain inhibitors also attenuated insulin secretory responses to the mitochondrial fuel-ketosocaproate and the Ca\(^{2+}\)-independent exocytosis trigger mastoparan. Glucose metabolism and intracellular calcium (Ca\(^{2+}\)), responses to glucose or ketosocaproate were also reduced, as was the exocytosis of insulin granules (measured by cell capacitance) in single beta cells. Thus, inhibition of calpain activity in islets attenuates insulin secretion, possibly by limiting the rate of glucose metabolism and exocytosis of insulin.

Exposure of rodent muscle strips to calpain inhibitors was shown to induce insulin resistance by impairing insulin-induced glucose transport and glycogen synthesis. Thus, these preliminary investigations suggest that calpain-sensitive pathways are present in pancreatic islets and muscle. Clearly, more detailed studies are needed to identify the specific calpain targets involved and to define their role in the normal control of insulin secretion and action and in the abnormalities in these processes that are responsible for the development of type 2 diabetes.

Why has it been so difficult to identify the genes responsible for the polygenic forms of type 2 diabetes, and what are the prospects for future progress? A perspective on the subject published by Cox emphasized that the experience to date gained from studies on CAPN16 is likely to provide a preview of the challenges that need to be overcome in the future.

The first important issue is that the CAPN16 variation implicated in susceptibility to type 2 diabetes was located in a noncoding rather than a coding sequence and leads to a significant reduction in skeletal muscle calpain-10 mRNA levels as well as insulin resistance. The latter functional result could not have been predicted from the genetic analyses and knowledge of the biology of calpains and could be obtained only from studies of the functional effects of CAPN16 variation in nondiabetic Pima Indians.

The second critical issue is that the mechanism for CAPN16 effects is complex and combinations of variants are more strongly associated with disease than individual polymorphisms. In the case of CAPN16, individuals heterozygous for the two different haplotypes that form the high-risk haplotype combination have approximately threefold increased risk compared with all other combinations of haplotypes and approximately eightfold increased risk compared with the lowest risk haplotype combination. Individuals homozygous for either of the haplotypes in the high-risk combination were not at increased risk of developing type 2 diabetes.

The third issue is that the physiologic mechanism or mechanisms by which genetic susceptibility loci cause disease may not be clear and may be difficult to determine. This is certainly the case with CAPN10 and with calpains in general, for which the primary physiologic function is unclear.

The fourth issue is that because multiple genetic mechanisms as well as environmental factors are involved in disease pathogenesis, replication may be difficult as the importance of specific genetic variations may differ in different populations.

In summary, therefore, as we move from studies of the monogenic forms of diabetes to studies that aim to understand the genetic, molecular, and physiologic basis of the polygenic forms of this condition, additional serious challenges must be met. However, in light of the complex nature of these disorders, understanding the genetic basis of these conditions is still the most likely pathway to solving the nature of these disorders.
INSULIN RESISTANCE AND THE RISK OF TYPE 2 DIABETES

Insulin Resistance

A substantial amount of data indicates that insulin resistance plays a major role in the development of glucose intolerance and diabetes. Insulin resistance is a consistent finding in patients with type 2 diabetes, and resistance is present years before the onset of diabetes. Prospective studies show that insulin resistance predicts the onset of diabetes.

The term insulin resistance indicates the presence of an impaired biologic response to either exogenously administered or endogenously secreted insulin. Insulin resistance is manifested by decreased insulin-stimulated glucose transport and metabolism in adipocytes and skeletal muscle and by impaired suppression of hepatic glucose output. Insulin sensitivity is influenced by a number of factors including age, weight, ethnicity, body fat (especially abdominal), physical activity, and medications. Insulin resistance is associated with the progression to IGT and type 2 diabetes, although diabetes is rarely seen in insulin-resistant persons without some degree of beta cell dysfunction. First-degree relatives of type 2 diabetics have insulin resistance even at a time when they are nonobese, implying a strong genetic component in the development of insulin resistance. There is also a strong influence of environmental factors on the genetic predisposition to insulin resistance and therefore to diabetes.

Obesity and Type 2 Diabetes

The association of obesity with type 2 diabetes has been recognized for decades. A close association between obesity and insulin resistance is seen in all ethnic groups and is found across the full range of body weights, across all ages, and in both sexes. A number of large epidemiologic studies showed that the risk for diabetes, and presumably insulin resistance, rises as body fat content increases from the very lean to the very obese, implying that the absolute amount of body fat has an effect on insulin sensitivity across a broad range. However, central (intra-abdominal) adiposity is more strongly linked to insulin resistance and a number of important metabolic variables, including plasma glucose, insulin, total plasma cholesterol and triglyceride concentrations, and decreased plasma high-density lipoprotein (HDL) cholesterol concentration, than is total adiposity. In addition, the effect of accumulation of abdominal fat on glucose tolerance is independent of total adiposity.

The reason for the relationship to intra-abdominal fat with abnormal metabolism is not clearly defined, but a number of hypotheses, which are not mutually exclusive, have been proposed. First, abdominal fat is more lipolytically active than subcutaneous fat, perhaps because of its greater complement of adrenergic receptors. In addition, the abdominal adipose store is resistant to the antilipolytic effects of insulin, including alterations in lipoprotein lipase activity, which leads to increased lipase activity and a greater flux of fatty acids into the circulation with the portal circulation receiving the greatest fatty acid load. The role of the liver in insulin resistance and hyperglycemia is discussed subsequently.

Skeletal Muscle Insulin Resistance

The primary site of glucose disposal after a meal is skeletal muscle, and the primary mechanism of glucose storage is through its conversion to glycogen. Studies using the hyperinsulinemic-euglycemic clamp technique have demonstrated that in insulin-resistant people with and without type 2 diabetes, there is a deficiency in the nonoxidative disposal of glucose related primarily to a defect in glycogen synthesis. Elevated free fatty acids (FFAs) predict the progression from IGT to diabetes. In the periphery, FFAs may not be markedly elevated because of efficient extraction by the liver and skeletal muscle. Thus, normal or minimally elevated FFA levels may not reflect the true exposure of fatty acids to peripheral tissues. Increases in fatty acid flux to skeletal muscle related to the increased visceral lipolysis have been implicated in the inhibition of muscle glucose uptake.

The Randle hypothesis, or the glucose-fatty acid cycle, was originally proposed to account for the ability of FFAs to inhibit muscle glucose utilization. Randle and colleagues demonstrated that fatty acids compete with glucose for substrate oxidation in isolated muscle. The increase in fatty acid metabolism leads to an increase...
in the intramitochondrial acetyl coenzyme A (CoA)/CoA and reduced nicotinamide adenine dinucleotide (NADH)/NAD⁺ ratios with subsequent inhibition of pyruvate dehydrogenase. The resulting increased intracellular mitochondrial (and cytosolic) citrate concentrations result in allosteric inhibition of phosphofructokinase, the key rate-limiting enzyme in glycolysis. Subsequent accumulation of glucose-6-phosphate would inhibit hexokinase II activity, resulting in an increase in intracellular glucose concentrations and decreased glucose uptake.

However, later studies have suggested that the primary effect of fatty acids, at least in the presence of raised insulin levels, is a decrease in glucose transport as measured by a reduction in the rate of accumulation of intracellular glucose and glycogen using 13C and 13N nuclear magnetic resonance spectroscopy. In normal subjects, elevated fatty acids, achieved by infusion of triglyceride emulsions and heparin (to activate lipoprotein lipase), resulted in a fall in intracellular glucose and glucose-6-phosphate concentrations that preceded the fall in glycogen accumulation. These results challenge the Randle hypothesis (which predicts a rise in intracellular glucose-6-phosphate concentrations) as the basis of the reduction in insulin sensitivity seen with elevated fatty acids. Similar decreases in glucose transport have been seen in patients with type 2 diabetes and lean, normoglycemic insulin-resistant offspring of type 2 diabetic individuals. These studies also found a decrease in the activity of phosphatidylinositol 3-phosphate kinase (PI 3-kinase) and increased protein kinase C-theta activity that may, in part, mediate the effect of high FFAs.

It has been found that insulin-stimulated glucose uptake is inversely related to the amount of intramuscular triglycerides. A strong correlation between intramuscular triglyceride concentration and insulin resistance has been demonstrated by evaluating intramuscular triglyceride with biopsy, computed tomographic scanning, and magnetic resonance imaging measurements. The latter method has been a valuable addition because the magnetic resonance signal can distinguish intramyocellular from extramyocellular fat and demonstrates the increased triglyceride accumulation within the myofiber itself. First-degree relatives of type 2 diabetics have an increase in intramyocellular fat, and in this group there is also a correlation with insulin resistance.

The mechanism for accumulation of triglyceride in the skeletal muscle of obese and insulin-resistant individuals is probably related to the mismatching of FFA uptake and oxidation. During resting postabsorptive conditions, about 30% of fatty acid flux in the plasma pool is accounted for by oxidation, with the remaining 70% of flux recycled into triglyceride, indicating a physiologic reserve that exceeds immediate tissue needs for oxidative substrates. The equilibrium between oxidation and reesterification within muscle is paramount in determining fatty acid storage within tissue. The uptake, transport, and metabolism of fatty acids are highly regulated processes (Fig. 29-6), and alteration of the balance between uptake and oxidation in skeletal muscle leads to increased intramyocellular triglyceride. The increased lipolysis associated with obesity provides an increased amount of FFA presented to muscle.

Increased muscle triglyceride content is not invariably linked to insulin resistance because exercise training is associated with increased muscle triglyceride content, and chronic exercise increases insulin sensitivity as well as the capacity for fatty acid oxidation.

There is a direct correlation between heart-type FABP content and insulin resistance in obese and insulin-resistant individuals. Some, but not all, studies have shown a decrease in heart-type FABP in insulin-resistant humans.

Fatty Acid Metabolism in Skeletal Muscle, Relationship to Insulin Sensitivity

The uptake of fatty acid from the serum, where it is mostly bound to albumen, is mediated by at least three families of proteins: fatty acid translocase, plasma membrane fatty acid binding protein (FABP-pm), and fatty acid transport protein. The levels of the putative transport proteins are regulated by exercise, correlated with body weight at least in men, and can be modulated by insulin infusion.

FABPs are capable of binding multiple hydrophobic ligands, including fatty acids, eicosanoids, and retinoids with high affinity. FABPs are thought to facilitate uptake of fatty acids and promote subsequent intracellular transport to subcellular organelles. There is a direct correlation between heart-type FABP content and oxidative capacity observed during development and among different muscle types. In mice with a disruption of the heart-type or adipocyte isoform of FABP, plasma fatty acid concentrations were significantly elevated while plasma glucose was decreased, suggesting a key role in normal regulation in fatty acid oxidation. Some, but not all, studies have shown a decrease in heart-type FABP in insulin-resistant humans.

Carotid palmitoyltransferase I (CPT-I) has been the subject of intense scrutiny for many years because of its central role in the balance between mitochondrial glycerol and fatty acid metabolism, primarily because of inhibition of mitochondrial fatty acid uptake by malonyl CoA. A specific isoform contributes 97% of the CPT-I in muscle and has 100-fold lower sensitivity to inhibition by malonyl CoA. This lower sensitivity to malonyl CoA inhibition suggests that the levels of CPT-I itself may be important in the balance of uptake and oxidation of fatty acids. Evidence for this in skeletal muscle stems from the finding that, as with other fatty acid-oxidizing enzymes, muscle CPT-I mRNA is regulated by PPAR activators, fat feeding, and exercise in rodents and is inversely correlated with obesity in humans.

Long-chain fatty acids, after passing through the inner mitochondrial membrane as acylcarnitines, are metabolized at the surface of the inner mitochondrial membrane by CPT-II and the long chain-specific oxidation system consisting of very-long-chain acyl CoA dehydrogenase (VLCAD) and the trifunctional protein (TFP) oxidation complex. Transfer of the acyl chain from carnitine to CoA catalyzed by CPT-II is followed by one cycle of oxidation catalyzed by VLCAD and TFP to yield a chain-shortened acyl CoA that can recycle through the same oxidation system. In actuality, four different acyl CoA dehydrogenase enzymes catalyze the initial dehydrogenation of straight-chain fatty acids in mitochondria. Three of themshort-chain acyl CoA dehydrogenase (SCAD), medium-chain acyl CoA dehydrogenase (MCAD), and long-chain acyl CoA dehydrogenase (LCAD) are soluble enzymes located in the mitochondrial matrix as homotrimers. A fourth, VLCAD, is attached to the inner membrane as a homodimer. Their names derive from the length of the fatty acids that they process. VLCAD and LCAD shorten the long-chain fatty acids into medium-chain fatty acids that can then be processed by MCAD and SCAD. The SCAD, MCAD, and LCAD monomers share a high degree of homology between them but not with VLCAD. At least some of these enzymes can be regulated in humans during exercise training.

Uncoupling protein-1 (UCP1) is clearly related to the uncoupling of oxidative phosphorylation in brown adipose tissue. UCP2 and UCP3 have structural similarities to UCP1, but it is not clear that they are actually uncouplers of oxidative phosphorylation. Newer members of the family, brain mitochondrial carrier protein 1 (BMCP1) and UCP4, have an even more distant sequence relationship. BMCP1 and UCP4 are predominantly expressed in neural tissues, namely the brain. UCP3 mRNA is found primarily in skeletal muscle and in brown adipose tissue. UCP2 has a ubiquitous tissue distribution. UCP2 and UCP3 mRNAs have been correlated with different physiologic states, and numerous studies indicate that expression of UCP2 and UCP3 is stimulated by thyroid hormones and in the presence of high levels of fatty acids. In humans, the levels of UCP2 and UCP3 mRNAs were up-regulated by a high-fat diet and the up-regulation was more
pronounced in humans with high proportions of type II A fibers. In a small study, exercise training in humans increased mitochondrial oxidative capacity but did not change UCP2 or UCP3 levels. Obesity itself was shown to be positively correlated with a splice isoform of UCP3. A unique polymorphism in the promoter region of UCP3 correlated with the expression of UCP3 in skeletal muscle.

Glucose Influence on Fatty Acid Metabolism

An emerging concept that could couple the increased fatty acid flux into skeletal muscle with impaired insulin action is the central role of malonyl CoA in regulating fatty acid and glucose oxidation (Fig. 29-7). Malonyl CoA is an allosteric inhibitor of CPT-I, the enzyme that controls the transfer of long-chain fatty acyl CoAs into the mitochondria. Even in insulin-resistant skeletal muscle, glucose uptake into the skeletal muscle is higher, especially at the elevated levels of glucose found in type 2 diabetes. The glucose is shunted toward the glycolytic pathway, generating acetyl CoA that can be converted to malonyl CoA in the cytoplasm by the action of the highly regulated enzyme acetyl CoA carboxylase (ACC).

In humans an infusion of insulin and glucose at a high rate leads to increases in the concentration of malonyl CoA in skeletal muscle and to decreases in whole-body and, presumably, muscle fatty acid oxidation. In the presence of elevated glucose and insulin levels, the tricarboxylic acid (TCA) cycle is activated, resulting in an increase in citrate in the cytoplasm through increased malate cycling in the mitochondria. The increased citrate is converted to acetyl CoA through citrate lyase and thus provides an indirect substrate for ACC. Citrate also allosterically activates ACC and makes ACC a better substrate for phosphatases that activate the enzyme. ACC is also regulated by a phosphorylation-dephosphorylation cycle, with adenosine monophosphate (AMP)-dependent protein kinase an important kinase, which inhibits both ACC basal activity and ACC activation by insulin. ACC then generates malonyl CoA that in turn allosterically inhibits CPT-I residing on the outer mitochondrial membrane, inhibiting uptake of acetyl CoA. The resulting buildup of long-chain acyl CoAs and diacylglycerols is proposed to activate one or more protein kinase C isoforms or other lipid-activated proteins, resulting in insulin resistance. Support for this hypothesis is the finding that exercise, which activates AMP-dependent kinase, inactivates ACC, lowers intracellular long-chain acyl CoA levels, and has an acute insulin-sensitizing effect.

Hyperinsulinemia and Insulin Resistance

Hyperinsulinemia per se has been proposed to cause insulin resistance. Elevated concentrations of insulin can cause insulin resistance by down-regulating insulin receptors and desensitizing postreceptor pathways. Del Prato and associates showed that 24 and 72 hours of sustained physiologic hyperinsulinemia in normal individuals specifically inhibited the ability of insulin to increase nonoxidative glucose disposal in association with an impaired ability of insulin to stimulate glycogen synthase activity. Suppression of insulin secretion in obese, insulin-resistant people results in increased insulin sensitivity.

Insulin Signaling

Insulin signaling is initiated through the binding to and activation of its cell-surface receptor and initiates a cascade of phosphorylation and dephosphorylation events, second messenger generation, and protein-protein interactions that result in the diverse metabolic events in nearly every tissue (Fig. 29-8) (Figure Not Available). The insulin receptor consists of two insulin-binding subunits and two catalytically active subunits that are disulfide linked into an 22 heterotetrameric complex. Insulin binds to the extracellular subunits, activating the intracellular tyrosine kinase domain of the subunit. One receptor subunit phosphorylates its partner on specific tyrosine residues that may have distinct functions such as stimulation of intercellular association of signaling molecules such as Shc and Grb, members of the insulin receptor substrate family (IRS1, 2, 3, 4), Shc adapter protein isoforms, and SIRP (signal regulatory protein) family members, Gab-1, Cbl, CAP, and APS; stimulation of mitogenesis; and receptor internalization.

Insulin receptor subunit has also been shown to undergo serine-threonine phosphorylation, which may decrease the ability of the receptor to autophosphorylate. The activities of a number of protein kinase C isoforms that catalyze the serine or threonine phosphorylation of the insulin receptor are elevated in animal models of insulin resistance and in insulin-resistant humans. Interventions that decrease serine phosphorylation of the insulin receptor result in increased insulin signaling. Termination of the insulin signaling event occurs by internalization and dephosphorylation of the receptor by protein tyrosine phosphatases. Increased activity of protein tyrosine phosphatase can attenuate insulin signaling. Two protein tyrosine phosphatases that have been shown to negatively regulate insulin signaling, PTP1B and LAR (leukocyte antigen related), have been reported to be elevated in insulin-resistant patients. Conversely, disruption of PTP1B in mice resulted in a marked increase in insulin sensitivity and resistance to diet-induced obesity.

Mutations in the insulin receptor are associated with rare forms of insulin resistance. These mutations affect insulin receptor number, splicing, trafficking, binding, and phosphorylation. The affected patients demonstrate severe insulin resistance, manifest as clinically diverse syndromes including the type A syndrome, leprechaunism, Rabson-Mendenhall syndrome, and lipodystrophic diabetes.

Downstream Events Following Insulin Receptor Phosphorylation

IRSs act as multifunctional docking proteins activated by tyrosine phosphorylation. The IRS proteins have multiple functional domains, including Pleckstrin homology (PH) and phosphotyrosine binding (PTB) and SH domains that interact with other proteins to mediate the insulin signaling events. Disruption of IRS1 in mice resulted in mild insulin resistance and growth retardation, whereas disruption of IRS2 resulted in beta cell failure and subsequent insulin resistance.

P3-kinase, which is regulated by interaction with IRS proteins, is necessary but not sufficient for the stimulation of the glucose transporter GLUT4-mediated increase in glucose transport in insulin-sensitive tissues. In addition, inhibition of PI 3-kinase activity with the fungal inhibitor wortmannin inhibited insulin-stimulated glucose uptake, glycogen synthesis, triglyceride accumulation, protein synthesis, and modulation of gene expression. P3-kinase generates 3,4,5-phosphoinositols, which activates several PIP3 (phosphatidylinositol-3,4,5 triphosphate)-dependent enzymes.

Figure 29-8 (Figure Not Available) Insulin signaling. The insulin receptor is autophosphorylated on multiple tyrosine residues, allowing the docking and activation of multiple signaling molecules, which mediate the increases in glucose uptake and metabolism as well as changes in protein and lipid metabolism. (From Satelli AR, Kahn CR. Insulin signaling and the regulation of glucose and lipid metabolism. Nature 2001, 414:798906.)

serine-threonine kinases, such as PI-dependent protein kinases 1 and 2, which in turn activates Akt, salt- and glucocorticoid-induced kinases. Protein kinase C, wortmannin-sensitive and insulin-stimulated serine kinase, and others.

Akt kinase (also known as protein kinase B) exists as three distinct isoforms that are activated by phosphorylation on specific threonine and serine residues. Activated Akt has the ability to phosphorylate proteins that regulate lipid synthesis, glycogen synthesis, protein synthesis, and apoptosis. Disruption of Akt2 resulted in insulin resistance and diabetes in mice. Several investigators have examined the role of PI 3-kinase and Akt in individuals with insulin resistance. Studies have shown a decrease in IRS-associated PI 3-kinase and Akt activity in insulin-resistant skeletal muscle; however, in some patients with reduced PI 3-kinase activity there was normal activation of Akt.

A primary effect of insulin is to stimulate translocation of the glucose transporter GLUT4 from an intracellular pool to the surface of cells, primarily in skeletal muscle and adipose tissue and heart. The mechanism by which the signaling pathways converge on the intracellular GLUT4-containing vesicles to cause GLUT4 translocation is not well understood. It appears that the number of glucose transporters in skeletal muscle of insulin-resistant persons is not changed but the ability of
insulin to effect this translocation is disrupted.

**Glucocorticoid-Induced Insulin Resistance**

Cushing's syndrome and exogenous glucocorticoid treatment have long been known to induce significant insulin resistance in humans. The exact mechanism is unknown, but it is associated with redistribution of fat from the periphery to the central compartment. Elevations in triglyceride and FFA levels also occur. At a molecular level, dexamethasone has differential effects on the proteins involved in the early steps in insulin action in liver and muscle. In both tissues, dexamethasone treatment results in a reduction in insulin-stimulated IRS1-associated PI 3-kinase, which may play a role in the pathogenesis of insulin resistance at the cellular level in these animals.

**Tumor Necrosis Factor**

Studies in humans and animal models of obesity have identified changes in the expression and activity of key molecules involved in the insulin signaling pathway. Decreases in the number and the kinase activity of insulin receptors[157] and impairment in the activation of IRS1, PI 3-kinase,[158][159] and protein kinase B[160] have been observed. Although the basis for this is, in general, unknown, a tumor necrosis factor (TNF)-mediated decrease in the activity of the intermediate steps in the insulin signaling cascade has been proposed. TNF-α made and secreted by adipocytes, is elevated in a variety of experimental models of obesity.[161] The kinase activity of the insulin receptor in rats[162] or in 3T3-L1 adipocytes[163] treated with TNF-α was reduced, possibly by increased serine phosphorylation.[164] Fat-fed mice with genetic ablation of TNF-α production had increased kinase activity of the insulin receptor compared with control mice and demonstrated increased insulin sensitivity.[165] In addition, rats treated with neutralizing antisera or soluble TNF receptors demonstrated an amelioration of their insulin resistance. As described later, other interventions to decrease TNF-α action result in increased insulin sensitivity.

**Glucotolerance, Glucosamine**

Hyperglycemia is a primary factor in the development of the complications of the disease, and decreases in average blood glucose have a profound effect to prevent complications in both type 1 and type 2 diabetes.[166] Hyperglycemia itself can cause insulin resistance. In Pima Indians, the level of fasting glycaemia is the primary determinant of insulin sensitivity.[167] The defect is primarily in skeletal muscle[168] and is related to the degree of hyperglycemia.

Entry of glucose into the cell results in its phosphorylation to glucose-6-phosphate, which has multiple metabolic fates. The enzyme glucose:fructose-6-phosphate amidotransferase (GFAT) carries out the rate-limiting step of the hexosamine pathway.[169] Evidence suggests that the hexosamine pathway underlies the defect in glucose utilization associated with hyperglycemia. Hexosamines, such as glucosamine, when incubated with adipose tissue, induce insulin resistance in fat cells[170] and in skeletal muscle.[171] Infusion of glucosamine into rats resulted in a dose-dependent increase in insulin resistance of skeletal muscle.[172] Finally, transgenic mice that overexpress GFAT specifically in skeletal muscle acquired severe insulin resistance.[173] By a pathway that is unclear, glucosamine overproduction resulted in a disruption of the ability of GLUT4 to translocate to the cell surface. Through its anti-insulin action, the hexosamine pathway has been hypothesized to be a glucose sensor that allows the cell to sense and adapt to the prevailing level of glucose.[174]

**Insulin Resistance and Lipodystrophy Associated with Human Immunodeficiency Virus Infection**

A syndrome with many of the clinical and metabolic features of insulin resistance is increasingly being recognized in patients with human immunodeficiency virus (HIV) infection. A novel form of lipodystrophy is observed in certain of these patients. This form of lipodystrophy is associated with significant insulin resistance and type 2 diabetes, dyslipidemia, elevated total and low-density lipoprotein (LDL) cholesterol and suppressed HDL cholesterol concentrations, and a susceptibility to lactic acidemia.[175][176][177][178]

Epidemiologic studies have associated this syndrome with previous or current treatment with antiretroviral protease inhibitors or nucleoside reverse transcriptase inhibitors. There is also an association with increased age.[179] Other potential contributing factors are male sex, diagnosis of the acquired immunodeficiency syndrome, responsiveness to antiretroviral treatment, and increases in CD4 T-cell counts. An increased emphasis has been placed on the role of protease inhibitors in the pathogenesis of the syndrome. Administration of these drugs or ritonavir to normal subjects caused increases in plasma triglyceride and very-low-density lipoprotein (VLDL) cholesterol and decreased plasma HDL cholesterol levels.[180][181] Indinavir administration for 4 weeks resulted in small increases in serum glucose and insulin levels and decreased insulin-mediated glucose disposal as assessed with a hyperinsulinemic, euglycemic clamp. In this study there were no changes in lipoprotein, triglycerides, or FFA levels.[182][183]

The metabolic basis of the molecular deficit is not clear. A number of protease inhibitors can inhibit glucose transport in vitro and in vivo, and there is evidence for a direct interaction with the GLUT4 glucose transporter[184] that could inhibit glucose uptake specifically in insulin-responsive tissue. Mitochondrial abnormalities have been described in subcutaneous adipose tissue biopsy specimens of HIV-infected patients with lipodystrophy compared with those without the syndrome.[185] A direct effect of protease inhibitors on differentiation of adipocytes has also been described.[186][187] At present, the precise mechanism for the lipodystrophy associated with HIV infection is not known.

**Mechanisms of Reducing Insulin Resistance**

The most effective measures to improve insulin sensitivity are weight loss and exercise. Both modalities are effective and can be additive in their ability to improve insulin action. Later in this chapter, the role of these interventions in the treatment of patients with type 2 diabetes is discussed. The scientific basis and molecular mechanisms responsible for the improvements in insulin sensitivity seen with these interventions are now summarized.

**Mechanisms for Improved Insulin Sensitivity with Weight Loss**

Weight loss can be a highly effective treatment for overweight patients with type 2 diabetes and other cardiovascular risk factors, and indeed it is advocated as the first line of therapy. Weight loss may also play a role in the prevention of type 2 diabetes.[188][189] In overweight patients with type 2 diabetes, weight loss can reduce hepatic glucose production, insulin resistance, and fasting hyperinsulinemia and can improve glycemic control. Weight loss in type 2 diabetes is also associated with a reduction in blood pressure and an improvement in the lipid profile. These benefits can occur with as little as 5% to 10% weight loss.[190][191][192] Indinavir administration for 4 weeks resulted in small increases in serum glucose and insulin levels and decreased insulin-mediated glucose disposal as assessed with a hyperinsulinemic, euglycemic clamp. In this study there were no changes in lipoprotein, triglycerides, or FFA levels.[193][194]

One possible mechanism for improvements in insulin sensitivity through weight loss may be effects on the pattern of muscle fatty acid metabolism and the accumulation of lipid within muscle. In this context, it would be important to know whether alterations in the pathways of fatty acid utilization in skeletal muscle represent primary defects in obese individuals or arise secondarily, after an individual has become obese. This question cannot be answered by cross-sectional comparisons of lean and obese subjects. One prospective clinical study indicated that lower rates of lipid oxidation were a predisposing factor for greater weight gain,[195] and collateral studies implicated altered skeletal muscle enzymes activities in impaired lipid oxidation.[196][197] A reduced reliance on lipid oxidation has also been identified as a risk factor for weight regain after weight loss.[198] These data raise the possibility that a potential impairment in the capacity for lipid oxidation may be a primary determinant of obesity. Weight loss can markedly improve insulin-resistant glucose metabolism in skeletal muscle. When the patient's response indicates a substantial acquired or secondary component of obesity-related insulin-resistant glucose metabolism, it is important to determine whether weight loss can modulate patterns of skeletal muscle metabolism of fatty acids, including the content of fat within muscle.

**Mechanisms for Improved Insulin Sensitivity with Exercise**

Exercise is clearly effective in increasing insulin sensitivity in animals and in humans. There appear to be two separable but related effects of exercise on insulin action. A single bout of exercise can result in an acute increase in insulin-independent glucose transport measurable during and for a relatively short period after exercise.[199][200][201][202][203] Like insulin, exercise and muscle contractions increase glucose transport by translocation of intracellular GLUT4 glucose transporters to
Acute Exercise

The signaling pathway leading to the exercise-induced increase in glucose transporter translocation and glucose transport is unknown, although there is ample evidence that the pathway is independent of the insulin-stimulated, receptor-mediated pathway. The effect of exercise and contractions on translocation and transport is additive to the maximal effect of insulin. Insulin-stimulated glucose transport in muscle is inhibited by specific inhibitors of PI 3-kinase, such as wortmannin, whereas transport or translocation stimulated by muscle contractions is insensitive to these inhibitors. Stimulation of muscle contractions in situ and exercise do not increase insulin receptor phosphorylation or tyrosine kinase activity, IRS phosphorylation, or PI 3-kinase activity. In addition, in many insulin-resistant states the acute exercise-stimulated (but not insulin-stimulated) glucose transport and GLUT4 translocation is normal. This has been demonstrated in the obese, insulin-resistant Zucker rat and in type 2 diabetic patients. Finally, hypoxia, a stimulus for glucose transport that is also independent of the insulin receptor-mediated pathway, is effective in increasing glucose transport in muscle strips from obese, insulin-resistant individuals and in patients with type 2 diabetes.

The acute effect of exercise and hypoxia may be mediated by AMP-dependent protein kinase (AMPK). AMPK is thought to be a sensor of intracellular energy stores and is activated by increases in intracellular AMP. A stable AMP analogue, 5-amino-4-imidazole carboxamide ribotide (ZMP), can be generated intracellularly from 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) and can activate AMPK in cells, leading to increased phosphorylation of known substrates for AMPK including 3-hydroxy-3-methylglutaryl CoA reductase, acetyl-CoA carboxylase, and creatine kinase. Treatment of incubated skeletal muscle with AICAR resulted in increased glucose uptake and glucose transporter translocation. Similarly, the inclusion of 2 mM AICAR in the perfusate of the rat hindlimb resulted in inactivation of ACC, decreases in malonyl CoA levels and a twofold increase in glucose uptake. The euglycemic clamp technique has been used in conscious rats to demonstrate that infusion of AICAR resulted in a more than twofold increase in glucose utilization. Uptake of the glucose analogue 2-deoxyglucose was also increased twofold in vivo in soleus and gastrocnemius muscles. As with previous studies, this uptake was not associated with PI 3-kinase activation, again indicating a separate pathway from that of insulin.

A second effect of exercise, which becomes evident as the acute effect on glucose transport reverses, is a large increase in the sensitivity of glucose transport to stimulation by insulin. This effect is due to translocation of more GLUT4 glucose transporters to the cell surface for any given dose of insulin. As with the acute stimulation of transport by exercise, the cellular mechanisms leading to enhanced translocation in response to submaximally effective stimuli are unknown. However, several studies have shown that steps in the insulin signaling cascade leading to activation of PI 3-kinase are not enhanced after a bout of exercise. There is no change in insulin binding to its receptor, insulin stimulation of receptor tyrosine kinase activity, increase in insulin-stimulated tyrosine phosphorylation of IRS1 or PI 3-kinase activity associated with IRS1.

Exercise Training

Exercise training also results in increases in insulin sensitivity and can delay or prevent the onset of type 2 diabetes in those at high risk. Using the hyperinsulinemic-euglycemic clamp, Perseghin and co-workers compared exercise training for 45 minutes on a stair-climbing machine 4 days per week for 6 weeks in normal insulin-sensitive subjects and a group of high-risk, insulin-resistant relatives of type 2 diabetics. A 100% increase in insulin sensitivity was seen in both groups without a significant change in body weight. Interestingly, the higher basal and glucose-stimulated insulin release seen in the insulin-resistant subjects was not altered after exercise training. The effect of exercise training on insulin sensitivity has been proposed to be due to up-regulation of glucose transporter number, changes in capillary density, and increases in the number of red, glycolytic (type Ila) fibers.
Mechanisms That Link Cardiovascular Disease and Insulin Resistance: Syndrome X

Myocardial infarction, stroke, and nonischemic cardiovascular disease are the cause of death in up to 80% of individuals with type 2 diabetes. Independent of other risk factors, type 2 diabetes increases the risk for cardiovascular morbidity and mortality but also provides a synergistic interaction with other risk factors such as smoking, hypertension, and dyslipidemia. In a Finnish population, diabetes increased the risk for myocardial infarction fivefold. and insulin resistance as measured by elevated fasting insulin levels increased the risk of death from heart disease. Women are particularly vulnerable to the cardiovascular effects of type 2 diabetes as they appear to lose the protective effects of estrogen in the premenopausal period.

A constellation of metabolic derangements that are frequently seen in patients with insulin resistance and type 2 diabetes are individually associated with an increased risk of cardiovascular disease. These patients have been variously designated as having syndrome X, the dysmetabolic syndrome, hypertension, obesity, noninsulin-dependent diabetes mellitus (NIDDM), dyslipidemia, and atherosclerotic cardiovascular disease (HONDRA); or the “deadly quartet.” The syndrome has also been associated with easily oxidized, small LDL particles; heightened blood clotting activity (e.g., increased plasminogen activator inhibitor 1); and elevated serum uric acid concentration. The central abnormality associated with syndrome X has been proposed to be insulin resistance. Some of the abnormalities have also been proposed to contribute to insulin resistance.

Perhaps the overriding risk factor for coronary artery disease in insulin resistance and type 2 diabetes is the associated dyslipidemia. The profile includes hypertriglyceridemia, low plasma HDL, and small, dense LDL particle concentrations. The percentage of men with type 2 diabetes with abnormal cholesterol levels is not different from that of nondiabetic men. However, diabetic women have nearly double the rate of hypercholesterolemia and greater changes in other lipid parameters that increase the risk for cardiovascular disease (Fig. 29-9). The physiologic basis for this abnormal lipid profile appears to be overproduction of apolipoprotein B-containing VLDL particles. The apolipoprotein B production by the liver is primarily post-translational and augmented by insulin and by the increased availability of FFAs in the portal circulation, probably as a result of increased lipolysis in the visceral adipose tissue. Part of the post-translational regulation may be due to insulin and fatty acid-mediated increases in microsomal triglyceride transfer protein levels that catalyze the transfer of lipids to apolipoprotein B and decrease the ubiquination-dependent degradation of apolipoprotein B.

The overproduction of VLDL triglyceride results in increased transfer of VLDL triglyceride to HDL particles in exchange for HDL cholesterol esters mediated by the cholesterol ester transfer protein. The triglyceride-rich HDL is hydrolyzed by hepatic lipase, which results in the generation of small HDL, which is degraded more readily by the kidney, resulting in low HDL levels in serum. Cholesterol ester transfer proteinmediated exchange of VLDL triglyceride for LDL cholesterol esters and subsequent triglyceride hydrolysis by hepatic lipase probably result in the generation of the small, dense LDL particles found in insulin-resistant subjects.

The increased risk of heart disease in patients with diabetes has prompted the recommendation that individuals with diabetes be treated for their dyslipidemia as aggressively as individuals who have had a previous myocardial infarction. In addition, individuals with the metabolic syndrome of insulin resistance and obesity are considered to be in a higher risk category and should also be aggressively treated in order to lower lipids.

Hypertension and overt diabetes double the risk of cardiovascular disease. Defects in vasodilatation and alterations in blood flow may provide a link to hypertension in insulin-resistant subjects. The normal vasodilatory response of insulin is disrupted in obese, insulin-resistant, and diabetic individuals, perhaps through inability of insulin to increase the production of the potent vasodilator nitric oxide by endothelial cells. The defect may be magnified by increases in plasma FFAs. Other proposed mechanisms for insulin resistance leading to hypertension are the activation of the sympathetic nervous system by insulin and the intrinsic ability of insulin to cause salt and water reabsorption in the kidney resulting in expanded plasma volume.

Hypertension itself, independent of other risk factors, has been associated with the propensity to become diabetic. A prospective cohort study found that type 2 diabetes was nearly 2.5 times more likely to develop in subjects with hypertension than in subjects with normal blood pressure. A possible mechanism is that an intrinsic defect in vasodilatation may contribute to insulin resistance by decreasing the surface area of the vasculature perfusing skeletal muscle, decreasing the efficiency of glucose uptake. Conversely, vasodilatory agents may improve glucose uptake and may even prevent the onset of diabetes, as has been observed with angiotensin-converting enzyme inhibitor therapy.

Several factors involved in clotting and fibrinolysis, including fibrinogen, factor VII, and plasminogen activator inhibitor 1 (PAI-1), have been shown to be increased in individuals with insulin resistance. PAI-1 expression in hepatocytes, endothelial cells, and adipose tissue, and insulin-sensitizing thiazolidinediones decreased PAI-1 activity.

Upper body rather than lower body obesity (the apple rather than the pear shape) is highly correlated with insulin resistance and risk for type 2 diabetes. Thus, the anatomic distribution of fat, rather than the overall degree of obesity, appears to determine risk for the metabolic syndrome. The reported association between increased abdominal (upper body) fat and an increased risk of coronary heart disease is related to visceral fat, for which the waist-to-hip ratio is a convenient index. A waist-to-hip ratio greater than 1.0 in men and 0.8 in women indicates abdominal obesity. Recently the National Cholesterol Education Program (NCEP) has suggested that a waist circumference >40 inches in men and >35 inches in women is a marker for the metabolic syndrome.
The Role of Increased Hepatic Glucose Production in the Hyperglycemia of Type 2 Diabetes and Impaired Glucose Tolerance

The disposal of glucose after meals depends on the ability of insulin to increase peripheral glucose uptake and simultaneously decrease endogenous glucose production. Although studies have suggested that the kidney can contribute up to 25% of endogenous glucose production, the defect in type 2 diabetes is primarily in defective regulation of glucose production from the liver [hepatic glucose output (HGO)]. Two routes of glucose production by the liver are glycolysis from stored glycogen and gluconeogenesis from two- and three-carbon substrates derived primarily from skeletal muscle. Under different conditions and at different times postprandially, the contribution of each of these to maintenance of glucose levels may vary. Using $^{13}$C nuclear magnetic resonance spectroscopy combined with measurement of wholebody glucose production in normal human subjects at different intervals after fasting, it was found that gluconeogenesis accounted for 50% to 96% of glucose production with the proportion increasing with increasing duration of fasting.

The production of glucose by the liver is regulated primarily by the relative actions of glucagon and insulin to activate or suppress glucose production, respectively, although the nervous system and glucose autoregulation of hepatic glucose production probably play less important roles. The ability of insulin to reduce HGO is an important mechanism for maintaining normal glucose tolerance. Under normal circumstances, insulin suppresses up to 85% of glucose production in normal individuals by directly inhibiting gluconeogenesis, especially at lower insulin concentrations. Under circumstances in which gluconeogenesis is enhanced by glucagon, the effects of insulin to suppress hepatic glucose production may be even greater. Glucagon increases gluconeogenesis by activation of the classical protein kinase cascade involving cyclic AMP (cAMP)-dependent protein kinase and phosphorylase and also increases gluconeogenesis in part by increasing the transcription of phosphoenolpyruvate carboxykinase through the cAMP response element binding protein.

Insulin decreases in endogenous glucose production by both direct and indirect mechanisms (Fig. 29-10). In its direct action, portal insulin suppresses glucose production by inhibiting gluconeogenesis through an increase in phosphodiesterase activity or changes in the assembly of protein phosphatase complexes. Insulin can also directly suppress gluconeogenesis by inhibiting the activation of phosphoenolpyruvate carboxykinase transcription through the insulin-dependent phosphorylation of the forkhead transcription factor, sequestering it in the cytoplasm.

The indirect or peripheral effect of insulin in controlling glucose production by the liver is twofold. First, insulin has a profound effect on decreasing glucagon secretion by the alpha cell of the pancreas through systemic and paracrine effects. The decrease in glucagon secretion decreases the activation of glycogenolysis and gluconeogenesis. The second important peripheral action of insulin is decreasing FFA levels by suppressing lipolysis. FFAs increase hepatic glucose production by stimulating gluconeogenesis. When the reduction in plasma FFAs during a hyperinsulinemic clamp was prevented by infusion of triglyceride emulsions with heparin (which results in increased FFA levels by activation of lipoprotein lipase), insulin-mediated suppression of HGO was reduced. The suppression of glucagon secretion and decrease in FFA delivery to the liver are additive in reducing liver glucose production.

Hepatic insulin resistance plays an important role in the hyperglycemia of type 2 diabetes, and the impairment in suppression of HGO appears to be quantitatively similar to or even larger than the defect in the stimulation of peripheral glucose disposal. There is a direct relationship between increases in HGO and fasting hyperglycemia (Fig. 29-11). Insulin-mediated suppression of HGO is impaired at both low and high plasma insulin levels in type 2 diabetic patients. Treatment of patients with metformin, which suppress hepatic glucose production, results in improvements in glucose tolerance.

Alterations in both the direct and indirect effects of insulin in type 2 diabetic patients appear to play a role in the elevation in hepatic glucose production. Defects in the direct effect of insulin to suppress hepatic glucose production that have been demonstrated in humans appear to be due to a large rightward shift in the steep dose-response curve for insulin's inhibition of gluconeogenesis. However, peripheral insulin resistance may play the bigger role in elevated hepatic glucose production in type 2 diabetes. The resistance of adipose tissue, especially visceral fat, to suppression of lipolysis by insulin is responsible for part of the inability of insulin to suppress hepatic glucose production by the indirect route, resulting in enhanced gluconeogenesis. In addition, the suppression of glucagon levels in humans with insulin resistance may be impaired, again leading to an increase in endogenous glucose production.
INSULIN SECRETION AND TYPE 2 DIABETES

Normal insulin secretory function is essential for the maintenance of normal glucose tolerance, and abnormal insulin secretion is invariably present in patients with type 2 diabetes. In this section, the physiology of normal insulin and the alterations that are present in persons with type 2 diabetes are reviewed.

Quantitation of Beta Cell Function

The measurement of peripheral insulin concentrations by radioimmunoassay is still the most widely used method for quantifying beta cell functions in vivo. Although this approach provides valuable information, it is limited by the fact that 50% to 60% of the insulin produced by the pancreas is extracted by the liver without ever reaching the systemic circulation. The standard radioimmunoassay for the measurement of insulin concentrations is also unable to distinguish between endogenous and exogenous insulin, making it ineffective as a measure of endogenous beta cell reserve in the insulin-treated diabetic patient. Anti-insulin antibodies that may be present in patients treated with insulin interfere with the insulin radioimmunoassay, making insulin measurements in insulin-treated patients inaccurate. Conventional insulin radioimmunoassays are also unable to distinguish between levels of circulating proinsulin and true levels of circulating insulin.

Insulin is derived from a single-chain precursor, proinsulin. Within the Golgi apparatus of the pancreatic beta cell, proinsulin is cleaved by convertases to form insulin, C peptide, and two pairs of basic amino acids. Insulin is subsequently released into the circulation at concentrations equimolar with those of C peptide. In addition, small amounts of intact proinsulin and proinsulin conversion intermediates are released. Proinsulin and its related conversion intermediates can be detected in the circulation, where they constitute 20% of the total circulating insulin-like immunoreactivity. In vivo, proinsulin has a biologic potency that is only about 10% of that of insulin and the potency of split proinsulin intermediates is between those of proinsulin and insulin. C peptide has no known conclusive effects on carbohydrate metabolism although certain physiologic effects of C peptide have been proposed. Unlike insulin, C peptide is not extracted by the liver and is excreted almost exclusively by the kidneys. Its plasma half-life of approximately 30 minutes contrasts sharply with that of insulin, which is approximately 4 minutes.

Because C peptide is secreted in equimolar concentrations with insulin and is not extracted by the liver, many investigators have used levels of C peptide as a marker of beta cell function. The use of plasma C-peptide levels as an index of beta cell function is dependent on the critical assumption that the mean clearance rates of C peptide are constant over the range of C-peptide levels observed under normal physiologic conditions. This assumption has been shown to be valid for both dogs and humans and this approach can be used to derive rates of insulin secretion from plasma concentrations of C peptide under steady-state conditions. However, because of the long plasma half-life of C peptide, under nonsteady-state conditions (e.g., after a glucose infusion) peripheral plasma levels of C peptide do not change in proportion to the changing insulin secretory rate. Thus, under these conditions, insulin secretion rates are best calculated with use of the two-compartment model initially proposed by Eaton and co-workers. Modifications to the C-peptide model of insulin secretion have been introduced. This approach combines the minimal model of insulin action with the two-compartment model of C-peptide kinetics and allows insulin secretion and insulin sensitivity to be derived after either intravenous or oral administration of glucose.
Signaling Pathways in the Beta Cell and Insulin Secretion

Figure 29-12 depicts the signaling pathways in the pancreatic beta cell that are involved in the stimulus-secretion coupling of insulin release. These pathways provide the mechanism whereby insulin secretion rates respond to changes in blood glucose concentrations. Glucose enters the pancreatic beta cell by a process of facilitated diffusion mediated by the glucose transporter GLUT2. Although levels of GLUT2 on the beta cell membrane are reduced in diabetic states for various reasons, it is not currently believed that this is a rate-limiting step in the regulation of insulin secretion.

The first rate-limiting step in this process is the phosphorylation of glucose to glucose-6-phosphate. This reaction is mediated by the enzyme glucokinase. There is considerable evidence that glucokinase, by determining the rate of glycolysis, functions as the glucose sensor of the beta cell and that this is the primary mechanism whereby the rate of insulin secretion adapts to changes in blood glucose. According to this view, as blood glucose levels increase more glucose enters the beta cell, the rate of glycolysis increases, and the rate of insulin secretion increases. A fall in blood glucose levels results in a fall in the rate of glycolysis and a reduction in the rate of insulin secretion.

Glucose metabolism produces an increase in cytosolic ATP, the key signal that initiates insulin secretion by causing blockade of the ATP-dependent K⁺ channel (KATP) on the beta cell membrane. Blockade of this channel induces membrane depolarization, which leads to an increase in cytosolic Ca²⁺ and insulin secretion. The biochemical events that link the increase in glycolysis to an increase in ATP are complex. Dukes and co-workers proposed the glycolytic production of NADH during the oxidation of glyceraldehyde-3-phosphate as the key process because NADH is subsequently processed into ATP by mitochondria through the operation of specific shuttle systems.

The rate of pyruvate generation has also been proposed as an explanation for the link between glucose metabolism and the increase in insulin secretion. According to this view, pyruvate generated by the glycolytic pathway enters the mitochondria and is metabolized further in the TCA cycle. Electron transfer from the TCA cycle to the respiratory chain by NADH and reduced flavin adenine dinucleotide (FADH₂) promotes the generation of ATP, which is exported into the cytosol. The increase in ATP closes ATP-sensitive K⁺ channels, which depolarizes the beta cell membrane and opens the voltage-dependent Ca²⁺ channels, leading to an increase in intracellular Ca²⁺. The increase in cytosolic Ca²⁺ is the main trigger for exocytosis, the process by which insulin-containing secretory granules fuse with the plasma membrane, leading to the release of insulin into the circulation. The increase in ATP not only closes KATP channels but also serves as a major permissive factor for movement of insulin granules and for priming of exocytosis.

Cyclic AMP also plays an important role in beta cell signal transduction pathways. This second messenger is generated at the plasma membrane from ATP and potentiates glucose-stimulated insulin secretion, particularly in response to glucagon, glucagon-like peptide 1 (GLP-1), and gastric inhibitory polypeptide. The cAMP-dependent pathways appear to be particularly important in the exocytic machinery.

KATP channels play an essential role in beta cell stimulus-secretion coupling. The reader is directed to an excellent review for more complete information. KATP channels comprise sulfonylurea receptors (SURs) and potassium inward rectifiers, Kir6.1 and Kir6.2, that assemble to form a large octameric channel with a (SUR/Kir6.x) stoichiometry. In the pancreatic beta cell the SUR1/Kir6.2 pairs constitute the KATP channel. KATP channels control the flux of potassium ions driven by an electrochemical potential. Opening these channels can set the resting membrane potential of beta cells below the threshold for activation of voltage-gated Ca²⁺ channels when plasma glucose levels are low, thus reducing insulin secretion. Changes in the cytosolic concentrations of ATP and adenosine diphosphate (ADP) as summarized earlier lead to closure of the channels and depolarization of the beta cell membrane. Mutations in both components of the beta cell KATP, SUR1, and Kir6.2 have been shown to lead to hypersecretion of insulin resulting clinically in either a recessive form of familial hyperinsulinemia or persistent hyperinsulinemic hypoglycemia of infancy.
Physiologic Factors Regulating Insulin Secretion

Carbohydrate Nutrients

The most important physiologic substance involved in the regulation of insulin release is glucose.\[439\] \[440\] \[441\] The effect of glucose on the beta cell is dose-related. Dose-dependent increases in concentrations of insulin and C peptide and in rates of insulin secretion have been observed after oral and intravenous glucose loads, with 1.4 units of insulin, on average, being secreted in response to an oral glucose load as small as 12 g.\[404\] \[405\] \[406\] \[407\] The insulin secretory response is greater after oral than after intravenous glucose administration.\[408\] \[409\] \[410\] \[411\] Known as the incretin effect,\[412\] \[413\] this enhanced response to oral glucose has been interpreted as an indication that absorption of glucose by way of the gastrointestinal tract stimulates the release of hormones and other mechanisms that ultimately enhance the sensitivity of the beta cell to glucose (see following discussion of hormonal factors). In a study involving nine normal volunteers in whom glucose was infused at a rate designed to achieve levels previously attained after an oral glucose load, the amount of insulin secreted in response to the intravenous load was 26% less than that secreted in response to the oral load.\[414\]

Insulin secretion does not respond as a linear function of glucose concentration. The relationship of glucose concentration to the rate of insulin release follows a sigmoidal curve, with a threshold corresponding to the glucose levels normally seen under fasting conditions and with the steep portion of the dose-response curve corresponding to the range of glucose levels normally achieved postprandially.\[415\] \[416\] \[417\] The sigmoidal nature of the dose-response curve has been attributed to a gaussian distribution of thresholds for stimulation among the individual beta cells.\[418\] \[419\] \[420\] \[421\]

When glucose is infused intravenously at a constant rate, an initial biphasic secretory response is observed that consists of a rapid, early insulin peak followed by a second, more slowly rising peak.\[422\] \[423\] \[424\] \[425\] The significance of the first-phase insulin release is unclear, but it may reflect the existence of a compartment of readily releasable insulin within the beta cell or a transient rise and fall of a metabolic signal for insulin secretion.\[426\] Despite early suggestions to the contrary,\[427\] \[428\] \[429\] \[430\] a subsequent study demonstrated that the first-phase response to intravenous glucose is highly reproducible within subjects.\[431\] \[432\] \[433\] \[434\] After the acute response, a second phase of insulin release occurs that is directly related to the level of glucose elevation. In vitro studies of isolated islet cells and the perfused pancreas have identified a third phase of insulin secretion commencing 1.5 to 3.0 hours after exposure to glucose and characterized by a spontaneous decline in secretion to 15% to 25% of the amount released during peak secretory level subsequently maintained for more than 48 hours.\[435\] \[436\] \[437\] \[438\]

In addition to its acute secretagogue effects on insulin secretion, glucose has intermediate and longer term effects that are physiologically and clinically relevant. In the intermediate term, exposure of the pancreatic beta cell to a high concentration of glucose primes its response to a subsequent glucose stimulus leading to a shift to the left in the dose-response curve relating glucose and insulin secretion.\[439\] \[440\] \[441\] \[442\] However, when pancreatic islets are exposed to high concentrations for prolonged periods, a reduction of insulin secretion is seen. Although all the precise mechanisms responsible for these adverse effects that have been termed glucotoxicity are not known, there is evidence that long-term exposure to high glucose reduces expression of a number of genes that are critical to normal beta cell function, including the insulin gene.\[443\] \[444\] \[445\] \[446\]

Noncarbohydrate Nutrients

Amino acids have been shown to stimulate insulin release in the absence of glucose, the most potent secretagogues being the essential amino acids leucine, arginine, and lysine.\[447\] \[448\] \[449\] The effects of arginine and lysine on the beta cell appear to be more potent than that of leucine. The effects of amino acids on insulin secretion are potentiated by glucose.\[450\] \[451\] \[452\] \[453\]

In contrast to amino acids, various lipids and their metabolites appear to have only minor effects on insulin release in vivo. Although carbohydrate-rich fat meals stimulate insulin secretion, carbohydrate-free fat meals have minimal effects on beta cell function.\[454\] Ketone bodies and short- and long-chain fatty acids have been shown to stimulate insulin secretion acutely both in isolated islet cells and in humans.\[455\] \[456\] \[457\] \[458\] The effects of elevated FFAs in the insulin secretory responses to glucose are related to the duration of the exposure. Zhou and Grill\[459\] first suggested that long-term exposure of pancreatic islets to FFAs inhibited glucose-induced insulin secretion and biosynthesis. This observation has been confirmed in rats.\[460\] In humans, it was demonstrated that the insulin resistance induced by an acute (90-minute) elevation in FFAs was compensated for by an appropriate increase in insulin secretion.\[461\] After chronic elevation of FFAs (48 hours), the beta cell compensatory response for insulin resistance was not adequate. Additional studies have demonstrated that the adverse effects of prolonged FFAs on glucose-induced insulin secretion are not seen in individuals with type 2 diabetes. From these results, it appears that elevated FFAs may contribute to the failure of beta cell compensation for insulin resistance.

Hormonal Factors

The release of insulin from the beta cell after a meal is facilitated by a number of gastrointestinal peptide hormones, including glucose-dependent insulinotropic peptide (GIP), cholecystokinin, and GLP-1.\[462\] \[463\] \[464\] \[465\] These hormones are released from small intestinal endocrine cells postprandially and travel in the blood stream to reach the beta cells, where they act through second messengers to increase the sensitivity of the islet cells to glucose. In general, these hormones are not of themselves secretagogues, and their effects are evident only in the presence of hyperglycemia.\[466\] \[467\] \[468\] \[469\] The release of these peptides may explain why the modest postprandial glucose levels achieved in normal subjects in vivo have such a dramatic effect on insulin production, whereas similar glucose concentrations in vitro elicit a much smaller response.\[470\] Similarly, this incretin effect could account for the greater beta cell response observed after oral as opposed to intravenous glucose administration.

Whether impaired postprandial secretion of incretin hormones plays a role in the inadequate insulin secretory response to oral glucose and to meals in IGT or diabetes is controversial.\[471\] \[472\] \[473\] \[474\] but pharmacologic doses of these peptides may have future therapeutic benefit. Subcutaneous administration of GIP-1, the most potent of the incretins, lowers glucose in type 2 diabetic patients by stimulating endogenous insulin secretion and perhaps by inhibiting glucagon secretion and gastric emptying.\[475\] \[476\] Because of its short half-life, however, its longer acting analogue, exendin-4, has greater therapeutic promise.\[477\]

Treatment with suryphysiologic doses of GIP during hyperglycemia has been shown to augment insulin secretion in normal\[478\] but not in diabetic humans.\[479\] \[480\] \[481\] \[482\] Although cholecystokinin has the ability to augment insulin secretion in humans, whether it is an incretin at physiologic levels is not firmly established.\[483\] \[484\] \[485\] \[486\] Its effects are also seen largely at pharmacologic doses.\[487\]

The postprandial insulin secretory response may also be influenced by other intestinal peptide hormones, including vasoactive intestinal polypeptide, somatostatin, gastrin, and gastrin,\[488\] \[489\] but the precise role of these hormones remains to be elucidated.

The hormones produced by pancreatic alpha and beta cells also modulate insulin release. Whereas glucagon has a stimulatory effect on the beta cell,\[490\] \[491\] somatostatin suppresses insulin release.\[492\] It is currently unclear whether these hormones reach the beta cell by traveling through the islet cell interstitium (thus exerting a paracrine effect) or through islet cell capillaries. Indeed, the importance of these two hormones in regulating basal and postprandial insulin levels under normal physiologic circumstances is in doubt. Paradoxically, the low insulin levels observed during prolonged periods of starvation have been attributed to the elevated glucagon concentrations seen in this setting.\[493\] \[494\] \[495\] \[496\] Other hormones that exert a stimulatory effect on insulin secretion include growth hormone,\[497\] glucocorticoids,\[498\] prolactin,\[499\] \[500\] placental lactogen,\[501\] \[502\] and the sex steroids.\[503\]

Whereas all of the preceding hormones may stimulate insulin secretion indirectly by inducing a state of insulin resistance, some may also act directly on the beta cell, possibly to augment its sensitivity to glucose. Thus, hyperinsulinemia is associated with conditions in which these hormones are present in excess, such as acromegaly, Cushing's syndrome, and the second half of pregnancy. Furthermore, treatments with placent lactogen,\[504\] hydrocortisone,\[505\] and growth hormone\[506\]
are all effective in reversing the reduction in insulin response to glucose that is observed in vitro after hypophysectomy. Although hyperinsulinemia after an oral glucose load has been observed in patients with hyperthyroidism, the increased concentration of immunoreactive insulin in this setting may reflect elevations in serum proinsulin rather than a true increase in serum insulin.

**Neural Factors**

The islets are innervated by both the cholinergic and adrenergic limbs of the autonomic nervous system. Although both sympathetic stimulation and parasympathetic stimulation enhance secretion of glucagon, the secretion of insulin is stimulated by vagal nerve fibers and inhibited by sympathetic nerve fibers. Adrenergic inhibition of the beta cell appears to be mediated by the $\beta$-adrenoceptor because its effect is attenuated by the $\beta$-antagonist phentolamine and reproduced by the $\alpha_2$-agonist clonidine. There is also considerable evidence that many indirect effects of sympathetic nerve stimulation play a role in regulation of beta cell function through stimulation or inhibition of somatostatin, $\gamma$-adrenoceptors, and neuropeptides galanin and neuropeptide Y.

Parasympathetic stimulation of islets results in stimulation of insulin, glucagon, and pancreatic polypeptide directly and through the neuropeptides vasoactive intestinal polypeptide, gastrin-releasing polypeptide, and pituitary adenylate cyclase-activating polypeptide. In addition, sensory innervation of islets may play a role in tonic inhibition of insulin secretion through the neuropeptides calcitonin generelated peptide and, less clearly, substance P.

The importance of the autonomic nervous system in regulating insulin secretion in vivo is unclear. The neural effects on beta cell function cannot be entirely dissociated from the hormonal effects because some of the neurotransmitters of the autonomic nervous system are, in fact, hormones. Furthermore, the secretion of insulinotropic hormones such as GIP and GLP-1 postprandially has been shown to be under vagal and adrenergic control.
Temporal Pattern of Insulin Secretion

It has been estimated that, in any 24-hour period, 50% of the total insulin secreted by the pancreas is secreted under basal conditions and the remainder is secreted in response to meals. The estimated basal insulin secretion rates range from 18 to 32 units per 24 hours (0.7 to 1.3 mg). After meal ingestion, the insulin secretory response is rapid and insulin secretion increases approximately fivefold over baseline to reach a peak within 60 minutes (Fig. 29-13; see Fig. 28-12). In these studies subjects consumed 20% of calories with breakfast and 40% with lunch and dinner, respectively. However, the amount of insulin secreted after each meal did not differ significantly. The rapidity of the insulin secretory response to breakfast is underscored by the fact that 71.6% ± 1.6% of the insulin secreted in the 4 hours after the meal was produced in the first 2 hours and the remainder in the next 2 hours. Insulin secretion did not decrease as rapidly after lunch and dinner and 62.8% ± 1.6% and 59.6% ± 1.4% of the total meal response were secreted in the first 2 hours after these meals.

The normal insulin secretory profile is characterized by a series of insulin secretory pulses. After breakfast, 1.8 ± 0.2 secretory pulses were identified in normal volunteers and the peaks of these pulses occurred 42.8 ± 3.4 minutes after the meal. Multiple insulin secretory pulses were also identified after lunch and dinner. After these meals, up to four pulses of insulin secretion were identified in both groups of subjects. Thus, in the 5-hour time interval between lunch and dinner, an average of 2.5 ± 0.3 secretory pulses were identified, and 2.6 ± 0.2 were identified in the same period after dinner.

Pulses of insulin secretion that did not appear to be meal-related were also identified. Between 11:00 AM and 6:00 AM and in the 3 hours before breakfast, on average 3.9 ± 0.3 secretory pulses were present in normal subjects. Thus, over the 24-hour period of observation, a total of 11.1 ± 0.5 pulses were identified in normal subjects. Close to 90% (87% ± 3%) of postmeal pulses in insulin secretion but only 47% ± 8% of nonmeal-related pulses were concomitant with a pulse in glucose.

Oscillatory Insulin Secretion

In vivo studies of beta cell secretory function have demonstrated that insulin is released in a pulsatile manner. This behavior is characterized by rapid oscillations occurring every 8 to 15 minutes that are superimposed on slower (ultradian) oscillations occurring at a periodicity of 80 to 150 minutes. The rapid oscillations persist in vitro and are therefore likely to be the result of metabolic pathways in the pancreatic beta cell that involved negative feedback loops with time lags.

The rapid oscillations of insulin are of small amplitude in the systemic circulation, averaging between 0.4 and 3.2 μU/mL in several published human studies. Because these values are close to the limits of sensitivity of most standard insulin radioimmunoassays, the characterization of these oscillations is subject to considerable pitfalls. Not the least of which is the need to differentiate between true oscillations of small amplitude and random assay noise. The latter problem has been overcome by the development of extremely sensitive enzyme-linked immunosorbent assays that allow the detection of extremely small changes in peripheral insulin concentrations. The application of these assays in studies involving frequent sampling from the peripheral circulation has led to a series of studies of the role of these oscillations in the overall regulation of insulin secretion.

These studies have suggested that increases in overall insulin secretion seen in response to a variety of secretagogues in various physiologic and pathophysiologic states are due to an increase in the amplitude of the bursts of insulin secretion. The studies have proposed that 75% of insulin secretion is accounted for by secretory bursts and the responses to GLP-1, sulfonylureas, and oral glucose are all mediated by an increase in the amplitude of insulin secretory pulses. Furthermore, consistent with observations made by O'Rahilly and colleagues a number of years ago, relatives of patients with type 2 diabetes demonstrate a disorderly profile of the insulin secretory oscillations. A number of mathematical programs have been developed that allow these insulin secretory oscillations to be evaluated and studied. The latest addition to the list is the development of ApEn and cross ApEn, which are statistics that measure temporal regularity of the oscillations in the insulin secretory profile.

The low amplitude of the rapid oscillations in the systemic circulation contrasts sharply with observations in the portal vein, where pulse amplitudes of 20 to 40 μU/mL have been recorded in dogs. Although the physiologic importance of these low-amplitude rapid pulses in the periphery is unclear, they are likely to be of physiologic importance in the portal vein. It is possible that the liver responds more readily to insulin delivered in a pulsatile fashion than to insulin delivered at a constant rate.
secretion without change in frequency, and there is a slight temporal advance of the glucose versus the insulin oscillation.

These findings suggest that the ultradian oscillations may be entirely accounted for by the major dynamic characteristics of the insulin-glucose feedback system, with no need to postulate the existence of an intrapancreatic pacemaker. In support of this hypothesis, Sturis and colleagues demonstrated that when glucose is administered in an oscillatory pattern, ultradian oscillations in plasma glucose and insulin secretion are generated that are 100% concordant with the oscillatory period of the exogenous glucose infusion. This close relationship between the ultradian oscillations in insulin secretion and similar oscillations in plasma glucose was further exemplified in a series of dose-response studies in which the largest amplitude oscillations in insulin secretion were observed in the subjects exhibiting the largest amplitude glucose oscillations, which in turn were directly related to the infusion dose of glucose. It has been shown that in normal humans, insulin is more effective in reducing plasma glucose levels when administered intravenously as a 120-minute oscillation than when delivered at a constant rate. These results indicate that the ultradian oscillations have functional significance.

Circadian variations in the secretion of insulin have also been reported. When insulin secretory responses were measured during a 24-hour period during which subjects received three standard meals, the maximal postprandial responses were observed after breakfast. These findings are mirrored by the results of studies in which subjects were tested for oral glucose tolerance at different times of the day and were found to exhibit maximal insulin secretory responses in the morning and lower responses in the afternoon and evening. These diurnal differences are also noted in tests for intravenous glucose tolerance. Furthermore, although ultradian glucose and insulin oscillations are closely correlated during a constant 24-hour glucose infusion, the nocturnal rise in mean glucose levels is not accompanied by a similar increase in the insulin secretory rate. It has been postulated that these diurnal differences may reflect diminished responsiveness of the beta cell to glucose in the afternoon and evening.
Insulin Secretion in Obesity and Insulin Resistance

Obesity and other insulin-resistant states are associated with a substantially greater risk for the development of type 2 diabetes. The ability of the pancreatic beta cell to compensate for insulin resistance determines whether blood glucose levels remain normal in insulin-resistant subjects or whether the subjects develop glucose intolerance or diabetes.

The nature of the beta cell compensation for insulin resistance involves hypersecretion of insulin even in the presence of normal glucose concentrations. This can occur only if beta cell sensitivity to glucose is increased. The increase in beta cell sensitivity to glucose seen in obesity appears to be mediated by two factors. First, increased beta cell mass is observed in obesity and other insulin-resistant states. Second, insulin resistance appears to be associated with increased expression of hexokinase in the beta cell relative to the expression of glucokinase. Because hexokinase has a significantly lower Michaelis constant (Km) for glucose than glucokinase, the functional effect of increased hexokinase expression is to shift the glucose-insulin secretion dose-response curve to the left, leading to increased insulin secretion across a wide range of glucose concentrations.

Assessment of the adequacy of the beta cell compensation for insulin resistance is important because this is the major determinant of the development of diabetes. In insulin-resistant states it is important to evaluate beta cell function in relation to the degree of insulin resistance. Kahn and co-workers studied the relationship between insulin sensitivity and beta cell function in 93 relatively young, apparently healthy human subjects of varying degrees of obesity. The sensitivity index SI was calculated using the minimal model of Bergman as a measure of insulin sensitivity and was then compared with various measures of insulin secretion. The relationship between the SI and the beta cell measures was curvilinear and reciprocal for fasting insulin (P < .0001), first-phase insulin response (AIR - acute insulin response) glucose; P < .0001), glucose potentiation slope (n = 56; P < .005), and beta cell secretory capacity (AIRmax; n = 43; P < .0001). The curvilinear relationship between SI and the beta cell measures could not be distinguished from a hyperbola, that is, SI × beta cell function = constant. The nature of this relationship is consistent with a regulated feedback loop control system such that for any difference in SI, a proportionate reciprocal difference occurs in insulin levels and responses in subjects with similar carbohydrate tolerance. Thus, in human subjects with normal glucose tolerance and varying degrees of obesity, beta cell function varies quantitatively with differences in insulin sensitivity. The increase in insulin secretion that is observed with a fall in SI should be viewed as the beta cell compensation that allows normal glucose tolerance to be maintained in the presence of insulin resistance.

The insulin resistance of obesity is characterized by hyperinsulinemia. Hyperinsulinemia in this setting reflects a combination of increased insulin production and decreased insulin clearance, but most evidence suggests that increased insulin secretion is the predominant factor. Both basal and 24-hour insulin secretory rates are three to four times higher in obese subjects and are strongly correlated with body mass index. Insulin secretory responses to intravenous glucose have been studied in otherwise healthy insulin-resistant subjects in comparison with insulin-sensitive subjects by means of a graded glucose infusion. Figure 29-15 depicts insulin concentrations and insulin secretion rates at each level of plasma glucose achieved, thereby constructing a glucose-insulin or glucose-insulin secretion rate dose-response relationship. Both insulin concentrations and insulin secretion rates are increased in insulin-resistant subjects, resulting from a combination of increased insulin production and decreased insulin clearance. For each level of glucose, insulin secretion rates are higher in the insulin-resistant subjects, reflecting an adaptive response of the beta cell to peripheral insulin resistance. Similar compensatory hyperinsulinemia has been demonstrated using other clinical techniques such as the frequency sampled intravenous glucose tolerance test in obesity and other insulin-resistant states such as late pregnancy.

The temporal pattern of insulin secretion is unaltered in obese subjects compared with normal subjects. Basal insulin secretion in obese subjects accounts for 50% of the total daily production of insulin, and secretory pulses of insulin occur every 1.5 to 2 hours. However, the amplitude of these pulses postprandially is greater in obese subjects. Nevertheless, when these postprandial secretory responses are expressed as a percentage of the basal secretory rate, the postprandial responses in obese and normal subjects are identical.
Insulin Secretion in Subjects with Impaired Glucose Tolerance

It has been suggested that insulin secretion may be normal in subjects with IGT. However, substantial defects in insulin secretion have been demonstrated in people with normal fasting glucose and glycated hemoglobin concentrations with glucose values greater than 140 mg/dL or 7.8 mmol/L 2 hours after ingestion of 75 g of glucose orally. Thus, defects in insulin secretion can be detected before the onset of overt hyperglycemia.

Detailed study of insulin secretion in patients with IGT has demonstrated that consistent quantitative and qualitative defects are seen in this group. During oral glucose tolerance testing, there is a delay in the peak insulin response. The glucose-insulin secretion dose-response relationship is flattened and shifted to the right (Fig. 29-16), and first-phase insulin responses to an intravenous glucose bolus are consistently decreased in relation to ambient insulin sensitivity. Further, abnormalities in first-phase insulin secretion were observed in first-degree relatives of patients with type 2 diabetes who exhibited only mild intolerance to glucose, and an attenuated insulin response to oral glucose was observed in normoglycemic co-twins of patients with type 2 diabetes. This pattern of insulin secretion during the so-called prediabetic phase was also seen in subjects with IGT who later developed type 2 diabetes and in normoglycemic obese subjects with a recent history of gestational diabetes. Another group at high risk for type 2 diabetes, Beta cell abnormalities may therefore precede the development of overt type 2 diabetes by many years.

The temporal pattern of insulin secretory responses is altered in IGT and is similar to but not as pronounced as that seen in diabetic subjects (see later). There is a loss of coordinated insulin secretory responses during oscillatory glucose infusion, indicating that the ability of the beta cell to sense and respond appropriately to parallel changes in the plasma glucose level is impaired. Abnormalities in rapid oscillations of insulin secretion have also been observed in first-degree relatives of patients with type 2 diabetes who have only mild glucose intolerance, further suggesting that abnormalities in the temporal pattern of beta cell function may be an early manifestation of beta cell dysfunction preceding the development of type 2 diabetes. Because an elevation in serum proinsulin is seen in subjects with diabetes, the contribution of proinsulin to the hyperinsulinemia of IGT has been questioned. Therefore, elevations in proinsulin, although elevations in fasting and stimulated proinsulin or proinsulin/insulin ratios have been found by many, although not all, investigators.

For by an increase in proinsulin, although elevations in fasting and stimulated proinsulin or proinsulin/insulin ratios have been found by many, although not all, investigators. Correlation of elevated proinsulin levels in IGT as a predictor of future conversion to diabetes has also been observed.
Insulin Secretion in Type 2 Diabetes Mellitus

Because of the presence of concomitant insulin resistance, patients with type 2 diabetes are often hyperinsulinemic, but the degree of hyperinsulinemia is inappropriately low for the prevailing glucose concentrations. Nevertheless, many of these patients have sufficient beta cell reserve to maintain a euglycemic state by dietary restriction with or without an oral agent. The beta cell defect in patients with type 2 diabetes mellitus is characterized by an absent first-phase insulin and C-peptide response to an intravenous glucose load and a reduced second-phase response. Although hyperglycemia may play a role in mediating these changes, the abnormal first-phase response to intravenous glucose persists in patients whose diabetic control has been greatly improved, consistent with the idea that patients with type 2 diabetes have an intrinsic defect in the beta cell. Furthermore, abnormalities in first-phase insulin secretion have also been observed in first-degree relatives of patients with type 2 diabetes who have only mild glucose intolerance, and an attenuated insulin response to oral glucose has been observed in normoglycemic co-twins of patients with type 2 diabetes group at high risk for type 2 diabetes and who can legitimately be classified as prediabetic. This pattern of insulin secretion during the so-called prediabetic phase is also seen in subjects with IGT who later develop type 2 diabetes and in normoglycemic obese subjects with a recent history of gestational diabetes, who are also at high risk for type 2 diabetes. Beta cell abnormalities may therefore precede the development of overt type 2 diabetes by many years.

Type 2 diabetes also affects proinsulin levels in serum. Increased levels of proinsulin are consistently seen in association with increases in the proinsulin/insulin molar ratio. The amount of proinsulin produced in this setting appears to be related to the degree of glycemic control rather than to the duration of the diabetic state, and in one series proinsulin levels contributed almost 50% of the total insulin immunoreactivity in type 2 diabetes patients who had marked hyperglycemia. In addition to intact proinsulin, the beta cell secretes one or more of the four major proinsulin conversion products (split 32,33-, split 65,66-, des-31,32-, and des-64,65-proinsulin) into the circulation. These conversion products are produced within the secretory granules of the islet as a result of the activity of specific conversion enzymes at the two cleavage sites in proinsulin linking the C peptide to the A and B chains.

The composition of the elevated proinsulin-like immunoreactivity (PLI) in patients with type 2 diabetes compared with control subjects has not been fully characterized. Hales and colleagues have developed immunoradiometric assays for this purpose. Using these assays, split 32,33-proinsulin was reported to be the predominant proinsulin conversion product in the circulation, although des-31,32-proinsulin levels may also be elevated. Insulin, proinsulin, and conversion product concentrations were also measured with these assays 30 minutes after oral glucose in patients with type 2 diabetes. Insulin was reduced in all patients, with no overlap between patients and controls, and concentrations of proinsulin and conversion products were elevated in the diabetic patients. These data highlight the importance of the potentially confounding effects of proinsulin and proinsulin conversion products in the interpretation of circulating immunoreactive insulin in patients with type 2 diabetes and emphasize the need to measure the concentrations of the individual peptides.

Abnormalities in the temporal pattern of insulin secretion have also been demonstrated in patients with type 2 diabetes. In contrast to normal subjects, in whom equal amounts of insulin are secreted basally and postprandially, in a given 24-hour period, patients with type 2 diabetes secrete a greater proportion of their daily insulin under basal conditions. This reduction in the proportion of insulin secreted postprandially appears to be related in part to a reduction in the amplitude of the secretory pulses of insulin occurring after meals rather than to a reduction in the number of pulses. In contrast to normal subjects, patients with type 2 diabetes have ultradian oscillations in insulin secretion that are less tightly coupled with oscillations in plasma glucose. Similar findings were observed in patients with IGT studied under the same experimental conditions and in a further group of type 2 diabetic patients studied under fasting conditions. The rapid insulin pulses are also abnormal in type 2 diabetes because the persistent regular rapid oscillations present in normal subjects are not observed. Instead, the cycles are of shorter duration and are irregular in nature. Similar findings were observed in a group of first-degree relatives of patients with type 2 diabetes who had only mild glucose intolerance, suggesting that abnormalities in oscillatory activity may be an early manifestation of beta cell dysfunction.

The effects of therapy on beta cell function in patients with type 2 diabetes have also been investigated. Although interpretation of the results in many instances is limited by the fact that beta cell function was not always studied at comparable levels of glucose before and during therapy, the majority of the studies indicated that improvements in diabetic control are associated with an enhancement of beta cell secretory activity. This increased endogenous production of insulin appears to be independent of the mode of treatment and is in particular associated with increases in the amount of insulin secreted postprandially. The enhanced beta cell secretory activity after meals reflects an increase in the amplitude of existing secretory pulses rather than an increased number of pulses. Despite improvements in glycemic control, beta cell function is not normalized after therapy, suggesting that the intrinsic defect in the beta cell persists.

Treatment with the sulfonylurea gliburide increases the amount of insulin secreted in response to meals but does not correct the underlying abnormalities in the pattern of insulin secretion. In particular, the abnormalities in the pulsatile pattern of ultradian insulin secretory oscillations persist on treatment with glyburide despite the increase in the amount of insulin secreted.

We have also investigated the effects on insulin secretion of improving insulin resistance in subjects with IGT by using the insulin-sensitizing agent troglitazone, a thiazolidinedione. Troglitazone therapy improved insulin sensitivity, and this was associated with enhanced ability of the pancreatic beta cell to respond to a glucose stimulus as judged by improvements in the dose-response relationships between glucose and insulin secretion as well as enhanced ability of the pancreatic beta cell to detect and respond to small oscillations in the plasma glucose concentration.
RODENT MODELS OF TYPE 2 DIABETES

A number of spontaneous and genetically selected animal models of type 2 diabetes have been identified. Most of the models combine the two main features of type 2 diabetes, obesity-associated insulin resistance and beta cell dysfunction with or without diminished beta cell mass. As with diabetes in humans, the different rodent models of type 2 diabetes have similarities but a number of overt and subtle differences make them useful surrogates for intensive study of the syndromes associated with type 2 diabetes.

An interesting observation is the striking sexual dimorphism in most rodent models of type 2 diabetes, with the male most often being affected exclusively, earlier, or more severely in most instances. In this regard, it is not like the human situation. The advent of transgenic and knockout technology in mice has produced a wide range of models of insulin resistance and beta cell dysfunction that results in hyperglycemia. It is beyond the scope of this chapter to review each of these, and the reader is referred to the primary literature for review of these animals. We limit our discussion to the well-documented spontaneous or derived models of the disease in rodents.

Mouse Models of Type 2 Diabetes

Leptin (Lep) and the Leptin Receptor (db)

The ob mutation, now designated Lep, was first described in 1960, but the gene mutation responsible for the syndrome was not described until the ob mutation was found to be in the gene for leptin. Mice homozygous for the ob mutation do not produce the satiety factor leptin and become markedly hyperphagic, obese, insulin-resistant, and hyperinsulinemic. They have a multitude of other pathohalamic functions that render them hypometabolic, contribute to the obesity, and also result in infertility. Leptin treatment of these mice results in decreased food intake and reverses many of their other metabolic defects. The ob mice develop obesity at weaning that becomes progressive because of hyperphagia. Insulin resistance is seen in muscle, adipose tissue, and liver, with a variety of signaling defects that are also reversible with insulin administration. The ob mouse becomes hyperglycemic and has a profound hyperinsulinemia associated with beta cell hyperplasia with up to a 10-fold increase in islet mass.

Parabiotic experiments between the ob and db mice suggested that the db mutation would be in the receptor for ob. This was confirmed with the identification of multiple mutations in the leptin receptor in db. Like ob mice, db mice are hyperphagic and begin to surpass their littermates in weight at weaning. They are progressively hyperinsulinemic, become hyperglycemic at 6 to 8 weeks, and because of a decline in beta cell function become markedly hyperinsulinemic at 4 to 6 months. The reason for the more severe diabetes in the db mouse is not clear, but it may be due to background strain differences as similar defects in insulin signaling are seen in this animal model as well. Treatment of both ob and db mice with insulin-sensitizing agents such as thiazolidinediones reversed the insulin resistance and ameliorated or prevented the onset of diabetes.

Agouti Mouse

Dominant "yellow" mutations in the agouti gene produce obesity and hyperglycemia. Depending on the background strain, the agouti mutation has a variable phenotype. In susceptible strains, the onset of hyperinsulinemia begins at 6 weeks of age and insulin levels continue to increase with age with beta cell hyperplasia and hypertrophy. The agouti mutation results in systemic production of a protein normally expressed in the skin, most frequently because of a retrotransposon insertion into the promoter region of the gene. Interestingly, a number of genes, including the fatty acid synthase gene, both have insulin and agouti response elements, which result in a marked increase in expression leading to increased hepatic fatty acid synthesis and enhanced fat deposition in adipocytes. The hyperglycemia is postprandial, and the fasting glucose levels are usually normal. The exact function of the agouti gene is unknown, but the animals are hyperphagic and show enhanced growth.

KK Mouse

These mice were originally bred for enhanced size but are not as obese as most other obese mice (usually less than 60 g). Breeding the KK into various background strains has produced variable insulin resistance, hyperinsulinemia, and hyperglycemia. The most studied strain is the KK, produced in Japan. This mouse has markedly increased insulin levels (>1000 µU/mL) when fed a high-fat diet. As the male mouse ages, glucose levels fall toward the normal range. The mutation responsible for the KK phenotype is unknown.

NZO Mouse

New Zealand obese (NZO) mice were derived by inbreeding of abdominally obese outbred mice. NZO neonates have high birth weights, and mice of both sexes are large and at weaning exhibit an elevated carcass fat content. Approximately 40% to 50% of group-caged NZO males, but not females, develop type II diabetes between 12 and 20 weeks of age when maintained with a chow diet containing 4.5% fat. Obesity in NZO mice is characterized by widespread accumulation of subcutaneous as well as visceral fat. The obesity in these mice is accompanied by glucose intolerance in males associated with increased hepatic and peripheral insulin resistance. In contrast to those in ob and db mice, genes encoding certain gluconeogenic and glycolytic enzymes in the liver retain normal responsiveness to insulin, although there is evidence for an inappropriately active fructose-1,6-biphosphatase. Defective beta cell insulin secretion from NZO islets in vitro and in vivo has been described. There appears to be a defect in the glycolytic pathway in beta cells leading to defective glucose-stimulated insulin release.

The genetics of NZO mice show a polygenic disorder, and none of the allelic variants have been discovered. Complicating the analysis of the model is the susceptibility of the mice to autoimmune disorders including a lupus-like syndrome and the insulin receptor. There is also a maternal influence in the periparturient period in the development of the disorder, which may reflect substances in the maternal milk.

Gold Thioglucose-Induced Diabetes

Gold thioglucose induces specific lesions in the ventromedial hypothalamus and induces an initial chronic hyperinsulinemia that leads to hypoglycemia, hyperphagia, obesity, and the development of insulin resistance and hyperglycemia. This model has been used as an example of pancreatic dysfunction preceding the induction of insulin resistance as opposed to pancreatic compensation for insulin resistance.

Diabetes Induced by Fat Ablation

Three models of insulin-resistant diabetes have been created in which adipose tissue has been genetically eliminated by overexpression of foreign genes using the fat-specific promoter aP2. Expression of an attenuated diphtheria toxin in adipose tissue resulted in an age-dependent loss of fat, progressive insulin resistance, and significant glucose intolerance, and diabetes. These mice represent a model of the human condition lipodystrophic diabetes and demonstrate the importance of fat in normal glucose homeostasis. It has been suggested that the lack of fat depots results in elevated
fatty acid delivery to liver and muscle and the development of insulin resistance. The diabetes in these animals can be variously treated by thiazolidinediones, \[587\] leptin administration, \[592\] and fat transplantation. \[591\] Interestingly, human lipodystrophy also responds to thiazolidinedione treatment, \[593\] suggesting that some of the effects of these compounds are not wholly dependent upon adipose tissue.

**C57BL/6J Mice Fed a High-Fat Diet**

Male C57BL/6J (also know as B6) mice fed a high-fat, high-carbohydrate diet (58% fat by kilocalories) or a "Western" diet developed hyperglycemia, hyperinsulinemia, hyperlipidemia, and increased adiposity. \[594\] Glucose-stimulated insulin secretion was blunted, and there was significant insulin resistance. \[595\] Despite obesity, plasma leptin levels in the Western diet-fed B6 mice were significantly lower than in control mice in the absence of hyperphagia. \[596\] The weight gain is due primarily to an increase in mesenteric adiposity, which makes this a good model for adult-onset type 2 diabetes.

**Nagoya-Shibata-Yasuda (NSY) Mice**

The NSY mouse shows male-specific, mild IGT with only a minority of the females becoming diabetic. \[597\] An impairment in beta cell function and obesity are present. These mice do not show the typical islet hyperplasia associated with insulin resistance.

**TallyHo Mice**

The TallyHo mouse also has a male-only development of diabetes associated with beta cell hyperplasia. Both male and

female TallyHo mice are obese, hyperinsulinemic, and hyperlipidemic, with the males having glucose levels greater than 500 mg/dL. \[600\]
**Rat Models of NIDDM**

**Zucker Diabetic Fatty (ZDF) Rat**

The orthologue of the db mouse, the obese Zucker rat (fa/fa), has a mutation in the leptin receptor that results in significant hyperphagia. This mutation is distinct from the mutations in ob in that it does not disrupt leptin receptor gene expression and does not affect ligand binding. This mutation results in a constitutive intracellular signaling domain, which may induce a desensitization of the leptin signaling pathways.

The selection of the inbred ZDF strain utilized Zucker (fa/fo) rats that had progressed to a diabetic phenotype. Brother-sister mating resulted in nearly 100% diabetes in the male rats receiving a 5% fat diet. Hyperglycemia begins to develop in males at 7 weeks of age, with serum glucose levels rising to 500 mg/dL by 12 weeks of age. The hyperinsulinemia precedes hyperglycemia with marked islet hyperplasia with dysmorphogenesis but by 19 weeks of age insulin levels drop concomitantly with islet atrophy, in part because of an imbalance of hyperplasia and apoptosis. The islets of prediabetic ZDF rats secrete significantly more insulin in response to glucose with elevated basal levels of insulin secretion and a leftward shift but a blunted glucose dose-response curve. Islets of prediabetic male ZDF rats also have defects in the normal oscillatory pattern of insulin secretion.

In contrast to the male ZDF rat, the female rat has significant insulin resistance but does not become diabetic unless given a proprietary high-fat diet (GMI 13004). The high-fat diet appears to have a direct effect on the beta cell as there is no change in peripheral insulin sensitivity (P. Hansen and C. F. Burant, unpublished). Interestingly, there is a decrease in peripheral triglyceride and FFA levels in the female rat after the institution of the high-fat diet.

The underlying genetic defect that results in beta cell failure in the ZDF rat is unknown. The beta cell number and insulin content are not different from those in homoyzogous normal animals, but insulin promoter activity is doubled in the ZDF rat. Insulin promoter mapping studies suggest that a critical region in the promoter of the insulin gene is affected. A number of other gene expression differences have been described in ZDF islets, including decreases in the expression of GLUT2, increases in glucokinase and hexokinase activity; decreases in mitochondrial metabolism; accumulation of intraslit lipid and long-chain fatty acyl CoA, which is associated with abnormal beta cell secretion; and increases in nitric oxide and ceramide accumulation, which is associated with apoptosis. Other gene expression changes are also found in the prediabetic rat islet. Which of these defects are important for the development of the diabetes is not clear. Despite the fixed genetic defect in the male animal that leads to diabetes, this defect interacts with the insulin resistance because treatment with insulin-sensitizing agents can prevent the onset of diabetes in the male and female. These agents are not effective in the male after establishment of diabetes; however, the female rat can respond to thiazolidinediones, even after significant hyperglycemia.

**Goto-Kakizaki (GK) Rats**

The GK inbred rat strain was derived from outbred Wistar rats by selection for IGT. Early in the development of diabetes, there are mild elevations of both glucose and insulin levels in the GK rat, but as the animals age, reduced beta cell mass is evident with markedly diminished insulin stores and abnormal secretory responses to glucose. A number of biochemical defects have been described in the islets of these animals, including decreased energy production, expression of proteins involved in insulin granule movement, and decreased adenylyl cyclase activity. Defects in peripheral signaling include decreased maximal and submaximal insulin-stimulated IRS1 tyrosine phosphorylation, IRS1-associated PI 3-kinase activity, and Akt activation in muscle and defective regulation of protein phosphatase-1 (PP-1), PP-2A, and mitogen-activated protein kinase activation by upstream insulin signaling components in adipocytes. Some of these defects may be due to hyperglycemia because they can be reversed by phlorizin-induced normalization of serum glucose.

**Bureau of Home Economics (BHE/Cdb) Rats**

The BHE/Cdb rat is a subline of the parent BHE obtained by selection for hyperglycemia and dyslipidemia without obesity. Glucose-stimulated insulin secretion is markedly diminished in these rats, a trait that is maternally inherited. A significant defect appears to be in the liver, where increased gluconeogenesis and lipogenesis precede the hyperglycemia, which may be due to defects in mitochondrial respiration associated with mitochondrial DNA mutations.

**Psammomys obesus (Sand Rat)**

This is a nutritionally induced obesity model of type 2 diabetes. Genetically, the Sand Rat is in reality a gerbil and the animal usually lives on a low-calorie vegetable diet. When given a high-carbohydrate diet, the Sand Rat rapidly becomes hyperglycemic secondary to weight gain associated with significant insulin resistance and enhanced hepatic glucose production. When a relatively hypocaloric diet is restored, the metabolic syndrome reverts to normoglycemia. A subpopulation of the Sand Rat develops frank beta cell failure and becomes ketogenic.

**Otsuka Long-Evans Tokushima Fatty (OLETF) Rats**

The OLETF rat strain was derived from the Long-Evans rat with polyuria, polydipsia, and mild obesity. About 90% of the male animals become diabetic by 1 year of age. Statistical tests have determined that the locus containing the cholecystokinin A receptor is responsible for about 50% of the NIDDM in the OLETF rats. The receptor is disrupted in the OLETF rat because of a 165-bp deletion in exon 1. Genetic segregation analysis has also shown interaction with a second locus, Odb2, which acts in a synergetic fashion to result in NIDDM, and both of these loci are required in homozygous OLETF rats to cause elevated plasma glucose.

The role of sex hormones is pronounced in this strain as orchietomy markedly reduces the incidence of diabetes whereas ovariectomy increases hyperglycemia to 30% in the female. Further, treatment of castrated males with testosterone restores the incidence to 89%. The islets undergo a progressive inflammatory reaction with progressive fibrosis. This reaction is associated with the impairment of beta cell function. Obesity and insulin resistance appear to precede the development of beta cell failure. Studies have also shown that obesity is necessary for the development of NIDDM in OLETF males and that insulin resistance may be closely related to fat deposition in the abdominal cavity. Troglitazone and metformin have been used successfully to treat the diabetes in the OLETF rat, with troglitazone completely preventing the beta cell morphologic and functional deterioration.

**Neonatal Streptozotocin**

Two models have been described in which a single dose of the beta cell toxic streptozotocin is given to 2-day-old female Wistar or male Sprague-Dawley rats. These animals have a transient hyperglycemia but develop IGT at 4 to 6 weeks of age. There is an initial reduction of beta cell mass with regeneration resulting in an approximately 50% reduction in adulthood.
MANAGEMENT OF TYPE 2 DIABETES

Over the last 10 years, a conceptual transformation in the principles of management of type 2 diabetes has occurred. Fundamentally, there has been a change in the level of concern about diabetes as a public health issue as well as in attitudes toward its treatment. Dramatic advances in the spectrum of pharmacologic agents and monitoring technology available for the treatment of diabetes have made it possible to lower glucose safely to the near-normal range in the majority of patients. Great strides have been made in establishing an evidence base for guidelines regarding glycemic control and efforts to reduce the risk of complications. Both corporate and government health insurance providers have greatly improved the extent to which diabetes equipment and supplies are covered.

A comprehensive review of all the subtleties of diabetes management in the 21st century is beyond the scope of this chapter. In the following pages, we deal with the salient features of the epidemiology of the complications of type 2 diabetes, diagnostic strategies, treatment guidelines, lifestyle interventions, and pharmacotherapy before turning briefly to a discussion of preventive measures for type 2 diabetes and its complications. An excellent source of information on these issues that is updated annually is the American Diabetes Association's Clinical Practice Recommendations. It is published as the first supplement to the journal Diabetes Care each January and is available online at www.diabetes.org by clicking "For Health Care Professionals"; near the end of that document is a listing of technical reviews, which are generally recent, fairly exhaustive treatments of most areas of interest in diabetes care.

Scope of the Problem

Type 2 diabetes is estimated to affect some 17 million to 20 million people in the United States. There is an epidemic of diabetes nationwide with a 6% annual growth rate in the prevalence of the disease. Worldwide, the prevalence of diabetes is increasing even faster. This increase is driven by population aging; population growth, particularly among ethnic groups with greater susceptibility to the disease; and dramatic increases in rates of obesity as a consequence of increasingly sedentary lifestyles and greater consumption of simple sugars and high-caloric-density foods. At least in the United States, opportunistic screening for diabetes in high-risk populations is recommended by professional societies and many insurers, resulting in an increase in the proportion of affected individuals diagnosed in this country from approximately one half a decade ago to about two thirds.

The morbidity, mortality, and expense associated with diabetes are staggering. In Western society, people with diabetes are three times more likely to be hospitalized than nondiabetic individuals. In the United States, diabetes is the leading cause of blindness and accounts for over 40% of the new cases of end-stage renal disease. The risk of heart disease and stroke is 2 to 4 times higher and the risk of lower extremity amputation is approximately 20 times higher for people with diabetes than for those without. Life expectancy is reduced by approximately 10 years in people with diabetes, and although diabetes is the seventh leading cause of death in the United States, this is clearly an underestimate. Despite the fact that some 70% of people with diabetes die of heart disease and stroke, only approximately 10% have diabetes listed as a contributing cause on death certificates.

Tragically, this enormous burden of death and disability has not been reduced by huge health care expenditures. In fact, the epidemic of diabetes is one of the drivers of increasing health care costs, with annual disbursements for people with diabetes approximately three to five times higher per capita than those for individuals without diabetes. In the United States, at least 15% of health care expenditures are related to the treatment of people with diabetes. Nevertheless, whereas rates of coronary artery disease are declining in the United States in general, this is not the case for people with diabetes. However, there is evidence that increased effort to control diabetes and its comorbidities can even reduce costs associated with diabetes and that a public health approach to diabetes can reduce the burden of complications of diabetes.
Screening and Diagnosis

The role of screening to make the diagnosis of diabetes in asymptomatic individuals is an area of substantial controversy. No prospective randomized trials have examined the benefit of such a screening program. On the other hand, it seems self-evident that early diagnosis and intervention have at least the potential to reduce complications in a disease in which 20% to 50% of patients have a complication at the time of diagnosis. The cost-effectiveness of universal approaches to diabetes screening has been called into question. The American Diabetes Association (ADA) recommendations for screening are based on a review that concludes, “Periodic, targeted, and opportunistic screening within the existing health care system seems to offer the greatest yield and likelihood of appropriate follow-up and treatment.” The ADA suggests that patients (i.e., screening should be performed only in the context of a routine health care setting) should be screened at 3-year intervals beginning at age 45 and that testing should be considered at an earlier age or be carried out more frequently if diabetes risk factors are present. Those risk factors are listed in Table 29-3.

Most groups recommend FPG as the most practical screening test, although it is recognized that its sensitivity is substantially lower than that of the OGTT. More recent data suggest that alternative screening strategies may have advantages. In a study employing glucose meters to measure random capillary blood glucose, values of 120 mg/dL or higher obtained at random without regard to meals were 75% to 84% sensitive and 86% to 90% specific for detecting diabetes as defined by either FPG or oral glucose tolerance testing. In the future, it is possible that well-validated models will allow us to predict diabetes risk from standard biologic measures such as body mass index, blood pressure, and lipids with greater precision than today.

Classically, diabetes has been diagnosed on the basis of prospective epidemiologic data associating circulating glucose levels with the future development of diabetic retinopathy. In 1997, recommendations were made by an expert committee to change the diagnostic criteria for diabetes to improve the sensitivity of FPG for the diagnosis of diabetes. They determined, from a review of several large data sets, that FPG greater than or equal to 126 mg/dL (7.0 mM) identified a population of people with a risk of retinopathy similar to that of those with a 2-hour value in an OGTT of 200 mg/dL or higher. In an effort to simplify the OGTT, only the 2-hour plasma glucose after a 75-g oral glucose load needs to be measured for diagnostic purposes. Furthermore, patients with classical symptoms of diabetes in association with a random glucose level of 200 mg/dL or higher also meet diagnostic criteria for diabetes. To avoid misclassification, it is further suggested that patients should meet one of the three diagnostic criteria on at least two separate days before making the diagnosis of diabetes.

Because macrovascular disease accounts for the majority of the morbidity and almost all the mortality associated with diabetes and the diagnosis of diabetes is associated with more stringent guidelines for the treatment of comorbidities such as dyslipidemia and hypertension, it seems likely that the diagnostic criteria for diabetes will be lowered again to make the fasting glucose cut points more sensitive. This seems appropriate, as it is clear that glucose levels above normal but below the current thresholds for diabetes are associated with increased cardiovascular risk. A debate unlikely to be answered in the next decade is whether it is acceptable to measure only fasting glucose as an index of glucose intolerance or whether it is cost-effective to use an oral challenge to ascertain fully glucose-related risks.
Glucose Treatment Guidelines

Prospective randomized clinical trials have documented improved rates of microvascular complications in patients with type 2 diabetes treated to lower glycemic targets. In the UK Prospective Diabetes Study (UKPDS), patients with newonset diabetes were treated with diet and exercise for 3 months with an average reduction in glycosylated hemoglobin or HbA\textsubscript{1c} from approximately 9% to 7% (upper limit of normal 6%). Those with FPG greater than 108 mg/dL (6 mM) were randomly assigned to two treatment policies. In the standard intervention, subjects continued the lifestyle intervention. Pharmacologic therapy was initiated only if the FPG reached 15 mM (270 mg/dL) or the patient became symptomatic. In the more intensive treatment program, all patients were randomly assigned and treated with either sulfonylurea, metformin, or insulin as initial therapy, with the dose increased to try to achieve an FPG less than 108 mg/dL. Combinations of agents were used only if the patients became symptomatic or FPG became greater than 270 mg/dL (15 mM). As a consequence of the design, although the HbA\textsubscript{1c} fell initially to about 6%, over the average 10 years of follow-up it rose to approximately 8%. The average HbA\textsubscript{1c} in the standard treatment group was approximately 1% higher. The risk of severe hypoglycemia was smaller the order of 1% to 5% per year in the insulin-treated patient group and weight gain was modest; both were higher in patients randomly assigned to insulin and lower in those receiving metformin. \textsuperscript{43} Associated with this improvement in glycemic control, there was a reduction in the risk of microvascular complications (retinopathy, nephropathy, and neuropathy) in the intensive group. Although there was a trend toward reduced rates of macrovascular events in the more intensively treated group, it did not reach statistical significance. \textsuperscript{43}

Similar reductions in microvascular events were observed in another trial of entirely different design and much smaller size. In the Kumamoto study, Japanese patients of normal weight with type 2 diabetes treated with insulin were randomly assigned to standard treatment or an intensive program of insulin therapy designed to achieve normal glycemia. The control group maintained HbA\textsubscript{1c} values at approximately 9%, whereas the HbA\textsubscript{1c} in the intensive group was reduced to approximately 7% and the separation maintained for 6 years. Again, there was a modest increased risk of hypoglycemia and weight gain, a reduction in microvascular complications, and a non-statistically significant trend toward reduced rates of vascular end points. \textsuperscript{45}

Although no interventional studies have documented a reduced risk of vascular end points associated with an improvement in glycemic control, multiple epidemiologic studies have suggested that there is an association between cardiovascular risk and HbA\textsubscript{1c}, FPG, and the 2-hour level in the OGTT. \textsuperscript{671} \textsuperscript{672} \textsuperscript{673} \textsuperscript{674} \textsuperscript{675} \textsuperscript{676} In the UKPDS epidemiologic analysis, there was a 16% reduction in cardiovascular disease rates per 1% reduction in HbA\textsubscript{1c} without evidence of a threshold or lower limit of benefit all the way into the normal range. \textsuperscript{672}

In Table 29-6, guidelines from the ADA and the American College of Endocrinology (ACE) are presented. The ADA suggests that the goal of treatment in the management of diabetes should be an HbA\textsubscript{1c} value less than 7%. \textsuperscript{672} Although initially developed on an ad hoc basis, this goal is supported by the clinical trial data as this level of glycemia was associated with improved outcomes in patients with type 2 diabetes in the preceding studies. The ACE, on the basis of the fact that in the same outcome studies normal glycemia levels were targeted and achieved in at least some subjects and that epidemiologic analyses suggest no threshold to the benefit of glucose lowering, has recommended an HbA\textsubscript{1c} goal of less than 6.5%. \textsuperscript{675} \textsuperscript{676} Because the average HbA\textsubscript{1c} in the United States is estimated to be in the 7.5% to 9.5% range, the argument about whether the HbA\textsubscript{1c} target should be 6.5% or 7% is of limited practical significance.

However, it should be recognized that there are potential adverse events related to pursuit of more aggressive targetsglycemia, long-term exposure to poorly studied combinations of medications, expense, life disruption caused by greater attention and effort to achieve lower glycemic targets, and the potential that great efforts expended in achieving extremely stringent glycemic goals will result in less attention to other health risks by patient or provider. No cohort of patients of substantial size has ever been reported in which an average HbA\textsubscript{1c} level less than 7% has been achieved over a time frame that exceeds more than a few months. Several adequately powered, randomized controlled clinical trials are under way or being planned to explore the effects of seeking more intensive glycemic targets (HbA\textsubscript{1c} < 6%). Although it is clear that many patients can achieve lower glucose levels with currently available drugs and lifestyle interventions, it remains theoretically possible that the risks would exceed the benefits of seeking glucose targets less than 7%.

With respect to fasting, premeal, or postprandial targets, there is little support for any particular level of glycemic control in the management of type 2 diabetes as no large-scale outcome study has targeted particular levels of glucose with home glucose monitoring. The ADA target of fasting and premeal plasma glucose levels of 90 to 130 mg/dL, is based on an estimate of the range of average glucose values that would be associated with a low risk of hypoglycemia and HbA\textsubscript{1c} less than 7%. \textsuperscript{673} The ACE target of less than 110 mg/dL is an effort to achieve normal levels of glycemia. \textsuperscript{672} However, it should be recognized that consistent fasting and premeal glucose levels less than 110 mg/dL would be expected to be associated with an HbA\textsubscript{1c} of approximately 5.5%. \textsuperscript{673}

The ADA has not set any treatment goals for postprandial glucose levels because there are no published studies in which even safety, much less outcome, is documented for targeting a particular level of postprandial glucose. \textsuperscript{673} However, the ADA statement on postprandial glucose recognizes that there are effective HbA\textsubscript{1c} -lowering agents that primarily target postprandial glucose levels and suggests that monitoring postprandial glucose levels may allow dose adjustment of these agents. \textsuperscript{673} Furthermore, they recognize that there are patients with diabetes who have average fasting glucose levels within targets but whose HbA\textsubscript{1c} is elevated and that monitoring and specifically treating postprandial elevations in these patients may provide improvements in HbA\textsubscript{1c}, perhaps with a lower risk of hypoglycemia and weight gain than further lowering fasting and premeal glucose levels. The ACE recommends targeting a 2-hour postprandial glucose less than 140 mg/dL (7.8 mM) in an effort to achieve near-normal glycemia. \textsuperscript{672} Consistent postprandial glucose values less than 140 mg/dL would be associated with average HbA\textsubscript{1c} levels of approximately 5.5%. \textsuperscript{673}

Lifestyle Intervention

The components of lifestyle intervention include medical nutrition counseling, exercise recommendations, and comprehensive diabetes education with the purpose of changing the paradigm of care in diabetes from provider-focused to patient-focused. Arguably, over the last 5 years, nothing has changed more fundamentally than the emphasis on lifestyle intervention. For decades, physicians and patients have paid lip service to the notion that lifestyle intervention is important. Now we have significant clinical trial evidence that each component of lifestyle intervention, when appropriately administered, can contribute to improved outcomes. Furthermore, since the Balanced Budget Act of 1997 and the passage of complementary legislation in most state governments, lifestyle intervention has been a covered benefit for most people. Although full implementation of these regulations is still in progress, they have dramatically expanded the proportion of the population with diabetes with insurance coverage for these essential services.

Education of Patients

Diabetes is a lifelong disease, and health care providers have almost no control over the extent to which patients adhere to the day-to-day treatment regimen. The appropriate role of the health care provider is to serve as a coach to the patient, who has primary responsibility for the delivery of daily care.

As a result, health care providers must carefully engage patients as partners in the therapeutic process. It is critical for the health care professional to understand the context in which patients are taking care of their disease. Using a prescriptive approach in which patients are told what to do can work in some situations but fails more often than not because of unrecognized barriers to the execution of a particular plan. For long-term success, diabetes self-management education is critical.

As defined by the ADA,259 diabetes self-management education is the process of providing the person with diabetes with the knowledge and skills needed to perform self-care, manage crises, and make lifestyle changes. As a result of this process, the patient must become a knowledgeable and active participant in the management of his or her disease. To achieve this,

</tbody>
</table>

A team of providers is generally required to implement fully the process of diabetes self-management education as the amount of information that needs to be exchanged is large and the range of expertise broad. It is generally not possible to cover the recommended content fully in the context of several or even many brief encounters with a physician in an office setting. Potential providers in a team care approach could include nurses, dietitians, exercise specialists, behavioral therapists, pharmacists, and other medical specialists including diabetologists or endocrinologists, podiatrists, medical subspecialists, obstetrician-gynecologists, psychiatrists, and surgeons. The potential role of the community in which the patient lives and works in the diabetes self-care process is enormous, including family, friends, employers, and health care insurance providers. Each potential member of the team has a role to play in the process, which must be reviewed and assessed frequently (Table 29-8). The primary role of the provider in this process is to provide guidance in goal setting to manage the risk of complications, suggest strategies to achieve goals and techniques to overcome barriers, provide training in skills, and help screen for complications. For this process to be a success, the patient must commit to the principles of self-care, participate fully in the development of a treatment plan, make ongoing decisions regarding self-care from day to day, and communicate honestly and with sufficient frequency with the team.

Fortunately, barriers to providing team care are becoming less daunting. Diabetes education programs are being established at a rapid rate. The American Association of Diabetes Educators (800-TEAM-UP4) and the ADA (800-DIABETEs) can provide information regarding diabetes educators and education programs in your area.

For team care to be most effective, communication, trust, and mutual respect are critical. Unfortunately, in many communities, the full benefit of the consultation and ongoing care with diabetes educators, nurses, dietitians, pharmacists, or others is not achieved because of overly hierarchical approaches to care. Nonphysicians, including patients, ought to provide suggestions regarding medication and lifestyle adjustments and

TABLE 29-7 – Curricular Areas That Should Be Addressed in Diabetes Self-Management Education

| PATHOPHYSIOLOGY OF THE PATIENT’S DIABETES AND ITS RELATIONSHIP TO TREATMENT OPTIONS |
|------|---------------------|
| INCORPORATING APPROPRIATE NUTRITIONAL MANAGEMENT |
| UTILIZING PHYSICAL ACTIVITY INTO LIFESTYLE |
| MONITORING BLOOD GLUCOSE, URINE KETONES (WHEN APPLICABLE), AND USING THE RESULTS TO IMPROVE CONTROL |

A significant clinical trial evidence that each component of lifestyle intervention, when appropriately administered, can contribute to improved outcomes.

Furthermore, since the Balanced Budget Act of 1997 and the passage of complementary legislation in most state governments, lifestyle intervention has been a covered benefit for most people. Although full implementation of these regulations is still in progress, they have dramatically expanded the proportion of the population with diabetes with insurance coverage for these essential services.

To commit to diabetes self-management (as defined above)
help in the process of identifying barriers to effective management such as lack of knowledge, lack of time, and lack of resources and strategies to overcome those barriers.

Perhaps some of the most overlooked contributors to ineffective care in the setting of type 2 diabetes are the relatively common barriers created by psychiatric, neurocognitive function, and adjustment disorders, which are largely responsive to psychosocial therapies.

With respect to self-management education, a technical review documents the effect of medical nutrition therapy and specific advice on diabetes-related outcomes such as HbA1c, weight, and proteinuria. These are summarized in Table 29-9. A comprehensive, individually negotiated nutrition program in which each patient's circumstances, preferences, and cultural background as well as the overall treatment program are considered is most likely to result in optimal outcomes. Because of the complexity of both the medical and nutritional issues for most patients, it is recommended that a registered dietitian, with specific skill and experience in implementing nutrition therapy in diabetes management, work collaboratively with the patient and other health care team members in providing medical nutrition therapy.

Analogously, physicians and other members of the health care team need to understand the major issues in diabetes and nutrition and support the nutritional plan developed collaboratively. Individualized dietary advice can be developed by a physician from a brief diet history obtained by asking: "What do you eat for breakfast? . . . lunch? . . . supper? Do you have snacks between breakfast and lunch? . . . lunch and supper? . . . supper and bedtime? What do you drink during the day?" Ideally, this information should be obtained at each visit, with specific suggestions for change that both patient and provider agree are important and achievable.

Easy issues to address include caloric beverages, which tend to elevate glucose levels dramatically and can generally be replaced quite painlessly by artificially sweetened alternatives. Juices generally are perceived as healthy but can significantly affect glycemic control and total calorie intake. Substituting low-fat products for higher fat alternatives is useful but needs to be done with the recognition that they are generally higher in carbohydrates. "Fat-free" and "sugar-free" foods need to be recognized as food that is not "free." Portion control and recipe modification are excellent dietary techniques, particularly for meals and fried foods.

Adequate spacing between meals is usually good advice for patients with type 2 diabetes because postprandial glucose levels generally peak 2 hours after a meal, when a snack would normally be taken. Eating approximately every 4 hours while awake is the most practical dietary plan for most overweight people. Frequent small meals have been shown to be of benefit when used in a controlled inpatient setting, but in general when overweight patients are encouraged to eat more frequently they often overeat more frequently. At a minimum, avoiding high-calorie snacks is reasonable advice for most people with diabetes. A repeated diet history and additional modest changes negotiated every few weeks to months by all health care providers (doctor, nurse, or dietitian) allow assessment of whether previously agreed to changes were enacted, reinforcement of the importance of dietary efforts, and slow eneishment of patients into more healthful dietary choices.

In general, the critical nutrient for glycemic consistency is carbohydrate. Essentially every molecule of carbohydrate consumed is converted to glucose in the gut and requires the action of insulin to be cleared from the circulation. A dietary term called carbohydrate counting can be used in patients with type 2 diabetes to facilitate consistent carbohydrate intake or to allow insulin dose adjustment in response to changes in carbohydrates consumed. Whereas the beta cell in type 2 diabetes has generally lost its responsiveness to glucose, the second phase of insulin secretion is largely spared in type 2 diabetes and is in part driven by amino acids and fatty acids. Therefore, including some protein and fat in each meal and snack is useful.

Dietary fat is the nutrient most closely associated in epidemiologic studies with the risk of developing type 2 diabetes. Although dietary fats clearly have an impact on glucose and triglycerides but are much less calorically dense and have a higher thermic effect, both of which tend to promote weight loss.

Dietary protein similarly has a minimal impact on glucose levels, although amino acids do promote insulin secretion, which may be advantageous in the setting of type 2 diabetes. Metabolism of protein results in the formation of acids and nitrogenous waste, which may result in bone demineralization and glomerular hyperfiltration. At least 0.8 g of high-quality protein per kilogram is generally recommended; otherwise, restriction of protein intake to 10% to 20% of total calories minimizes potential adverse long-term effects of high protein intake.

The role of vitamins, trace minerals, and nutritional supplements in the treatment of diabetes is poorly understood. There are some who are absolutely convinced of adverse long-term effects of high protein intake.

<td>Although the use of low-glycemic-index foods may reduce postprandial hyperglycemia, there is not sufficient evidence of long-term benefit to recommend use of low-glycemic-index diets as a primary strategy in food or meal planning.</td>
</tr>
<tr>
<td>As with the general public, consumption of dietary fiber is to be encouraged; however, there is no reason to recommend that people with diabetes consume a greater amount of fiber than other Americans.</td>
</tr>
<tr>
<td>Carbohydrate and monounsaturated fat should together provide 60%-70% of energy intake. However, the metabolic profile and need for weight loss should be considered when determining the monounsaturated fat content of the diet.</td>
</tr>
<tr>
<td>Sucrose and sucrose-containing foods should be eaten in the context of a healthy diet.</td>
</tr>
<tr>
<td><strong>Protein</strong></td>
</tr>
<tr>
<td>In persons with controlled type 2 diabetes, ingested protein does not increase plasma glucose concentrations, although protein is just as potent a stimulant of insulin secretion as carbohydrate.</td>
</tr>
</tbody>
</table>
For persons with diabetes, especially those not in optimal glucose control, the protein requirement may be greater than the recommended dietary allowance (RDA) but not greater than usual intake.

The long-term effects of diets high in protein and low in carbohydrate are unknown. Although such diets may produce short-term weight loss and improved glycemia, it has not been established that weight loss is maintained long-term. The long-term effect of such diets on low-density lipoprotein (LDL) cholesterol is also a concern.

Fat

Less than 10% of energy intake should be derived from saturated fats. Some individuals (i.e., persons with LDL cholesterol 100 mg/dL) may benefit from lowering saturated fat intake to less than 7% of energy intake.

To lower LDL cholesterol, energy derived from saturated fat can be reduced if weight loss is desirable or replaced with either carbohydrate or monounsaturated fat if weight loss is not a goal.

Dietary cholesterol intake should be less than 300 mg/day. Some individuals (i.e., persons with LDL cholesterol 100 mg/dL) may benefit from lowering dietary cholesterol to less than 200 mg per day.

Intake of trans-unsaturated fatty acids should be minimized.

Polyunsaturated fat intake should be approximately 10% of energy intake.

Reduced-fat diets, when maintained long-term, contribute to modest loss of weight and improvement in dyslipidemia.

Energy balance and obesity

In insulin-resistant individuals, reduced energy intake and modest weight loss improve insulin resistance and glycemia in the short term.

Structured programs which emphasize lifestyle changes including education, reduced fat (<30% of daily energy) and energy intake, regular physical activity, and regular participant contact can produce long-term weight loss on the order of 5% to 7% of starting weight.

Exercise and behavior modification are most useful as adjuncts to other weight loss strategies. Exercise is helpful in maintenance of weight loss.

Standard weight reduction diets, when used alone, are unlikely to produce long-term weight loss. Structured, intensive lifestyle programs are necessary.

Micronutrients

There is no clear evidence of benefit from vitamin or mineral supplementation in people with diabetes who do not have underlying deficiencies.

Routine supplementation of the diet with antioxidants is not advised because of uncertainties related to long-term efficacy and safety.

Alcohol

If individuals choose to drink alcohol, daily intake should be limited to one drink for adult women and two drinks for adult men. One drink is defined as 12 oz of beer, 5 oz of wine, or 1.5 oz of 80 proof spirits.

To reduce risk of hypoglycemia, alcohol should be consumed with food.

Children and adolescents with diabetes

Individualized food or meal plans and intensive insulin regimens can provide flexibility for children and adolescents with diabetes to accommodate irregular mealtimes and schedules, varying appetite, and varying activity levels.

Nutrient requirements for children and adolescents with type 1 or type 2 diabetes appear to be similar to those of other same-age children and adolescents.

Older adults

Energy requirements for older adults are less than for younger adults.

Physical activity should be encouraged.

In the elderly, undernutrition is more likely than overnutrition and therefore caution should be exercised when prescribing weight loss diets.

Acute complications

Glucose is the preferred treatment for hypoglycemia, although any form of carbohydrate that contains glucose may be used.

Ingestion of 15 to 20 g of glucose is an effective treatment for hypoglycemia but blood glucose may be corrected only temporarily.

Blood glucose should be evaluated in approximately 60 minutes, as additional treatment may be necessary.

During acute illnesses, testing blood glucose and blood or urine for ketones, drinking adequate amounts of fluids, and ingesting carbohydrates are important.

Hypertension

In both normotensive and hypertensive individuals, a reduction in sodium intake lowers blood pressure. The goal should be to reduce sodium intake to 2400 mg (100 mmol) or 6000 mg sodium chloride (salt) per day.

A modest amount of weight loss beneficially affects blood pressure.

Dyslipidemia

For persons with elevated LDL cholesterol, saturated fatty acids and trans-saturated fatty acids should be limited to less than 10% and perhaps to less than 7% of energy.

Energy derived from saturated fat can be reduced if weight loss is desirable or replaced with either carbohydrates or monounsaturated fats if weight loss is not a goal.

For persons with elevated plasma triglycerides, reduced high-density lipoprotein (HDL) cholesterol, and small dense LDL cholesterol (the metabolic syndrome), improved glycemic control, modest weight loss, dietary saturated fat restriction, increased physical activity, and incorporation of monounsaturated fats may be beneficial.

Nephropathy

In individuals with microalbuminuria, reduction of protein to 0.8 to 1.0 g/kg body weight per day and in individuals with overt nephropathy, reduction to 0.8 g/kg body weight per day may slow the progression of nephropathy.

Catabolic illness

The energy needs of most hospitalized patients can be met by providing 2535 kcal/kg body weight.

Protein needs are between 1.0 to 1.5 g/kg body weight; the higher end of the range being for more stressed patients.

Prevention of diabetes

Structured programs which emphasize lifestyle changes including education, reduced fat and energy intake, regular physical activity and regular participant contact can produce long-term weight loss of 5%-7% of starting weight and reduce the risk for developing diabetes.

All individuals, especially family members of persons with type 2 diabetes, should be encouraged to engage in regular physical activity to decrease risk of developing type 2 diabetes.

often counterproductive to engage in scholarly discussion of the nature of the evidence base for their decision. At a minimum, discussion should include the
documented efficacy of more classical lifestyle and pharmacologic intervention and the idea that these efforts should not be left by the wayside when budgetary constraints affect potentially more effective interventions. A multivitamin containing at least 400 μg of folic acid is probably a reasonable nutritional supplement for most patients with type 2 diabetes, and supplementation with folic acid (1 mg), vitamin B12 (400 μg), and pyridoxine (10 mg) has been shown to reduce the rate of restenosis after coronary angioplasty, presumably by reducing homocysteine levels.

Although there are proponents of a wide range of dietary composition, there are few data to support these recommendations from long-term outcome studies of prescribed diets. Mixed meals containing 10% to 20% of calories from protein, no more than 10% of calories from saturated fat, and the remainder largely from monounsaturated fats (seeds, nuts, avocados, olives, olive oil, canola oil) and carbohydrates, particularly whole grains, fruit, vegetables, and low-fat milk, are probably more acceptable. The most readily available. There is evidence to suggest that a diet rich in complex carbohydrates and low in fat and animal protein is a beneficial component of comprehensive lifestyle management in the setting of cardiovascular disease.

Weight loss is a goal of many patients with and without diabetes and certainly is associated with improvements in glycemic control, insulin resistance, circulating lipids, and blood pressure. Numerous clinical studies demonstrate that intensive lifestyle programs involving frequent contact with patients, individualized counseling, and education aimed at reducing dietary fat and calorie intake coupled with regular physical activity and efforts to understand and control behaviors that result in overeating can produce modest weight loss that can be largely maintained with sustained effort.

Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose (SMBG) has not been demonstrated in clinical trials to change outcomes in type 2 diabetes when evaluated in isolation. However, multiple diabetes management programs have been demonstrated to help reduce complications. In all of these, SMBG is an integral part of the process, suggesting that SMBG is at least a component of effective therapy. The frequency and type of monitoring in diabetes therapy should be determined in consultation with the patient, taking into account the nature of the diabetes, the overall treatment plan and goals, and the patient's abilities. SMBG is particularly recommended for all patients with type 2 diabetes taking insulin or sulfonylureas as it allows the identification of minimal or asymptomatic episodes of hypoglycemia. Although severe hypoglycemia is relatively rare in type 2 diabetes, it can have devastating consequences such as trauma or self-injury or change in the perceived ability of a patient to continue to live independently as a result of confusion or loss of consciousness. Also, it is essential to have patients critically assess the nature of any hypoglycemic symptoms that may occur. Many patients are fearful or overconcerned about hypoglycemia and routinely consume extra calories in response to a variety of life's circumstances, such as when they are hungry, nervous, or upset. Monitoring generally document that most symptoms in patients with type 2 diabetes are not related to hypoglycemia and should not be treated with excessive caloric consumption.

Timing of SMBG varies depending on the diabetes type. It is important to advise patients to vary the time of the day at which blood glucose levels are checked. For some patients, the highest blood glucose of the day is the morning glucose, whereas for others the highest is before bed. Particularly in early diabetes, gestational diabetes, and well-controlled diabetes, monitoring 1 to 2 hours after meals allows patients to assess the effect of their lifestyle and pharmacologic efforts in controlling postprandial glucose levels, which are the only glycomic abnormality present. Monitoring and thus targeting therapy at just one time of day can leave the patient with a less than ideal overall response to therapy.

When glucose control is poor, having patients concentrate on premeal glucose levels is adequate. Once the premeal glucose levels reach the middle to low 100s, many advocate that patients switch to checking 1- to 2-hour postprandial glucose levels because it amplifies the observed effect of diet on glycemic control and enables patients to see that moderate changes in meal plan, activity, and medications have a significant impact on glycemic control. Even after substantial inappropiate changes in food intake, activity, or timing or dose of medication, blood sugar values often return to near-normal levels overnight or by the time of the next meal.

The frequency of glucose monitoring needs to be matched to individual patients' needs and treatment. Many clinicians ask patients to monitor at least once a day, varying among before breakfast, lunch, supper, bedtime, and mid-sleep as well as with hypoglycemic symptoms. Others ask intensively insulin-treated patients to monitor with intensity similar to that described for patients with type 1 diabetes (four times per day before meals with weekly checks at least once after breakfast, lunch, supper, and at midsleep as well as with symptoms). Some ask for sets of glyemic readings more infrequently (e.g., fasting and 1 hour after the biggest meal). In the subset of patients who achieve stable blood glucose levels without significant hypoglycemia, it is generally appropriate to decrease the frequency of SMBG to a few times a week. It is critical that SMBG be performed enough that both patient and provider have a good understanding of both the adequacy of the treatment regimen and the stability of glycemic control.

It has been widely assumed that the benefits of SMBG stem from the effect of putting patients in a situation in which they can be in control of their own therapy. If patients are aware of the glycemic targets associated with the outcomes they seek to achieve, SMBG enables them to evaluate critically their response to therapy and assure themselves that they are reaching their goals. It is generally useful for patients to keep a daily diary of their SMBG results, not only so that they can assess their own progress but also so that their health care providers can be informed as well. Fortunately, many patients now have the technological ability to perform daily or more frequent SMBG, record the results as instructed, and discuss them with their health care team only at quarterly or semiannual visits despite the fact that their control is inadequate. Unless SMBG results are entirely within agreed to targets, they should be communicated and reviewed at least monthly with a member of the health care team by telephone, fax, mail, or e-mail or at an interim visit to trigger changes in therapy as the need arises. Unfortunately, such services are generally unremunerated and may
become an unsustainable burden on health care teams.

Finally, one of the most difficult areas in which to keep current is the area of available equipment and supplies, particularly for glucose monitoring. A useful resource in this regard is the annual Resource Guide, which comes out as the January issue of Diabetes Forecast, a magazine for lay people with diabetes and their families. It is available online at the ADA Web site (www.diabetes.org) by clicking on “Community and Resources” on the left and then “Diabetes Forecast” below and finally on “Back Issues” to find the most recent January issue.
Pharmacotherapy of Type 2 Diabetes

The revolution in the treatment of type 2 diabetes since 1995 in the United States has been driven by the release of multiple new classes of drugs that independently address different pathophysiological mechanisms that contribute to the development of diabetes. The available oral antidiabetic agents can be divided by mechanism of action into insulin sensitizers with primary action in the liver, insulin sensitizers with primary action in peripheral tissues, insulin secretagogues, and agents that slow the absorption of carbohydrates. Insulin therapy in the setting of type 2 diabetes effectively is a supplement to endogenous insulin secretion. The relative benefits of lifestyle intervention and the six classes of drugs available for the management of type 2 diabetes are found in Table 29-10 (Table Not Available). This area has been the subject of extensive reviews. Because of limitations of space, in the following discussion the principles outlined in these reviews are summarized and limited additional references provided.

Insulin Sensitizers with Predominant Action in the Liver: Biguanides

Metformin is the only biguanide available in the United States. Phenformin was removed from the United States market in the 1970s because of deaths associated with lactic acidosis. Phenformin and buformin remain available in some countries around the world. Although metformin has been available in Europe for almost 40 years, it has been marketed in the United States only since 1995. The precise mechanism of action of metformin is unknown. Its major activity is to reduce hepatic insulin resistance and thereby gluconeogenesis and glucose production. It has more inconsistently demonstrated effects to improve insulin sensitivity in peripheral tissues. Because of its limited duration of action, it is generally taken at least twice daily, although a sustained-release formulation is now available.

As biguanides do not increase insulin levels, they are not associated with a significant risk of hypoglycemia. The most common adverse events are gastrointestinal nausea, diarrhea, crampy abdominal pain, and dysgeusia. About one third of patients have some gastrointestinal distress, particularly early in their course of treatment. This distress can be minimized by starting with a low dose once daily with meals and titrating upward slowly (over weeks) to effective doses. Sustained-release metformin is associated with less frequent and severe upper gastrointestinal symptoms, the more common of the adverse effects of metformin, but can increase the frequency of diarrhea, a much less common adverse effect overall. The vast majority of patients note no adverse effects with metformin therapy, and at least 90% tolerate it adequately with long-term use. Perhaps as a result of clinical or subclinical gastrointestinal effects, metformin is associated with less weight gain than other antidiabetic agents and in some studies modest mean weight loss.

The other side effect of concern with metformin is lactic acidosis, which is quite rare and occurs almost exclusively in patients who are at high risk of developing lactic acidosis apart from metformin therapy. As a result, it is recommended that high-risk patients avoid use of metformin. The package insert suggests that metformin is absolutely contraindicated in patients with renal insufficiency as the drug is cleared renally; it states that the drug should not be used in males with a serum creatinine greater than or equal to 1.5 mg/dL and in females at 1.4 mg/dL.

Obviously, there is a complex relationship between serum creatinine and renal function. Thus, reasonable practice would generally involve avoiding the use of metformin entirely in patients with an estimated creatinine clearance from the Cockcroft-Gault equation of less than 50 mL/min and avoiding greater than half-maximal doses of metformin in patients with an estimated creatinine clearance between 50 and 70 mL/min. As a reminder, according to the Cockcroft-Gault equation, creatinine clearance equals [(140 age)(weight in kg)]/(72 × serum creatinine in mg/dL)

TABLE 29-10 -- Comparisons of Therapies for Type 2 Diabetes

(Not Available)

in males, and this is multiplied by 0.85 in females. Therefore, a 30-year-old, 250-pound construction worker with a creatinine of 1.6 has a normal creatinine clearance of 103 mL/min, whereas an 80-year-old, 110-pound woman with a creatinine of 0.8 has a low creatinine clearance of 44 mL/min. Metformin is also contraindicated in patients with congestive heart failure requiring treatment, in those with hepatic insufficiency, and in the setting of alcohol abuse. Caution is required in elderly people, patients with acute illness or poorly controlled chronic illness, and in the setting of simultaneous treatment with nephrotoxic drugs (e.g., contrast dye).

The glucose-lowering efficacy and the prevalence of adverse gastrointestinal effects increase proportionately in the dose range 500 to 2000 mg/day. The maximal dose of 2550 mg does not generally provide additional benefit beyond that seen at 2000 mg daily. A new formulation of metformin combined with glyburide has been developed to maximize glucose-lowering effectiveness through the synergy of using an insulin secretagogue and thereby minimize gastrointestinal effects and is available in tablets with metformin/glyburide ratios of 250/1.25, 500/2.5, and 500/5. The formulations containing proportionally lower glyburide doses (250/1.25 and 500/2.5) seem to perform similarly to the higher dose combinations and thus are preferred.

Arguably, metformin has the best record of accomplishment among oral antidiabetic agents in outcome studies. In the UKPDS, among overweight subjects, those randomly assigned to metformin not only had improvements in microvascular complications similar to those of subjects randomly assigned to insulin and sulfonylurea but also demonstrated a reduction in diabetes-related deaths and myocardial infarction. The validity of this observation has been challenged because of unusual responses in a subsequent subrandomization. The beneficial effect of metformin on macrovascular complications through mechanisms independent of glycemic control is certainly plausible and supported by such observations as metformin-associated modest reductions in LDL, triglycerides, blood pressure, and procoagulant factors.

Insulin Sensitizers with Predominant Action in Peripheral Insulin-Sensitive Tissues: Thiazolidinediones

The thiazolidinedione class of drugs, often termed TZDs or glitazones, has engendered great enthusiasm and controversy since the first agent, troglitazone, was approved in 1997. Troglitazone was withdrawn from the United States market in the year 2000, largely because the remaining agents (pioglitazone and rosiglitazone) were thought to be safer than troglitazone, with which rare fatal hepatotoxicity was associated. These agents are believed to work through binding and modulation of the activity of a family of nuclear transcription factors termed peroxisome proliferator-activated receptors (PPARs). They are associated with slow improvement in glycemic control over weeks to months in parallel with an improvement in insulin sensitivity and reduction of FFA levels.

Each of these agents varies in important ways with regard to potency, pharmacokinetics, metabolism, binding characteristics, and demonstrated lipid effects. At the same time, all are effective glucose-lowering agents that are remarkably well tolerated with weight gain and fluid retention (and associated edema formation and hemodilution) as the only significant adverse effects. There is no substantial evidence that these newer agents are associated with hepatotoxicity, but this record of safety has been established in the setting of careful liver function test monitoring. Therefore, it is important to continue to recommended that the glitazones not be used in patients with active hepatocellular disease or in patients with unexplained serum alanine aminotransferase (ALT) levels greater than 2.5 times the upper limit of normal as well as to recommend serum ALT monitoring before initiating therapy, every 2 months for the first year and intermittently thereafter.

Whether there are clinically important differences between the two currently available agents is hotly debated, but definitive answers await adequately powered head-to-head studies that are under way. The promise of the glitazone class to reverse or prevent the negative cardiovascular associations of insulin resistance in parallel with its demonstrated effect of improving insulin sensitivity is exciting but unproven and under formal study in a series of randomized prospective clinical trials.
Almost all of the available data with regard to vascular effects of this class come from studies with troglitazone and include the following tantalizing clinical associations: reduced carotid intimal medial thickness, normalization of vascular endothelial function, improvements in dyslipidemia, lower blood pressure, and improved fibroin and coagulation parameters. A second attribute of the glitazones that has generated great enthusiasm is an effect to improve insulin secretory dynamics in subjects with diabetes and IGT. These observations provide hope that glitazone therapy may be useful in preventing diabetes or in halting the progression of established diabetes, thereby reducing the need for additional drug therapy over time. It is critical to recognize that the proven effects of pioglitazone and rosiglitazone to date are limited to improvements in glycemic control and changes in lipid parameters.

The adverse effect that has engendered the greatest concern regarding this class of drugs is weight gain. Careful study indicates that the weight gain is a result of subcutaneous and not visceral fat accumulation and that there is, in fact, a reduction in visceral fat, hepatic fat, and intramyocellular fat. Thus, the weight gain observed with glitazones, while having obvious negative consequences from the cosmetic standpoint, is perhaps less likely to cause significant adverse cardiovascular effects. Both weight gain and fluid retention are more common and severe in patients with the greatest glycemic responses, making expectant management of these adverse effects mandatory. All patients prescribed glitazones should be counseled to redouble lifestyle efforts to minimize weight gain.

With regard to edema, with appropriate caution almost no one should need to withdraw from therapy as a result of fluid retention. The patients most likely to experience edema are those treated with insulin and those with preexisting edema. Thus, women, overweight patients, and those with diastolic dysfunction or renal insufficiency are at greatest risk. It is prudent to teach patients with preexisting edema how to assess pitting pretibial edema at home and suggest that they make a habit of checking nightly. If they note a pattern of increasing edema at home, patients can be instructed to restrict sodium intake, to start a diuretic, or to increase their diuretic by some specified quantity on their own as needed.

In the edematous patient, people treated with insulin, and those at higher risk of fluid retention, it is prudent to initiate therapy with the lowest marketed dose of glitazone. When patients return for their 2-month ALT check, if the glycemic response has been inadequate and significant edema has not developed, increasing the dose of glitazone further with continued expectant management of edema can be accomplished. Most patients with mild edema respond to a low-dose thiazide diuretic (e.g., hydrochlorothiazide [HCTZ] at 25 mg). In patients with more extensive edema, a combination of low-dose thiazide diuretic with moderate-dose loop diuretic is sometimes required. Anecdotal reports suggest that avoidance of nonsteroidal anti-inflammatory agents and dihydropyridine calcium channel blockers can reduce the frequency of edema as an adverse event. It should be noted that fluid retention to the point of congestive heart failure and anasarca has been reported and that in some patients edema is refractory to diuretic therapy.

### Insulin Secretagogues

Currently available insulin secretagogues all bind to the sulfonylurea receptor (SUR1), a subunit of the ATP-sensitive potassium channel (K\(_{ATP}\)) on plasma membrane of pancreatic beta cells. The SUR1 subunit regulates the activity of the channel, and also binds ATP and ADP, effectively functioning as a glucose sensor and trigger for insulin secretion. Sulfonylurea binding as well as increases in intracellular ATP and decreases in ADP as a result of fuel metabolism lead to closing of the channel. The membrane depolarization that ensues causes the opening of voltage-dependent L-type calcium channels. Subsequent calcium influx results in an increase in intracellular calcium, which leads to insulin secretion. Differences in pharmacokinetic and binding properties of the various insulin secretagogues result in the specific responses that each agent produces. The major difference between them seems to be related to duration of action and to fairly subtle variations in their hypoglycemic potential.

### Sulfonylureas

The sulfonylureas have been available since the 1950s. They have a relatively slow onset of action and variable duration of action. There are numerous choices available (Table 29-11), which can be divided into first- and second-generation agents. In general, the second-generation agents are more potent and as a result have fewer adverse effects and drug-drug interactions. Glipizide-GITS (gastrointestinal therapeutic system) and gliclazide are preferred agents as they can be given as a once-daily dose (without additional effect with twice-daily dosing) in the vast majority of patients and involve a relatively low risk of hypoglycemia and weight gain. Glimepiride and glipizide-GR are the most commonly prescribed insulin secretagogues despite the fact that essentially all marketed oral secretagogues have been shown to have a significantly lower hypoglycemic potential.

An unusual characteristic of sulfonylureas is that the maximum marketed dose is generally two to four times higher than the maximally effective dose. There has been concern over the years that sulfonylureas may result in increased arrhythmic cardiovascular events in patients with diabetes as a result of their activity on vascular and cardiac SUR2 receptors with an effect of blunting ischemic preconditioning, a protective autoregulatory mechanism in the heart. There is some evidence to suggest that this may be less likely to occur with glipizide than with gliburide, but it is also a rationale to avoid high-dose sulfonylurea therapy. Sulfonylureas are arguably the most cost-effective glucose-lowering agents and therefore are clearly worthy of their widespread use. In general, limiting the dose to one-fourth maximal, unless higher doses are clearly demonstrated to provide significant benefits in glycemic control, minimizes both costs and adverse events. Small doses of sulfonylurea (e.g., 0.5 to 1 mg of gliburide or 2.5 mg of glipizide-GITS) are remarkably effective, particularly in patients on concomitant insulin-sensitizing therapy, and are almost uniformly well tolerated.

### Repaglinide

Repaglinide is a member of the meglitinide family of insulin secretagogues, distinct from the sulfonylureas. It has a short half-life and a distinct SUR1 binding site. As a result of more rapid absorption, it produces a generally faster and briefer stimulus to insulin secretion. As a result, it is generally taken with each meal and provides better postprandial control and generally less hypoglycemia and weight gain than glyburide. Repaglinide does seem to have a longer residence time on the sulfonylurea receptor and a prolonged effect on fasting glucose despite the fact that its pharmacologic half-life is quite short. Repaglinide is available in 0.5, 1, and 2 mg tablets. The maximal dose is 4 mg with each meal. As is the case with the sulfonylureas, there is a modest glucose-lowering advantage of high doses versus moderate doses of repaglinide.

### Nateglinide

Nateglinide is a derivative of phenylalanine, structurally distinct from both sulfonylureas and the meglitinides. It has a quicker onset and shorter duration of action than repaglinide. Its interaction with SUR1 is fleeting. As a result, its effect in lowering postprandial glucose is quite specific and it has little effect in lowering fasting glucose. This provides advantages (less hypoglycemia) and disadvantages (less overall glucose-lowering effectiveness). Therefore, nateglinide is most appropriately used when fasting glucose levels are modestly elevated in the setting of early diabetes or in combination with insulin sensitizers or long-acting evening insulin. Nateglinide is available as 120-mg tablets and is taken with each meal. A 60-mg tablet is available but is not generally used except in patients with minimal hyperglycemia.

The rationale for stimulating insulin secretion in a way that minimizes fasting hyperinsulinemia and maximizes postprandial control is compelling. Furthermore, these newer agents demonstrate little binding to the vascular smooth muscle and cardiac SUR2 receptors. However, the use in the United States of these newer glinide agents has been modest, in part because of the need for multiple daily doses, greater expense than with sulfonylureas, and lack of head-to-head comparative studies that demonstrate superiority over newer sulfonylureas already perceived as having low potential for producing hypoglycemia and weight gain.

### Glitazones

- **Carbohydrate Absorption Inhibitors:** -Glucosidase Inhibitors

- Glucosidase inhibitors (AGIs) work to inhibit the terminal step of carbohydrate digestion at the brush border of the intestinal epithelium. As a result, carbohydrate absorption is shifted more distally in the intestine and is therefore delayed, allowing the sluggish insulin secretory dynamics characteristic of type 2 diabetes to catch up with carbohydrate absorption. There are two currently available agents, acarbose and miglitol. Their use in the United States has been limited by a number of factors, including the need to administer the medication at the beginning of each meal, flatulence as a common side effect, and only modest reductions in blood glucose. These factors should be balanced against the AGI’s ability to lower postprandial glucose, thereby improving glycemia without increasing weight or hypoglycemic risk. Even though they may potentially lower glucose in everyone, the extent of the lowering is generally modest, calling into question their utility in the
of insulin in type 2 diabetes is designed to supplement endogenous production of insulin both in the basal state to modulate hepatic glucose production and in the postprandial state, in which a surge in insulin release normally facilitates glucose clearance into muscle and fat for storage to allow intraprandial metabolism. Currently, the vast majority of insulin used worldwide is of recombinant human origin. The available formulations largely differ in their pharmacokinetics as reviewed in Table 29-12.

Insulin lispro and insulin aspart are rapid-acting insulin analogues that have an onset of action in 5 to 15 minutes, peak activity in approximately 1 hour, and a duration of activity of approximately 4 hours. Regular insulin is approximately half as fast as the rapid-acting analogue with onset in 30 minutes, a peak at 2 to 4 hours, and a duration of action of 6 to 8 or more hours. Intermediate-acting insulin analogues have been shown to provide a modest reduction in hypoglycemia. Insulin analogues have been shown to provide a modest reduction in hypoglycemia. Insulin analogues are rare, as are chronic skin reactions like lipodystrophy and lipoatrophy. It should be noted that the absolute risk of severe hypoglycemia in patients with type 2 diabetes is relatively small, approximately one third to one tenth as high as in similarly treated patients with type 1 diabetes. This risk can be further minimized with appropriate education of patients and expectant home glucose monitoring at times when unrecognized hypoglycemia is most likely to occur.

Long-acting insulin analogue with distinctive properties. It provides a flat, peakless profile of activity with a duration of action of more than 24 hours in most patients. Premixed insulin formulations provide greater convenience and accuracy of mixing than those mixed by patients. Premixed formulations available in the United States are 70/30 and 50/50 mixtures of NPH and regular insulin, a 75/25 mixture of lispro insulin in its NPH-like formulation with insulin lispro, and a 70/30 mixture of insulin aspart with its NPH-like congener. Premixed insulin provides a profile of activity as expected from the addition of the activities of its components.

Adverse events associated with insulin are well known and include weight gain and hypoglycemia. It is interesting that both fast-acting and long-acting insulin analogues have been shown to provide a modest reduction in hypoglycemia. Insulin allergies are rare, as are chronic skin reactions like lipodystrophy and lipoatrophy. It should be noted that the absolute risk of severe hypoglycemia in patients with type 2 diabetes is relatively small, approximately one third to one tenth as high as in similarly treated patients with type 1 diabetes. This risk can be further minimized with appropriate education of patients and expectant home glucose monitoring at times when unrecognized hypoglycemia is most likely to occur.

A significant challenge in clinical decision making in diabetes is that the increased availability of therapeutic options for antidiabetic therapy is ahead of adequate prospective outcome studies. Currently available clinical trial data have not identified the preferred agents in type 2 diabetes, either as initial therapy or in subsequent care. Each class of drugs and even agents within each class have advantages and limitations, and individual issues may significantly affect the appropriate choice of therapy in particular patients. Table 29-10 (Table Not Available) highlights some of the relative advantages and disadvantages of various agents and classes.

A general approach in the absence of any patient-specific factors is suggested in the algorithm presented in Figure 29-20. A growing body of evidence indicates that the use of metformin as initial therapy in combination with diet and exercise can provide impressive lowering of glucose with essentially no risk of hypoglycemia. Because this agent is available as a generic preparation, relative cost is low, and if the response is judged to be inadequate a thiazolidinedione, sulfonylurea, or glinide can be added. It has been proposed that the use of metformin alone or in combination with a thiazolidinedione may lead to a greater reduction in cardiovascular risk than similarly effective (with respect to glycaemia) approaches that increase insulin levels. At present, the data are not definitive on this point.

Patients with higher levels of glucose (generally FPG > 200 mg/dL) almost always require agents to increase insulin levels. Because insulin, sulfonylureas, and glinides provide much faster improvements in overall control that metformin, glitazones, or AGIs, they are preferred in patients with higher levels of glucose either as monotherapy or as part of initial combined therapy. Starting a patient with a low dose of a glimepiride, glipizide-GITS, or insulin combined with either metformin, glitazone, or AGI is a reasonable initial approach to the poorly controlled condition.

In patients who have reasonable control of fasting and preprandial plasma glucose levels (more than 50% of values less than 130 mg/dL) whose overall control as assessed by HbA1c, is still higher than desired, monitoring may be either inaccurate or ineffective or postprandial plasma glucose (PPG) levels may be elevated. As it can be more difficult to have patients monitor in the postprandial state, it is important to remember that without specific therapy, almost all patients with type 2 diabetes have elevated PPG. Thus, in such patients, targeting presumed PPG elevations with the use of AGIs, glinides, or rapid-acting insulin analogues can theoretically lower average glucose with a lower risk of weight gain and hypoglycemia than with sulfonylureas or long-acting insulin.

The most critical issue in long-term glycemic management is that of continuously reassessing with patients the adequacy of their control, examining glucose monitoring logs and HbA1c values, and refining treatment regimens to achieve optimal control with the lowest dose of the least number of medications. Most patients in specialty care require two or more drugs to achieve recommended targets. Many patients require three or more (particularly if you consider long-acting and short-acting insulin analogues) and many of the three-drug combinations have been evaluated in modest-sized studies and have been shown to be safe and effective. Generally, it is preferred to add agents if there was an improvement in control with the first agent selected and to continue to add agents as needed to achieve goals. Subsequent back-titration to optimize treatment is often possible when glycemic goals are achieved. The selection of initial therapy should be based on mutually (patient and provider) recognized priorities. Increasingly, practitioners are using submaximal doses of agents in combination to increase the ratio of efficacy to adverse effects and in recognition of the potential synergy of sensitizers and secretagogues as well as the value of treatment of postprandial glucose and fasting glucose in combination therapy.

When adding insulin in the management of inadequately controlled type 2 diabetes, some practitioners prefer to stop the oral antidiabetic agents and switch to insulin. Most generally continue the oral agents and add an evening dose of insulin. Classically, bedtime NPH insulin and more lately bedtime insulin glargine have been preferred for initiating insulin therapy. In more overweight patients (>120% of ideal body weight), the use of mixed insulin (or premixed insulin) at supper can help clear glucose elevations after the evening meal, generally the largest meal of the day. This works quite well in most patients, although some experience nocturnal hypoglycemia, which is less common with mixtures employing rapid-acting insulin analogues. There are data suggesting that glargine given at bedtime can similarly provide for lower morning glucose values with less nocturnal hypoglycemia than NPH insulin, particularly in more overweight patients. Many patients eventually require more complex regimens—twice-daily injections, split-mix insulin, multiple injection regimens, and rarely insulin pump therapy. It should be noted that a minority of patients with type 2 diabetes have a better response to insulin administered in the morning than in the evening.

It is important that both patient and health care provider agree on how to reach the goals of therapy. Therefore, biases and concerns of the patient should be addressed when trying to determine which agent should be prescribed. These biases can be elucidated in interviews with patients through discussions of various strategies.

**Strategies**

**Minimal Cost Strategy**

For a large proportion of patients, particularly those who are elderly, drug costs are an overwhelming issue. Diet and exercise can be extremely effective and almost free. The least expensive drugs for the treatment of diabetes are the sulfonylureas; metformin has become available in generic formulations. Thus, a minimum cost strategy could start with a sulfonylurea and progress to the addition of generic metformin or bedtime or presupper insulin and finally two or more insulin injections per day if necessary. In the Veterans Administration Cooperative Study, excellent control was achieved in the context of a comprehensive program of diabetes education using a combination of daytime sulfonylurea and evening insulin. Although insulin is relatively inexpensive, in high doses (1 U/kg or more) the costs begin to rise, conversely insulin for adding metformin or a thiazolidinedione. It should be noted that most pharmaceutical companies have programs to provide no-cost or low-cost medication to the poor. Many of these are listed with links at www.needymeds.com. Furthermore, for increasing numbers of patients, the major driving force in their drug expenses is the number of prescriptions as each is associated with a copayment, providing a rationale for using combination agents.

**Minimum Weight Gain Strategy**

Weight gain associated with the treatment of diabetes is of concern to most clinicians and is often an overriding issue with patients. A strategy to minimize weight gain would emphasize diet and exercise and would almost certainly employ metformin or an AGI as initial therapy with the addition of the other agent if one was inadequate. As sulfonylureas and repaglinide seem to have a modest weight-sparing effect in combination therapy with insulin, one or the other could be added before insulin administration in such a strategy. As discussed earlier, the weight gain associated with thiazolidinediones, although certainly a cosmetic issue, may not be associated with increased cardiovascular risk.

**Minimal Injection Strategy**

Too many patients are determined to avoid insulin injections at any cost. The minimal injection strategy involves sulfonylureas, metformin, AGIs, and thiazolidinediones, which can be added in any order. Insulin, probably as a bedtime or presupper dose to minimize the inconvenience, would be added only if absolutely necessary. The strategy of using thiazolidinediones early in the course of diabetes in the hope that this may reduce the rate of progressive beta cell dysfunction remains unproved. It is important to try to dispel notions that insulin therapy is difficult, ominous, or fraught with peril by highlighting its efficacy and the great strides that have been made in insulin formulations and delivery devices. Most patients require insulin at some point in their lifetime.
Minimal Insulin Resistance Strategy

The possible atherogenic effects of insulin have been widely touted in the lay press and by marketing programs within the pharmaceutical industry. The relationship between circulating insulin levels and cardiovascular risk in nondiabetic populations is incontrovertible but probably related to the presence of insulin resistance rather than the insulin concentrations per se. Furthermore, in essentially all studies of intensive management with insulin, improved outcomes were observed with insulin treatment. There are no clinical data to suggest that exogenous insulin is associated with adverse side effects or long-term complications beyond its hypoglycemic effects and the associated weight gain. In any case, this strategy is analogous to the minimal injection strategy except that the order of introduction of agents is perhaps important. The thiazolidinediones have the greatest efficacy in reducing insulin resistance, metformin is second, and AGIs are third, with nateglinide associated with more specific stimulation of insulin levels after meals than the other insulin secretagogues, which all increase peripheral insulin levels less than injected insulin.

Minimal Effort Strategy

Many patients are capable of making only a minimal effort with regard to their diabetes. Questioning patients about their pill-taking history and their realistic ability to comply with a prescribed frequency of therapy is important. Taking a once-a-day sulfonylurea or thiazolidinedione requires the least effort by the patient. Taking bedtime insulin is actually relatively well accepted by patients to whom this consideration is important. Developing strategies to improve adherence and increase motivation is certainly a long-term goal in this population.

Hypoglycemia Avoidance Strategy

This is another important consideration for many patients. The AGIs have been reported in small studies to reduce "reactive" hypoglycemia. Other oral agents could be added in any order with the exception that insulin secretagogues would be added last, their dose minimized, and glyburide avoided. Nateglinide in particular among the secretagogues is associated with an exceptionally low risk of significant hypoglycemia. The insulin analogues are associated with a lower risk of hypoglycemia than human insulin.

Postprandial Targeting Strategy

Achieving postprandial glucose targets is generally associated with better control than just meeting premeal targets. On the basis of epidemiologic studies, it has been suggested that PPG is more highly correlated with cardiovascular disease risk than fasting glucose levels. Correction for confounding variables such as components of the multiple metabolic syndrome has not been performed, however. Furthermore, there are no outcome studies that have demonstrated the superiority of these approaches in the setting of type 2 diabetes. Control of postprandial glycemia can be achieved only with specific lifestyle efforts and pharmacologic agents, which target postprandial glucose. Postprandial glucose monitoring is helpful in this regard as it reinforces the goals and is the most effective measure to assess the effectiveness of treatment. Techniques that can improve postprandial control include lowering the carbohydrate content of meals, adding fiber, substituting monounsaturated fats for carbohydrates, encouraging physical activity after meals, adding AGIs with meals, and using rapidacting insulin analogues. Nateglinide and repaglinide provide a theoretical advantage in this situation compared with other secretagogues, although formal head-to-head studies have not been completed comparing the glinides with gliclazide and glipizide-GITS.
Prevention of Type 2 Diabetes

The possibility that type 2 diabetes can be prevented in high-risk individuals has been formally tested in a series of large-scale clinical trials. The Da Qing study randomly assigned clinics in an industrial city in China to a dietary intervention, exercise intervention, combined diet and exercise, or no intervention at all. Among the clinics, 577 subjects with IGT were studied. In this study, the interventions were quite modest and conducted largely in group settings. All three interventions led to reductions in the risk of conversion to diabetes of 31% to 46% compared with the control groups.\[^{691}\]

In a Finnish study, a similar number of middle-aged obese subjects with IGT were randomly assigned to a control group that received minimal lifestyle advice or to intensive, individualized instruction on food intake, increased physical activity, and weight reduction. The intensive lifestyle therapy group demonstrated a 58% relative risk reduction compared with the control group in the incidence of diabetes.\[^{692}\]

In the United States, the Diabetes Prevention Program enrolled over 3000 middle-aged, overweight subjects with IGT including substantial representation from high-risk minority groups. The intensive lifestyle group in this study also demonstrated a 58% relative risk reduction in the progression to diabetes.\[^{690}\]

In the Diabetes Prevention Program, there was another arm of the study that evaluated the ability of metformin at 500 mg twice a day to prevent the development of diabetes. It was moderately successful, with a 31% relative risk reduction in the progression of diabetes, although the benefit seemed to be greater in younger, more overweight, and more hyperglycemic subjects. In other studies not yet fully published, other oral antidiabetic agents (troglitazone in the Troglitazone in the Prevention of Diabetes (TRIPOD) study\[^{690A}\] and acarbose in the STOP-NIDDM study\[^{690B}\]) have been reported to reduce the risk of developing diabetes. Patients and families as well as health care professionals are excited about the possibilities of preventing the disease.

The success of the lifestyle interventions is impressive, demonstrating conclusively that with a variety of techniques it is possible for patients to achieve physiologically relevant changes in body weight. Medications overall had less positive impact than lifestyle intervention, although troglitazone did perform remarkably well in diabetes prevention. The questions that arise from these results are how to screen for people at risk and what intervention should be initiated in those with an interest in prevention.

It seems reasonable to screen on the basis of current recommendations as outlined earlier primarily for case finding but also recognizing that patients with abnormal glucose values (fasting greater than 110 mg/dL or IGT with an OGTT) would be ideal candidates for preventive strategies. Certainly, high-risk individuals should be counseled on nutritional approaches to achieve weight loss, instructed to increase physical activity, and observed prospectively to determine whether progression of hyperglycemia has occurred. Treatment for other cardiovascular risk factors should also be considered if they are present. In the absence of outcome studies, it is difficult to recommend drug therapy to prevent diabetes because significant complications are unlikely to develop in the short window of time during which glucose levels increase from a fasting glucose of 110 to 126 mg/dL. An extension phase of the Diabetes Prevention Program that is under way should provide evidence concerning whether prevention or delay in the development of diabetes will prevent death or disability.
Future Directions

The present-day management of type 2 diabetes is significantly more effective and easier for patients than the situation that prevailed even 10 years ago. A better understanding of the barriers to effective diabetes management and how to overcome them would be of great benefit. The epidemic in diabetes and obesity that is under way coupled with the predicted early death and disability that follow threatens to overwhelm our health care system. Practical, cost-effective public health approaches to stem this tide are desperately needed.

Novel pharmaceutical agents including glucagon receptor antagonists, inhibitors of gluconeogenic and glycogenolytic pathways, activators of the insulin signaling pathways, modifiers of lipid metabolism, and antiobesity agents are areas of early pharmaceutical development.

There is tremendous interest in developing novel PPAR modulators that preserve the glucose-lowering effectiveness of the glitazones, enhance the lipid benefits, and mitigate the effects on fluid retention and weight gain. As these PPAR-active agents are thought to exert their action in the nucleus, there is reason to believe that such a goal is achievable. There are dozens of compounds in early stages of development and several already in phase III trials. The major barrier to success in this arena is the lack of well-validated animal models to predict human responses. Novel methods of insulin delivery similarly have generated a great deal of enthusiasm among patients, particularly techniques to deliver insulin orally or by inhalation. There is considerable controversy in the endocrine community in this regard. On the one hand, it seems unlikely that oral insulin delivery would be efficient enough to treat insulin resistance effectively; on the other hand, any delivery into the portal system could be more effective and perhaps have an improved safety profile because of preferential inhibition of hepatic glucose production.

The area of gut hormones offers promise for advances in treatment of type 2 diabetes. Amylin, the second beta cell hormone, is known to act centrally to suppress postprandial glucagon secretion, slow gastric emptying, and increase satiety. Synthetic amylin is in late-phase trials, and although only modestly effective as a glucose-lowering agent, it does seem to be well tolerated and is associated with weight reduction.

GLP-1 is a gut hormone secreted from intestinal cells that has an overlapping but generally more robust profile of action than amylin with the additional effect of preserving functioning beta cell mass. GLP-1 is rapidly degraded in the circulation, and thus inhibitors of the degrading enzyme (dipeptidylpeptidase IV [DP-IV]) as well as DP-IVresistant analogues are being investigated in clinical trials. Additional studies will determine whether glucagon-like peptides provide the next major class of antidiabetic agents.

In 1984, Sutherland and co-workers transplanted the tail of the pancreas from nondiabetic identical twins to their twin mates with type 1 diabetes. In contrast to the transplantation of organs such as kidneys, in which the transplants are accepted between identical twins, pancreatic islets but not acinar pancreas were rapidly destroyed. The diabetes of the twin transplant recipients was cured for only a matter of weeks. In retrospect, the results of these transplants were predictable, given the autoimmune nature of type 1A diabetes and similar results in animal models of the disorder. Following this clinical study, type 1 diabetes became one of the most intensively studied autoimmune disorders, and the National Institutes of Health has designated type 1A diabetes a Priority One target for the development of a preventive immunologic vaccine. Knowledge of the immunogenetics and immunopathogenesis of type 1A diabetes is beginning to influence clinical care, greatly influences current clinical research, and will, we hope, lead to disease prevention.
DIFFERENTIAL DIAGNOSIS OF TYPE 1 DIABETES

An expert committee of the American Diabetes Association, with its etiologic diagnostic criteria (Table 30-1), has recommended dividing type 1 diabetes into type 1A (immune-mediated) and type 1B (other forms of diabetes with severe insulin deficiency). At the onset of diabetes, distinguishing type 1A diabetes from type 2 diabetes, let alone type 1B diabetes, is not always a simple task. The best current criterion for diagnosis of type 1A diabetes is the presence of anti-islet autoantibodies measured with highly specific (and reasonably sensitive) autoantibody radioassays.

The presence of autoantibodies with assays defined as positive in less than 1 of 100 control subjects (specificity 99%) is reasonably diagnostic of type 1A diabetes. Non-Hispanic white children presenting with diabetes usually have type 1A diabetes, whereas adults older than 40 years usually have type 2 diabetes. More than 90% of such children presenting with diabetes express one of three commonly measured autoantibodies (see later). In contrast, among black or Hispanic American children, almost one half lack any autoantibody. Most of these children appear to have an early age of onset of type 2 diabetes mellitus, and many have attendant risk factors such as obesity and lack human leukocyte antigen (HLA) alleles associated with type 1A diabetes (see later). Imagawa and co-workers described an unusual form of diabetes. The patients had normal hemoglobin A\textsubscript{1c} (HbA\textsubscript{1c}) despite severe hyperglycemia, suggesting that the diabetes had been present for only a short time. Histologic examination of pancreatic sections demonstrated pancreatitis but no insulitis, and anti-islet autoantibodies were not detected. It is likely that this represents one of the first examples of type 1B diabetes although a fulminant type 1A is possible.

Obesity does not protect an individual from the development of type 1A diabetes, although it is usually associated with insulin-resistant forms of diabetes. It is also important to realize that individuals can have both insulin resistance and type 1A diabetes, and such autoantibody-positive individuals with both can present with diabetes with high levels of fasting insulin or C peptide but loss of stimulated insulin secretion. With current assays for anti-islet autoantibodies, a subset of children with type 1A diabetes are negative for the autoantibodies. Some children (relatively uncommon), as they progress to diabetes, lose expression of all autoantibodies by the time of diagnosis. Such type 1A autoantibody-negative children typically have HLA alleles associated with type 1A diabetes, are not insulin resistant, may present with ketoacidosis, and, with time, lose C peptide secretion. The diagnosis is not, however, clear at diabetes onset, and perhaps designations such as anti-islet autoantibody positive and negative are more accurate with current laboratory tests.
ANIMAL MODELS OF TYPE 1A DIABETES

In relation to other autoimmune disorders, type 1A diabetes is unusual in having a series of spontaneous animal models of the disease. These animal models provide clues to potential mechanisms of pathogenesis and allow testing of therapies for disease prevention. Tests of new therapies may not be applicable to humans because many more are efficacious in certain animal models than in humans. It should also be recognized that many of the spontaneous animal models are inbred and thus not diabetic at any locus, whereas all humans have different alleles at tens of thousands of loci. Thus, each animal model may or may not provide insights into one of the forms of human diabetes.

Despite the preceding caveats, the animal models are remarkably similar to humans in a number of key immunologic parameters. The most notable include the importance of the major histocompatibility complex (MHC) for disease and the presence of lymphocytic islet invasion followed by specific destruction of islet beta cells. For reasons that are currently unclear, given specific HLA molecules, humans, rats, and mice have a marked propensity for autoimmunity directed at islet beta cells. This propensity may be related to a specific lack of tolerance to a single islet molecule such as insulin, to specific sensitivity of islet beta cells to immune-mediated destruction, or to factors not currently appreciated. It is likely that understanding this propensity will lead to effective therapies.

Polygenic Spontaneous Animal Models

NOD Mouse

The nonobese diabetic (NOD) mouse is the most intensively studied animal model. As with type 1A diabetes of humans, specific HLA class II and class I (see later) molecules are central for disease pathogenesis. The NOD mouse has mutations that cause absence of the I-E (histocompatibility) molecule (similar to human DR) and an unusual I-A (similar to human DQ). The I-A molecule in the NOD mouse is termed I-A<sup>g7</sup> which designates a specific amino acid sequence. HLA class II molecules (in humans there are three, DP, DQ, and DR) function to bind peptides and present these peptides to the T-cell receptor of CD4 (“helper”) T lymphocytes. The genes were termed immune response genes because common variations in their sequences (allelic variation) determine the peptides to which an individual mouse or person can mount a T-cell response. Thus, a central role for these molecules in immune function and autoimmunity is expected. If the lack of I-E expression is corrected in the NOD mouse with introduction of an I-E transgene, diabetes is prevented. If a different I-A sequence is introduced as a transgene into the NOD mouse, diabetes is also prevented. In addition to these class II molecules determining diabetes susceptibility, more than 15 other genetic loci contribute to disease, each with a relatively small contribution, each neither necessary nor sufficient. Thus, inheritance of diabetes in the NOD mouse is polygenic. One manner in which the NOD mouse differs from humans is that more female than male NOD mice develop diabetes.

NOD mice, like humans, produce anti-insulin autoantibodies before the development of diabetes. Autoantibodies usually appear between 6 and 8 weeks of age, and diabetes usually develops after 16 weeks of age. Studies of islet beta cell mass indicate islet beta cell destruction and beta cell regeneration months before the onset of diabetes, although there is convincing evidence of an acceleration of beta cell destruction at disease onset. T cells and not autoantibodies mediate islet beta cell destruction, with clones of T cells reacting with several antigens able to transfer disease. A large number of T-cell clones reacting with insulin and reacting with unknown antigens have been characterized. There is debate about whether any given autoantigen is primary.

Diabetes can be prevented in the NOD mouse with more than 100 different therapies. Most, but not all, of these therapies target the immune system, and a number of these therapies are now in clinical trials in humans. Consistent with diabetes being mediated by T lymphocytes, immunosuppression or genes that block T-cell function prevent disease. Administration of high doses of nicotinamide delays the development of diabetes in NOD mice. Some of the most interesting therapies utilize autoantigens as “vaccines,” and in particular both glutamic acid decarboxylase (GAD) and insulin, when administered to the mice, prevented diabetes. The insulin molecule does not have to be metabolically active, and a dominant insulin peptide, insulin peptide B:9-23, given as a single subcutaneous injection prevented diabetes in 90% of susceptible NOD mice. It is thought that vaccination prevents diabetes by generating T lymphocytes (e.g., T<sub>n2</sub> type, transforming growth factor producing) that target an islet molecule (e.g., insulin) but that produce protective cytokines (e.g., interleukin-4, interleukin-10, transforming growth factor) when they home to the islets.
Oligogenic Animal Models

BB Rat

The BB (biobreeding) rat was the first intensively studied animal model of type 1A diabetes. The diabetes in this model differs from human diabetes in that diabetes-prone BB rats have an autosomal recessive mutation that produces a severe T-cell lymphopenia.\(^4\) One can induce diabetes in a related strain of rat, termed BB diabetes resistant (BB-DR), by administration of a monoclonal antibody that depletes T lymphocytes. As in humans and the NOD mouse, the disease depends upon specific class II alleles (similar to human HLA-DR and HLA-DQ) of the histocompatibility complex, in particular RT1-U. Of note, diabetes can be induced to develop in a series of rat strains with RT1-U (see later). Additional genes segregate to create diabetes susceptibility, but the number of genes is much less than for NOD mice.\(^4\)\(^5\)\(^6\) Prevention of diabetes in BB rats is more difficult than in NOD mice, which may be related to the severe T-cell lymphopenia. For example, insulin administration to BB rats prevented both diabetes and insulitis, but, in contrast to NOD mice, metabolically active insulin and insulin doses that induce hypoglycemia were usually required for prevention.\(^4\)\(^3\)

Long-Evans Tokushima Lean (LETL) Rat

Like BB rats, this strain has the RT-1U alleles and has an oligogenic inheritance of diabetes.\(^6\)\(^7\)
Induced Models of Type 1A Diabetes

Diabetes or insulitis can be induced in several strains of animals with drugs that induce islet destruction and broadly activate immune responses or with specific islet antigens. The drug streptozotocin is directly toxic to islet beta cells. In high doses, it rapidly induces diabetes. In low doses, a more chronic development of diabetes occurs that is likely to have some immunologic derivation. Surprisingly, administration of copolymer of polyinosinic and polycytidylic acids (poly-IC), a simple polynucleotide that activates interferon production when administered to a number of rat strains with the diabetes-susceptible RT1-U alleles, induced insulitis and diabetes. This suggests that many animals are susceptible to diabetes or insulitis given a strong immunologic stimulus. A ubiquitous heat shock protein has been administered to produce a transient form of diabetes in mice. Peptides of this heat shock protein are in clinical trials as a diabetes vaccine.
HISTOPATHOLOGY OF TYPE 1A DIABETES

As in animal models, type 1A diabetes of humans is characterized by selective destruction of the beta cells within islets. The noninsulin-producing cells of the islets remain in patients with long-standing type 1 diabetes, and these remaining islets lacking insulitis and beta cells are termed pseudoatrophic. A remarkable feature of the pancreas of patients with new-onset diabetes is heterogeneity of islet lesions. Within the same section of pancreas, a normal islet with no infiltrate may coexist with an islet containing beta cells with intense infiltration and a pseudoatrophic islet that has no infiltrate. This spottiness of the pathologic process is reminiscent of the destruction of areas of the skin in patients with vitiligo, in which melanocytes are destroyed in patches. Such heterogeneity of lesions may underlie the chronic development of type 1A diabetes in humans.

Islets of patients with type 1A diabetes overexpress class I HLA antigens, relatively rarely express class II HLA molecules on beta cells, express interferon, and up-regulate Fas molecules on all islet cells. The hypothesis that class II HLA expression contributes directly to beta cell autoimmunity is controversial. There is evidence that such expression in animal models does not activate autoimmunity, and it is questioned whether insulin- and class I positive islet cells are not macrophages that have ingested dead beta cells. Antigen presentation requires costimulatory molecules in addition to class II molecules, and beta cells do not express these costimulatory molecules. The specific manner by which the immune system destroys beta cells is not known, and molecules such as Fas may be important because T cells expressing Fas ligand may induce apoptosis of beta cells. Cytokines and CD8 cytotoxic lymphocytes are also likely to contribute to beta cell destruction.

Searches for viral particles and viral ribonucleic acid (RNA) within islets of patients with new-onset diabetes have been unrewarding but newer technologies and concepts should facilitate additional studies. In contrast to the islets of patients with new-onset diabetes, the pancreas of identical twin donors has been described as normal and the pancreas from patients with long-standing diabetes is composed of pseudoatrophic islets without markers of immune activation. A subset of patients with diabetes of several years’ duration still have insulitis, however.
GENETICS OF TYPE 1A DIABETES

It has long been recognized that diabetes is a heterogeneous group of disorders. It is also becoming apparent that type 1A diabetes is heterogeneous. There are probably many genetic forms of type 1A diabetes, with most forms influenced by HLA class II molecules. This group of disorders is likely to be linked by the presence of immunologic abnormalities that foster loss of tolerance to self-antigens. Individuals with specific HLA class I and class II molecules with immune dysfunction are susceptible to "target" islet autoantigens. It is noteworthy that many of the genes underlying diabetes susceptibility are similar in diverse countries, with specific alleles of those genes differing in their frequency. Several monogenic forms of type 1A diabetes can now be identified. It is not clear whether these genetically characterized forms of diabetes should now be included in the group of "Other Defined Causes of Diabetes." For the great majority of patients with type 1A diabetes, most of the genes causing diabetes susceptibility remain to be identified.

Monogenic Forms of Type 1A Diabetes

Autoimmune Polyclinocrine Syndrome Type I (AIRE Gene)

The autoimmune polyendocrine syndrome type I (APS-I) is rare, with an increased incidence in Finland, Sardinia, and among Iranian Jews, but has a worldwide occurrence. The disorders of the syndrome such as type 1 diabetes, mucocutaneous candidiasis, hypoparathyroidism, Addison's disease, and hepatitis (see Chapter 37 for more detailed discussion) identify a unique syndrome, and patients with this group of disorders almost always have mutations of the AIRE (autoimmune regulator) gene on chromosome 21. This gene apparently encodes a deoxyribonucleic acid (DNA) binding protein. The function of the gene is unknown, but its expression in lymphoid tissue and the clinical syndrome suggests an essential role in maintaining self-tolerance. There is considerable variability in the diseases expressed even for siblings with the same mutation. Some of this variability is likely to be influenced by genetic loci other than the AIRE gene. One example is the observation that although 18% of patients with APS-I develop type 1 diabetes, those with the common diabetes-protective HLA allele DQB1*0602 appear to have some protection from diabetes although not from Addison's disease.

X-Linked Polyendocrinopathy, Immune Dysfunction, and Diarrhea (Scurfy Gene)

The syndrome of X-linked polyendocrinopathy, immune dysfunction, and diarrhea (XPID) is associated with overwhelming neonatal autoimmunity, with most children dying in the first few days of life or as infants. In this syndrome lymphocytes invade multiple organs. It is associated with insulitis and beta cell destruction as well as lymphocytic intestinal inflammation with flattened villi and severe malabsorption. It is inherited as an X-linked recessive disease affecting only males, with a frequent clinical history of lack of male births. The disease apparently results from mutations of the scurfy gene, whose function is currently unknown but which, like the AIRE gene of APS-I, is a transcription factor.

Associated Autoimmune Disorders

Idiopathic Type 1A Diabetes

Descriptive Genetics

In the United States, the risk of childhood diabetes is approximately 1 in 300. [5] This is 15-fold less than the diabetes risk for a first-degree relative of a patient with type 1 diabetes (Table 30-2). [6] It is 150-fold less than the risk for a monozygotic twin of a patient with type 1 diabetes. [7] Although the population risk of type 1 diabetes in Japan is 15-fold less than in the United States, the risk for an identical twin in Japan is similar to that for an identical twin in the United States. [8] This suggests that when genetic susceptibility is present, either in Japan or in the United States, the diabetes risk is extremely high. Although the risk of diabetes is much greater for relatives of patients with type 1A diabetes, it is important to realize that most (>85%) individuals in whom type 1A diabetes develops do not have a first-degree relative with the disease. The frequency of sporadic cases results in part from the fact that almost 40% of individuals in the general population carry high-risk HLA alleles for type 1A diabetes (see "The Major Histocompatibility Complex").

The highest known incidence of type 1A diabetes is found in Finland and Sardinia. Finland now has an annual incidence approaching 50 per 100,000 children. Over the past four decades the incidence has increased almost threefold, suggesting a dramatic environmental change (either an increase of causative factors or a decrease of protective factors).

Twin Studies

Twin studies of diabetes have an impressive pedigree. The study of monozygotic twins of patients with diabetes by Pyke and co-workers [9] contributed to the recognition of distinct forms of diabetes, initially termed adult-onset and juvenileonset, subsequently termed insulin-dependent and noninsulin-dependent, and now termed type 1 and type 2 diabetes. [10] The concordance rate for monozygotic and dizygotic twins

provides important information regarding genetic factors contributing to a disease because monozygotic twins share all germ line-inherited polymorphisms or mutations whereas dizygotic twins are similar to siblings of patients with a disease and have only one half of genes in common. For a locus that contributes to disease in a recessive manner, only one fourth of dizygotic twins would be homozygous to a sibling with diabetes at that locus but all monozygotic twins would be homozygous for all recessive loci of their diabetic twin mate. Although overall concordance rates of monozygotic twins for type 1 diabetes are calculated, it is likely that type 1 diabetes is heterogeneous and that groups of monozygotic twins may have different genetic etiologies. With such genetic heterogeneity, one would expect different concordance rates for different genetic diseases.

Redondo and co-workers [11] have analyzed prospective follow-up data from a large series of initially discordant monozygotic twins from Great Britain combined with a series from the United States. Progression to diabetes was identical for both series of twins. Of note, there was no length of time of discordance beyond which a monozygotic twin mate did not have a risk of type 1 diabetes. Nevertheless, the hazard rate for development of diabetes decreased as the period of discordance increased. There was also a marked variation in the risk of diabetes relative to the age at which diabetes developed in the index twin. The overall rate of concordance for monozygotic twins was 50%. However, if type 1 diabetes developed in the index twin after age 25, the concordance rate by life table analysis was less than 10% (Fig. 30-1). If diabetes developed in the index twin prior to age 5, the concordance rate was 70% by 40 years of follow-up. This analysis of monozygotic twins suggests genetic heterogeneity but also confirms that a significant subset of monozygotic twins do not progress to diabetes. This suggests that either environmental factors, random factors, or nongerm line-inherited variations (e.g., imprinting, T-cell receptor polymorphisms, somatic mutations) contribute to diabetes risk.

An important unanswered question (given the limited number and size of studies) is whether dizygotic twins of patients with type 1A diabetes have a diabetes risk greater than that of siblings. If the risk is identical, it suggests that environmental factors whose presence is time-dependent (e.g., uncommon infections) may have little influence on the development of diabetes. Dizygotic twins differ from siblings in terms of a greater commonality of environment over time (e.g., common pregnancy). Studies of dizygotic twins suggest that their risk of diabetes may not differ from that of siblings or at most is increased by a factor of 2 compared with the 10-fold increase for monozygotic twins.

Genetic factors influence not only the development of diabetes but also the expression of anti-islet autoantibodies. For identical twins the expression of anti-islet autoantibodies is tightly linked to the eventual progression to overt diabetes, and monozygotic twins have a high prevalence of expression of autoantibodies. Dizygotic twins much less often express anti-islet autoantibodies, and the prevalence is similar to that of siblings. [12]

Associated Autoimmune Disorders

Because type 1A diabetes is an immune-mediated illness that develops in a genetically susceptible individual, it is not surprising that most patients with type 1A have one or more additional autoimmune diseases. The most common associated disorders are thyroid autoimmunity (Graves’ disease or Hashimoto’s thyroiditis) and celiac disease (Table 30-3).

The Major Histocompatibility Complex

The most important loci determining the risk of type 1 diabetes are within the MHC on chromosome 6p21 (Fig. 30-2), in particular HLA class II molecules (DR, DQ, and DP). [13] In addition, standard class I loci (HLA A, B, and C) influence disease, and it is likely that additional loci within the MHC that influence immune function contribute to diabetes risk. [14] Figure 30-2 illustrates the MHC. The nomenclature for alleles of this region is somewhat daunting, but with definitions of several terms and a description of the basis for classification it is comprehensible.

HLA molecules function to present peptides to T lymphocytes. Each molecule is made up of two chains, each chain encoded by a separate gene. These molecules are extremely polymorphic in amino acid sequence. Each polymorphic variant of each chain is designated with a gene locus name (e.g., DRB1) followed by an asterisk (*), followed by two

Digits referring to the serologic specificity (from the time when typing was performed with antibodies), followed by two digits for the specific allele (now determined with DNA-based typing), followed by a single digit to distinguish silent nucleotide polymorphisms (nucleotide differences that do not change amino acid sequence). For example, the designated allele DRB1*0405 has DR4 serologic specificity and is associated with high diabetes risk. For DR alleles, one usually specifies only the DRB chain because the DNA chain is not polymorphic. For the class II molecules (A, B, and C) one also specifies only a single chain because the other chain, \( \alpha \), -microglobulin is minimally polymorphic. There are more than 240 different known alleles of DRB1. Each individual inherits two DRB1 alleles, one from each parent.

Because HLA gene loci are in close proximity to each other on the sixth chromosome, one usually inherits a group of alleles as a unit, and this is termed a haplotype. For example, the alleles A*0101, B*0801, DRB1*0301, and DQA1*0501, DQB1*0201 constitute a common haplotype associated with diabetes risk. When specific alleles of different genes are nonrandomly associated with each other on a haplotype (such as the preceding alleles A1, B8, and DR3), the alleles are said to be in linkage disequilibrium.

Two MHC haplotypes, one inherited from each parent, constitute the MHC genotype. This genotype ultimately determines the MHC-encoded risk for type 1A diabetes. For DQ molecules, both of the chains (DQA and DQB) are polymorphic. This adds an important level of diversity in that the protein chains encoded by the alleles of one haplotype may combine with the chains encoded by the other haplotype. For example, individuals with the highest risk genotype DRB1*0301, DQA1*0501, DQB1*0201 and DRB1*0405, DQA1*0301, DQB1*0302 can produce four different DQ molecules: DQA1*0501, DQB1*0201 and DQA1*0301, DQB1*0302 as expected but also DQA1*0501, DQB1*0302 and DQA1*0301, DQB1*0201. The DQ molecule DQA1*0501, DQB1*0201 is also called DQ2 and DQA1*0301, DQB1*0302 is called DQ8. A common DQ molecule, DQA1*0102, DQB1*0602, provides dominant protection from type 1 diabetes and is termed DQ2.

The major determinants of diabetes susceptibility are DR and DQ molecules, and specific alleles of both DR and DQ can either increase or decrease the risk of diabetes. Table 30-4 summarizes the diabetes risk associated with a number of DR and DQ haplotypes.

In a number of studies, children at birth, either from the general population or relatives of patients with type 1 diabetes, have been HLA typed. The typing is relatively straightforward and either is based on direct DNA sequencing of polymerase chain reaction amplified DNA fragments or utilizes DNA probes that hybridize specifically to different allelic sequences. In Denver, Colorado, 2.4% of newborns have the highest risk DR-DQ genotype for type 1A diabetes, namely DR3-DQ2 with DR4-DQ8 (DR3/4 DQ8/2 heterozygotes). Fifty percent of children younger than 10 years and approximately 30% of older children who develop diabetes have this highest risk genotype. One can estimate that approximately 1 of 16 children with the highest risk HLA genotype from the general population progress to diabetes (versus a population risk of 1 per 300). Alternatively, 15 of 16 children from the general population who are DQB1/DQ2 heterozygotes do not develop diabetes.

Ninety-five percent of individuals who develop diabetes who have either DR3-DQ2 or DR4-DQ8, do as approximately 40% of the general population. The protective haplotype DRB1*1501, DQA1*0102, DQB1*0602 is present in 20% of the general population and less than 3% of patients with type 1A diabetes. A DR allele, DRB1*1401, also appears to provide dominant protection. There are additional high-risk haplotypes that are not common, such as DQA1*0401, DQB1*0402. It was proposed as a simple rule that the presence of aspartic acid at position 57 of the DQ chain and arginine at DQ 52 is associated with diabetes risk. As illustrated before, there are many exceptions to this rule, and knowledge of the complete sequences (allele) rather than dependence on this rule is essential.

**Insulin Locus**

Almost two decades ago, Bell and colleagues discovered that variations in the number of nucleotide repeat elements 5 of the insulin gene were associated with the development of type 1A diabetes. The longest group of repeats was associated with decreased diabetes risk. These studies have been replicated, and the locus of importance is clearly limited to the insulin gene. Of note, the protective insulin gene polymorphism is associated with greater insulin messenger RNA expression within the thymus. Hannan advanced the hypothesis that within lymphoid organs there are peripheral

</table>
There is an international effort to define additional genes that contribute to the development of type 1A diabetes. The genes associated with the two monogenic forms of polyendocrinopathy (AIRE gene and XPID gene), HLA genes, and the insulin gene are to date the only clearly identified genes. Much of the effort in searching for relevant genes has analyzed the common inheritance of genetic regions for pairs of diabetic siblings. With such an analysis, a long list of genes for type 1 diabetes, termed iddm loci, have been proposed, each with a specific number (e.g., iddm1 is the MHC, iddm2 the insulin gene, and iddm15 a locus on chromosome 6q).

Such studies are likely to generate at least as many false-positive loci as true loci, and the difficulty in replicating findings attests to the problems. Polymorphisms of the CTLA4 gene (iddm12) contribute to Graves’ disease and apparently to diabetes in some but not all populations.

One locus for which a consensus appears to be developing that it is “real” is the iddm15 locus. This locus is, however, on 6q21 and is loosely linked (30 cM) to the MHC, and it is important to rule out an influence of class I HLA alleles in accounting for iddm15. One locus, iddm17, was identified not through analysis of sibling pairs but by intensive study of a single family with 21 members with type 1A diabetes. It appears that this locus, in combination with high-risk HLA alleles within the initial family studied, creates a risk of diabetes approaching 40%, and there is preliminary evidence that the same locus may influence diabetes risk in a subset of families in the United States. As reflected by this single family, it is not yet clear whether type 1A diabetes is of polygenic origin with small effects of many genes determining risk or oligogenic but heterogeneous. If it is oligogenic, a few (e.g., less than three) genes may determine risk in each family.

In summary, many putative diabetes loci have been identified outside the HLA region, but until actual genes contributing to diabetes risk are identified, these loci are unlikely to contribute to genetic counseling or clinical care. HLA typing is being utilized to define the risk of diabetes at birth. The defined risk can be extremely high, depending on the relationship to a proband with diabetes and the specific HLA genotype. For example, siblings of patients with type 1A diabetes with the DR3-DQ2/DR4-DQ8 genotype appear to have a diabetes risk that exceeds 50%. In contrast, children from the general population with the same HLA DR and DQ genotype have a risk of less than 6%. In addition to influencing diabetes risk, specific HLA genotypes contribute to risk for associated autoimmune disorders. It is remarkable that one third of DR3-DQ2 homozygous patients with type 1A diabetes express transglutaminase autoantibodies and half of them have celiac disease on biopsy.
ENVIRONMENTAL FACTORS

Despite more than three decades of research, there is only one environmental factor clearly associated with type 1A diabetes, namely congenital rubella infection (see later). The association of only one factor is probably related to the long prodromal phase that precedes type 1A diabetes, which makes the discovery of relevant environmental factors particularly difficult. A number of factors can induce type 1A diabetes in animal models, one of the most interesting being the Kilham rat virus infection of BB-DR rats. In this model, which lacks the lymphopenia of the related BB strain, diabetes does not develop unless the animals are infected with Kilham virus (a parvovirus) or injected with poly-IC. Poly-IC mimics double-stranded RNA and induces high levels of interferon. The Kilham virus apparently does not directly infect islets and is thought to be an immune activator similar to poly-IC. Diabetes induction is dependent on specific class II alleles termed RT1-U, and a number of animal strains with RT1-U are susceptible to diabetes. If these animal models are relevant to humans, it may be that many environmental stimuli in a genetically susceptible host activate autoimmunity.

In countries throughout the world the incidence of type 1A diabetes is increasing, particularly for children in whom the disease develops before age 5. This is strong evidence that environmental factors related to diabetes risk have changed over the past four decades. Factors that increase diabetes risk may be increasing or, just as likely, factors that suppress the development of diabetes may be decreasing. For example, in animal models of type 1A diabetes (NOD mouse and BB rat), infections with common viruses usually decrease the development of diabetes.

Infections

Congenital rubella, but not noncongenital infection, greatly increases the development of type 1A diabetes. The children with diabetes usually have high-risk HLA alleles and these children frequently have thyroid autoimmunity. The manner by which this congenital infection increases diabetes development is currently unknown. Hypotheses have ranged from potential molecular mimicry to long-term alteration in T-cell function secondary to the congenital insult.

Enteroviruses are small RNA viruses that frequently infect young children. Initial anecdotal reports that coxsackievirus infections may cause diabetes evaluated children with severe infections with death at diabetes onset. These studies preceded the realization that type 1A diabetes is not an acute disease, and it is likely that viral infection at the onset of type 1 diabetes is most often incidental. At the time of presentation with diabetes, almost all children have elevated HbA1c, reflecting probably months of hyperglycemia preceding diagnosis. A description from Japan of individuals with acute-onset diabetes with normal HbA1c, elevated amylase, and infiltrates within the exocrine but not endocrine pancreas appears to represent a form of type 1B diabetes.

The potential importance of enteroviral infection has been emphasized by studies from Scandinavia in which enteroviral infection was evaluated during pregnancy and in infancy. Infection is usually detected by either changes in antiviral antibodies or detection of enteroviral RNA by molecular techniques. Although some studies have reported increased enteroviral infection during pregnancy in mothers whose children have developed diabetes, others have not. As infants with a genetic risk for the development of diabetes are followed from birth, it becomes possible to analyze prospectively the expression of enterovirus RNA. Studies by Hultyn and colleagues found that enteroviral infection is associated with the appearance of anti-islet autoantibodies. Similar studies from Denver, Colorado, did not find an association. The major difference between the two studies appears to be the lower rate of enteroviral infection in Finnish control subjects compared with Colorado control subjects with rates of infection similar to those in cases.

Other viruses are being evaluated for association with the triggering of autoimmunity. One study from Australia found an association with rotavirus infection. Rotavirus infection is common in young children. The Australian study did not find an increase in rotavirus infection compared with that in control subjects but reported an association of rotavirus infection with increases of anti-islet autoantibodies. Studies from Denver did not indicate an increase in rotavirus infection in infants developing autoantibodies.
Vaccination

It has been claimed that the timing of routine childhood vaccinations influences the development of type 1A diabetes. This is an important health concern if parents alter their family's childhood vaccination because of concern about development of diabetes. A series of studies have been carried out and do not provide evidence that childhood vaccinations influence the development of diabetes.
Diet

A disease such as celiac disease is critically dependent on the ingestion of a specific food, namely the wheat protein gliadin. In addition, a number of dietary modifications altered the development of diabetes in NOD mice and BB rats. Investigators have championed the hypothesis that early introduction of bovine milk increases the development of diabetes. This hypothesis is primarily based on retrospective studies associating early or increased bovine milk ingestion (or less breast-feeding) with an increased risk of type 1A diabetes. Several prospective studies in which infants are observed until the development of anti-islet autoantibodies have failed to find an association or have found a weak association with either breast-feeding or bovine milk ingestion. Pilot studies of an infant formula lacking bovine milk proteins have been initiated in Finland. Preliminary data suggest that such a restricted diet may produce a small decrease of cytoplasmic islet cell autoantibodies but not of GAD65 autoantibodies.

Figure 30-3 (Figure Not Available) Hypothetical stages in the development of type 1A diabetes beginning with genetic susceptibility and ending with complete beta cell destruction. (Modified from Eisenbarth GS. Type 1 diabetes mellitus: A chronic autoimmune disorder. N Engl J Med 1986, with modifications by Jay Skyler, University of Miami.)
NATURAL HISTORY OF TYPE 1A DIABETES

We typically divide the development of type 1A diabetes into a series of stages beginning with genetic susceptibility and ending with essentially complete beta cell destruction (Fig. 30-3). It is, however, likely that both genes and environmental factors influence the course of development of type 1A diabetes during the complete prediabetic period. For instance, injection of immunostimulants such as Freund's adjuvant can prevent progression to diabetes in animals with insulitis. Mathis and co-workers have proposed the existence of "checkpoints" in the development of diabetes, and such checkpoints may have a strong genetic component. As discussed subsequently, type 1A diabetes is quite predictable given specific immunologic, genetic, and metabolic characteristics, and it is such characteristics that set the stage for preventive trials.

Genetic and Immunologic Heterogeneity by Age of Onset

Type 1A diabetes can develop at any age, from the neonatal period to the sixth decade of life. In that identical twins can become concordant 30 years after their twin mate, not all age heterogeneity can be ascribed to different genetic syndromes. Nevertheless, there is an overall correlation between the age at which diabetes develops in one twin or sibling and the age of development of diabetes in his or her relative. As discussed earlier, children in whom type 1A diabetes develops at an early age more often are DR3/4, DQ8/2 heterozygotes. In addition, there is evidence that class I HLA alleles (or other nonclass II genes with the HLA region) may influence the age of diabetes onset (e.g., the A24 allele). At the other end of the age spectrum, there is evidence that the protective HLA allele DQA1*0102, DQB1*0602 is not as protective for young adults as it is for children.

The most characteristic difference related to the age of diabetes onset is the presence of higher levels of insulin autoantibodies in children who develop the disease at an early age (e.g., younger than 5 years). The high levels and frequent positivity of insulin autoantibodies make measurement of IAA (insulin autoantibodies) the best single marker for diabetes development in young children. For children in whom autoantibodies arise in the first 3 years of life, insulin autoantibodies often appear first. In contrast, GAD65 autoantibodies are more often positive in adults developing type 1A diabetes. The correlation of levels of insulin autoantibodies and age of diabetes onset may be related to children with higher levels progressing more rapidly to diabetes. Such rapid progression, however, occurs only if insulin autoantibodies are present with another islet autoantibody (see "Combinatorial Autoantibody Prediction").
Combinatorial Autoantibody Prediction

The most specific anti-islet autoantibody assays are usually set with cutoffs above the 99th percentile of control populations. Thus, with three major autoantibody assays (GAD65, ICA512 [islet cell antibody], and insulin) one would predict that approximately 3 of 100 normal individuals would express one or more of the three autoantibodies. Because approximately 3 of 1000 children develop type 1A diabetes, this suggests that in the great majority of antibody-positive individuals, diabetes never develops or may develop late in life.

A relatively low positive predictive value for single antibodies may be due to methodologic limitations or the presence of autoantibodies identical to those of prediabetics but found in some individuals who do not progress to diabetes. It is likely that both occur. For example, a low positive (but > 99th percentile) autoantibody result of a control subject is often not confirmed on repeated testing. Autoantibodies of prediabetic individuals usually react with multiple epitopes of the ICA512 molecule, whereas false-positive autoantibodies frequently react with only one or no clearly defined epitope of the molecule, suggesting that false-positive and diabetes-associated anti-ICA512 autoantibodies differ. There are, however, individuals, usually adult relatives of patients with type 1A diabetes (often with DQB1*0602), with extremely high levels of GAD65 autoantibodies that react with multiple GAD epitopes with no evidence of progression to diabetes. 142

Assessment of the significance of an autoantibody result (as for any diagnostic test) is improved by taking into account the prior probability of disease. A patient with overt diabetes and expression of a single anti-islet autoantibody has a high probability of type 1A diabetes. An individual from the general population or even a relative expressing a single autoantibody (and remaining with a single autoantibody) has a much lower risk of progressing to type 1A diabetes. 142

Usually, in attempting to improve the specificity of a test, one sacrifices sensitivity. For prediction of type 1A diabetes, because three biochemical autoantibodies are measurable, one can combine the tests with the observation that the presence of two or more autoantibodies is associated with a very high risk of diabetes. 143 144

Approximately 1 of 350 individuals from the general population express two or more of the GAD65, ICA512, or insulin autoantibodies, which approaches population estimates of type 1A diabetes. Among first-degree relatives of patients with type 1A diabetes, two or more autoantibodies indicate a risk over 10 years of more than 90%, whereas a single autoantibody is associated with a risk of less than 20% over 10 years. 143
Metabolic Progression before Hyperglycemia

The intravenous glucose tolerance test aids in evaluating the time to onset of diabetes among individuals expressing anti-islet autoantibodies. Most commonly, glucose is given at 0.5 g/kg over 5 minutes (maximum 35 g, 25 g/dL) and insulin levels are measured before and 1 and 3 minutes after the glucose infusion. Most individuals within a year of overt diabetes have no first-phase insulin secretion after intravenous glucose. The diagnosis of type 1A diabetes usually relies upon the presence of fasting hyperglycemia, but with prospective evaluation many individuals have diabetes by the 120-minute criteria on oral glucose tolerance with nondiagnostic fasting glucose.
C-Peptide Loss after Hyperglycemia

Following the diagnosis of diabetes, levels of C peptide can be utilized to assess remaining beta cell function. C-peptide levels are usually measured in the fasting state or after intravenous glucagon or with a standard meal (e.g., Sustacal). Such measurements are primarily of importance for trials of therapies to alleviate loss of insulin secretion after diagnosis. Determination of C peptide provides the best current measure for assessing the impact of new therapies. As shown in the Diabetes Control and Complications Trial (DCCT), a small amount of remaining C peptide is associated with impressive metabolic benefit.
Type 1A Diabetes with Pregnancy

Approximately 5% of women with gestational diabetes (diabetes diagnosed during pregnancy) have an early form of type 1A diabetes that is discovered during pregnancy. These women express anti-islet autoantibodies and progress to overt diabetes more rapidly after pregnancy.
Latent Autoimmune Diabetes of Adults

Type 1A diabetes can occur at any age. Depending on the population, between 5% and 15% of individuals with what appears to be type 2 diabetes express anti-islet autoantibodies. Multiple studies have demonstrated that such individuals progress relatively rapidly (within 3 years) to insulin-requiring diabetes. The HLA alleles of such individuals reflect that of type 1A diabetes.
Transient Hyperglycemia

A significant number of children are evaluated by endocrinologists for transient hyperglycemia. The usual history is of severe stress associated with hyperglycemia that resolves within days to a month. Such children may be in the "honeymoon" phase of type 1A diabetes or may truly have a transient episode of hyperglycemia. Rarely, diabetes in children is misdiagnosed (e.g., the authors have seen a child with normal HbA1c values for several years who stopped insulin and was subsequently found to have renal glucosuria and not diabetes). Children without severe stress with transient hyperglycemia or with a relative with type 1A diabetes are more likely to have early type 1A diabetes. Absence of anti-islet autoantibodies and a normal intravenous glucose tolerance test are strongly indicative of transient hyperglycemia and not type 1A diabetes. It is not known whether children with transient hyperglycemia are at increased risk for type 2 diabetes later in life.
IMMUNOTHERAPY OF TYPE 1A DIABETES

At the onset of type 1A diabetes, a major clinical research goal is the prevention of further beta cell destruction. At present there is no proven safe and effective therapy to prevent such further destruction or to prevent the development of type 1A diabetes in those at risk (e.g., genetically at risk individuals with anti-islet autoantibodies). A number of clinical trials have been completed and a large number of trials are under way or about to be initiated.

Immunosuppression

The earliest studies of therapies to prevent beta cell destruction utilized immunosuppressive agents. Large trials of cyclosporine indicated that while administered it prevented further loss of C-peptide secretion and improved metabolic function. It did not, however, maintain a nondiabetic state when therapy was instituted after the onset of diabetes, and with discontinuation of the drug individuals rapidly lost C-peptide reserve. The combination of inability to “cure” diabetes and toxicities associated with cyclosporine (in particular nephrotoxicity and concern about increased risk of malignancy) has ruled out its use. Other immunosuppressive agents such as prednisone or azathioprine had relatively little effect. A small study suggested that methotrexate, another common immunotherapeutic agent, is ineffective. Thus, at present, although type 1A diabetes is an immune-mediated disorder, it is not treated with common immunotherapeutic agents. A pilot study of a specific antibody to CD3 has been reported and further essential trials are underway.
Immunologic Vaccination

In animal models (especially the NOD mouse) it is relatively easy to prevent type 1 diabetes. Potentially the most exciting modalities utilize forms of immunologic vaccination. Much of the excitement derives from the specificity of the therapy and relatively low risk compared with immunosuppression and not from demonstrated efficacy in humans. The basic concept behind the bulk of such therapies is the induction of lymphocytes that target a given islet antigen and upon encountering their target antigen (e.g., insulin) produce cytokines that suppress autoimmunity and tissue destruction.

A general class of T lymphocytes termed Th2 T cells produce the cytokine interleukin-4 rather than interferon and interleukin-2 (Th1 T cells) and decrease cell-mediated immune destruction. Induction of a protective immune response may depend upon the route of administration of the given antigen (e.g., oral tolerance) or the utilization of an altered antigen (e.g., altered peptide ligands). For example, insulin given either orally or by subcutaneous injection prevented diabetes in NOD mice. Intact insulin is not necessary because insulin B chain and an immunodominant B:923 peptide of insulin were also effective. The latter molecules have no insulin-like metabolic effect but are able to activate T lymphocytes that target insulin.

The Diabetes Prevention Trial Type 1 is studying both oral insulin and parenteral injections of low doses of insulin. The results of the parenteral trial did not demonstrate a reduction in the risk of developing diabetes. The oral trial will continue for several more years (relatives of patients with type 1A diabetes can be screened for this trial by calling 1-800-HALT-DM1). A peptide of a heat shock protein (p277) is being studied, and trials of the GAD65 molecule are about to be initiated.
Other Therapies

A review by Atkinson and Leiter\textsuperscript{14} pointed out that more than 100 different interventions prevent diabetes in NOD mice. The relative ease of diabetes prevention in this animal model provides the basis for a number of trials initiated in humans. The largest such European trial (ENDIT, European Nicotinamide Trial) utilizes nicotinamide in gram doses. Nicotinamide is able to prevent diabetes induced by the drug streptozotocin and probably acts by preserving nicotinamide adenine dinucleotide levels in islet cells or blocking cytokine-induced destruction. There have been a number of studies of nicotinamide, including a randomized placebo-controlled trial in children and a small trial in at-risk relatives, that found no effect of nicotinamide.\textsuperscript{15,166} Other trials suggest some preservation in adult patients presenting with type 1A diabetes.\textsuperscript{167} The ENDIT trial should provide definitive information concerning the potential effect (or lack of effect) of nicotinamide.
IMMUNOLOGY OF ISLET-PANCREATIC TRANSPLANTATION

Pancreatic transplantation for patients requiring a kidney transplant is an accepted clinical procedure. Patients with a kidney transplant receive immunosuppressive drugs, and results for pancreatic transplantation in this setting have progressively improved. With a successful pancreas transplant, hyperglycemia is "immediately" reversed and there is some evidence of improved long-term outcomes. Nevertheless, the surgery is extensive and there are multiple potential complications associated with the transplant. Diabetes can recur because of either recurrent autoimmunity or more often allograft rejection. It is difficult to monitor specific islet destruction, and with the development of hyperglycemia it is usually not possible to restore euglycemia.

Up until studies from Edmonton the results of islet transplantation have been poor, with less than 10% of patients with type 1A diabetes becoming insulin independent at 1 year. In contrast, with autotransplants of patients with pancreatitis most patients become insulin independent and remain so. The Edmonton group has utilized meticulous islet isolation techniques, transplantation of islets from two pancreases, and an immunosuppressive regimen utilizing the new drug rapamycin. With this regimen more than a dozen patients have had successful transplants, and the longest duration after transplantation has been 18 months. With the Edmonton regimen, insulin antibodies decreased and there was no new development or increase of either GAD65 or ICA512 autoantibodies. With other regimens, marked increases of such autoantibodies appeared to herald loss of islet function.

The Edmonton protocol is now being tested in a series of specialized centers throughout North America and Europe, and the applicability of the technique should be rapidly evaluated. Even if the Edmonton results are reproduced at multiple centers, the number of islets available from cadaveric donors for transplantation is limited. Further research to allow xenogeneic transplantation or production of islets from stem cells is essential.
INSULIN AUTOIMMUNE SYNDROME

The insulin autoimmune syndrome, also termed Hirata syndrome, is rare and typically associated with hypoglycemia. These patients have extremely high concentrations of autoantibodies reacting with human insulin. It is thought that inappropriate (nonregulated) release of autoantibody-bound insulin produces the hypoglycemia. The disease occurs most commonly in Asian individuals. Among 50 Japanese patients with the syndrome and the typical polyclonal anti-insulin autoantibodies, 96% had a DRB1, DR4 allele and 84% (42 of 50) the DRB1*0406 allele. In contrast, patients with monoclonal anti-insulin autoantibodies do not have such a remarkable HLA association. Most patients develop the disease in association with treatment with sulfhydryl-containing medications, in particular methimazole. Treatment usually consists of stopping these medications, and for more than 75% the disease remits.
INSULIN ALLERGY

Mild forms of immune reactivity to insulin are not uncommon. Essentially all patients treated with human insulin produce anti-insulin autoantibodies measurable with sensitive fluid phase radioassays. The levels of these autoantibodies are relatively low and they do not appear to interfere with insulin therapy, although there are reports correlating insulin antibodies with macrosomia. With the introduction of recombinant human insulin replacing animal insulins, symptomatic immune responses to insulin such as immediate hypersensitivity, delayed hypersensitivity, lipoatrophy, and lipohypertrophy have decreased. Allergic reactions can occur with insulin analogues, although this is uncommon. More common perhaps are allergies to protamine used to complex insulin in neutral protamine Hagedorn (NPH) formulations as well as to the lubricants, preservatives, and plastics in bottles, stoppers, syringes, and needles. The usual therapy consists of switching the type or formulation of insulin followed by oral antihistamines for immunoglobulin E-mediated local reactions, followed by insulin desensitization or addition of small amounts of glucocorticoids to the insulin injected for local delayed hypersensitivity reactions.
ANTIINSULIN RECEPTOR AUTOANTIBODIES

Antiinsulin receptor autoantibodies (type B insulin resistance) are associated with both hypoglycemia and insulin resistance. It appears that antiinsulin receptor autoantibodies can act as either an antagonist or agonist. This syndrome is rare and is often associated with nonorgan specific autoimmunity.
CLINICAL PRESENTATION

The peak age of presentation of type 1 diabetes in children is around the age of puberty. The symptoms and signs are related to the presence of hyperglycemia and the resulting effects on fluid and electrolyte balance. They generally include polyuria, polydipsia, polyphagia, weight loss, and blurred vision. Because infection may have precipitated the initial presentation, symptoms of infection may also be present such as fever, sore throat, cough, or dysuria. In children in particular the onset of symptoms may occur over a brief period and families may be able to date their onset with considerable accuracy. Onset of symptoms may also be insidious, particularly in older persons with type 1 diabetes, and may occur over a time frame of weeks or even months.

If onset of type 1 diabetes is associated with ketoacidosis, which is not uncommon, additional symptoms related to this acute metabolic complication of diabetes are also present. These symptoms can include abdominal pain, nausea, and vomiting. Variable effects on mental status may be seen, ranging from slight drowsiness to profound lethargy and even coma if the condition has been untreated for a significant period of time.

Laboratory Findings

Plasma glucose concentrations at presentation are elevated, usually in the range 300 to 500 mg/dL. If the presentation is uncomplicated, the remainder of the fluid and electrolyte measurements may be completely normal. On the other hand, if diabetic ketoacidosis is present, the measurements reflect the presence of an acidosis as well as more severe dehydration. Thus, in diabetic ketoacidosis, the serum sodium value is frequently at the lower limit of normal or even mildly reduced, reflecting the osmotic effect of hyperglycemia and on occasion the presence of vomiting with continued water intake. A sodium value less than 120 mmol/L is usually associated with severe hypertriglyceridemia that can lead to spurious hyponatremia. Despite significant losses of potassium in the urine and total-body potassium deficits, the presence of acidosis usually leads to an elevated serum potassium concentration at the time of the initial presentation. Serum bicarbonate concentrations are usually less than 10 mg/dL, and elevations in serum concentrations of triglyceride and free fatty acids are found. Levels of ketone bodies are also elevated. Because dehydration is invariably present, this leads to increases in the concentrations of blood urea nitrogen and creatinine. In conjunction with the increase in serum glucose, the increases in blood urea nitrogen invariably increase the serum osmolality, often to greater than 300 mmol/kg.
TREATMENT OF TYPE 1 DIABETES

Importance of Tight Glucose Control

The overriding principle in the treatment of the majority of patients with type 1 diabetes is that a health care team that includes a physician, diabetes nurse educator, nutritionist, and other health care professionals as appropriate should work closely with the patient to achieve blood glucose concentrations as close to normal as possible because these are associated with a reduced risk of diabetic complications. Although studies in animal models and epidemiologic studies suggested that tighter glucose control was associated with better long-term outcomes for the diabetic patient in terms of a reduced risk of complications, the most definitive study in this regard has been the Diabetes Control and Complications Trial (DCCT) that was completed in 1993. This landmark study was performed in a total of 1441 patients with type 1 diabetes with no retinopathy at baseline (the primary prevention cohort) and 715 with mild retinopathy (the secondary intervention cohort) who were randomly assigned to intensive therapy or conventional therapy.

Intensive therapy consisted of insulin administration by an external pump or by three or more daily insulin injections. The dosage was adjusted according to the results of self-monitoring of the blood glucose performed at least four times per day as well as in response to dietary intake and anticipated exercise. The goals of intensive therapy were to achieve blood glucose concentrations between 70 and 120 mg/dL before meals, values less than 180 mg/dL after meals, a weekly 3-hour measurement greater than 65 mg/dL, and an HbA1c value within the normal range (6.0% or less). Patients in the intensive treatment group visited their centers each month and had more frequent contacts with a member of the health care team, generally weekly, to review and adjust their regimens.

Conventional therapy consisted of one or two daily injections of insulin, including mixed intermediate and rapid-acting insulins, daily self-monitoring of urine or blood glucose, and education about diet and exercise. The goals of conventional therapy included absence of symptoms of hyperglycemia; absence of ketonuria; maintenance of normal growth, development, and ideal body weight; and freedom from frequent severe hypoglycemia.

The entire cohort of patients was observed for a mean of 6.5 years and 99% of the patients completed the study. Although only 5% of the subjects in the intensive treatment group were able to sustain the goal of a normal HbA1c over time, they nevertheless did have significantly lower average values (approximately 7%) over time than the subjects in the conventional treatment group (approximately 9%). Average capillary blood glucose profiles in the intensive treatment group were 155 ± 30 mg/dL compared with 231 ± 55 mg/dL in the conventional therapy group (P < .0001). These differences in glucose control formed the basis of analyses to determine the effects of lower levels of glycemia on diabetic complications.

When both the primary prevention and secondary intervention cohorts were considered, intensive therapy reduced the risk of proliferative or severe nonproliferative retinopathy by 47% and the need for treatment by photocoagulation by 56%. Intensive therapy reduced the mean adjusted risk of microalbuminuria (defined as urinary albumin excretion of > 40 mg per 24 hours) by 34% in the primary prevention cohort and by 43% in the secondary intervention cohort. The risk of albuminuria was reduced by 56% in the secondary intervention cohort. Intensive therapy reduced the appearance of neuropathy by 69% in the primary prevention cohort and by 57% in the secondary intervention cohort.

There has been considerable controversy regarding potential adverse effects of aggressive insulin therapy in exacerbating the predisposition to macrovascular disease. In this study intensive insulin therapy reduced the development of hypercholesterolemia, defined as a serum concentration of low-density lipoprotein cholesterol greater than 160 mg/dL, by 34% and the risk of macrovascular disease by 41%, although the latter differences were not statistically significant.

Was there an increase in adverse events associated with the intensive treatment regimen? Overall mortality did not differ in the two treatment groups and was actually less than expected on the basis of population-based mortality studies. However, the incidence of severe hypoglycemia was approximately three times higher in the intensive therapy group than in the conventional therapy group (P < .001). Some of the episodes of hypoglycemia were quite severe, resulting in motor vehicle accidents or the need for hospitalization. Severe hypoglycemia occurred more often during sleep and of episodes that occurred while the patients were awake, a significant proportion (approximately one third) were not associated with warning symptoms. In intensively treated subjects predictors of hypoglycemia included a history of severe hypoglycemia, longer duration of diabetes, higher baseline HbA1c, and a lower recent HbA1c.

Weight gain also occurred more frequently in the intensively treated patients. Intensive therapy was associated with a 33% increase in risk of becoming overweight, defined as a body weight more than 120% above the ideal. Five years into the trial, patients being treated intensively had gained a mean of 4.6 kg more than patients receiving conventional therapy. Among subjects in the top quartile of weight gain, changes in plasma lipids, blood pressure, and body fat distribution were observed that were similar to those seen with insulin resistance.
Goals of Treatment

On the basis of these results, the authors of the study recommended that most patients with type 1 diabetes be treated with an intensive treatment regimen under the close supervision of a health care team consisting of a physician, nurses, nutritionist, and behavioral and exercise specialists as needed. However, for certain groups of patients this recommendation may need to be modified because the risk-benefit ratio may not be as favorable as it was in the cohorts with mild or no diabetic complications that were studied in the DCCT. Patients for whom it may be appropriate to be more cautious about instituting intensive treatment regimens include children younger than 13 years, elderly people, and patients with advanced complications such as end-stage renal disease or significant cardiovascular or cerebrovascular disease. It has also been reported that instituting aggressive insulin therapy in subjects with proliferative or severe nonproliferative retinopathy may lead to accelerated progression of retinopathy after the start of intensive therapy. Treatment of the eye disease should be considered before instituting an aggressive insulin regimen. In addition, patients who do not experience warning adrenergic symptoms of hypoglycemia (hypoglycemia unawareness) are at significantly greater risk for severe recurrent hypoglycemia, and this may prevent the safe institution of tight glucose control.

From Diabetes Care 2002; 25:S33549, Table 6.

*The values shown in this table are by necessity generalized to the entire population of individuals with diabetes. Patients with comorbid diseases, the very young and older adults, and others with unusual conditions or circumstances may warrant different treatment goals. These values are for nonpregnant adults. Values above or below these levels are not goals, nor are they acceptable in most patients. They are an indication for a significant change in the treatment plan. Additional action suggested depends on individual patients’ circumstances. Such actions may include enhanced diabetes self-management education, comanagement with a diabetes team, referral to an endocrinologist, change in pharmacologic therapy, initiation of or increase in self-monitored blood glucose, or more frequent contact with the patient. Ac1c is referenced to a nondiabetic range of 4.0-6.0% (mean 5.0%, standard deviation 0.5%). Values calibrated to plasma glucose. Measurement of capillary blood glucose.

The American Diabetes Association revises and publishes treatment guidelines annually as the first supplement to Diabetes Care. The recommendations for 2002 are listed in Table 30-5. The goal of therapy is to achieve average preprandial plasma glucose concentrations in the range of 90 to 130 mg/dL, average bedtime plasma glucose values between 110 and 150 mg/dL, and Ac1c values less than 7%. It is recognized that in order to achieve glucose control at this level patients need to monitor glucose levels at least three or four times per day and receive nutritional counseling and training in self-management of the insulin doses and problem solving to allow them to deal with the problems that they encounter in their daily lives. Hospitalization may be necessary for the initiation of therapy.
Team Approach to Treatment

As alluded to previously, because of the complex nature of modern intensive diabetes treatment regimens and the need for regular feedback and modification of the parameters of treatment, it has now become generally accepted that intensive insulin regimens can be instituted more effectively by a health care team rather than a physician alone. Members of the team can include diabetes nurse educators, nutritionists, psychologists, or medical social workers, and others such as exercise physiologists may also be included depending on the needs of a particular patient. A critical aspect of intensive diabetes treatment is the need to monitor continuously the effectiveness of specific components of the regimen and to make adjustments in response to changing life circumstances of the patient.
Pharmacokinetics of Available Insulin Preparations

In the past, insulin for human use was obtained from animal sources—beef and pig. With advances in recombinant DNA technology, it is now possible to produce large quantities of insulin with an amino acid structure identical to that of human insulin using laboratory strains of Escherichia coli bacteria or yeast that have been genetically altered by the addition of the gene for human insulin production. All forms of insulin have identical physiologic effects. They differ in the rapidity of the onset of action, the time from injection to peak action, and the duration of action depending on the chemical nature of the particular insulin preparation. These data are summarized in Table 30–6. The available insulins can be divided into three broad categories on a pharmacokinetic basis.

### Rapid-Acting Insulins

These insulins have an onset of action within an hour or less and are used to reduce the peak of glycemia that occurs after meal ingestion.

1. **Regular insulin.** This form of insulin consists of zinc-insulin crystals dissolved in a clear fluid. The pharmacokinetic profile of regular insulin is related to the fact that after subcutaneous injection it tends to self-aggregate, first into dimers and then into hexamers, which result from the self-association of three dimers. Only the monomeric and dimeric forms can be absorbed to any appreciable degree. The resulting relative delay in the onset and duration of action of regular insulin limits its effectiveness in controlling postprandial glucose.

2. **Insulin lispro** of recombinant DNA origin is a human insulin analogue created when amino acids at positions 28 and 29 on the human insulin B chain are reversed. Insulin lispro was the first insulin analogue to receive approval by the United States Food and Drug Administration. It is chemically Lys(B28), Pro(B29) insulin and is created in a special nonpathogenic laboratory strain of E. coli bacteria that has been genetically altered by the addition of the gene for insulin lispro. The effect of this amino acid rearrangement is to reduce the capacity of the insulin to self-aggregate in subcutaneous tissues, resulting in behavior similar to that of monomeric insulin. This leads to more rapid absorption and shorter duration of action of lispro compared with regular insulin when given by subcutaneous injection. However, lispro is not intrinsically more active and on a molar basis is equipotent to human insulin. When they are given by intravenous injection, the pharmacokinetic profiles of lispro and human regular insulin are similar. Because of its rapid onset of action within 5 to 15 minutes of administration and peak action within 1 to 2 hours, lispro is the first insulin that mimics the time course of the increase in plasma glucose seen after ingestion of a carbohydrate-rich meal.

3. **Insulin aspart** differs from human insulin by substitution of aspartic acid for proline in position 28 on the chain, and this also leads to a more rapid onset and duration of action analogous to those of insulin lispro.

### Intermediate-Acting Insulins

These forms of insulin have a significantly longer delay in their onset and duration of action. In the setting of type 1 diabetes they are generally used in combination with a rapidly acting form of insulin although they may be given before bedtime to limit hyperglycemia overnight and in the early hours of the morning. In general, treatment with monomeric insulin analogues (lispro and aspart) is associated with a lower risk of hypoglycemia, particularly in sleep, than treatment with regular insulin. It is quite easy to document improved glycemic control in the postprandial state. Finally, patients may inject these insulin analogues immediately before or after meals instead of 30 to 60 minutes before meals as is classically recommended with regular insulin, providing greater convenience. These features have been exploited in clinical trials to produce modest improvements in overall control with monomeric insulin analogues versus regular insulin.

### Long-Acting Insulins

These forms of insulin have a significantly longer delay in their onset and duration of action. In the setting of type 1 diabetes they are generally used in combination with a rapidly acting form of insulin although they may be given before bedtime to limit hyperglycemia overnight and in the early hours of the morning.

1. **NPH insulin.** This is a crystalline suspension of insulin with protamine and zinc providing an intermediate-acting insulin with onset of action in 1 to 3 hours, duration of action up to 24 hours, and peak action from 6 to 8 hours.

2. **Lente insulin.** This is an amorphous and crystalline suspension of insulin with zinc resulting in an intermediate pharmacokinetic profile. It generally has a slightly longer onset, peak, and duration of action than NPH insulin.

### Long-Acting Insulins

Even after an overnight fast, the normal pancreas continues to secrete insulin. Investigators have long attempted to develop forms of insulin with pharmacokinetic properties that simulate the basal production of insulin.

1. **Ultralente insulin.** Ultralente insulin is also a preparation of insulin consisting of zinc insulin crystals. It has an onset of action in 2 to 4 hours and a prolonged duration that may be as long as 24 hours. The peak of action is broad and spans 8 to 16 hours. This formulation of insulin is arguably the most variably absorbed and can be associated in some patients with substantial variability in glycemic control.

2. **Insulin glargine.** Insulin glargine is a recombinant human insulin analogue that is long acting. It differs from human insulin in that the amino acid asparagine at position A21 is replaced by glycine and two arginines are added to the C-terminus of the B chain. In the injection solution at pH 4, insulin glargine is completely soluble. However, it has low aqueous solubility at neutral pH. After injection into the subcutaneous tissue, the acidic solution is neutralized, leading to the formation of microprecipitates from which small amounts of insulin glargine are slowly released, resulting in a broad increase in concentration over a 24-hour period with no pronounced peak. It thus simulates the basal production of insulin. In other respects the mechanism of action of glargine insulin is similar to that of aspartic acid for proline in position 28 on the chain, and this also leads to a more rapid onset and duration of action analogous to those of insulin lispro.
of human insulin, and on a molar basis its glucose-lowering effects are similar to those of human insulin when given intravenously. Because this insulin is provided in an acid vehicle, it cannot be mixed with other forms of insulin or intravenous fluids and some patients have greater discomfort with injection at least some of the time. In general, glargine is less variably absorbed than Ultralente, NPH, and Lente insulin and in clinical trials in patients with type 1 diabetes has been associated with a reduced risk of hypoglycemia, particularly nocturnal hypoglycemia. In about 10% of patients, insulin glargine must be taken twice daily to provide 24-hour coverage of basal insulin needs. In a smaller proportion of patients, there may be a modest peak in effect approximately 2 hours after injection.
Approach to the Treatment of Type 1 Diabetes

Levels of glucose control equivalent to those achieved in the intensive treatment group in the DCCT are not possible in the majority of patients unless the insulin regimen utilizes more than two injections of insulin with the patient adjusting the insulin dose depending on the results of self-monitoring of glucose as well as on the basis of dietary intake and physical activity. The reason for this is relatively simple. In patients with little or no endogenous insulin production, the exogenous insulin regimen needs to simulate the multiphasic profile of insulin secretory responses to meals and snacks present in normal subjects if levels of glycemia approaching normal are to be achieved.

A number of regimens have been used to achieve these ends. Three basic approaches are reviewed, although it is clear that other possible approaches may be effective in individual patients. Achieving the glycemic goals of therapy is far more important than the details of the insulin regimen. Nevertheless, one of the following three general approaches to therapy is most likely to lead to the desired outcome.

Combination of Rapid-Acting and Intermediate-Acting Insulin with Breakfast and Dinner and Intermediate-Acting Insulin at Bedtime

The rationale for these regimens is that the rapid-acting insulin (regular, lispro, or aspart) limits the postprandial glycemia after breakfast and dinner, the intermediate-acting insulin (NPH or Lente) administered before breakfast limits glycemia in the afternoon, and the intermediate-acting insulin before dinner limits glycemia in the early hours of the morning. Although such a regimen may be sufficient to achieve glucose targets in some patients, in many individuals the intermediate-acting insulin given before dinner is insufficient to control elevations in blood glucose commonly seen in the early morning (dawn phenomenon). Attempts to increase the dose of intermediate-acting insulin at dinner expose the patient to a greater risk of hypoglycemia in the middle of the night, hence the need for a smaller dose at bedtime to provide sufficient insulin to restrain the dawn phenomenon the following morning while moderating the risk of nocturnal hypoglycemia. This three-injection regimen was the mainstay of therapy in the DCCT but is rapidly being supplanted by regimens that take greater advantage of the availability of insulin analogues.

Combination of Rapid-Acting Insulin Given with Meals and Long-Acting Insulin at Bedtime

This combination of insulins can also simulate the pattern of insulin production that occurs normally. Use of monomeric insulin analogues provides excellent meal coverage. Use of insulin glargine provides excellent control of the fasting plasma glucose. This combination of rapid-acting monomeric insulin analogues with insulin glargine is rapidly supplanting human insulin-based treatment regimens as it seems to be associated with less variability in glycemic control associated with lower risks of hypoglycemia. Human Ultralente can be used as the basal insulin in such a regimen but would generally need to be administered twice daily.

Insulin Administration by an External Insulin Pump

An alternative method of delivering insulin is by an external mechanical pump. This approach involves the administration of a rapidly acting insulin preparation delivered by continuous subcutaneous infusion through a catheter usually inserted into the subcutaneous tissues of the anterior abdominal wall. The pumps deliver insulin as a programmed basal infusion as well as patient-directed boluses given before meals or snacks or in response to elevations in the blood glucose concentration outside the desired range. With currently available pumps, the basal insulin infusion rate (usually approximately 1 U/hour) can be programmed either to continue at a constant rate over the 24-hour period or more commonly to increase and decrease at predetermined times of the day to prevent anticipated excursions in the blood glucose concentration, for example, morning rises in glucose. Newer pumps provide the ability to use multiple basal profiles to deal with recurrent patterns (e.g., menstruation, weekends, activity). Protocols for insulin administration by the pump usually require approximately half the insulin to be administered as a basal infusion and the remainder as premeal boluses.

Insulin administration by an external pump has some advantages over regimens that utilize multiple insulin injections. Only rapidly acting insulin is used in the insulin pump. Consequently, adjustments to the basal insulin infusion rate or changes in the size and timing of the insulin boluses result in more rapid changes in the blood glucose concentration than are possible when adjustments are made to the dose of intermediate-acting or long-acting insulin. This leads to greater flexibility for the patient. It has been suggested that use of lispro insulin may lead to a lower risk of hypoglycemia.

However, there are also disadvantages of insulin pump therapy. There

CSII, continuous subcutaneous insulin infusion.

*Assumes preprandial target of 4.4 to 7.2 mmol/L (80 to 130 mg/dL). Initial supplements may be based on previous experience or 1500 rule (1500/total insulin dose = the effect of 1 U insulin on blood glucose decrease in mg/dL). Plans should be individualized for each patient. This example would likely be treated with 50 units per day of insulin. Refers to the amount of time between injecting the insulin and eating.*

is a significant initial cost of the pump itself. Furthermore, the tubing, which needs to be changed every 24 to 72 hours, and other supplies are expensive. The risk of infection at the site of insulin administration is significant. Infections occur on average once annually per patient even in the best of practices, and although these can usually be treated by changing the site of infusion and giving a short course of oral antibiotics, if an abscess develops surgical drainage may be necessary. In addition, because only rapidly acting insulin is used, pump failure as a result of mechanical malfunction or catheter-related problems can quickly result in severe
hyperglycemia and even ketoacidosis. Patients treated with insulin pump therapy must monitor glucose frequently and always be alert to the possibility of failure of the infusion system.

Controlled clinical trials have indicated that on average intensive insulin regimens that use multiple insulin injections lead to levels of glucose control similar to those achieved with the insulin pump. On the other hand, there are some patients who never achieve adequate control with multiple daily injections but experience dramatic improvements with pump therapy. According to the Clinical Practice Recommendations of the American Diabetes Association, the insulin pump should be used only by candidates strongly motivated to improve glucose control and willing to work with their health care provider in assuming substantial responsibility for their day-to-day care. They must also understand and demonstrate use of the insulin pump and self-monitoring of blood glucose and be able to use the data obtained in an appropriate fashion.
Algorithms of Insulin Administration

An essential component of intensive regimens of insulin replacement is the need to make regular adjustments to the insulin dose depending on the prevailing blood glucose concentration. Algorithms have been developed to guide these adjustments that aim to simulate the normal feedback control of insulin secretion whereby hyperglycemia stimulates and hypoglycemia inhibits insulin secretion. They all involve frequent monitoring of the blood glucose concentration, generally three or four times per day or more, with increases in the insulin dose if glucose levels are above the target upper level that is judged to be acceptable and reductions in the insulin dose if glucose levels are below the acceptable lower level. Many algorithms are in use; one example is shown in Table 30-7.
Complications of Insulin Therapy

Hypoglycemia

The most serious complication of intensive regimens of insulin replacement is hypoglycemia, and this is generally the factor that limits patients’ ability to achieve tight glucose control. In the DCCT, patients in the intensive treatment group had an approximately threefold greater risk of hypoglycemia than those in the conventional treatment group. Hypoglycemia may be life-threatening, leading to motor vehicle accidents, serious falls with fractures, and seizures. Patients with type 1 diabetes have serious defects in mechanisms responsible for glucose counterregulation, and this is a major underlying reason for the predisposition to hypoglycemia. Glucose counter-regulation is reviewed in detail in Chapter 32.

The risk of hypoglycemia can be reduced if all patients treated with intensive regimens of insulin replacement are carefully educated about recognition of hypoglycemic symptoms and measures that should be taken to avoid more serious hypoglycemia after symptoms are initially experienced. Certain patients, particularly those with long-standing diabetes and autonomic neuropathy, may not subjectively sense symptoms of hypoglycemia even in the presence of low glucose concentrations. Glycemic targets of therapy should be adjusted upward in these subjects because they are at particularly high risk of hypoglycemia. Similarly, patients with advanced end-stage microvascular or macrovascular diabetic complications in whom the benefit of intensive glucose control is likely to be less should not be exposed to the increased risk of hypoglycemia that is inherent in extremely intensive insulin treatment regimens.

In addition to the availability of glucose tablets, hard candy or other sources of a readily absorbable form of carbohydrate, all patients with type 1 diabetes should have emergency glucagon kits at home and at work, assuming that there are people in those settings who can be trained in their use. The administration of 0.5 to 1 mg of glucagon intramuscularly to a severely symptomatic person with hypoglycemia rapidly raises the plasma glucose concentration to an acceptable range and avoids the difficulties and dangers associated with attempting to get a stuporous or disoriented individual to ingest glucose by mouth. Nevertheless, because of occasional failures of glucagon to reverse hypoglycemia fully, friends and family members should always be instructed to call for medical assistance as soon as the injection is provided.

Weight Gain

Improvement in glucose control with a reduction in glycosuria is invariably associated with weight gain as the leakage of calories into the urine is reduced or eliminated. In addition, increased food intake to treat or prevent hypoglycemia can contribute to weight gain. Insulin itself may stimulate appetite. As a result of the combination of all these effects, weight gain is common, particularly with intensive regimens of insulin replacement.

Worsening of Retinopathy

Institution of regimens of tight glucose control has been reported to exacerbate the underlying retinopathy. Thus, if a patient with serious background or proliferative retinopathy presents in poor glucose control, consideration should be given to ophthalmologic treatment of the retinopathy before instituting tight glucose control.

Insulin Allergy

Insulin allergy has become much less common with the use of human insulin. Most manifestations of allergic reactions to insulin consist of local wheal-and-flare reactions at the site of injection. The allergic reaction can be to the insulin itself or to other components of the insulin preparation such as the protamine in NPH insulin. Occasionally, more generalized allergic reactions occur, and even more rarely anaphylactic reactions take place. In general, mild local allergic reactions to insulin can be treated with antihistamines. More severe reactions require desensitization. Admission to the hospital is necessary, and under close supervision of a physician with access to equipment for emergency resuscitation a protocol is followed in which the patient is exposed to gradually increasing amounts of insulin administered according to a set schedule.
ACUTE DIABETIC EMERGENCIES: DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) is a life-threatening condition in which severe insulin deficiency leads to hyperglycemia, excessive lipolysis, and unrestrained fatty acid oxidation producing the ketone bodies acetone, hydroxybutyrate, and acetoacetate. This results in metabolic acidosis, dehydration, and deficits in fluid and electrolytes. Excess secretion of primarily glucagon as well as catecholamines, glucocorticoids, and growth hormone in combination with insulin deficiency produces hyperglycemia by stimulating glycogenolysis and gluconeogenesis and impairing glucose disposal. DKA is a far more characteristic feature of type 1 than of type 2 diabetes but may be seen in persons with type 2 diabetes under conditions of stress such as occurs with serious infections, trauma, and cardiovascular or other emergencies.

Clinical Presentation

Patients with uncontrolled diabetes present with nonspecific complaints. If the disease follows an indolent course over months to years, patients can manifest profound wasting, cachexia, and prostration similar in degree to those of patients with long-standing malignancy or chronic infection. With significant physical or emotional stress, sudden metabolic decompensation can occur. The cases of DKA that are misdiagnosed usually occur in patients with new-onset diabetes. Polyuria (or at least nocturia) and weight loss are almost always present, although often not reported by the patient. Any patient with severe illness (acute or chronic) or neurologic changes should have glucose and electrolytes measured.

In DKA, metabolic decompensation usually develops over a period of hours to a few days. Patients with DKA classically present with lethargy and a characteristic hyperventilation pattern with deep slow breaths (Kussmaul's respirations) associated with the fruity odor of acetone. They often complain of nausea and vomiting, with abdominal pain being somewhat less frequent. The abdominal pain can be quite severe and may be associated with distention, ileus, and tenderness without rebound but usually resolves relatively quickly with therapy unless there is underlying abdominal pathology. Most patients are normotensive, tachycardic, and tachypneic with signs of mild to moderate volume depletion. Hypothermia has been described in DKA, and patients with underlying infection may not manifest fever. Cerebral edema does occur, generally during therapy. Patients with DKA can be stuporous with obvious profound dehydration and often demonstrate focal neurologic deficits such as Babinski’s reflexes, asymmetric reflexes, cranial nerve findings, paresis, fasciculations, and aphasia.
Laboratory Test Results and Differential Diagnosis

Laboratory tests that would be routinely monitored in the setting of DKA include the following:

1. Hemoglobin, white blood cell and differential count.
2. Glucose, creatinine, blood urea nitrogen (BUN), and serum potassium.
3. Serum sodium, chlorine, bicarbonate, and anion gap.

The sine qua non of DKA is acidosis, and the serum HCO₃⁻ concentration is usually less than 10 mEq/L. The acidosis is due to production and accumulation of ketones in the serum. Three ketones are produced in DKA: ketoacids, -hydroxybutyrate, and acetoacetate, as well as the neutral ketone aceton. Ketones can be detected in serum and urine using the nitroprusside reaction on diagnostic strips for use at the patient's bedside or in the clinical laboratory. This test detects -hydroxybutyrate more effectively than aceton and does not detect an increased concentration of -hydroxybutyrate. Particularly in severe DKA, -hydroxybutyrate is the predominant ketone, and it is possible although unusual to have a negative serum nitroprusside reaction in the presence of severe ketosis. However, under these circumstances the serum HCO₃⁻ is still markedly reduced and the anion gap is increased, indicative of the presence of metabolic acidosis. The urinary -hydroxybutyrate can be measured at many centers and commercially but is not usually readily available. The anion gap is a readily available index for unmeasured anions in the blood (normal < 14 mEq/L): Anion gap = sodium (chloride + bicarbonate) - lactate - protein - ketone.

Most patients with DKA present with an anion gap greater than 20 mEq/L, and some with a gap greater than 40 mEq/L. However, occasional patients have a hyperchloremic metabolic acidosis without a significant anion gap. Patients with DKA almost invariably have large amounts of ketones in their urine. The serum glucose in DKA is usually in the 500 mg/dL range. However, an entity known as euglycemic DKA has been described, particularly in the presence of decreased oral intake or in pregnancy, in which the serum glucose is normal or near normal but the patient requires insulin therapy for the clearance of ketoacidosis. The arterial pH is commonly less than 7.3 and can be as low as 6.5. There is partial respiratory compensation with hypocarbia. Patients are often mildly hyperosmolar, although osmolalities of greater than 330 mOsm/kg are unusual without mental status changes.

Not all patients with hyperglycemia and an anion gap metabolic acidosis have DKA and other causes of metabolic acidosis must be considered in these patients, particularly if the serum or urine ketone measurements are not elevated. The following causes of metabolic acidosis need to be considered in the differential diagnosis of DKA.

1. Lactic acidosis is the most common cause of metabolic acidosis in hospitalized patients and can be seen in patients with uncomplicated diabetes as well as those with DKA. Lactic acidosis usually occurs in the setting of decreased tissue oxygen delivery resulting in the nonoxidative metabolism of glucose to lactic acid. Lactic acidosis complicates other primary metabolic acidoses as a consequence of dehydration or shock, and assessing its relative contribution can be difficult. The presentation is identical to that of DKA. In pure lactic acidosis, the serum glucose and ketones should be normal and the serum lactate concentration should be greater than 5 mM. The therapy of lactic acidosis is directed at the underlying cause and optimizing tissue perfusion.

2. Starvation ketosis results from inadequate carbohydrate availability resulting in physiologically appropriate lipolysis and ketone production to provide fuel substrates for muscle. The blood glucose is usually normal. Although the urine can have large amounts of ketones, the blood rarely does. Arterial pH is normal, and the anion gap is at most mildly elevated.

3. Alcoholic ketoacidosis is a more severe form of starvation ketosis wherein the appropriate ketogenic response to poor carbohydrate intake is increased through as yet poorly defined effects of alcohol on the liver. Classically, these patients are long-standing alcoholics for whom ethanol has been the main caloric source for days to weeks. The ketoacidosis occurs when for some reason alcohol and caloric intake decreases. In isolated alcoholic ketoacidosis, the metabolic acidosis is usually mild to moderate in severity. The anion gap is elevated. Serum and urine ketones are always present. However, alcoholic ketoacidosis produces an even higher ratio of -hydroxybutyrate to acetoacetate than DKA, and negative or weakly positive nitroprusside reactions are common. Respiratory alkalosis associated with delirium tremens, agitation, or pulmonary processes often normalizes the pH but should be evident with careful analysis of acid-base status. Usually, the patient is normoglycemic or hypoglycemic, although mild hyperglycemia is occasionally present. Patients who are significantly hyperglycemic should be treated as if they have DKA. The therapy of alcoholic ketoacidosis consists of thiamine, carbohydrates, fluids, and electrolytes with special attention to the more severe consequences of alcohol toxicity, alcohol withdrawal, and chronic malnutrition. In more severely ill patients in whom alcoholic ketoacidosis is considered a possibility, there is usually another underlying illness such as pancreatitis, gastrointestinal bleeding, hepatic encephalopathy, delirium tremens, or infection complicated by concomitant lactic acidosis.

4. Uremic acidosis is characterized by extremely large elevations in the BUN (often > 200) and creatinine (>10) with normoglycemia. The pH and anion gap are usually only mildly abnormal. The treatment is supportive with careful attention to fluid and electrolytes until dialysis can be performed. Rhabdomyolysis is a cause of renal failure in which the anion gap can be significantly elevated and acidosis can be severe. There should be marked elevation of creatine phosphokinase and myoglobin. It should be noted that mild rhabdomyolysis is not uncommon in DKA, but the presence of hyperglycemia and ketonemia leaves no doubt about the primary etiology of the acidosis.

5. Toxic ingestions can be differentiated from DKA by history and laboratory investigation. Salicylate intoxication produces an anion gap metabolic acidosis usually with a respiratory alkalosis. The plasma glucose is normal or low, the osmolality normal, ketones negative, and salicylates can be detected in the urine or blood. It should be noted that salicylates can cause a false-positive glucose determination when using the cupric sulfate method and a false-negative result when using the glucose oxidase reaction. Methanol and ethylene glycol also produce an anion gap metabolic acidosis without hyperglycemia or ketones but need to be kept in mind primarily because they produce an increase in the measured serum osmolality but not in the calculated serum osmolyte osmolar gap. Their serum levels can also be measured. Isopropyl alcohol does not cause a metabolic acidosis but should be remembered because it is metabolized to aceton, which can produce a positive result in the nitroprusside reaction commonly used for the detection of ketoads. These intoxications must be appropriately treated.

Rare cases of anion gap acidoses have been reported with other ingestions including toluene, iron, hydrogen sulfide, nalidixic acid, papaverine, paraldehyde, strychnine, isoniazid, and outdated tetacycline.

When DKA is considered, the diagnosis can be made quickly with routine laboratory tests. Blood and urine glucose and ketones can be obtained in minutes with glucose oxidase/impregnated strips and the nitroprusside reaction, respectively.

Osmolality

The increase in osmolality that occurs in DKA is must be differentiated from the increase in osmolality seen in hyperosmolar-hyperglycemic nonketotic (diabetic) coma (HHNC). The osmolality can be measured by freezing point depression or estimated using the following formula: Osmolarity (mOsm/L) = 2 × sodium + glucose/18 + urea/2.8 + ethanol/4.6

Patients with DKA not uncommonly present with hyperosmolarity and coma. In HHNC, the osmolality is generally greater than 350 mOsm/L and can exceed 400 mOsm/L. The serum sodium and potassium can be high, normal, or low and do not reflect total-body levels, which are uniformly depleted. The glucose is usually greater than 600 mg/dL, and levels over 1000 mg/dL are quite common. In pure HHNC, there is not a significant metabolic acidosis or anion gap.

It should be remembered that patients often present with combinations of the preceding findings. HHNC can involve mild to moderate ketonemia and acidosis. Alcoholic ketoacidosis can contribute to either DKA or HHNC. Lactic acidosis is common in severe DKA and HHNC. Any patient with hyperglycemia greater than 250 mg/dL and an anion gap metabolic acidosis should be treated by the general principles outlined in the following with special consideration of other possible...
contributing metabolic acidoses.
Therapy

The optimal management of DKA has been the source of considerable controversy over the past half-century. Only recently have prospective studies of various therapeutic approaches been performed. The guidelines we propose rely heavily on prospective studies of DKA by Kitabchi and co-workers. The general approach is to (1) provide necessary fluids to restore the circulation, (2) treat insulin deficiency with continuous insulin, (3) treat electrolyte disturbances, (4) observe the patient closely and carefully, and (5) search for underlying causes of metabolic decompensation.

Fluids

Volume contraction is one of the hallmarks of DKA. It can contribute to acidosis through lactic acid production as well as decreased renal clearance of organic and inorganic acids. It contributes to hyperglycemia by decreasing renal clearance of glucose. If decreased tissue perfusion is significant, it causes insulin resistance by decreasing insulin delivery to the sites of insulin-mediated glucose disposal, namely muscle and adipose tissue, as well as through stimulation of catecholamine and glucocorticoid secretion. Fluid deficits on the order of 5 to 10 L are common in DKA. It should be remembered that the urine produced during the osmotic diuresis of hyperglycemia is approximately half-normal with respect to sodium. Therefore, water deficits are in excess of sodium deficits. Historically, large quantities of isotonic intravenous fluids have been administered rapidly to patients in DKA. Therefore, patients with a history of congestive heart failure, chronic or acute renal failure, severe hypotension, or significant pulmonary disease, early invasive hemodynamic monitoring should be considered.

When there is physical evidence of dehydration that is, hypotension, decreased skin turgor, or dry mucous membranes administer 1 L of normal saline over the first hour and 200 to 500 mL/hour in subsequent hours until hypotension resolves and adequate circulation is maintained. If hypotension is severe with clinical evidence of hyperperfusion and does not respond to crystalloid, therapy with colloid is considered, often in combination with invasive hemodynamic monitoring. If there is no hypotension and no concern about renal failure, administer 1 L of half-normal saline over the first hour.

During that first hour, the laboratory data usually return and can be quite helpful in planning further therapy. Despite the excess of water losses over sodium, the measured sodium is usually low because of osmotic effects of glucose. These osmotic effects can be corrected using a simple formula: Corrected sodium concentration = measured sodium + 0.016(glucose 100) - (sodium/140) 1

Severe hypertglycemia, which is common in severe diabetes, can cause a false decrease in the serum sodium concentration by approximately 1.0 mEq/L at a serum lipid concentration of 460 mg/dL. An estimated water deficit can be calculated using the corrected sodium: Water deficit in liters = 0.6 (weight in kg - corrected sodium) - (sodium/140)

Using these formulas, a 70-kg patient with a measured sodium level of 140 mEq/L and a glucose concentration of 1000 mg/dL would have a calculated water deficit of 4.3 L. If the patient is normotensive after the first liter of fluids, it would be reasonable to aim to replace urinary losses with one-half normal saline and also provide approximately one half the water deficit as 5% dextrose over the first 12 to 24 hours (using the preceding example, 2 L) and the remainder over the subsequent 24 hours. The plan for fluid therapy should be continuously reevaluated in light of the clinical and laboratory response of the patient. When the serum glucose reaches 250 to 300 mg/dL, all fluids should contain 5% dextrose and therapy should be aimed at maintaining the serum glucose in that range for 24 hours to allow slow equilibration of osmotically active substances across cell membranes.

The primary goal of fluid therapy is to maintain an adequate circulation and secondly to maintain a brisk diuresis. Beyond that, pulmonary edema, hyperchloremic metabolic acidosis, and a rapid fall in the serum osmolality should be avoided by frequent monitoring of the patient, glucose, and electrolytes. It has been demonstrated that fluid administration and subsequent continued osmotic diuresis are responsible for a large portion of the initial decline in glucose during therapy.

Insulin

Insulin is the mainstay of therapy of DKA because it is essentially an insulin-deficient state. In the past, high doses of insulin (upward of 50 U/hour) were favored. In later studies, low-dose insulin therapy (0.1 U/kg per hour) has been shown to be as effective as higher doses in producing a decrease in serum glucose and clearance of ketones. Furthermore, low-dose therapy results in a reduction in the major morbidity of intensive insulin therapy, namely hypoglycemia and hypokalemia.

Studies have also shown that intravenous insulin is significantly more effective than intramuscular or subcutaneous insulin in lowering the ketone body concentration over the first 2 hours of therapy. The subcutaneous route is inappropriate for the critically ill patient because of the possibility of tissue hypoperfusion and slower kinetics of absorption. There are numerous studies that attest to the efficacy of intramuscular therapy in severe DKA. In cases in which there is insufficient nursing monitoring or intravenous access to allow safe intravenous administration, intramuscular therapy would be the route of choice.

Lastly, it has been shown that a 10-U intravenous insulin priming dose when insulin therapy is started significantly improves the glycemic response to the first hour of therapy. The rationale is to saturate insulin receptors fully before beginning continuous therapy and to avoid the lag time necessary to achieve steady-state insulin levels. When mixing insulin in normal saline, it does not seem to be necessary to add albumin to prevent insulin adsorption to the infusion set. However, the intravenous tubing should be flushed with the insulin infused before use.

In the rare instances in which the glucose does not decrease at least 10% or 50 mg/dL in an hour, the insulin infusion rate should be increased by 50% to 100% and a second bolus of intravenous insulin administered. As the glucose level decreases, it is usually necessary to decrease the rate of infusion. After the glucose reaches approximately 250 mg/dL, it is prudent to decrease the insulin infusion rate and administer dextrose. It usually takes an additional 12 to 24 hours to clear ketones from the circulation after hyperglycemia is controlled. With resolution of ketosis, the rate of infusion approaches the physiologic range of 0.3 to 0.5 U/kg per day.

When the decision is made to feed the patient, the patient should be switched from intravenous or intramuscular therapy to subcutaneous therapy. Subcutaneous insulin should be administered before a meal and the insulin drip discontinued approximately 30 minutes later. The glucose should be checked in 2 hours and at least every 4 hours subsequently until a relatively stable insulin regimen is determined.

Potassium

Potassium losses during the development of DKA are usually quite high (3 to 10 mEq/kg) and are mediated by shifts to the extracellular space secondary to acidosis and protein catabolism compounded by hyperaldosteronism and osmotic diuresis. Although most patients with DKA or HHNC have normal or even high serum potassium at presentation, the initial therapy with fluids and insulin causes it to fall.

Our approach has been to monitor the electrocardiogram (ECG) for signs of hyperkalemia (peaked T wave, QRS widening) initially and to administer potassium if these are absent and the serum potassium is less than 5.5 mEq/L. If the patient is oliguric, we do not administer potassium unless the serum concentration is less than 4 mEq/L, or there are ECG signs of hypokalemia (U wave), and even then it is done with extreme caution. With therapy of DKA, the potassium level always falls, usually reaching a nadir after several hours. We usually replace potassium at 10 to 20 mEq/hour, one half as potassium chloride and one half as potassium phosphate, and monitor serum levels at least every 2 hours initially as well as follow ECG morphology. Occasionally, patients with DKA who have had protracted courses with vomiting present with hypokalemia and acidosis and may require 40 to 80 mEq/hour by central line to avoid further decreases in the serum potassium.
Like potassium, phosphate is depleted in patients with DKA. Although patients usually present with elevated serum phosphate, the serum level declines with therapy. No well-documented clinical significance of these findings has been determined and no benefit of phosphate administration has been demonstrated, but most authorities recommend phosphate therapy as before and monitoring for its possible complications—hypocalcemia and hypomagnesemia.

**Bicarbonate**

Serum bicarbonate is always low in DKA, but a true deficit is not present because the ketoacid and lactate anions are metabolized to bicarbonate during therapy. The use of bicarbonate in the therapy of DKA is highly controversial. No benefit of bicarbonate therapy has been demonstrated in clinical trials. In fact, in two trials, hypokalemia was more common in bicarbonate-treated patients. There are theoretical considerations against the use of bicarbonate. Cellular levels of 2,3-diphosphoglycerate are depleted in DKA, causing a shift in the oxyhemoglobin dissociation curve to the left and thus impairing tissue oxygen delivery. Acidemia has the opposite effect, and therefore reversing acidosis acutely could decrease tissue oxygen delivery. In addition, there are in vitro data suggesting that pH is a regulator of cellular lactate metabolism and correction of acidosis could increase lactate production. These observations are of questionable clinical relevance, however.

We reserve bicarbonate therapy for use (1) in patients with severe acidosis (pH < 6.9), (2) in the presence of hemodynamic instability if the pH is less than 7.1, or (3) in cases of hyperkalemia with ECG findings. When bicarbonate is used, it should be used sparingly and considered a temporizing measure while definitive therapy with insulin and fluids is under way. Approximately 1 mEq/kg of bicarbonate is administered as a rapid infusion over 10 to 15 minutes with further therapy based on repeated arterial blood gases every 30 to 120 minutes. Potassium therapy should be considered before treatment with bicarbonate as transient hypokalemia is not an uncommon complication of the administration of alkali.

**Monitoring**

It is possible to manage many cases of mild DKA without admission to the intensive care unit, depending on staff availability. We routinely admit patients with DKA to the intensive care unit if they have a pH less than 7.3. If mental status is compromised, prophylactic intubation is considered and nasogastric suctioning is always performed because of frequent ileus and danger of aspiration. If the patient cannot void at will, bladder catheterization is necessary to follow urine output adequately. ECG monitoring is continuous with hourly documentation of QRS intervals as well as T-wave morphology. Initially, serum glucose, electrolytes, BUN, creatinine, calcium, magnesium, phosphate, ketones, lactate, creatine phosphokinase, and liver function tests as well as urinalysis, ECG, upright chest radiograph, complete blood count, and arterial blood gases are obtained. If there is any concern about possible toxic ingestions, toxicology screening is also performed. Subsequently, glucose and electrolytes are measured at least hourly, calcium, magnesium, and phosphate every 2 hours; and BUN, creatinine, and ketones every 6 to 24 hours.

It is often not necessary to monitor arterial blood gases routinely because bicarbonate and anion gap are relatively good indices of the response to therapy. Monitoring venous pH has also been shown to reflect acidemia and response to therapy adequately. Usually, frequent blood work is necessary only for the first 12 hours or so. In the severely ill patient with obvious underlying disease, the course is often more protracted and, particularly when venous access is a problem, early consideration should be given to placement of an arterial line. A flow sheet tabulating these findings as well as mental status, vital signs, insulin dose, fluid, and electrolytes administered, and urine output allows easy analysis of response to therapy. When the acidosis begins to resolve and the response to therapy becomes predictable, it is reasonable to curtail laboratory use. If cardiovascular status is unclear or troublesome, invasive hemodynamic monitoring is an appropriate guide for fluid therapy. The goals should be to achieve hemodynamic stability rapidly and to correct DKA fully in 12 to 36 hours.

**Search for Underlying Causes**

After stabilizing the patient, a careful history and physical examination and a diagnostic strategy should be aimed at determining the precipitating event. In most inner-city practices, the most common cause of DKA is noncompliance with insulin therapy and is usually easily treated. The second most common cause is infection, with viral syndromes, urinary tract infection, pelvic inflammatory disease, and pneumonia predominating. It is often difficult to determine initially whether the patient is infected. Fever can be absent in a significant proportion of patients with diabetic emergencies. The white blood cell count is not uncommonly elevated in the range of 20,000 or higher even in the absence of infection. As a result, cultures should be performed for most patients, and if there is significant concern about infection, empirical broad antibiotic coverage should be considered pending microbiologic findings.

Special consideration should be given to ruling out meningitis in the patient with altered mental status. In this regard, most would perform lumbar punctures in all patients with meningismus and in patients with disproportionate mental status changes. If the index of suspicion is lower, a head CT is performed, and if normal, a lumbar puncture should be performed. The cerebrospinal fluid glucose is not particularly useful in determining whether the fluid is infected, and a cerebrospinal fluid glucose level less than 100 mg/dL is unusual when the serum glucose is greater than 250 mg/dL. The relative frequency of sinus infection (particularly Mucor), foot infection, bacterial arthritis, cholecystitis, cellulitis, and necrotizing fasciitis should also be considered.

Pneumonia can be difficult to diagnose in patients with dehydration because the alveolar edema fluid that shows up as an infiltrate on chest radiographs is often not present but develops along with progressive hypoxia during hydration. To avoid this occurrence, we administer intravenous fluid judiciously to patients we suspect have pneumonia. Pancreatitis and pregnancy are common precipitants and should be especially considered when assessing the abdominal pain that is almost ubiquitous at presentation. Abdominal guarding and tenderness associated with vomiting are common, and rebound is occasionally present. These symptoms and findings usually resolve quickly with therapy in the absence of intra-abdominal pathology. The serum amylase is often elevated without pathologic significance, although lipase is usually more specific. Acute myocardial infarction and stroke as well as thromboembolic phenomena are frequent precipitants and complications of DKA.

The more insulin resistant the patient seems to be, the more likely one is to find a precipitating cause. If a precipitating cause is found, treatment is essential if adequate metabolic control is to be achieved.
Complications and Prognosis

It should now be possible to treat almost all cases of DKA successfully. The most troublesome complication is cerebral edema. It is common particularly in children and can be fatal. In most series, specific causes could not be assigned, although aggressive hydration, particularly with hypotonic fluids, may contribute. In 50% of patients who subsequently had a respiratory arrest, there were premonitory symptoms, and despite early intervention only half of them avoided severe or fatal brain damage. Other complications of life-threatening severity that have been reported include the acute respiratory distress syndrome and bronchial mucous plugging. Arterial and venous thromboembolic events are quite common. Standard prophylactic low-dose heparin is certainly reasonable in patients with DKA, but currently no indication exists for full anticoagulation.

Chapter 31 - Complications of Diabetes Mellitus

BIOCHEMISTRY AND MOLECULAR CELL BIOLOGY

All forms of diabetes, both inherited and acquired, are characterized by hyperglycemia, a relative or absolute lack of insulin, and the development of diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nerve. Diabetes is also associated with accelerated atherosclerotic macrovascular disease affecting arteries that supply the heart, brain, and lower extremities. Pathologically, this condition resembles macrovascular disease in nondiabetic patients but is more extensive and progresses more rapidly. As a consequence of its microvascular pathology, diabetes mellitus is now the leading cause of new blindness in people 20 to 74 years of age and the leading cause of end-stage renal disease (ESRD).

People with diabetes mellitus are the fastest growing group of renal dialysis and transplant recipients. The life expectancy of patients with diabetic end-stage renal failure is only 3 or 4 years. More than 60% of diabetic patients are affected by neuropathy, which includes distal symmetrical polyneuropathy.

Figure 31-1 Relative risks for the development of diabetic complications at different levels of mean hemoglobin A1c (HbA1c, glycated hemoglobin), obtained from the Diabetes Control and Complications Trial. (Adapted from Skyler J: Diabetic complications: the importance of glucose control. Endocrinol Metab Clin North Am 1996, 25:243254.)

Large, prospective clinical studies show a strong relationship between glycemia and diabetic microvascular complications in both type 1 and type 2 diabetes mellitus. There is a continuous, though not linear, relationship between level of glycemia and the risk of development and progression of these complications. Hyperglycemia and the dyslipidemia induced by insulin resistance both appear to play important roles in the pathogenesis of macrovascular complications.

Shared pathophysiologic features of microvascular complications

In the retina, glomerulus, and vasa nervorum, diabetes-specific microvascular disease is characterized by similar pathophysiologic features.

Requirement for Intracellular Hyperglycemia

Clinical and animal model data indicate that chronic hyperglycemia is the central initiating factor for all types of diabetic microvascular disease. Duration and magnitude of hyperglycemia are both strongly correlated with the extent and rate of progression of diabetic microvascular disease. In the Diabetes Control and Complications Trial (DCCT), for example, type 1 diabetic patients whose intensive insulin therapy resulted in hemoglobin A1c levels 2% lower than those receiving conventional insulin therapy had a 76% lower incidence of retinopathy, a 54% lower incidence of nephropathy, and a 60% reduction in neuropathy.

Although all diabetic cells are exposed to elevated levels of plasma glucose, hyperglycemic damage is limited to those cell types (e.g., endothelial cells) that develop intracellular hyperglycemia. Endothelial cells develop intracellular hyperglycemia because, unlike many other cells, they cannot down-regulate glucose transport when exposed to extracellular hyperglycemia. As illustrated in Figure 31-2, vascular smooth muscle cells, which are not damaged by hyperglycemia, show an inverse relationship between extracellular glucose concentration and subsequent rate of glucose transport measured as 2-deoxyglucose uptake. In contrast, vascular endothelial cells show no significant change in subsequent rate of glucose transport after exposure to elevated glucose concentrations. That intracellular hyperglycemia is necessary and sufficient for the development of diabetic pathology is further demonstrated by the fact that overexpression of the GLUT1 glucose transporter in mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype, inducing the same increases in collagen type IV, collagen type I, and fibronectin gene expression as diabetic hyperglycemia.
Abnormal Endothelial Cell Function

Early in the course of diabetes mellitus, before structural changes are evident, hyperglycemia causes abnormalities in blood flow and vascular permeability in the retina, glomerulus, and peripheral nerve vasa nervorum. The increase in blood flow and intracapillary pressure is thought to reflect hyperglycemia-induced decreased nitric oxide (NO) production on the efferent side of capillary beds, and possibly an increased sensitivity to angiotensin II. As a consequence of increased intracapillary pressure and endothelial cell dysfunction, retinal capillaries exhibit increased leakage of fluorescein and glomerular capillaries have an elevated albumin excretion rate (AER). Comparable changes occur in the vasa vasorum of peripheral nerve. Early in the course of diabetes, increased permeability is reversible; as time progresses, however, it becomes irreversible.

**Figure 31-3** Overexpression of GLUT1 in mesangial cells cultured in normal glucose mimics the diabetic phenotype. Mesangial cells transfected with either LacZ (MCLacZ) or GLUT1 (MCGT1)-expressing constructs were cultured in 5-mM glucose, and the amount of the indicated matrix components secreted was determined. (From Heilig CW, Concepcion LA, Riser BL, et al. Overexpression of glucose transporters in rat mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype. J Clin Invest 1995; 96:18021814.)
Increased Vessel Wall Protein Accumulation

The common pathophysiologic feature of diabetic microvascular disease is progressive narrowing and eventual occlusion of vascular lumina, which results in inadequate perfusion and function of the affected tissues. Early hyperglycemia-induced microvascular hypertension and increased vascular permeability contribute to irreversible microvessel occlusion by three processes:

The first is an abnormal leakage of periodic acid-Schiff (PAS)-positive, carbohydrate-containing plasma proteins, which are deposited in the capillary wall and which may stimulate perivascular cells such as pericytes and mesangial cells to elaborate growth factors and extracellular matrix.

The second is extravasation of growth factors, such as transforming growth factor-β1 (TGF-β1), which directly stimulates overproduction of extracellular matrix components, and may induce apoptosis in certain complication-relevant cell types.

The third is hypertension-induced stimulation of pathologic gene expression by endothelial cells and supporting cells, which include glut-1 glucose transporters, growth factors, growth factor receptors, extracellular matrix components, and adhesion molecules that can activate circulating leukocytes. The observation that unilateral reduction in the severity of diabetic microvascular disease occurs on the side with ophthalmic or renal artery stenosis is consistent with this concept.
