Microvascular Cell Loss and Vessel Occlusion

The progressive narrowing and occlusion of diabetic microvascular lumina are also accompanied by microvascular cell loss. In the retina, diabetes mellitus induces programmed cell death of Müller cells and ganglion cells, pericytes, and endothelial cells. In the glomerulus, declining renal function is associated with widespread capillary occlusion and podocyte loss, but the mechanisms underlying glomerular cell loss are not yet known. In the vasa nervorum, endothelial cell and pericyte degeneration occur, and these microvascular changes appear to precede the development of diabetic peripheral neuropathy. The multifocal distribution of axonal degeneration in diabetes supports a causal role for microvascular occlusion, but hyperglycemia-induced decreases in neurotrophins may contribute by preventing normal axonal repair and regeneration.

Figure 31-4 Development of retinopathy during posthyperglycemic normoglycemia (“hyperglycemic memory”). Quantitation of retinal microaneurysms and acellular capillaries in normal dogs, dogs with poor glycemic control for 5 years, dogs with good glycemic control for 5 years, dogs with poor glycemic control for 2.5 years (P G), and the same dogs after a subsequent 2.5 years of good glycemic control (P G). (Adapted from Engerman RL, Kern TS. Progression of incipient diabetic retinopathy during good glycemic control. Diabetes 1987; 36:808-812.)
Development of Microvascular Complications During Posthyperglycemic Euglycemia ("Hyperglycemic Memory")

Another common feature of diabetic microvascular disease has been termed hyperglycemic memory, or the persistence or progression of hyperglycemia-induced microvascular alterations during subsequent periods of normal glucose homeostasis. The most striking example of this phenomenon is the development of severe retinopathy in histologically normal eyes of diabetic dogs that occurred entirely during a 2.5-year period of normalized blood glucose that followed 2.5 years of hyperglycemia (Fig. 31-4). Normal dogs were compared to diabetic dogs with either poor control for 5 years, good control for 5 years, or poor control for 2.5 years (P G a) followed by good control for the next 2.5 years (P G b). Hb A1c values for both the good control group and the P G b group were identical to the normal group. Hyperglycemia-induced increases in selected matrix gene transcription also persist for weeks after restoration of normoglycemia in vivo, and a less pronounced, but qualitatively similar, prolongation of hyperglycemia-induced increase in selected matrix gene transcription occurs in cultured endothelial cells. 24

Data from the DCCT study suggest that hyperglycemic memory occurs in patients. In the secondary-intervention cohort, there was no difference in the incidence of sustained progression of retinopathy for the first 3 years, no difference in development of clinical albuminuria for 4 years, and no difference in the rate of change in creatinine clearance during the entire study. For neuropathy, the sural nerve sensory conduction velocity did not differ between the groups for 4 years, and intensive therapy did not slow the rate of decline of autonomic function at all. 25, 26, 27 Even more strikingly, the effects of former intensive and conventional therapy on the occurrence and severity of retinopathy and nephropathy were shown to persist for 4 years after the DCCT, despite nearly identical glycosylated hemoglobin values during the 4-year follow-up (8.2% versus 7.9%, respectively) (Fig. 31-5). 26 Together, these observations from animal and clinical studies imply that hyperglycemia induces prolonged and sometimes irreversible changes in long-lived intracellular molecules that persist and cause continued pathologic function in the absence of continued hyperglycemia.
Genetic Determinants of Susceptibility to Microvascular Complications

Clinicians have long observed that different patients with similar duration and degree of hyperglycemia differed markedly in their susceptibility to microvascular complications. Such observations suggested that genetic differences existed that affected the pathways by which hyperglycemia damaged microvascular cells. The leveling of risk of overt proteinuria after 30 years’ duration of type 1 diabetes at 27% is evidence that only a subset of patients are susceptible to development of diabetic nephropathy.\(^3\)

![Figure 31-6 Familial clustering of diabetic nephropathy. Prevalence of diabetic nephropathy in two studies of diabetic siblings of probands with or without diabetic nephropathy.](image)

A role for genetic determinant of susceptibility to diabetic nephropathy is most strongly supported by the demonstration of familial clustering of diabetic nephropathy. In two studies of families with two or more siblings having type 1 diabetes, if one diabetic sibling had advanced diabetic nephropathy, the other diabetic sibling had a nephropathy risk of 83% or 72%; in contrast, the risk was only 17% or 22% if the index patient did not have diabetic nephropathy (Fig. 31-6).\(^3\)\(^,\)\(^4\)\(^,\)\(^5\) For retinopathy, the DCCT reported familial clustering as well, with an odds ratio of 5.4 for the risk of severe retinopathy in diabetic relatives of positive versus negative subjects from the conventional treatment group.\(^6\)\(^,\)\(^7\)\(^,\)\(^8\)

Numerous associations have been made between various genetic polymorphisms and the risk of various diabetic complications. Examples include the 5’ insulin gene polymorphism,\(^9\) the G2m\(^23\) immunoglobulin allotype,\(^10\) angiotensin-converting enzyme (ACE) insertion/deletion polymorphisms,\(^11\)\(^12\) HLA-DQB1*0201/0302 alleles,\(^13\)\(^14\) polymorphisms of the aldose reductase gene,\(^15\)\(^16\) and a polymorphic CCTTT (n) repeat of NO synthetase (NOS) 2A.\(^17\) In all of these studies, there is no indication that the polymorphic gene actually plays a functional role rather than simply being in linkage disequilibrium with the locus encoding the unidentified relevant genes.
PATHOPHYSIOLOGIC FEATURES OF MACROVASCULAR COMPLICATIONS

Unlike microvascular disease, which occurs only in patients with diabetes mellitus, macrovascular disease resembles that in subjects without diabetes. However, subjects with diabetes have more rapidly progressive and extensive cardiovascular disease (CVD), with a greater incidence of multivessel disease and a greater number of diseased vessel segments than nondiabetic persons. Although dyslipidemia and hypertension occur with great frequency in type 2 diabetic populations, there is still excess risk in diabetic subjects after adjusting for these other risk factors. Diabetes itself may confer 75% to 80% of the excess risk of coronary disease in these diabetic subjects, and it enhances the deleterious effects of the other major cardiovascular risk factors.

In subjects with or without diabetes, atherosclerosis begins with endothelial dysfunction or injury. These endothelial changes or injury induce the secretion of chemokines such as monocyte chemoattractant protein 1 ( MCP-1 ), increase the expression of endothelial adhesion molecules for leucocytes and platelets, and enhance permeability to lipoproteins and other plasma components. As detailed in Chapter 34 , this leads to recruitment of monocyte-macrophages to the subendothelial space and to the infiltration of plasma LDL, which binds to arterial proteoglycan. The retained LDL then undergoes oxidation and is taken up by macrophages.

Activated macrophages and other leukocytes, as well as adherent aggregated platelets, stimulate smooth muscle cell proliferation and elaboration of extracellular matrix, culminating in the formation of a complex lesion filled with prothrombotic material contained by a fibrin cap. Rupture of this fibrin cap by matrix metalloproteinases causes thrombus formation and arterial occlusion. Because macrovascular disease also occurs in nondiabetic subjects, diabetes is thought to accelerate the process by increasing endothelial cell dysfunction and by exacerbating dyslipidemia.

The pathogenesis of endothelial cell dysfunction in diabetic arteries appears to involve both insulin resistance and hyperglycemia. In vitro studies suggest that insulin has both antiatherogenic and proatherogenic effects. One major antiatherogenic effect is the stimulation of endothelial NO production. NO released from endothelial cells is a potent inhibitor of platelet aggregation and adhesion to the vascular wall. Endothelial NO also controls the expression of genes involved in atherosclerosis. It decreases expression of the chemoktractant protein MCP-1, and of surface adhesion molecules such as CD11/CD18, P-selection, vascular cell adhesion molecule-1 ( VCAM-1 ), and intercellular adhesion molecule-1 ( ICAM-1 ). Endothelial cell NO also reduces vascular permeability and decreases the rate of oxidation of low-density lipoprotein (LDL) to its proatherogenic form.

Finally, endothelial cell NO inhibits proliferation of vascular smooth muscle cells. Two major proatherogenic effects of insulin are the potentiation of platelet-derived growth factor (PDGF)-induced vascular smooth muscle cell (VSMC) proliferation and the stimulation of VSMC plasminogen activator inhibitor 1 (PAI-1) production. Since insulin-induced NO production is mediated by the insulin receptor substrate P13 kinase signal transduction pathway, while the effects on smooth muscle cells are mediated by the ras Raf mek kin signal kinase transduction pathway, it has been proposed that pathway-selective insulin resistance in arterial cells may contribute to diabetic atherosclerosis. Recently, evidence of such selective vascular resistance to insulin has been demonstrated in the obese zucker rat.

Hyperglycemia also inhibits arterial NO production, both in vivo and in vitro. Similarly, hyperglycemia potentiates PDGF-induced VSMC proliferation and stimulates endothelial cell PAI-1 production. In addition, hyperglycemia has a variety of other proatherogenic effects on endothelial cells, platelets, and monocyte/macrophages. These include increased expression of MCP-1, up-regulation of adhesion molecules such as ICAM-1 and VCAM-1, potentiation of collagen-induced platelet activation, and increased secretion of collagen type IV and fibronectin.

Both insulin resistance and hyperglycemia have been implicated in the pathogenesis of diabetic dyslipidemia as well. Insulin resistance is associated with a characteristic lipoprotein profile that includes a high very-low-density lipoprotein (VLDL), a low high-density lipoprotein (HDL), and small, dense LDL. Both low HDL and small, dense LDL are each independent risk factors for macrovascular disease. This profile arises as a direct result of increased net free fatty acid (FFA) release by insulin resistant adipocytes and small, dense LDL are each independent risk factors for macrovascular disease. This profile arises as a direct result of increased net free fatty acid (FFA) release by insulin resistant adipocytes.

of cholesteryl ester transfer protein, excess VLDL transfers significant amounts of triglyceride to both HDL and LDL while depleting HDL and LDL of cholesteryl ester. The resultant triglyceride-enriched HDL carries less cholesteryl ester reverse cholesterol transport to the liver, and loss of ApoA1, from these particles reduces the total concentration of HDL available for reverse cholesterol transport. The triglyceride-enriched, cholesteryl ester depleted LDL is smaller and denser than normal LDL, allowing it to penetrate the vessel wall and be oxidized more easily.

Hyperglycemia appears to contribute to diabetic dyslipidemia by causing delayed clearance of postprandial lipoproteins, resulting in elevated levels of atherogenic cholesterol-enriched remnant particles. This remnant clearance defect is caused by a hyperglycemia-induced reduction in expression of the heparin sulfate proteoglycan perlecain on hepatocytes. Perlecain interaction with apoB48 containing lipoprotein remnant particles is necessary for efficient uptake by the LDL receptor-related protein.

The importance of hyperlipidemia in the pathogenesis of diabetic macrovascular disease in patients with type 2 diabetes is underscored by recent studies validating that effective treatment of hyperlipidemia in such patients substantially reduces their risk of CVD. The importance of hyperglycemia in the pathogenesis of diabetic macrovascular disease is suggested by the observation that carotid wall thickness is increased in persons with established diabetes but not in persons with impaired glucose tolerance.

The United Kingdom Prospective Diabetes Study (UKPDS) identified hyperglycemia as an important risk factor for macrovascular disease in type 2 diabetes, and numerous correlational studies show that hyperglycemia is a continuous risk factor for macrovascular disease. Similarly, glycated hemoglobin A1c is an independent risk factor for CVD in type 1 diabetes. The relative importance of hyperglycemia in type 1 patients is suggested by the 41% reduction in macrovascular...
disease \( (P = .06) \) observed in the intensive therapy group of the DCCT.\[\]
Four major hypotheses about how hyperglycemia causes diabetic complications have generated a large amount of data as well as several clinical trials based on specific inhibitors of these mechanisms. Until recently, there was no unifying hypothesis linking these four mechanisms together, nor was there an obvious connection between any of these mechanisms, each of which responds quickly to normalization of hyperglycemia, and the phenomenon of hyperglycemic memory (see earlier).

### Increased Polyol Pathway Flux

#### Aldose Reductase Function

Aldose reductase (alditol:NAD(P)+ 1-oxidoreductase, EC 1.1.1.21) is a cytosolic, monomeric oxidoreductase that catalyzes the NADPH-dependent reduction of a wide variety of carbohydrate compounds including glucose. Triphosphopyridine nucleotide, reduced form of NADP (NADPH) is the cofactor in both this reaction and in the regeneration of glutathione by glutathione reductase. Aldose reductase has a low affinity (high Michaelis constant \([K_m]\)) for glucose, and at the normal glucose concentrations found in nondiabetic patients, metabolism of glucose by this path pathway constitutes a small percentage of total glucose utilization. In a hyperglycemic environment, however, increased intracellular glucose results in increased enzymatic conversion to the polyalcohol sorbitol, with concomitant decreases in NADPH. In the polyol pathway, sorbitol is oxidized to fructose by the enzyme sorbitol dehydrogenase, with NAD+ reduced to NADH.

#### Biochemical Consequences of Increased Polyol Pathway Flux

A number of mechanisms have been proposed to explain the potential detrimental effects of hyperglycemia-induced increases in polyol pathway flux. These include sorbitol-induced osmotic stress, decreased Na+/K+ ATPase activity, increased cytosolic NADH/NAD+, and decreased cytosolic NADPH. Sorbitol does not diffuse easily across cell membranes, and it was originally suggested that this resulted in osmotic damage to microvascular cells. However, sorbitol concentrations measured in diabetic vessels and nerves are far too low to cause osmotic damage.

Another early suggestion was that increased flux through the polyol pathway decreased Na+/K+ ATPase activity. Although this was originally thought to be mediated by polyol-pathway-linked decreases in phosphatidylinositol synthesis, it has been shown to result from activation of protein kinase C (PKC) (see later).

Hyperglycemia-induced activation of PKC increases cytosolic phospholipase A₂ activity, which increases the production of two inhibitors of Na+/K+ ATPase, arachidonate and prostaglandin E₂ (PGE₂)\(^{1,2}\).

More recently, it has been proposed that oxidation of sorbitol by NAD+ increases the cytosolic ratio of NADH/NAD⁺, thereby inhibiting activity of the enzyme glyceraldehyde-3-phosphate dehydrogenase and increasing concentrations of triose phosphate. \(^{1,3}\) Elevated triose phosphate concentrations could increase formation of both methylglyoxal, a precursor of advanced glycation end products (AGEs), and dialglycerol (DAG) (via -glycerol-3-phosphate), thus activating PKC (discussed in subsequent sections). Although increased NADH production is supported by the observation that hyperglycemia increases both lactate concentration and the lactate/pyruvate ratio, there is no direct evidence that the concentrations of NADH and NAD+ , as opposed to NADH and NAD⁺ flux, are altered. In endothelial cells, where aldose reductase activity is low, increased NADH production may also reflect hyperglycemia-induced increased flux through glycolysis \(^{1,2}\) and through the glucuronic acid pathway. \(^{1,2}\)

Other evidence presented in support of this hypothesis includes the observation that administration of pyruvate can prevent diabetes-related endothelial dysfunction in some systems. However, the observed effects of pyruvate on microvascular function may reflect its potent antioxidant properties rather than effects on the NADH/NAD⁺ ratio, because reactive oxygen species (ROS) also partially inhibit glyceraldehyde-3-phosphate dehydrogenase and increase glyceraldehyde-3-phosphate levels. \(^{1,2}\) The source of hyperglycemia-induced ROS is discussed later in this section.

It has also been proposed that reduction of glucose to sorbitol by NADPH consumes the cofactor NADPH. Because NADPH is required for regenerating reduced glutathione (GS), this could induce or exacerbate intracellular oxidative stress. Less reduced glutathione has in fact been found in the lens of transgenic mice that overexpress aldose reductase, and this is the most likely mechanism by which increased flux through the polyol pathway has deleterious consequences. \(^{1,2}\)

#### Hyperglycemia-induced inhibition of glucose-6-phosphate dehydrogenase, the major source of NADPH regeneration, may further reduce NADPH concentration in some vascular cells or neuronal cells. \(^{1,2}\)
Advanced Glycation End-Product Inhibitors

The hydrazine compound aminoguanidine was the first AGE inhibitor discovered, and its effect on diabetic pathology has been investigated in the retina, kidney, nerve, and artery. In the rat retina, diabetes causes a 19-fold increase in the number of acellular capillaries. Aminoguanidine treatment of diabetics prevented excess AGE accumulation and reduced the number of acellular capillaries by 80%. Diabetes-induced pericyte dropout also was markedly reduced by aminoguanidine treatments.

Similar results have been obtained in animal models of diabetic kidney disease. Diabetes increased AGEs in the renal glomerulus, and aminoguanidine treatment prevented this diabetes-induced increase. Untreated diabetic animals developed albuminuria that averaged 30 mg every 24 hours for 32 weeks. This was more than a 10-fold increase above control levels. Untreated diabetic animals also developed the characteristic structural feature of human diabetic nephropathy (i.e., increased fractional mesangial volume). When diabetic animals were treated with aminoguanidine, the increase was completely prevented. A structurally unrelated AGE inhibitor, OPB-9195, also prevented the development and progression of experimental diabetic nephropathy by blocking type IV collagen overproduction and normalizing the expression of TGF-.

In the peripheral nerve of diabetic rats, both motor nerve and sensory NCVs are decreased after 8 weeks of diabetes. Nerve action potential amplitude is decreased by 37% and peripheral nerve blood flow is decreased by 57% after 24 weeks of diabetes. Aminoguanidine treatment prevented each of these abnormalities of diabetic peripheral nerve function.

In a large randomized, double-blind, placebo-controlled, multicenter trial of aminoguanidine in type 1 diabetic patients with overt nephropathy, aminoguanidine lowered total urinary protein and slowed progression of nephropathy, over and above the effects of existing optimal care. In addition, aminoguanidine reduced the progression of diabetic retinopathy (defined as an increase by three or more steps in the Early Treatment Diabetic Retinopathy Study [ETDRS] scale).
Activation of Protein Kinase C

Mechanism of Hyperglycemia-Induced Protein Kinase C Activation

PKCs are a family of at least 11 isoforms, 9 of which are activated by the lipid second-messenger DAG. Intracellular hyperglycemia increases DAG content in cultured microvascular cells and in the retina and renal glomeruli of diabetic animals. Increased de novo synthesis of DAG activates PKC both in cultured vascular cells and in retina and glomeruli of diabetic animals. Increased DAG primarily activates the and isoforms of PKC, but increases in other isoforms have also been found, such as PKC- and PKC-epsilon isoforms in the retina and PKC- and PKC- in the glomerulus of diabetic rats.

Consequences of Hyperglycemia-Induced Protein Kinase C Activation

In early experimental diabetes, activation of PKC- isoforms has been shown to mediate retinal and renal blood flow abnormalities, perhaps by depressing NO production and increasing endothelin-1 activity. Abnormal activation of PKC has been implicated in the decreased glomerular production of NO induced by experimental diabetes and in the decreased smooth muscle cell NO production induced by hyperglycemia. PKC activation also inhibits insulin-stimulated expression of endothelial nitric oxide synthase (eNOS) messenger RNA (mRNA) in cultured endothelial cells. Hyperglycemia increases endothelin 1-stimulated mitogen-activated protein kinase activity in glomerular mesangial cells by activating PKC isoforms. The increased endothelial cell permeability induced by high glucose in cultured cells is mediated by activation of PKC,- however. Activation of PKC by elevated glucose levels also induces expression of the permeability-enhancing factor VEGF in smooth muscle cells.

In addition to affecting hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC contributes to increased microvascular matrix protein accumulation by inducing the expression of TGF-, , fibronectin, and 1 (IV) collagen in both cultured mesangial cells and in the glomeruli of diabetic rats. This effect appears to be mediated through PKC's inhibition of NO production. Hyperglycemia-induced expression of laminin C1 in cultured mesangial cells is independent of PKC activation, however. Hyperglycemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor PAI-1 and in the activation of the pleiotropic transcription factor NF- in cultured endothelial cells and vascular smooth muscle cells.
Increased Hexosamine Pathway Flux

A fourth hypothesis about how hyperglycemia causes diabetic complications has recently been formulated, in which glucose is shunted into the hexosamine pathway (Fig. 31-14). In this pathway, fructose-6-phosphate is diverted from glycolysis to provide substrates for reactions that require UDP-N-acetylglucosamine, such as proteoglycan synthesis and the formation of O-linked glycoproteins. Inhibition of the rate-limiting enzyme in the conversion of glucose to glucosamine, glutamine:fructose-6-phosphate amidotransferase, blocks hyperglycemia-induced increases in the transcription of both TGF-β and TGF-β1. This pathway has previously been shown to play an important role in hyperglycemia-induced and fat-induced insulin resistance.

![Figure 31-14](image)

Figure 31-14 Schematic representation of the hexosamine pathway. The glycolytic intermediate fructose-6-phosphate (Fruc-6-P) is converted to glucosamine-6-phosphate (Glc-6-P) by the enzyme glutamine:fructose-6-phosphate amidotransferase (GFAT). Increased donation of N-acetylglucosamine moieties to serine and threonine residues of transcription factors such as Sp1 increases production of such complication-promoting factors as PAI-1 and TGF-β. See text for additional abbreviations. (Adapted from Du XL, Edelstein D, Rossetti L, et al. Hyperglycemia-induced mitochondrial superoxide overproduction activates the hexosamine pathway and induces plasminogen activator inhibitor-1 expression by increasing Sp1 glycosylation. Proc Natl Acad Sci USA 2000; 97:12222-12226.)

The mechanism by which increased flux through the hexosamine pathway mediates hyperglycemia-induced increases in gene transcription has not been clear, but the observation that Sp1 sites regulate hyperglycemia-induced activation of the PAI-1 promoter in vascular smooth muscle cells suggests that covalent modification of Sp1 by N-acetylglucosamine may explain the link between hyperglycemia-induced changes in gene transcription and hexosamine pathway activation. Virtually every RNA polymerase II transcription factor examined has been found to be O-GlcNacylated, and the glycosylated form of Sp1 appears to be more transcriptionally active than the deglycosylated form of the protein. A four-fold increase in Sp1 O-GlcNacylation caused by inhibition of the enzyme O-GlcNac-N-acetylglucosaminidase resulted in a reciprocal 30% decrease in its level of serine/threonine phosphorylation, supporting the concept that O-GlcNacylation and phosphorylation compete to modify the same sites on this protein.

GlcNac modification of Sp1 may regulate other glucose-responsive genes in addition to TGF-β and PAI-1. Glucose-responsive transcription is regulated by Sp1 sites in the acetyl-CoA carboxylase gene, the rate-limiting enzyme for fatty acid synthesis, for example, and it appears that post-translational modification of Sp1 is responsible for this effect. Because virtually every RNA polymerase II transcription factor examined has been found to be O-GlcNacylated, it is possible that reciprocal modification by O-GlcNacylation and phosphorylation of transcription factors other than Sp1 may function as a more generalized mechanism for regulating glucose-responsive gene transcription.

In addition to transcription factors, many other nuclear and cytoplasmic proteins are dynamically modified by O-GlcNAc moieties and may exhibit reciprocal modification by phosphorylation in a manner analogous to Sp1. Thus, activation of the hexosamine pathway by hyperglycemia may result in many changes in both gene expression and in protein function that together contribute to the pathogenesis of diabetic complications.
DIFFERENT PATHOGENIC MECHANISMS REFLECT A SINGLE HYPERGLYCEMIA-INDUCED PROCESS

Although specific inhibitors of aldose reductase activity, AGE formation, and PKC activation each ameliorate various diabetes-induced abnormalities in animal models, there has been no apparent common element linking the four mechanisms of hyperglycemia-induced damage discussed in the preceding section. It has also been conceptually difficult to explain the phenomenon of hyperglycemic memory (discussed in an earlier section) as a consequence of four processes that quickly normalize when euglycemia is restored. These issues have now been resolved by the recent discovery that each of the four different pathogenic mechanisms reflects a single hyperglycemia-induced process: overproduction of superoxide by the mitochondrial electron transport chain.

Hyperglycemia increases ROS production inside cultured bovine aortic endothelial cells. To understand how this occurs, a brief overview of glucose metabolism is helpful. Intracellular glucose oxidation begins with glycolysis in the cytoplasm, which generates NADH and pyruvate. Cytosolic NADH can donate reducing equivalents to the mitochondrial electron transport chain via two shuttle systems, or it can reduce pyruvate to lactate, which exits the cell to provide substrate for hepatic gluconeogenesis. Pyruvate can also be transported into the mitochondria, where it is oxidized by the tricarboxylic acid (TCA) cycle to produce carbon dioxide ($\text{CO}_2$), water ($\text{H}_2\text{O}$), four molecules of NADH, and one molecule of FADH$_2$. Mitochondrial NADH and FADH$_2$ provide energy for adenosine triphosphate (ATP) production via oxidative phosphorylation by the electron transport chain. Electron flow through the mitochondrial electron transport chain is carried out by four inner membrane-associated enzyme complexes, plus cytochrome-c and the mobile carrier ubiquinone. NADH derived from both cytosolic glucose oxidation and mitochondrial TCA cycle activity donates electrons to NADH:ubiquinone oxidoreductase (Complex I). Complex I ultimately transfers its electrons to ubiquinone. Ubiquinone can also be reduced by electrons donated from several FADH$_2$-containing dehydrogenases, including succinate:ubiquinone oxidoreductase (Complex II) and glycerol-3-phosphate dehydrogenase. Electrons from reduced ubiquinone are then transferred to cytochrome-c oxidoreductase (Complex III) by the ubiquinol-cytochrome-c oxidoreductase radical-generating Q cycle. Electron transport then proceeds through cytochrome-c, cytochrome-c oxidase (Complex IV), and finally, molecular oxygen.

Electron transfer through Complexes I, III, and IV generates a proton gradient that drives ATP synthase (Complex V). When the electrochemical potential difference generated by this proton gradient is high, the life of superoxide-generating electron transport intermediates such as ubiquinol is prolonged. There appears to be a threshold value above which superoxide production is markedly increased (Fig. 31-15).

Using inhibitors of both the shuttle that transfers cytosolic NADH into mitochondria, and the transporter that transfers cytochrome c pyruvate into the mitochondria, the TCA cycle was shown to be the source of hyperglycemia-induced ROS in endothelial cells. Overexpression of uncoupling protein 1 (UCP-1), a specific protein uncoupler of oxidative phosphorylation capable of collapsing the proton electrochemical gradient, also prevented the effect of hyperglycemia. These results demonstrate that hyperglycemia-induced intracellular ROS are produced by the proton translocating Q-cycle carrier generated by the mitochondrial electron transport chain. Overexpression of manganese superoxide dismutase, the mitochondrial form of this antioxidant enzyme, also prevented the effect of hyperglycemia. This result demonstrates that superoxide is the reactive oxygen radical produced by this mechanism.

The effect of hyperglycemia-induced mitochondrial superoxide overproduction on polyol pathway flux was evaluated after first determining that sorbitol in these cells was exclusively derived from aldose reductase activity. Sorbitol levels were 2.6-fold higher than baseline (5-mM glucose) when endothelial cells were incubated in 30-mM glucose (Fig. 31-16). Hyperglycemia-induced sorbitol accumulation was completely prevented by UCP-1 and superoxide dismutase (Mn-SOD) (see Fig. 31-16), indicating that mitochondrial superoxide overproduction stimulates aldose reductase activity. This effect appears to reflect the well-described reversible inhibition of glyceraldehyde-3-phosphate dehydrogenase by ROS, which increases glyceraldehyde-3-phosphate levels and the levels of proximal glycolytic metabolites, including glucose (Fig. 31-17).

Next, the effect of hyperglycemia-induced mitochondrial superoxide overproduction on intracellular AGE formation was determined. In bovine aortic endothelial cells, hyperglycemia increases intracellular AGEs primarily, if not exclusively, by increasing the formation of AGE-forming methylglyoxal. Therefore, the effect of UCP-1 and Mn-SOD on hyperglycemia-induced formation of intracellular methylglyoxal-derived AGEs was examined (see Fig. 31-16). Each of these agents completely prevented hyperglycemia-induced formation of intracellular AGEs (see Fig. 31-16), indicating that mitochondrial superoxide initiates intracellular AGE formation. Because methylglyoxal is formed by fragmentation of glyceraldehyde-3-phosphate, this dependency on increased mitochondrial superoxide production also likely reflects increased glyceraldehyde-3-phosphate levels due to inhibition of glyceraldehyde-3-phosphate dehydrogenase by ROS (see Fig. 31-17).

The effect of UCP-1 and Mn-SOD on hyperglycemia-induced activation of PKC was also evaluated (see Fig. 31-16). Each of these agents completely inhibited PKC activation, suggesting that mitochondrial superoxide overproduction initiates the hyperglycemia-induced de novo synthesis of DAG that activates PKC. Most likely this too reflects increased glyceraldehyde-3-phosphate levels due to inhibition of glyceraldehyde-3-phosphate dehydrogenase by ROS (see Fig. 31-17).

Finally, the effect of hyperglycemia-induced mitochondrial superoxide overproduction on the hexosamine pathway was determined. Hyperglycemia induced an increase in hexosamine pathway activity that was completely prevented by UCP-1, Mn-SOD, and azaserine, an inhibitor of the rate-limiting enzyme in the hexosamine pathway.

Hyperglycemia-induced activation of the redox-sensitive pleiotropic transcription factor NF-B was also prevented by inhibition of mitochondrial superoxide overproduction.
A POSSIBLE MOLECULAR BASIS FOR HYPERGLYCEMIC MEMORY

In contrast to the four known hyperglycemia-inducible abnormalities of intracellular metabolism, hyperglycemia-induced mitochondrial superoxide production may provide an explanation for the development of complications during posthyperglycemic normoglycemia (hyperglycemic memory). Hyperglycemia-induced increases in superoxide would not only increase aldose reductase activity, AGE formation, PKC activity, and hexosamine pathway activity but may also induce mutations in mitochondrial DNA (mtDNA), Mitochondria are more vulnerable to mutation because mtDNA contains virtually no introns, lacks protective histones, and has no effective DNA repair mechanism. Defective electron transport complex subunits encoded by mutated mtDNA would eventually cause increased superoxide production at physiologic concentrations of glucose, with resultant continued activation of the four pathways despite the absence of hyperglycemia.

Figure 31-16 Effect of agents that alter mitochondrial electron transport chain function on the three main pathways of hyperglycemic damage. A, Hyperglycemia-induced protein kinase C (PKC) activation. B, Intracellular advanced glycation end-product (AGE) formation. C, Sorbitol accumulation. Cells were incubated in 5-mM glucose, 30-mM glucose alone, and 30-mM glucose plus either agents that uncouple oxidative phosphorylation and reduce the high mitochondrial membrane potential (TTFA, CCCP, UCP-1), or dismutate superoxide (Mn-SOD). See text for additional abbreviations. (From Nishikawa T, Edelstein D, Du XL, et al. Normalizing mitochondrial superoxide production blocks three pathways of hyperglycaemic damage. Nature 2000; 404:787-790.)
PROSPECTS FOR PHARMACOLOGIC INTERVENTION

Aldose Reductase Inhibitors

In vivo studies of polyol pathway inhibition have yielded promising results with neuropathy but disappointing results in other target tissues of diabetic complications. During the course of a 5-year study, nerve conduction velocity (NCV) progressively decreased in untreated diabetic dogs, whereas this decrease was prevented by treatment with an aldose reductase inhibitor (ARI). Positive effects of ARIs on human diabetic neuropathy have been reported. In contrast, aldose reductase inhibition failed to prevent retinopathy in the 5-year study in dogs, nor did it prevent capillary basement membrane thickening in the retina, kidney, or muscles. A 3-year human trial also failed to show any effect on diabetic retinopathy.
Advanced Glycation End-Product Inhibitors

The hydrazine compound aminoguanidine was the first AGE inhibitor discovered, and its effect on diabetic pathology has been investigated in the retina, kidney, nerve, and artery. In the rat retina, diabetes causes a 19-fold increase in the number of acellular capillaries. Aminoguanidine treatment of diabetics prevented excess AGE accumulation and reduced the number of acellular capillaries by 80%. Diabetes-induced pericyte dropout also was markedly reduced by aminoguanidine treatments.

Similar results have been obtained in animal models of diabetic kidney disease. Diabetes increased AGEs in the renal glomerulus, and aminoguanidine treatment prevented this diabetes-induced increase. Untreated diabetic animals developed albuminuria that averaged 30 mg every 24 hours for 32 weeks. This was more than a 10-fold increase above control levels. Untreated diabetic animals also developed the characteristic structural feature of human diabetic nephropathy (i.e., increased fractional mesangial volume). When diabetic animals were treated with aminoguanidine, the increase was completely prevented. A structurally unrelated AGE inhibitor, OPB-9195, also prevented the development and progression of experimental diabetic nephropathy by blocking type IV collagen overproduction and normalizing the expression of TGF-β.

In the peripheral nerve of diabetic rats, both motor nerve and sensory NCVs are decreased after 8 weeks of diabetes. Nerve action potential amplitude is decreased by 37% and peripheral nerve blood flow is decreased by 57% after 24 weeks of diabetes. Aminoguanidine treatment prevented each of these abnormalities of diabetic peripheral nerve function.

In a large randomized, double-blind, placebo-controlled, multicenter trial of aminoguanidine in type 1 diabetic patients with overt nephropathy, aminoguanidine lowered total urinary protein and slowed progression of nephropathy, over and above the effects of existing optimal care. In addition, aminoguanidine reduced the progression of diabetic retinopathy (defined as an increase by three or more steps in the Early Treatment Diabetic Retinopathy Study [ETDRS] scale).
Protein Kinase C Inhibitors

The recent development of a isoform-specific PKC inhibitor has allowed in vivo studies to go forward, because the toxicity of non-selective PKC inhibitors precludes their use. LY333531 inhibits PKC-α and PKC-δ with a half-maximal inhibitory constant (IC₅₀) that is at least 50-fold less than for other PKC isoforms. Treatment with LY333531 significantly reduced PKC activity in the retina and renal glomeruli of diabetic animals. Concomitantly, LY333531 treatment significantly reduced diabetes-induced increases in retinal mean circulation time, normalized diabetes-induced increases in glomerular filtration rate (GFR), and partially corrected urinary AER. Treatment of db/db mice with LY333531 for a longer period also ameliorated accelerated glomerular mesangial expansion. Clinical trials of LY333531 in human diabetic patients are currently in progress.
Future Drug Targets

The recent discovery that each of the four different pathogenic mechanisms discussed in this section reflect a single hyperglycemia-induced process suggests that interrupting the overproduction of superoxide by the mitochondrial electron transport chain would normalize polyol pathway flux, AGE formation, PKC activation, hexosamine pathway flux, and NF-κB activation. Novel compounds that act as superoxide dismutase/catalase mimetics already exist, and these compounds have been shown to normalize hyperglycemia-induced mitochondrial superoxide overproduction. These and the other agents described in this section may have unique clinical efficacy in preventing the development and progression of diabetic complications.
RETNOPATHY, MACULAR EDEMA, AND OTHER OCULAR COMPLICATIONS

Diabetic retinopathy is a well-characterized, sight-threatening, chronic microvascular complication that eventually affects virtually all patients with diabetes mellitus. Diabetic retinopathy is characterized by gradually progressive alterations in the retinal microvasculature, leading to areas of retinal nonperfusion, increased vasopermeability, and pathologic intracellular proliferation of retinal vessels. The complications associated with the increased vasopermeability, termed macular edema, and uncontrolled neovascularization, termed proliferative diabetic retinopathy (PDR), can result in severe and permanent visual loss. Despite decades of research, there is presently no known means of preventing diabetic retinopathy and, despite effective therapies, diabetic retinopathy remains the leading cause of new-onset blindness in working-aged Americans. With appropriate medical and ophthalmologic care, however, more than 90% of visual loss resulting from diabetic retinopathy can be prevented.

Thus, until a cure for diabetes is discovered, the primary clinical care emphasis for the prevention of vision loss is appropriately directed at the early identification, accurate classification, and timely treatment of retinopathy. Emphasis must also be placed on ensuring compliant life-long routine ophthalmologic follow-up of the diabetic patient and optimization of associated systemic disorders.

EPIDEMIOLOGY AND IMPACT

Sixteen million Americans have diabetes mellitus, but only half are aware that they have the disease. Diabetic retinopathy is the leading cause of new cases of legal blindness among Americans between the ages of 20 and 74 years. There is a higher risk of more frequent and severe ocular complications in type 1 diabetes. Approximately 25% of patients with type 1 diabetes have retinopathy after 5 years, with this figure increasing to 60% and 80% after 10 and 15 years, respectively. However, because there are more adult-onset cases than juvenile-onset cases, type 2 disease accounts for a higher proportion of patients with visual loss. The most threatening form of retinopathy (PDR) is present in approximately 25% of type 1 patients with diabetes of 15 years' duration. An estimated 700,000 persons have PDR, 130,000 with high-risk PDR, 500,000 with macular edema, and 325,000 with clinically significant macular edema (CSME) in the United States. An estimated 63,000 cases of PDR, 29,000 high-risk PDR, 80,000 macular edema, 56,000 CSME, and 5000 new cases of legal blindness occur each year as a result of diabetic retinopathy. Blindness has been estimated to be 25 times more common in persons with diabetes than in those without the disease.

Estimates of the medical and economic impact of retinopathy-associated morbidity have been performed using computer simulations that incorporate clinical trial and cost reimbursement data to model effects of applying accepted evaluation and treatment techniques to patients with type 1 and type 2 diabetic retinopathy. The models predict that in the absence of good glycemic control, 72% of patients with type 1 diabetes will develop PDR requiring panretinal photocoagulation (PRP) over their lifetime and that 42% will develop macular edema. If patients with type 1 diabetes receive currently suggested treatment, there is a predicted cost of $966 per person-year of vision saved from PDR and $1120 per person-year of central acuity saved from macular edema as of 1990. Indeed, current estimates are that only 60% of patients in need of retinopathy treatment are receiving appropriate ophthalmic care. If all patients with both type 1 and type 2 diabetes were to receive care according to currently suggested guidelines, annual savings of $624 million and 173,540 person-years of sight would be realized.

The DCCT showed that both the rate of development of any retinopathy as well as the rate of retinopathy progression once it was present were significantly reduced after 3 years of intensive insulin therapy, an effect maintained even 4 years after conclusion of the study. Applying DCCT intensive insulin therapy to all persons in the United States with insulin-dependent diabetes mellitus would result in a gain of 920,000 person-years of sight, although the costs of intensive therapy are three times that of conventional therapy.
PATHOPHYSIOLOGY

A detailed discussion of the pathophysiologic mechanisms underlying diabetic retinopathy and other diabetes-related complications has been presented earlier in this chapter. The earliest histologic effects of diabetes mellitus in the eye include loss of retinal vascular pericytes (supporting cells for retinal endothelial cells), thickening of vascular endothelium basement membrane, and alterations in retinal blood flow. With increasing loss of retinal pericytes, the retinal vessel wall develops outpouchings (microaneurysms) and becomes fragile.

Clinically, microaneurysms and small retinal hemorrhages may not always be readily distinguishable and are evaluated together as "hemorrhages and microaneurysms" (Fig. 31-19A) (Figure Not Available) (see also Color Plate). Rheologic changes occur in diabetic retinopathy resulting from increased platelet aggregation, integrin-mediated leukocyte adhesion, and endothelial damage. Disruption of the blood retinal barrier may ensue, characterized by increased vascular permeability. The subsequent leakage of blood and serum from the retinal vessels results in retinal hemorrhages, retinal edema, and hard exudates (Fig. 31-19A and C) (Figure Not Available). Moderate visual loss follows if the fovea is affected by the leakage.

With time, increasing sclerosis and endothelial cell loss lead to narrowing of the retinal vessels, which decreases vascular perfusion and may ultimately lead to obliteration of the capillaries and small vessels (Fig. 31-19 B) (Figure Not Available). The resulting retinal ischemia is a potent inducer of angiogenic growth factors. Several angiogenic growth factors have been isolated from eyes with diabetic retinopathy, including IGFs, bFGF, hepatocyte growth factor (HGF), and VEGF. These factors promote the development of new vessel growth and retinal vascular permeability. Indeed, inhibition of molecules such as VEGF and their signaling pathways can suppress the development of retinal neovascularization and retinal vascular permeability.

New vessels tend to grow in regions of strong vitreous adhesion to the retina, such as at the optic disc and major vascular arcades (Fig. 31-19 D and E) (Figure Not Available). The posterior vitreous face also serves as a scaffold for pathologic neovascularization, and the new vessels commonly arise at the junctions between perfused and nonperfused retina. When the retina is severely ischemic, the concentration of angiogenic growth factors may reach sufficient concentration in the anterior chamber to cause abnormal new vessel proliferation on the iris and the anterior chamber angle. Uncontrolled anterior segment neovascularization may result in rubeotic glaucoma because the fibrovascular proliferation in the angle of the eye causes blockage of aqueous outflow through the trabecular meshwork.

Proliferating new vessels in diabetic retinopathy have a tendency to bleed, which results in preretinal and vitreous hemorrhages (VHs) (Fig. 31-19 E and F) (Figure Not Available). Although the presence of a large amount of blood in the preretinal space or vitreous cavity per se is not damaging to the retina, these intraocular hemorrhages often cause prolonged visual loss by blocking the visual axis. Membranes on the retinal surface can be induced by blood and result in wrinkling and traction on the retina. Although all retinal neovascularization eventually becomes quiescent, as with most scarring processes there is progressive fibrosis of the new vessel complexes that is associated with contraction. However, in the eye, such forces may exert traction on the retina, leading to tractional retinal detachment and retinal tears that may result in severe and permanent visual loss if left untreated (Fig. 31-19 G and H) (Figure Not Available).

In short, causes of visual loss from complications of diabetes mellitus include retinal ischemia involving the fovea, macular edema or near the fovea, preretinal or vitreous hemorrhages, retinal detachment, and neovascular glaucoma. Visual loss may also result from more indirect effects of disease progression in diabetic patients, such as retinal vessel occlusion, accelerated atherosclerotic disease, and embolic phenomena.

Figure 31-18 Diabetic retinopathy pathogenesis flow chart. The schematic flow chart represents the major preclinical and clinical findings associated with the full spectrum of diabetic retinopathy and macular edema. VEGF, vascular endothelial growth factor.
CLINICAL FEATURES

Risk Factors

Duration of diabetes is closely associated with the onset and severity of diabetic retinopathy. Diabetic retinopathy is rare in prepubescent patients with type 1 diabetes, but nearly all patients with type 1 diabetes and more than 60% of patients with type 2 diabetes develop some degree of retinopathy after 20 years. In patients with type 2 diabetes, approximately 20% have retinopathy at the time of diabetes diagnosis and most have some degree of retinopathy over subsequent decades.

Diabetic retinopathy is the most frequent cause of new-onset blindness among American adults aged 20 to 74 years. In the Wisconsin Epidemiologic Study of Diabetic Retinopathy, approximately 4% of patients younger than 30 years of age at diagnosis and nearly 2% of patients older than 30 years of age at diagnosis were legally blind. In the younger-onset group, 86% of blindness was attributable to diabetic retinopathy. In the older-onset group, where other eye diseases were also common, 33% of the cases of legal blindness were due to diabetic retinopathy.

Lack of glycemic control is another significant risk factor for the onset and progression of diabetic retinopathy. The DCCT demonstrated a clear relationship between hyperglycemia and diabetic microvascular complications, including retinopathy in 1441 patients with type 1 diabetes. In patients monitored 4 to 9 years, the DCCT showed that intensive insulin therapy reduced or prevented the development of retinopathy by 27% as compared with conventional therapy. Additionally, intensive insulin therapy reduced the progression of diabetic retinopathy by 34% to 76% and had a substantial beneficial effect over the entire range of retinopathy severity. This improvement was achieved with an average 10% reduction in Hb A1c from 8% to 7.2%. These results underscore that although intensive therapy does not prevent retinopathy completely, it reduces the risk of retinopathy onset and progression.

Renal disease, as manifested by microalbuminuria and proteinuria, is yet another significant risk factor for onset and progression of diabetic retinopathy. Hypertension is associated with PDR and is an established risk factor for the development of macular edema. Additionally, elevated serum lipid levels are associated with extravasated lipid in the retina (hard exudates) and visual loss.
Clinical Findings

Clinical findings associated with early and progressing diabetic retinopathy include hemorrhages or microaneurysms (H/Ma), cotton-wool spots (CWSs), hard exudates, intraretinal microvascular abnormalities (IRMAs), and venous caliber abnormalities (VCABs), such as venous loops, venous tortuosity, and venous beading (see Fig. 31-19A and C) (Figure Not Available). Microaneurysms are saccular outpoucings of the capillary walls that can leak fluid and result in intraretinal hemorrhages. The intraretinal hemorrhages can be "flame-shaped" or "dot/blot" like in appearance, reflecting the architecture of the layer of the retina in which they occur. IRMAs are either new vessel growth within the retinal tissue itself or shunt vessels through areas of poor vascular perfusion. It is common for IRMAs to be adjacent to CWSs, which are caused by microinfarcts in the nerve fiber layer. VCABs are a sign of severe retinal hypoxia. In some cases of extensive vascular loss, however, the retina may appear free of nonproliferative lesions. Such areas are termed "featureless retina" and are a sign of severe retinal hypoxia.

Vision loss from diabetic retinopathy generally results from persistent, nonclearing vitreous hemorrhage, traction retinal detachment, or diabetic macular edema (DME) (see Fig. 31-18 and Fig. 31-19 (Figure Not Available)). Neovascularization with fibrous tissue contraction can distort the retina and lead to traction retinal detachment. The new vessels may bleed, causing preretinal or vitreous hemorrhage. The most common cause of vision loss from diabetes, however, is macular disease and macular edema. Macular edema is more likely to occur in patients with type 2 diabetes, which represents 90% of the diabetic population. In diabetic macular disease, macular edema involving the fovea or nonperfusion of the capillaries in the central macula is responsible for the loss of vision.

<th>TABLE 31-1 – Glossary &amp; Abbreviations Pertinent to Diabetic Eye Disease</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Background Diabetic Retinopathy (BDR):</strong> An outdated term referring to some stages of nonproliferative diabetic retinopathy. Because this terminology is not closely associated with disease progression, it has been replaced by the various levels of nonproliferative diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Cotton Wool Spot:</strong> A gray or white area lesion in the nerve fiber layer of the retina resulting from stasis of axoplasmic flow as a result of infarction.</td>
</tr>
<tr>
<td><strong>Diabetes Control &amp; Complications Trial (DCCT):</strong> A multicenter randomized, clinical trial designed to address whether intensive insulin therapy could prevent or slow the progression of systemic complications of diabetes mellitus.</td>
</tr>
<tr>
<td><strong>Diabetic Retinopathy (DR):</strong> Retinal pathology related to the underlying systemic disease of diabetes mellitus.</td>
</tr>
<tr>
<td><strong>Diabetic Retinopathy Study (DRS):</strong> The first multicenter randomized clinical trial to demonstrate the value of laser scatter (panretinal) photocoagulation in reducing the risk of visual loss among patients with all levels of diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Diabetic Retinopathy Vitrectomy Study (DRVS):</strong> A multicenter clinical trial demonstrating the value of early vitrectomy for patients with very advanced diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Early Treatment Diabetic Retinopathy Study (ETDRS):</strong> A multicenter randomized clinical trial that addressed at what stage of retinopathy scatter (panretinal) photocoagulation was indicated, whether focal photocoagulation was effective for preventing moderate visual loss from clinically significant macular edema, and whether aspirin therapy altered the risks for outcome or treatment of diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Focal Laser Photocoagulation:</strong> A type of laser treatment used for patients with clinically significant macular edema whose main goal is to reduce vascular leakage either by focal treatment of leaking retinal microaneurysms or by application of therapy in a grid-like pattern.</td>
</tr>
<tr>
<td><strong>Hard Exudate:</strong> Lipid accumulation within the retina as a result of increased vasopermeability.</td>
</tr>
<tr>
<td><strong>High-Risk-Characteristic Proliferative Diabetic Retinopathy (HRC-PDR):</strong> Proliferative diabetic retinopathy of a defined extent, location, and/or clinical findings that is particularly associated with severe visual loss.</td>
</tr>
<tr>
<td><strong>Intraretinal Hemorrhage:</strong> A small to moderate hemorrhage that occurs within the retina.</td>
</tr>
<tr>
<td><strong>Intraretinal Macular Edema (IRME):</strong> Thickening of the retina in the macular region of sufficient extent and location to threaten central visual function.</td>
</tr>
<tr>
<td><strong>Intraretinal Microvascular Abnormalities (IRMAs):</strong> An early vascular abnormality consisting of an outpouching of the retinal microvasculature.</td>
</tr>
<tr>
<td><strong>Neovascular Glaucoma (NVG):</strong> Elevation of intraocular pressure caused by the development of neovascularization in the anterior segment of the eye.</td>
</tr>
<tr>
<td><strong>Neovascularization at the Disc (NVD):</strong> Retina neovascularization occurring at or within 1500 µm of the optic disc.</td>
</tr>
<tr>
<td><strong>Neovascularization Elsewhere (NVE):</strong> Retinal neovascularization that is located more than 1500 µm away from the optic disc.</td>
</tr>
<tr>
<td><strong>Neovascularization of the Iris (NVI):</strong> Neovascularization occurring on the iris (rubeosis iris), usually as a result of extensive retinal ischemia.</td>
</tr>
<tr>
<td><strong>No Light Perception (NLP):</strong> The inability to perceive light.</td>
</tr>
<tr>
<td><strong>Nonproliferative Retinopathy (NPDR):</strong> Severities of diabetic retinopathy that precede the development of proliferative diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Preproliferative Retinopathy (PPDR):</strong> An outdated term referring to more advanced levels of nonproliferative diabetic retinopathy. Because this terminology is not closely associated with disease progression, it has been replaced by the various levels of nonproliferative diabetic retinopathy.</td>
</tr>
<tr>
<td><strong>Proliferative Diabetic Retinopathy (PDR):</strong> An advanced level of diabetic retinopathy, where proliferation of new vessels occurs on or within the retina.</td>
</tr>
<tr>
<td><strong>Rubeosis Iris:</strong> Retinal neovascularization of the iris (NVI).</td>
</tr>
</tbody>
</table>
Diabetic retinopathy is broadly classified into non-PDR (NPDR) and PDR categories. Macular edema may coexist with either group and is not used in the classification of level of retinopathy. The historical terms background retinopathy and preproliferative diabetic retinopathy have been replaced to reflect the specific characteristics and risk stratification of the prognostically important subgroups in NPDR. Generally, diabetic retinopathy progresses from no retinopathy, through mild, moderate, severe, and very severe nonproliferative disease and eventually on to PDR. Level of NPDR is determined by the extent and location of clinical manifestations of retinopathy. Mild NPDR is characterized by limited microvascular abnormalities such as H/Ma, CWS, and increased vascular permeability. Moderate and severe NPDR are characterized by increasing severity of H/Ma, VCABs, IRMA, and vascular closure.

PDR is characterized by vasoproliferation of the retina and its complications, including new vessels on the optic disc (NVD), new vessels elsewhere on the retina (NVE), preretinal hemorrhage (PRH), vitreous hemorrhage, and fibrous tissue proliferation (FP). On the basis of the extent and location of these lesions, PDR is classified as early PDR or high-risk PDR. Larger areas of these complications as well as new vessels that are near the optic disc are associated with greater risks of visual loss. The level of NPDR establishes the risk of progression to sight-threatening retinopathy and dictates appropriate clinical management and follow-up.
Classification of Diabetic Macular Edema

Diabetic macular edema can be present with any level of diabetic retinopathy. When it involves or threatens the center of the macula, it is called CSME (defined earlier). CSME exists if there is retinal thickening at or within 500 µm of the fovea, hard exudates with adjacent retinal thickening at or within 500 µm of the fovea, or an area of retinal thickening 1500 µm or more in diameter, any part of which is within 1500 µm of the fovea. CSME is a clinical diagnosis that is not dependent on visual acuity or results of ancillary testing such as fluorescein angiography.
Other Ocular Manifestations of Diabetes

All structures of the eye are susceptible to complications of diabetes. The consequence of these changes can range from being unnoticed by both patient and physician, to symtomatic but not sight-threatening, to requiring evaluation to rule out potentially life-threatening underlying causes other than diabetes.

Mononeuropathies of the third, fourth, or sixth cranial nerves may arise in association with diabetes, with the fourth cranial nerve being least likely diabetes-associated.  Nerve palsies present a significant diagnostic challenge because misdiagnosis may result in a life-threatening lesion remaining untreated. In one review of cranial nerve palsies treated in a diabetic patient population in 1967, 42% of mononeuropathies were not diabetic in origin. This finding underscores the danger of routinely attributing mononeuropathies to the diabetic condition itself without carefully ruling out other potential causes. The percentage of all extracranial muscle palsies attributable to diabetes mellitus is estimated at 4.5% to 6%. Mononeuropathies may be the initial presenting sign of new-onset diabetes, and diabetes should therefore be considered in the differential diagnosis of any mononeuropathy affecting the extracranial muscles, even in patients who do not claim a history of diabetes. Diabetes-induced third-, fourth-, and sixth-nerve palsies are usually self-limited and should resolve spontaneously in 2 to 6 months. Palsies may recur or subsequently develop in the contralateral eye.

The optic disc can be affected by diabetes in a variety of ways other than NVD or NVE. Diabetic papillopathy must be distinguished from other causes of disc swelling such as true papilledema from increased intracranial pressure, pseudopapilledema such as optic nerve head drusen, toxic optic neuropathies, neoplasms of the optic nerve, and hypertension. Optic disc pallor can occur following spontaneous remission of proliferative retinopathy or remission following scatter (panretinal) laser photoacoagulation (see Fig. 31-19). Because diabetes poses an increased risk for the development of open-angle glaucoma, the disc pallor following remission of retinopathy or PRP must be considered when evaluating the optic nerve head for glaucoma.

A potentially serious diabetic ocular complication is neovascularization of the iris (NVI). Usually the new iris vessels are first observed at the pupillary border, followed by a fine network of vessels over the iris tissue progressing into the filtration angle of the eye. Closure of the angle by the fibrovascular network results in neovascular glaucoma. Neovascular glaucoma is difficult to manage and requires aggressive treatment. Diabetes is the second leading cause of neovascular glaucoma, accounting for 32% of cases. NVI occurs in 4% to 7% of diabetic eyes and may be present in up to 40% to 60% of eyes with proliferative retinopathy. When possible, scatter (panretinal) laser photoacoagulation is the principal therapy for NVI, although other approaches such as goniotherapy, topical/systemic antiglaucoma medications, and antiglaucomatous filtration surgery are available when needed.

The cornea of the diabetic person is more susceptible to injury and slower to heal after injury than is the nondiabetic cornea. The diabetic cornea is also more prone to infectious corneal ulcers, which can lead to rapid loss of vision, need for corneal transplant, or loss of the eye if not treated aggressively. Consequently, diabetic patients using contact lenses should exercise caution and maintain careful monitoring.

Open-angle glaucoma is 1.4 times more common in the diabetic population than in the nondiabetic population. The prevalence of glaucoma increases with age and duration of diabetes, but medical therapy for open-angle glaucoma is generally effective.

Diabetes effects on the crystalline lens can result in transitory refractive changes, alterations in accommodative ability, and cataracts. Refractive change can be significant and is related to fluctuation of blood glucose levels with osmotic lens swelling. Cataracts occur earlier in life and progress more rapidly in the presence of diabetes. Cataracts are 1.6 times more common in people with diabetes than in those without diabetes. In patients with earlier-onset diabetes, duration of diabetes, retinopathy status, diuretic use, and glycosylated hemoglobin are risk factors. In patients with later-onset diabetes, age of the patient, lower intraocular pressure, smoking, and lower diastolic blood pressure (BP) may be additional risk factors. Diabetic patients undergoing simultaneous kidney or pancreas transplantation are at an increased risk of developing all types of cataract, independent of the use of corticosteroids after transplantation. Both phacoemulsification and extracapsular cataract extraction with intraocular lens implantation are appropriate surgical therapies. The principal determinant of postoperative vision and progression of retinopathy is related to the preoperative presence of diabetic macular edema and level of NPDR.

Other findings with higher frequency among patients with diabetes include xanthelasma, microaneurysms of the bulbar conjunctiva, posterior vitreous detachment, and the rare but frequently fatal orbital fungal infection Mucorales (phycomycosis). Prompt diagnosis and treatment of Mucor is crucial, although the survival rate still remains at only 57%.
MONITORING AND TREATMENT OF DIABETIC RETINOPATHY

Appropriate clinical management of diabetic retinopathy has been defined by results of four major, randomized, multicentered clinical trials (Fig. 31-20: the Diabetic Retinopathy Study [DRS], the Early Treatment Diabetic Retinopathy Study [ETDRS], the Diabetic Retinopathy Vitrectomy Study [DRVS], and the DCCT). These studies have elucidated the progression rates of each level of diabetic retinopathy; defined follow-up intervals; and elucidated the proper delivery, timing, and resulting effectiveness of glycemic control and laser photocoagulation surgery (Figs. 31-21, 31-22, 31-23, 31-24). They have also established guidelines for vitrectomy surgery.

Comprehensive Eye Examination

An accurate ocular examination detailing the extent and location of retinopathy-associated findings is critical for making monitoring and treatment decisions in patients with diabetic retinopathy. As detailed later, most of the blindness associated with advanced stages of retinopathy can be averted with appropriate and timely diagnosis and therapy. Unfortunately, many diabetic patients do not receive adequate eye care at an appropriate stage in their disease. In one study, 55% of patients with high-risk PDR and CSME had never had laser photocoagulation. In fact, 11% of type 1 and 7% of type 2 patients with high-risk PDR necessitating prompt treatment had not been examined by an ophthalmologist within the past 2 years.

Dilated ophthalmic examination is superior to nondilated evaluation because only 50% of eyes are correctly classified as to presence and severity of retinopathy through undilated pupils. Appropriate ophthalmic evaluation entails pupillary dilation, slit lamp biomicroscopy, examination of the retinal periphery with indirect ophthalmoscopy or mirrored contact lens, and sometimes gonioscopy. Because of the complexities of the diagnosis and treatment of PDR and CSME, ophthalmologists with specialized knowledge and experience in the management of diabetic retinopathy are required to determine and provide appropriate surgical intervention. Thus, it is recommended that all patients with diabetes should have dilated ocular examinations by an experienced care provider (ophthalmologist or optometrist) and should be under the direct or consulting care of an ophthalmologist experienced in the management of diabetic retinopathy at least by the time severe diabetic retinopathy or diabetic macular edema is present.
Initial Ophthalmic Evaluation

The recommendation for initial ocular examination in persons with diabetes is based on prevalence rates of retinopathy (see Fig. 31-21). Approximately 80% of type 1 patients have retinopathy after 15 years of disease, but only about 25% have any retinopathy after 5 years. The prevalence of PDR is less than 2% at 5 years and 25% by 15 years. For type 2 diabetes, the onset date of diabetes is frequently unknown, and more severe disease can be observed at diagnosis. Up to 3% of patients first diagnosed after age 30 (type 2) can have CSME or high-risk PDR at the time of initial diagnosis of diabetes. Thus, in patients older than 15 years of age, initial ophthalmic examination is recommended beginning 5 years after the diagnosis of type 1 diabetes mellitus and on diagnosis of type 2 diabetes mellitus (see Fig. 31-21).

Puberty and pregnancy can accelerate retinopathy progression. The onset of vision-threatening retinopathy is rare in children prior to puberty, regardless of the duration of diabetes. However, if diabetes is diagnosed between the ages of 10 and 30, significant retinopathy may arise within 6 years of disease. Diabetic retinopathy can become particularly aggressive during pregnancy in patients with diabetes. In the past, the prognosis for pregnancy in the diabetic patient with microvascular complications was so poor that pregnant diabetic patients were frequently advised to avoid or terminate pregnancies. With recognition of the importance of glycemic control, many diabetic patients in the child-bearing age now experience a safe and satisfying pregnancy and childbirth with minimal risk to both the mother and the baby. There are excellent recent reviews on this subject.

Ideally, patients with diabetes who are planning pregnancy should have a comprehensive eye examination within 1 year prior to conception (see Fig. 31-23). Patients who become pregnant should have a comprehensive eye examination in the first trimester of pregnancy. Close follow-up throughout pregnancy is indicated, with subsequent examinations determined by the findings present at the first-trimester examination. This guideline does not apply to women who develop gestational diabetes, because such individuals are not at increased risk of developing diabetic retinopathy.
Follow-up Ophthalmic Examination

Follow-up ocular examination is determined from the risk of disease progression at any particular retinopathy level (see Fig. 31-22). As described earlier, NPDR is categorized into four levels of severity based on clinical findings compared to stereo fundus photographic standards: mild, moderate, severe, and very severe. Progression of nonproliferative retinopathy to the visually threatening level of high-risk PDR is closely correlated with NPDR level (Table 31-2). Progression rates from each individual NPDR level to any other retinopathy level are also known. These are used to define standard minimal follow-up intervals as detailed in Figure 31-22 and Table 31-3. Patients with no clinically evident diabetic retinopathy and no known ocular problems require annual comprehensive ophthalmic examinations even if totally asymptomatic.
Diabetic Retinopathy

As detailed earlier, the extent and location of neovascularization determine the level of PDR. PDR is best evaluated by dilated examination using slit lamp biomicroscopy, combined with indirect ophthalmoscopy, and/or stereo fundus photography. Without photocoagulation, eyes with high-risk PDR have a 28% risk of severe visual loss within 2 years. This compares with a 7% risk of severe visual loss after 2 years for eyes with PDR but without high-risk characteristics. Severe visual loss is defined as best-corrected acuity of 5/200 or worse on two consecutive visits 4 months apart. The DRS demonstrated that scatter (panretinal) laser photocoagulation was effective in reducing the risk of severe vision loss from PDR by 50% or more. The ETDRS demonstrated that PRP applied when an eye approaches or just reaches high-risk PDR reduces the risk of severe vision loss to less than 4%. Prompt PRP is indicated for all patients with high-risk PDR, often indicated for patients with PDR less than high risk and, on occasion, advisable for patients with severe or very severe NPDR, especially in the setting of type 2 diabetes.

Severe visual loss is defined as best-corrected acuity of 5/200 or worse on two consecutive visits 4 months apart. The DRS demonstrated that scatter (panretinal) laser photocoagulation was effective in reducing the risk of severe vision loss from PDR by 50% or more. The ETDRS demonstrated that PRP applied when an eye approaches or just reaches high-risk PDR reduces the risk of severe vision loss to less than 4%. Prompt PRP is indicated for all patients with high-risk PDR, often indicated for patients with PDR less than high risk and, on occasion, advisable for patients with severe or very severe NPDR, especially in the setting of type 2 diabetes.

In scatter PRP, 1200 to 1800 laser burns are applied to the peripheral retinal tissue, actually focally destroying the outer photoreceptor and retinal pigment epithelium of the retina (see Fig. 31-19) (Figure Not Available). Large vessels are avoided, as are areas of preretinal hemorrhage. The treatment is thought to exert its effect by increasing oxygen delivery to the inner retina and decreasing viable hypoxic growth factor-producing cells. The total treatment is usually applied over two or three sessions, spaced 1 to 2 weeks apart. Follow-up evaluation usually occurs at 3 months.

The response to PRP varies. The most desirable effect is to see a regression of the new vessels, although stabilization of the neovascularization with no further growth may result. This later situation requires careful clinical monitoring. In some cases, new vessels continue to proliferate, requiring additional PRP (see Fig. 31-24). The DRVS, completed in 1989, demonstrated that early PPV in persons with severe fibrovascular proliferation was more likely to result in better vision and less likely to result in poor vision, particularly in patients with type 1 diabetes. PPV is surgery within the eye aimed primarily at removing abnormal fibrovascular tissue, alleviating retinal traction, and removing vitreous opacities such as vitreous hemorrhage. The actual outcome data from this study may not be totally applicable due to the dramatic advances in surgical techniques and the advent of laser endophotocoagulation that have occurred in the intervening years.
Macular Edema

Untreated CSME is associated with an approximately 25% chance of moderate visual loss after 3 years (defined as at least doubling the visual angle, e.g., 20/40 to 20/80). Macular edema is best evaluated by dilated examination using slit lamp biomicroscopy or stereo fundus photography. Focal laser photoacoagulation is generally indicated for patients with CSME (see Fig. 31-19 C [Figure Not Available] and see Fig. 31-22 ). The ETDRS demonstrated that focal laser photoacoagulation for CSME reduced the 5-year risk of moderate vision loss from nearly 30% to less than 15%. In focal laser photoacoagulation, lesions from 300 to 3000 µm from the center of the macula that are contributing to thickening of the macular area are directly photoacoagulated. These lesions are generally identified by fluorescein angiography and consist primarily of leaking microaneurysms. When leakage is diffuse, or microaneurysms innumerable, photoacoagulation may be applied to the macula in a grid configuration, avoiding the fovea region.

Although fluorescein angiography is useful for guiding therapy once CSME has been diagnosed, it is not required for the diagnosis of CSME or PDR because these findings should be clinically evident in most cases (Fig. 31-25). Fluorescein angiography is a valuable test for guiding treatment of CSME, identifying macular capillary nonperfusion, and evaluating unexplained visual loss. However, there are risks associated with fluorescein angiography, including nausea, urticaria, hives, and rarely death (1 in 222,000 patients) or severe medical sequelae (1 in 2000 patients). Thus, fluorescein angiography is not part of the examination of an otherwise normal patient with diabetes, and the procedure is usually contraindicated in patients with known allergy to fluorescein dye or pregnancy.

Follow-up evaluation of focal laser surgery generally occurs after 3 months (Table 31-3, see also Fig. 31-22). In the cases where macular edema persists, further treatment may be necessary. In the presence of macular edema, patients with severe or very severe NPDR should be considered for focal treatment of macular edema whether or not the macular edema is clinically significant because they are likely to require scatter laser photoacoagulation in the near future and because scatter photoacoagulation may exacerbate existing macular edema.

Control of Systemic Disorders

In addition to the importance of intensive glycemic control in reducing the onset and progression of diabetic retinopathy as discussed earlier, it is critical for optimal ocular health of diabetic patients that several other systemic considerations be optimized.

Patients with diabetes mellitus commonly suffer from concomitant hypertension. Patients with type 1 diabetes have a 17% prevalence of hypertension at baseline and a 25% incidence after 10 years. There is a 38% to 68% prevalence in type 2 diabetes. In most studies, hypertension is correlated to the duration of diabetes, higher glycosylated hemoglobin level, presence of gross proteinuria, and male gender. Elevated BP exacerbates the development and progression of diabetic retinopathy. The risk of PDR is associated with the presence of hypertension at the baseline visit, higher glycosylated hemoglobin levels, and presence of more severe levels of retinopathy and diffuse macular edema, and more severe levels of retinopathy and more rapid progression of retinopathy when compared with diabetic patients without hypertension. The large randomized, prospective UKPDS in 1148 patients with type 2 diabetes demonstrated a 34% (P = .0004) and 47% (P = .004) reduction in risk of diabetic retinopathy progression and moderate visual acuity loss, respectively, in patients assigned to intensive BP control. These effects were independent of glycemic control and the risk reductions were similar, regardless of whether the hypertension was controlled with ACE inhibitor (captopril) or beta blocker (atenolol). Overall, hypertension appears to be a significant risk factor in the development and progression of diabetic retinopathy and should be rigorously controlled. Until the results of specific trials investigating the BP levels required to minimize end organ damage in patients with diabetes are known, target BP should most likely be maintained as low as safely possible.

Associations between renal and retinal angiopathy are numerous. Proteinuria or microalbuminuria is associated with retinopathy. The presence and severity of diabetic retinopathy are indicators of the risk of gross proteinuria. The presence of proteinuria predicts PDR. Half of all patients with type 1 diabetes mellitus with PDR and 10 or more years of diabetes have concomitant proteinuria. In type 1 diabetes mellitus, the prevalence of PDR increases from 7% at onset of microalbuminuria to 29% 4 years after onset of albuminuria as compared with 3% and 8%, respectively, in patients without persistent microalbuminuria. The Appropriate Blood Pressure Control in Diabetes (ABCD) Trial found both the severity and progression of retinopathy were associated with overt albuminuria. The presence of gross proteinuria at baseline is associated with 95% increased risk of developing macular edema among patients with type 1 diabetes mellitus, and dialysis may improve macular edema in diabetic patients with renal failure.

Despite these associations, the frequent coexistence of retinal and renal microangiopathies and factors such as associated hypertension and disease duration may confound these results. Overall, it is important to carefully consider the renal status of any patient with diabetes mellitus and to ensure that the patient is receiving optimal care in this regard. In addition, rapidly progressive retinopathy, especially in a patient with long history of diabetes mellitus and where retinopathy has been previously stable, should suggest the need for renal evaluation.

Although dyslipidemia is a clear risk factor in diabetic renal disease, the effects of serum lipids on retinopathy and macular edema are less certain. In 2709 ETDRS patients in whom serum levels were measured, elevated total cholesterol, LDL cholesterol, and triglyceride levels were associated with faster development of hard exudates (P < .001, P = .04, and P = .01, respectively), and the risk of moderate visual loss was associated with the extent of exudate. Owing to their salutary effects on cardiovascular morbidity for individuals at risk, lipid-lowering recommendations are currently given to all patients with diabetes and elevated cholesterol levels, irrespective of their retinopathy status.

The precise effects of exercise and physical exertion on diabetic retinopathy remain unknown. Exercise may help reduce the risk of diabetic complications by improving cardiovascular function, increasing HDL, protecting weight control, and increasing insulin sensitivity. In general, exercise and physical activity have not been shown to accelerate diabetic retinopathy, and no studies on exercise and type 1 diabetes show a detrimental effect on the development of PDR. However, physical exercise can have potentially detrimental effects on retinopathy and vision, especially when advanced retinal disease is present. Such adverse effects might be mediated by elevated systolic BP with subsequent vitreous hemorrhage, or decreases in already compromised tissue oxygen concentrations. However, the exact threshold for hemorrhage from the abnormal new vessels in PDR is unknown, with up to 84% of vitreous hemorrhages associated with exercise no more strenuous than walking in some studies. In general, people with PDR should avoid anaerobic exercise and exercise that involves straining, jarring, near-maximal isometric contractions, or Valsalva-type maneuvers such as high-impact aerobics, jogging, or heavy weight training. Beneficial low-risk exercises include stationary cycling, low-intensity machine rowing, swimming, and walking. Because of the beneficial effects, all patients with diabetes should be encouraged to participate in regular physical exercise programs specifically tailored to their individual ocular status.

As conclusively demonstrated by the ETDRS, the use of aspirin in diabetic patients is not associated with an increased risk of hemorrhage and has no demonstrated impact on the progression of retinopathy or macular edema. There is one case report of vitreous hemorrhage associated with retinopathy after thrombolysis. However, approximately 90,000 patients have been involved in clinical trials of thrombolytic agents in myocardial infarction, of which 10% had diabetes mellitus without any reports of ocular complications.

Smoking is a certain risk factor for CVD, progression of albuminuria to proteinuria, and nephropathy in both type 1 and 2 diabetic patients. However, the effects of smoking in diabetic retinopathy are unclear, because some studies have suggested an association whereas others have not. Because smoking has detrimental effects on the cardiovascular system and the development of nephropathy, smoking in patients with diabetes mellitus should be discouraged in the strongest possible terms.

Low hematocrit was an independent risk factor in the ETDRS analysis of baseline risk factors for development of high-risk PDR and of severe visual loss. A cross-sectional study involving 1691 patients revealed a twofold increased risk of any retinopathy in patients with a hemoglobin level of less than 12 g/dL as compared to those with a higher hemoglobin concentration using multivariate analyses controlling for serum creatinine, proteinuria, and other factors. In patients with retinopathy, those with low hemoglobin levels have a fivefold increased risk of severe retinopathy compared with those with higher hemoglobin levels. There have been limited reports of resolution of macular edema and hard exudate with improvement or stabilization of visual acuity in erythropoietin-treated patients after an increase in mean hematocrit. In view of the potential association of low hematocrit and diabetic retinopathy, it is important to ensure that patients with diabetic
Retinopathy and anemia are receiving appropriate management.

In summary, diabetes is clearly a multisystem disease requiring a medical team approach. Even with regard to ocular health, this necessitates the involvement of multiple health care specialists for optimal patient care.
Investigational Approaches

Our understanding of the basic molecular mechanisms underlying the development, progression, and damage from diabetic retinopathy has markedly expanded in recent years. There is considerable evidence to suggest that significant beneficial effects may be achieved using pharmacologic interventions to prevent or delay the development of nonproliferative retinopathy, suppress retinal vascular leakage, and inhibit intraocular neovascularization. Such efforts hold promise for the prevention of visual loss without the retinal damage inherent with current photocoagulation therapies. Indeed, numerous pharmacologic agents are in or approaching clinical trial for indications involving diabetic retinopathy, macular edema, and other ocular disorders. Results from these trials should become available within the next few years and may herald a new era in our therapeutic approach to diabetic ocular complications.
DIABETIC NEPHROPATHY

Diabetic nephropathy is clinically defined by persistent proteinuria greater than 500 mg/24 hours in a person with diabetic retinopathy without other renal disease. The distribution of renal disease due to type 2 diabetes is uneven among racial groups. American Indians, African Americans, and Mexican Americans have a greater incidence than non-Hispanic whites. Genetic predisposition, environmental factors, delayed diagnosis of type 2 diabetes, and subadequate medical care in minority groups contribute in undefined amounts to such disparity.

PATHOLOGY

Kidney injury in diabetes is indistinguishable by diabetes type and affects glomeruli, arterioles, tubules, and interstitium. Glomerular lesions include diffuse and nodular forms of intracapillary glomerulosclerosis (Fig. 31-26 A to C) (see also Color Plate). The diffuse type is characterized by mesangial expansion with increased PAS-positive matrix material, thickening of capillary wall and basement membrane. In type 1 diabetes, an early structural abnormality of diabetic nephropathy is glomerular basement membrane thickening (Fig. 31-27 D). Also noted in early and sequential biopsies is an increase in mesangial fractional volume (mesangial volume per glomerulus). With progression, capillary wall thickening and mesangial widening lead to capillary narrowing and reduced glomerular capillary filtration surface area. In diabetic patients, there is good correlation between the degree of mesangial expansion and the severity of clinical diabetic nephropathy.

Although nodular lesions were first thought to be pathognomonic for diabetic glomerulopathy, they may also be noted by light microscopy in amyloidosis, dysproteinemias (multiple myeloma and heavy chain disease), and glomerulonephritis (mesangial proliferative and membranoproliferative). Typical nodules are well-demarcated, PAS-positive globular structures exaggerating the diffuse lesions, and they occur at the periphery of the glomeruli. Additionally, hyaline deposits (so-called exudative or insudative lesions), consisting of plasma proteins and lipids, are present in arterioles (hyaline arteriosclerosis), capillary walls (fibrin cap), and Bowman's capsules (capsular drops). Hyaline arteriosclerosis or arteriolar hyalinosis, prominent in diabetic nephropathy, affects afferent as well as efferent arterioles. Initially, collections of hyaline material (hyaline drops) aggregate in the wall of juxtaglomerular arterioles. Gradually, these drops increase in size and replace the entire wall structure. Progression of glomerular and arteriolar changes ends in complete sclerosis. Østerby and associates

Despite narrowing, hyaline arteriosclerosis, glomerular sclerosis or occlusion, and interstitial fibrosis,
NEPHROPATHY IN TYPE 1 DIABETES

The natural history of diabetic nephropathy has been extensively studied in type 1 diabetes because it is usually possible to specify the exact time of onset. As first described by Mogensen, there are five distinct stages.\[405\] The course of diabetic nephropathy can be followed by two main variables: proteinuria and GFR (Fig. 31-28).

Stage 1: Glomerular Hyperfiltration and Renal Enlargement

Glomerular hyperfiltration and kidney enlargement typify the first stage. In 1934, Cambier noted that inulin clearances were greater than normal in type 1 diabetes.\[431\] Subsequent studies, using creatinine clearance or radionuclide techniques, validated this finding.\[432\]\[433\]\[434\] At onset of type 1 diabetes, approximately one third of individuals have an elevated GFR that is 20% to 40% higher than that of age-matched normal subjects.\[435\] No single pathophysiologic mechanism totally explains both kidney enlargement and glomerular hyperfiltration. Hyperglycemia, hormonal and vasoactive factors, enhanced renal plasma flow, and elevated transglomerular hydrostatic pressure gradient have been proposed as determinants of diabetic hyperfiltration.\[436\]\[437\]\[438\] With intensive insulin therapy, hyperglycemia decreases and GFR starts to decline within 3 to 8 days and drops further over the next few months.\[435\]\[439\] Thus, hyperfiltration may be an early indicator of individual susceptibility to hyperglycemia-induced renal changes. Hyperfiltration is a predictor of clinical nephropathy in some individuals. Mogensen's initial findings\[440\] that an elevated GFR predicts subsequent glomerulopathy in type 1 patients, previously contested, were confirmed by two different reports.\[441\]\[442\] In an 8-year prospective study of diabetic adolescents, Rudberg and colleagues showed that an increase of the initial GFR significantly predicted nephropathy.\[443\] Recently, Chiarelli and associates, in a 10-year longitudinal study, indicated glomerular hyperfiltration increased the risk of developing microalbuminuria in diabetic children.\[444\] Short-term or long-term intensive insulin treatments did not reduce kidney size in type 1 diabetic individuals.\[445\]\[446\]
Stage 2: Early Glomerular Lesions or Silent Stage with Normal Albumin Excretion

Early glomerular lesions, consisting of glomerular basement membrane thickening and mesangial matrix expansion, characterize the second stage. Those structural changes appear 18 to 36 months after onset of type 1 diabetes and may become prominent after 3.5 to 5 years. During this stage of morphologic changes, microalbuminuria, seen only after exercise or during episodes of very poor metabolic control, may be the only clinically detectable evidence of renal involvement. Otherwise, nephropathy is silent with normal AER (<25 mg/day).
Stage 3: Incipient Diabetic Nephropathy or Microalbuminuria Stage

The third stage, also called incipient diabetic nephropathy, is characterized by persistent and usually increasing microalbuminuria. Hypertension may also be a feature of the microalbuminuric stage. Hyperfiltration and renal enlargement persist, though to a lesser degree. Microalbuminuria, defined as urinary AER greater than 30 mg/24 hours or 20 µg/minute and less than 300 mg/24 hours or 200 µg/minute, represents the first laboratory evidence of diabetic renal disease. Total daily AER varies greatly and is increased by hypertension, strenuous exercise, fever, poor glycemic control, and congestive heart failure (CHF). Therefore, a diagnosis of incipient diabetic nephropathy is made only when microalbuminuria is detected in at least two of three urine specimens over several months.

Hemodynamic abnormalities and variable glomerular charge-selective properties due to loss of negatively charged proteoglycans contribute to variability of microalbuminuria. Measurements of urinary AER can be carried out by 24-hour, overnight, or short-term urine collections. Determinations of albumin:creatinine ratio (30-300 mg/g) or albumin concentration from an early morning urine sample are acceptable for screening, but timed urine collection is more accurate. The prevalence of microalbuminuria varies from 25% to 40% in individuals with type 1 diabetes for 5 to 15 years. Persistent microalbuminuria rarely occurs during the first 5 years of type 1 diabetes or before puberty. Consequently, screening in type 1 subjects should start after 3 years of diabetes duration or with puberty. Microalbuminuria is a sign of renal damage in both types of diabetes that predicts later nephropathy and, ultimately, ESRD. Therefore, detection of microalbuminuria represents a vital step in the early management of diabetic renal disease.
Stage 4: Clinical or Overt Diabetic Nephropathy: Proteinuria and Falling Glomerular Filtration Rate

Albuminuria greater than 300 mg/24 hours, relentless decline of renal function, and hypertension define the fourth stage of diabetic nephropathy. This stage, though variable, usually occurs 15 to 20 years after the onset of type 1 diabetes and after 5 or more years of diagnosed type 2 diabetes. The amount of urinary protein can be as little as 500 mg, but it can reach massive proportions, such as 20 to 40 g/24 hours. Continuing urinary protein loss of this magnitude is associated with increased glomerular pore size. There is a high mortality rate associated with proteinuria. Median survival is 10 years from the onset of proteinuria.

Diagnoses other than diabetic nephropathy should be pursued whenever a nephrotic syndrome develops in a patient with short-term type 1 diabetes or in the absence of retinopathy. Similarly, a diagnosis of diabetic nephropathy is prudently doubted when progressive renal insufficiency in a diabetic patient is not accompanied by macroalbuminuria (AER > 300 mg/24 hours). Percutaneous renal biopsy to clarify the renal disorder is indicated in such instances. In the follow-up of more than 90 patients with insulin-dependent diabetes and diabetic nephropathy, Viberti and co-workers have not encountered a single case of progressive renal failure without macroalbuminuria.

In subjects with type 1 diabetes, the prevalence of arterial hypertension ranges from 65% to 79% when macroalbuminuria is present. Hypertension intensifies the rate of progression of established diabetic renal disease. When structural kidney changes are advanced, GFR will invariably decrease. Without treatment, GFR usually declines in a linear fashion at a rate ranging from 7.5 to 28 mL/minute per year.
Stage 5: End-Stage Renal Disease

After 20 to 30 years of type 1 diabetes, about 30% to 40% of patients progress to ESRD. Recently, the interval between the onset of persistent proteinuria and the final stage of diabetic nephropathy has been lengthened by early and intensive treatment of hypertension and enhanced metabolic control of hyperglycemia.
NEPHROPATHY IN TYPE 2 DIABETES

Although renal structural changes and severity of target organ damage are similar in both types of diabetes, delayed diagnosis has complicated the construction of the natural history of diabetic renal disease in type 2 diabetes. The results of studies about renal hemodynamics and hypertrophy in newly diagnosed and established patients have been inconsistent. For example, Vora and associates reported that 45% of their 110 patients with type 2 diabetes had a GFR higher than 120 mL/minute per 1.73 m² and 16% had frank hyperfiltration (GFR > 140 mL/minute per 1.73 m²). By contrast, Schmitz and colleagues did not observe hyperfiltration in their newly diagnosed patients with type 2 diabetes (GFR 106 ± 14 mL/minute per 1.73 m²).

Fourteen percent to 24% of newly diagnosed patients with type 2 diabetes have microalbuminuria, which is associated with hyperglycemia, elevated BP, smoking, and hyperlipidemia. Microalbuminuria in type 2 diabetes is partially reversed by reduction of hyperglycemia and high BP. In a systematic review of the literature linking microalbuminuria to cardiovascular mortality in individuals with type 2 diabetes, Dinneen and Genstein found that the prevalence of microalbuminuria ranged from 20% to 36% in diabetic patients. There was also a significant association between microalbuminuria and total or cardiovascular mortality. Microalbuminuria raised the overall odds ratio for death to 2.4 and cardiovascular mortality to 2.0 over those without microalbuminuria. For older people, other causes of microalbuminuria should be considered before attributing this abnormality to type 2 diabetes. In a population-based study in southern Wisconsin, the prevalence of overt proteinuria in a 10-year interval was 33%. GFR of diabetic Arizona Pima Indians with macroalbuminuria declined by 35% over a 4-year period. Hypertension is highly characteristic of renal disease in type 2 diabetes, whether the individuals are normoalbuminuric, microalbuminuric, or macroalbuminuric.
Dietary Protein and Lipid Restriction

Rodent studies show that a low-protein diet reduces glomerular hypertension and prevents glomerular injury and albuminuria. In type 1 diabetic subjects with microalbuminuria and glomerular hyperfiltration, short-term dietary protein restriction (0.6 to 0.8 g/kg per day) decreases urinary AER and hyperfiltration. Long-term studies of protein restriction have been criticized for using creatinine clearance or the reciprocal of the serum creatinine instead of inulin clearance or radionuclide techniques to assess renal function. From a meta-analysis of five studies, Pedrini and colleagues concluded that dietary protein restriction delayed progression of diabetic nephropathy in subjects with type 1 diabetes, a finding disputed by Parving. In type 2 diabetes, trials of protein restriction are few and positive results have not been attained.

Abnormal lipid metabolism is highly prevalent in diabetic individuals with nephropathy, especially in those with a nephrotic syndrome. Although rodent studies imply that hyperlipidemia is important in the pathogenesis of glomerular injury, only suggestive data in humans have been reported. Nevertheless, treatment of dyslipidemia is paramount in the overall management of diabetes because it decreases the risk of CVDs.
OTHER DIABETES-ASSOCIATED RENAL DISEASES

Three other renal conditions are associated with diabetes: (1) urinary tract infection, (2) papillary necrosis, and (3) radiocontrast-induced renal failure. In long-standing type 1 diabetes, diabetic women, but not diabetic men, have an increased frequency of urinary tract infection. Diabetic patients are also at risk for emphysematous pyelonephritis, a rare, life-threatening complication of upper urinary tract infections, characterized by gas in the renal parenchyma or perirenal space. Renal ultrasonography or computed tomographic (CT) scanning is necessary to detect upper urinary tract complications early for appropriate treatment. Parenteral antimicrobial therapy and close metabolic control of diabetes with insulin therapy are mandatory, but nephrectomy or drainage is often necessary to preserve life.

Renal papillary necrosis, a severe destruction of renal parenchyma due to impaired blood flow to the inner medulla and papilla of the kidney, although observed in urinary infections, analgesic abuse, and sickle cell disease, is most common in diabetes. Clinical manifestations comprise flank pain, hematuria, chills, fever, and septicemia. Red and white blood cells, bacteria, and fragments of renal papillae can be seen in strained urine. Ureteral obstruction due to papilla fragments should be relieved promptly.

Radiocontrast-induced renal failure occurs more frequently in type 1 and 2 diabetic patients than in nondiabetic patients when the serum creatinine level is higher than 2 mg/dL. The use of radiographic contrast medium in a diabetic patient with renal insufficiency should be limited whenever possible. When angiography is unavoidable, patients should be aware of the risk of acute renal failure. Hydration before and after contrast injection may reduce the risk of nephropathy. A highly encouraging report indicates that pretreatment with acetylcysteine may protect against radiographic contrast media nephropathy.
HYPORENINEMIC HYPOALDOSTERONISM

Hyporeninemic hypoaldosteronism is prevalent in patients with renal insufficiency due to diabetic nephropathy. The syndrome of hyporeninemic hypoaldosteronism is characterized by normal cortisol levels, hyperkalemia, and low plasma renin, angiotensin II, and aldosterone levels. Most patients with the syndrome manifest a coexistent hyperchloremic metabolic acidosis. In diabetes mellitus, low plasma renin activity is due to defective conversion of prorenin to active renin. Increased extracellular volume due to diabetic nephropathy may, in part, diminish renin release. In this case, hyporeninemia is corrected by diuresis.

Clark and co-workers suggest that an increase in ANP contributes to hypoaldosteronism and hyperkalemia in the syndrome of acquired hypoaldosteronism. ACE inhibitors, non-steroidal anti-inflammatory drugs (NSAIDs), cyclosporine, potassium-sparing diuretics, trimethoprim, and pentamidine all can accentuate the hyperkalemia of hyporeninemic hypoaldosteronism.
TREATMENT OF DIABETIC NEPHROPATHY

Experience of the past two decades convincingly demonstrates that intensive control of hyperglycemia and adequate lowering of hypertensive BP are the key components of diabetic nephropathy management. Control of both hyperglycemia and hypertension has modified the natural course of diabetic nephropathy by reversing functional changes and by stabilizing progression of structural abnormalities (Fig. 31-29).

Glycemic Control

Large-scale, prospective trials provide compelling evidence that intensive glycemic control prevents diabetic nephropathy. The DCCT, which strived for near-normoglycemia in patients with type 1 diabetes, showed a 39% reduction in the risk of developing microalbuminuria and a 54% reduction in the occurrence of albuminuria. The UKPDS, comparing intensive blood glucose with conventional therapy in type 2 diabetes, found a 25% risk reduction (7% to 40%; \( P = .0099 \)) in microvascular complications, including progressive nephropathy. Degradation of insulin is compromised in renal failure. Consequently, progressive reductions in oral agent and insulin doses are necessary to minimize hypoglycemia. Metformin, a powerful hypoglycemic drug, is contraindicated in renal insufficiency (serum creatinine > 2.0 mg/dL) because of the risk of fatal lactic acidosis.
Blood Pressure Control

Early diagnosis and intensive treatment of arterial hypertension, whether with ACE inhibitors or other antihypertensive drugs in combination with low-dose diuretics, are essential for diabetic patients with diabetic renal disease. Effective BP control reduces albuminuria, delays progression of nephropathy, postpones renal insufficiency, and improves survival in type 1 and type 2 diabetic patients with diabetic nephropathy. Moreover, risk of fatal or nonfatal cardiovascular events is decreased in diabetic patients when systolic hypertension is treated.

The National Kidney Foundation Hypertension and Diabetes Executive Committees Working Group has lowered the previously recommended BP level of 130/85 to 130/80 mm Hg to optimally preserve renal function and reduce cardiovascular events in diabetic nephropathy. Two or more antihypertensive drugs are usually required to achieve this new target. Additional BP levels lower than 125/75 mm Hg are recommended for people who have proteinuria higher than 1 g/day and renal insufficiency regardless of etiology. Hypoproteinemic diabetic patients with renal insufficiency are susceptible to striking fluid retention, making BP control refractory to usual antihypertensive therapy. Dietary salt restriction and a combination of loop diuretics plus metolazone, a quinazoline diuretic, are necessary. A regimen of furosemide, 80 mg twice a day, and metolazone (Zaroxolyn), 10 mg twice a day, usually is effective as long as the creatinine clearance is higher than 10 mL/minute.

ACE inhibitors are efficient in both types of diabetes. Apart from reducing arterial BP, they are renoprotective due to their ability to decrease intraglomerular pressure.

Several randomized, controlled trials in normotensive type 1 and type 2 diabetic subjects with incipient nephropathy demonstrate that ACE inhibitors reduce microalbuminuria and may even preempt progression to overt nephropathy. Bakris and associates suggest that combining a calcium antagonist with an ACE inhibitor results in a greater decrease in urinary protein excretion and slower GFR decline. In addition, this combination permits equivalent BP reduction by lower doses of both drugs. ACE inhibitors can worsen hyperkalemia in diabetic patients with hyporeninemic hypoaldosteronism and induce temporary renal failure in those with bilateral renal artery stenosis or single-kidney and renal stenosis. Approximately one in five diabetic patients treated with ACE inhibitors discontinued the drug because of persistent nonproductive cough.

A related class of antihypertensive drugs, the angiotensin receptor blockers, block angiotensin II at the receptor level. Whether angiotensin receptor blockers will match the ACE inhibitors in improving the natural history of renal diseases is the subject of two large prospective, randomized trials in type 2 diabetic patients.
Dietary Protein and Lipid Restriction

Rodent studies show that a low-protein diet reduces glomerular hypertension and prevents glomerular injury and albuminuria. In type 1 diabetic subjects with microalbuminuria and glomerular hyperfiltration, short-term dietary protein restriction (0.6 to 0.8 g/kg per day) decreases urinary AER and hyperfiltration. Long-term studies of protein restriction have been criticized for using creatinine clearance or the reciprocal of the serum creatinine instead of inulin clearance or radionuclide techniques to assess renal function. From a meta-analysis of five studies, Pedrini and colleagues concluded that dietary protein restriction delayed progression of diabetic nephropathy in subjects with type 1 diabetes, a finding disputed by Parving. In type 2 diabetes, trials of protein restriction are few and positive results have not been attained.

Abnormal lipid metabolism is highly prevalent in diabetic individuals with nephropathy, especially in those with a nephrotic syndrome. Although rodent studies imply that hyperlipidemia is important in the pathogenesis of glomerular injury, only suggestive data in humans have been reported. Nevertheless, treatment of dyslipidemia is paramount in the overall management of diabetes because it decreases the risk of CVDs.
Uremia Therapy

While renal function relentlessly deteriorates, patients with diabetic renal disorder should be instructed as to the available options in uremia therapy, including home or facility hemodialysis, continuous ambulatory peritoneal dialysis, continuous cyclic peritoneal dialysis, living related or cadaveric kidney transplant, and combined pancreas and kidney transplant (Table 31-4). A small number of uremic diabetic patients, severely debilitated by extensive co-morbid conditions, may choose death instead of renal replacement therapy. As reported by the U.S. Renal Data System (USRDS) in 2000, 531 for 102,942 diabetic patients receiving uremia therapy in 1998, about 74% were treated with facility hemodialysis, but only 7.5% elected peritoneal dialysis. A few (0.7%) adopted home hemodialysis, although this therapy, by consensus, is superior to facility dialysis. Approximately 17% of diabetic ESRD patients had a functioning kidney transplant in the United States in 1998. Kidney transplantation, the best option in uremia therapy for diabetic patients, provides patient survival and rehabilitation that is greater than the best dialytic therapy. 532

Although combined pancreas plus kidney transplantation, when successful, offers exquisite glycemic control and better quality of life, the prospective recipient risks a serious surgical complication rate. 533

The USRDS reports that diabetic ESRD patients treated with hemodialysis have better survival than those receiving peritoneal dialysis. 534 In contrast, the Canadian-USA (CANUSA) Peritoneal Dialysis Study found superior survival of diabetic ESRD patients treated by peritoneal dialysis in Canada. 535 Overall, survival of diabetic patients receiving uremia therapy, irrespective of modality, is vastly inferior to that of nondiabetic patients. 536 Five-year survival rates are 21% to 31%. Such disparity is the result of cardiovascular complications, cerebrovascular and peripheral vascular disease, plus a greater risk of septicemia.

Diabetic patients with renal failure exhibit symptoms and signs of uremia at a lower serum creatinine than that of nondiabetic patients. As a result, renal replacement therapy is frequently initiated earlier in their deterioration. The end of conservative management is often forced by severe hypervolemia precipitating the start of dialytic therapy. When creatinine clearance falls below 70 mL/minute, individuals with diabetic nephropathy who had been followed by their internists through microalbuminuric and/or macroalbuminuric stages should be referred to nephrologists for pre-ESRD education and planning for management of renal insufficiency (Fig. 31-30).

Delayed referral to renal specialists contributes to late arteriovenous access construction for hemodialysis and increases morbidity, mortality, and utilization of health care resources. 535 Lameir and co-workers, assessing physicians’ referral patterns, note that internists, cardiologists, and endocrinologists refer their patients to nephrologists too late, meaning that urgent hemodialysis must be performed via insertion of a temporary jugular or femoral catheter (Fig. 31-31).

Caring for patients afflicted by diabetic nephropathy is demanding and is better accomplished by a team composed of primary care physician, cardiologist, ophthalmologist, podiatrist, nutritionist, and nurse-educator. Evidence-based data suggest that diabetic nephropathy prevention has been suboptimal in the United States. 535 Constant effort to diagnose type 2 diabetes early, education of diabetic individuals, and primary care providers represent the initial steps of diabetic nephropathy prevention. Better patient management starting in the early phases of diabetic renal disease will prevent or attenuate progression of diabetic nephropathy and will reduce the incidence of cardiovascular complications.
DIABETIC NEUROPATHIES

Diabetic neuropathy (DN) is a common and troublesome complication of diabetes mellitus, leading to great morbidity and mortality and resulting in a huge economic burden for care of the patient with diabetes mellitus. It is the most common form of neuropathy in the developed countries of the world, accounts for more hospitalizations than all the other diabetic complications combined, and is responsible for 50% to 75% of nontraumatic amputations. Diabetic neuropathy is not a single entity but a set of clinical syndromes that affect distinct regions of the nervous system, singly or combined. It may be silent and go undetected while nonetheless exercising its ravages, or it may present with clinical symptoms and signs that are nonspecific and insidious and progress slowly, mimicking those seen in many other diseases.

PREVALENCE

Diabetic neuropathy is a heterogeneous disorder that encompasses a wide range of abnormalities affecting proximal and distal peripheral sensory and motor nerves as well as the autonomic nervous system. For these reasons, it has been difficult to obtain precise estimates of the true prevalence, and reports vary from 10% to 90% in diabetic patients, depending on the criteria and methods used to define neuropathy. Twenty-five percent of patients attending a diabetes mellitus clinic volunteered symptoms; 50% were found to have neuropathy after a simple clinical test such as the ankle jerk or vibration perception threshold (VPT) test; almost 90% tested positive to sophisticated tests of autonomic function or peripheral sensation. Neurologic complications occur equally in type 1 and type 2 diabetes mellitus and additionally in various forms of acquired diabetes.

The major morbidity associated with somatic neuropathy is foot ulceration, the precursor of gangrene and limb loss. DSPN increases the risk of amputation 1.7-fold: 12-fold if there is deformity (itself a consequence of neuropathy) and 36-fold if there is a history of previous ulceration. About 85,000 amputations are performed in the United States each year—one every 2 minutes—and neuropathy is considered to be the major contributor in 87% of cases. It is also the most life-spoiling of the diabetic complications and has tremendous ramifications for the quality of life of the person with diabetes. Once autonomic neuropathy sets in, life can become quite dismal, and the mortality rate approximates 25% to 50% within 5 to 10 years.
NATURAL HISTORY

The natural history of diabetic neuropathy separates patients into two very distinctive entities: (1) those who progress gradually with increasing duration of diabetes mellitus and (2) those who have a relatively explosive onset and experience remission almost completely. Sensory and autonomic neuropathies generally progress, whereas mononeuropathies, radiculopathies, and acute painful neuropathies, although symptoms are severe, are short-lived and tend to recover.

Progression of DSPN is related to glycemic control in both type 1 and type 2 diabetes mellitus. The most rapid deterioration of nerve function occurs soon after the onset of type 1 diabetes mellitus, and within 2 to 3 years there is a slowing of the progress with a shallower slope to the curve of dysfunction. In contrast, slowing of NCVs in type 2 diabetes mellitus may be one of the earliest neuropathic abnormalities and is often present at diagnosis. After diagnosis, slowing of NCVs generally progresses at a steady rate of approximately 1 m/second each year, and the level of impairment is positively correlated with duration of diabetes mellitus. Although most studies have documented that symptomatic patients are more likely to have slower NCVs than patients without symptoms, these do not relate to the severity of symptoms.

In a long-term follow-up study of patients with type 2 diabetes mellitus, electrophyslogic abnormalities in the lower limb increased from 8% at baseline to 42% after 10 years, and a decrease in sensory and motor amplitudes, indicating axonal destruction, was more pronounced than the slowing of the NCVs. An increase of about 2 points in an 80-point clinical symptom and sign scale (neurologic symptom score [NSS] and neurologic impairment score [NIS]) can be expected per year. These scales contain information on motor, sensory, and autonomic signs and symptoms. Using objective measures of sensory function such as the VPT test, the rate of decline in function has been reported as 1 or 2 vibration units per year.

In a 6-year cohort study, elevated VPT (>6.5 vibrations) was found in 62.5% of patients. The risk factors were male sex, age, and increased AER. However, there now appears to be a decline in this rate of evolution. For example, in the nerve growth factor (NGF) study, the VPT at the beginning of the study in the placebo group was identical to that at the end of 1 year. This is particularly important in planning studies on the treatment of DSPN, which have always relied on differences between drug treatment and placebo and have been successful because of the decline in nerve function in the placebo-treated patients. According to the earlier data on rates of change, clinically meaningful loss of VPT and NCV has been estimated to take at least 3 years, dictating a future need to carry out studies over a longer period when considering only large-fiber dysfunction.

We must recognize that DSPN is a disorder in which the prevailing abnormality is loss of axons that electrophysiologically translates to a reduction in amplitudes and not conduction velocities, and changes in NCV may not be an appropriate means of monitoring progress or deterioration of nerve function. It has always been advocated that diabetes mellitus affects the longest fibers first, hence, the increased predisposition in taller individuals. Now it seems that small-fiber involvement may herald the onset of neuropathy and even diabetes mellitus itself. Small-fiber function is not detectable using standard electrodiagnostic methods and requires measurement of sensory, neurovascular, and autonomic thresholds and cutaneous nerve fiber density.

There are few data on the longitudinal trends in small-fiber dysfunction and the mutual concurrence and development of peripheral somatic and autonomic neuropathies. Toyry and associates reported that the development of autonomic and peripheral somatic neuropathies was divergent in patients with type 2 diabetes mellitus, suggesting different pathophysiologic processes for these neuropathies. Much remains to be learned of the natural history of diabetic autonomic neuropathy.

Karamitos and colleagues reported that the progression of diabetic autonomic neuropathy is significant during the 2 years subsequent to its discovery. The mortality for diabetic patients with autonomic neuropathy has been estimated to be 44% within 2.5 years of diagnosing symptomatic autonomic neuropathy. A meta-analysis of 14 longitudinal studies revealed that the mortality rate after 5.8 years of diabetes with asymptomatic autonomic neuropathy was 27%.
CLASSIFICATION

Diabetic neuropathy is not a single entity but a number of different syndromes, ranging from subclinical to clinical manifestations depending on the classes of nerve fibers involved. According to the San Antonio Convention, the main groups of neurologic disturbance in diabetes mellitus include the following:

1. Subclinical neuropathy, determined by abnormalities in electrodiagnostic and quantitative sensory testing without concomitant clinical sign and symptoms.
2. Diffuse clinical neuropathy, which may be proximal or distal and have large symmetrical sensorimotor or small-fiber and autonomic dysfunction.
3. Focal neuropathies, which include mononeuropathies and entrapment syndromes.

The onset of neuropathy may be acute, with pain or, insidious, with chronic pain as well as clinical features of a mixed sensorimotor dysfunction.
PATHOGENESIS

Focal Neuropathies

Mononeuropathies are caused by microscopic vasculitis and subsequent ischemia or infarction of nerve. Focal ischemia results in segmental demyelination followed by remyelination. In diabetic patients, remyelination is defective and delays the repair of focal deficits. Delayed remyelination may be a consequence of diabetes-induced Schwann cell dysfunction. However, in most cases, recovery does occur because adjacent fascicles take over the function of the damaged ones.

It is not clear why diabetic nerves are more susceptible to entrapment syndromes. Upton and McComas suggested that serial constrictions impairing axoplasmic flow may combine to cause nerve dysfunction and that diabetic patients who have severely impaired axoplasmic flow are more frequent. It was thought that mechanical rather than microvascular factors account for pathologic features of compressed nerves. However, the increased prevalence may be related to repeated undetected trauma, susceptibility of diabetic nerves to injury, accumulation of AGEs, or accumulation of fluid or edema within the confined space of the carpal tunnel.
Distal Symmetrical Polyneuropathy

For a detailed discussion of the different theories on pathogenesis of DSPN, the reader is referred to several excellent recent reviews. However, we do review the principal theories on pathogenesis. DSPN is a heterogeneous disease with widely varying pathology, suggesting differences in pathogenic mechanisms for the different clinical syndromes. Recognition of the clinical homologue of these pathologic processes is the first step in achieving the appropriate form of intervention. Figure 31-32 summarizes our current view of the pathogenesis of DSPN. This figure depicts multiple causes, including metabolic, vascular, autoimmune, oxidative stress, and neurohormonal growth factor deficiency.

Metabolic Hypothesis of Nerve Damage

Although there is increasing evidence that the pathogenesis of DSPN consists of several mechanisms, the prevailing theory is that persistent hyperglycemia is the primary factor. Persistent hyperglycemia (or glucose toxicity) or insulin deficiency may precipitate metabolic or vascular events. Metabolic defects include alteration of the poloy or sorbitol pathway, abnormalities in lipid metabolism, deficiencies of dihomo-γ-linolenic acid (GLA) and N-acetyl-l-carnitine (which are significant in diabetes), glycation or AGE formation, increased oxidative stress, and diabetes mellitus-induced growth factor defects. The results of the DCCT endorse the importance of glycemic control in preventing neuropathy. However, it is not unusual that metabolic factors can account for all patients with neuropathy or for the heterogeneity of the clinical syndromes.

Immune Hypothesis of Nerve Damage

Data from several large epidemiologic studies show that neurallogic signs precede the diagnosis of diabetes in up to 11% of diabetes patients. The neuropathogenic process in some patients with diabetes mellitus may be independent of hyperglycemia. A number of autoimmune phenomena have been described in these patients that might induce immune system responses, including antiphospholipid antibodies (PLAs), a family of closely related immunoglobulins that interact with one or more negatively charged phospholipids (constituents of nervous tissues), and sera with high titers of IgG-PLA that inhibit cell growth and differentiation in a neoblastoma cell line. Anti-PLAs have been found in 88% of a diabetic population with neuropathy compared with 32% in diabetes mellitus patients without apparent neurologic complications and 2% in the general population. Because PLAs are associated with a tendency to vascular thrombosis, their presence may provide a link between the immune and vascular theories of causation of neuropathy.

Autoantibodies to the gangliosides, siaio- and asialo-GM1, have been described in diabetes mellitus patients with neuropathy characterized by a slight emphasis on a motor deficit with electrophysiological signs of demyelination. It is argued that anti-GM1 antibodies are not pathogenic but passively reflect cellular destruction. A number of observations, however, suggest that they have pathogenic potential. Indeed, there may be differences in responsiveness based on the distribution of these antibodies among the immunoglobulin classes. As yet, there is no known autoimmune mechanism in the pathogenesis of the disease, but our understanding of autoimmune neuromopathy is constantly being fueled by new evidence. This area of research in diabetes promises to be exciting and fruitful.

Microvascular Hypothesis

The peripheral and autonomic nervous system has an important role in the control and regulation of microvascular function. As a corollary, microvascular perfusion is essential for the integrity of nerves. Microvascular insufficiency due to impaired vasoconstriction and vasodilation to various stimuli has been proposed as a possible cause of DSPN by a number of investigators. The interest in microvascular derangements in DSPN arises from studies suggesting that absolute or relative ischemia may exist in the nerves of diabetes mellitus subjects due to altered function of the endoneural and epineurial blood vessels. Histopathologic studies show the presence of different degrees of endoneurial and epineurial microvasculopathy, mainly vessel basement membrane thickening and obstruction of vasa nervorum.

A number of functional disturbances are found in the microvasculature of the nerves of patients with diabetes mellitus. These include decreased neural blood flow, increased vascular resistance, decreased neural P0.2 and altered vascular permeability characteristics, such as loss of the anionic charge barrier and decreased charge selectivity. Decreased neural blood flow and increased vascular resistance in diabetes mellitus may result from alterations in microvascular reactivity, such as impaired dilator responses to substance P, calcitonin gene-related peptide (CGRP), and reactive hyperemia. Vasomotion, the rhythmic contraction exhibited by arterioles and small arteries, is disordered in diabetes mellitus patients, and the warm thermal sensory threshold correlated significantly with the mean amplitude of vasomotion. This indicates an interaction between C-fiber function and vasomotion, but it is not clear whether the neurologic deficit precedes or follows the loss of normal vascular motility.

It also has been shown that abnormalities of cutaneous blood flow correlated with indices of small fiber neuropathy. Metabolic dysfunction of both central and reflex vasoconstrictor sympathetic nerves, together with abnormal vascular smooth muscle metabolism, may alter vascular tone and increase arteriolar and shunt blood flow, both of which would increase capillary pressure. This might be similar to the mechanism of disordered kidney function in diabetes. In contrast, disordered endothelial and smooth muscle metabolism, resulting in impaired NO generation, or resistance to the vasodilatory actions of NO, would lead to reduced microvascular responses to both flow-mediated vasodilation following ischemia and hyperemia following injury. These defects have now been reported prior to the onset of diabetes mellitus, in family members, and co-segregate with other components of the metabolic syndrome, including hypertension, dyslipidemia with elevated triglyceride levels, and insulin resistance.

Thus, it is possible that ischemia precedes neuropathy or that both conditions are the result of separate processes caused by the same etiologic factors and each accelerates the other's progress; that is, vascular insufficiency causes nerve damage and nerve dysfunction impairs blood flow. Whatever the case, the loss of the neurovascular function reduces the required nutritional delivery to skin and subcutaneous tissue and, coupled with impaired perception, predisposes the limb to injury, ulceration, and infection that may culminate in gangrene.

![Figure 31-32](image-url)
Adult dorsal root ganglia and sympathetic neurons, both of which are affected in DSPN, are dependent on NGF for their maintenance or survival. NGF has been implicated in diverse and widespread activities, including vasodilatation, gut motility, and nociception. Numerous data suggest that a decline in NGF synthesis in diabetes mellitus plays a role in the pathogenesis of DSPN by causing a functional deficit in small fibers. These fibers have a role in pain and thermal sensation. The effect of NGF depletion may be mediated through the down-regulation of neurofilament gene expression or mRNAs that encode the precursor molecules of substance P both shown to be NGF-dependent. Another member of the neurotrophin family, neurotrophin 3, may be important for the survival and function of the large nerve fibers subserving position, vibration, and possibly motor functions.

IGF-I and IGF-II, which are implicated in the growth and differentiation of neurons and IGF receptors, are present in nerve tissues (i.e., neurons, Schwann cells, ganglia) involved in DSPN. IGFs and their binding proteins are regulated by insulin and the glycemic state. One consequence of insulin insufficiency in diabetes mellitus is a reduction in circulating IGF-I concentration. It seems reasonable to hypothesize that abnormal IGF-I and IGF-II metabolism plays a role in some aspect of DSPN. Little is known, however, about the other effects of diabetes mellitus on local expression, synthesis, and transport of these growth factors in nerve tissue.

Laminin, a large heterotrimeric protein present in the basal lamina of nerves, appears to be important in nerve regeneration and its expression. Laminin also exerts antiapoptotic properties against the neurotoxicity of sera of patients with diabetes mellitus.

**Oxidative Stress Hypothesis**

Reactive oxygen species (ROS) can regulate multiple signaling mediators linked with important processes that may involve various components of the nerve, dorsal root ganglia, and the vasa nervorum. These processes include metabolism, immune response, cell-cell adhesion, inflammation, cell proliferation, aging, and cell death. Hyperglycemia generates free radicals primarily through increasing flux through the mitochondrial electron transport chain. Formation of AGEs and interaction with the AGE receptor may also lead to the generation of ROS in some cell types.

A prominent role of these reactive molecules as mediators of cellular processes that lead to endothelial cell dysfunction in diabetes mellitus has been suggested. One of the most extensively investigated redox-sensitive molecular paths is that involving a nuclear factor, NF-B. It is a classic member of the Rel family of transcription factors and is known to regulate a diverse set of cellular functions, such as cell growth, immune response, cell survival and development. There are five members of the family, and they tend to form homo- and heterodimers as well as with other members of the family. High glucose and AGE-mediated activation of NF-B is regarded as a key event in the transformation of the vasculature and accelerated vascular disease as well as smooth muscle dysfunction in diabetes mellitus. It is also potentially reversible with the powerful antioxidant, -lipoic acid.

In summary, DSPN is a heterogeneous disease with widely varying pathology, suggesting differences in pathogenic mechanisms for the different clinical syndromes. Recognition of the clinical homologue of these pathologic processes is the first step in achieving the appropriate form of intervention.
CLINICAL PRESENTATION AND TREATMENT OPTIONS

The spectrum of clinical neuropathic syndromes described in patients with diabetes mellitus includes dysfunction of almost every segment of the somatic peripheral and autonomic nervous system \[568\] \[563\] (Fig. 31-33). Each syndrome can be distinguished by its pathophysiologic, therapeutic, and prognostic features.

### Focal Neuropathies

#### Mononeuropathies

Mononeuropathies occur primarily in the older population, their onset is generally acute and associated with pain, and their course is self-limiting, resolving within 6 to 8 weeks. These are due to vascular obstruction after which adjacent neuronal fascicles take over the function of those infarcted by the clot. \[563\]

**Treatment**

Treatment is predominantly symptomatic for pain. If there is weakness such as of the facial muscles, physical therapy and electrical stimulation may be necessary to prevent the weakness from becoming permanent.

#### Entrapment Syndromes

Entrapment syndromes that start slowly, progress, and persist without intervention must be distinguished from mononeuropathies. Common entrapment sites in diabetes mellitus patients involve median, ulnar, radial, femoral, and lateral cutaneous nerves of the thigh, peroneal nerves, and medial and lateral plantar nerves. Entrapment syndromes are found in one third of patients with diabetes. For example, carpal tunnel syndrome occurs twice as frequently in people with diabetes mellitus compared with a normal healthy population. It is important, therefore, to elicit a detailed history of the distribution of pain and weakness and to perform the equivalent of Tinel's test at various levels of entrapment. If recognized, the diagnosis can be confirmed by electrophysiologic studies.

**Treatment**

The mainstays of nonsurgical treatment are resting the joint traversed by the nerve, aided by the placement of splints in a neutral position for day and night use; diuretics to reduce edema; addition of nonsteroidal anti-inflammatory drugs (NSAIDs), and steroids and local anesthetic injections. Surgical treatment consists of sectioning the constrictive tendon sheath. The decision to proceed with surgery is based on many considerations, including severity of symptoms, appearance of motor weakness, and failure of nonsurgical treatment.
Diffuse Neuropathies

Proximal Motor Neuropathies

For many years, proximal motor neuropathy has been considered to be a component of diabetic neuropathy. Its pathogenesis was not understood, and its treatment was neglected with the anticipation that the patient would eventually recover, albeit over a period of some 1 to 2 years, suffering considerable pain, weakness, and disability. The condition is known by a number of synonyms: proximal neuropathy, femoral neuropathy, diabetic amyotrophy, and diabetic neuropathic cachexia. Proximal motor neuropathy can be clinically identified based on the following common features:

1. Primarily affects the elderly.
2. Gradual or abrupt onset.
3. Begins with pain in the thighs and hips or buttocks, followed by significant weakness of the proximal muscles of the lower limbs with inability to rise from the sitting position (positive Gower's maneuver).
4. Begins unilaterally and spreads bilaterally.
5. Coexists with DSPN.
6. Is characterized by spontaneous or percussion-provoked muscle fasciculation.

Proximal motor neuropathy is now recognized as being secondary to a variety of causes unrelated to diabetes mellitus but that occur more frequently in patients with diabetes mellitus than in the general population. The condition includes patients with chronic inflammatory demyelinating polyneuropathy (CIDP), mononuclear gangliopathy, circulating GM1 antibodies and antibodies to neuronal cells, and inflammatory vasculitis. It was formerly thought to resolve spontaneously in 1.5 to 2 years, but now, if found to be immune-mediated, it can resolve within days of initiation of immunotherapy. The condition is readily recognizable clinically with prevailing weakness of the iliopsoas, obturator, and adductor muscles, together with relative preservation of the gluteus maximus and minimus and hamstrings.

Affected patients have great difficulty rising out of chairs unaidered and often use their arms to assist themselves. Heel or toe standing is surprisingly good. In the classic form of diabetic amyotrophy, axonal loss is the predominant process and the proximal motor neuropathy coexists with DSPN.

Electrophysiologic evaluation reveals lumbosacral plexopathy. In contrast, if demyelination predominates and the motor deficit affects proximal and distal muscle groups, the diagnosis of CIDP, mononuclear gangliopathy of unknown significance, and vasculitis should be considered. Biopsy of the obturator nerve reveals deposition of immunoglobulin, demyelination, and inflammatory cell infiltrate of the vasa nervorum. Cerebrospinal fluid protein content is high, and the lymphocyte count is elevated.

Treatment options include intravenous immunoglobulin for CIDP, plasma exchange for mononuclear gangliopathy of unknown significance, and vasculitis should be considered. Biopsy of the obturator nerve reveals deposition of immunoglobulin, demyelination, and inflammatory cell infiltrate of the vasa nervorum. Cerebrospinal fluid protein content is high, and the lymphocyte count is elevated.

Distal Symmetrical Polyneuropathy

Distal symmetrical polyneuropathy (DSPN) is the most common and widely recognized form of diabetic neuropathy. The onset is usually insidious but occasionally is acute, following stress or initiation of therapy for diabetes mellitus. DSPN may be either sensory or motor and involve small nerve fibers, large nerve fibers, or both.

Small-fiber dysfunction usually occurs early and often is present without objective signs or electrophysiologic evidence of nerve damage. It is manifested by early lower limb symptoms of pain and hyperalgesia in the lower limbs, followed by a loss of thermal sensitivity and reduced light touch and pinprick sensation. DSPN may be accompanied by loss of cutaneous nerve fibers that stain positive for the neuronal antigen protein gene product (PGP) 9.5 (Fig. 31-34) (Figure Not Available) as well as impaired neurovascular blood flow. Small-fiber neuropathies, however, can present in a variety of ways.

Small-Fiber Neuropathy

Acute Painful Polyneuropathy

In some patients, a predominantly small-fiber neuropathy develops, manifested by pain and paresthesias early in the course of diabetes mellitus. It may be associated with the onset of insulin therapy and has been termed insulin neuritis. By definition, it has been present for less than 6 months. Symptoms often are exacerbated at night and are manifested in the feet more than the hands. Spontaneous episodes of pain can be severely disabling. The pain varies in intensity and character. In some patients, the pain has been variably described as burning, lancinating, stabbing, or sharp. Paresthesias or episodes of distorted sensation, such as pins and needles, tingling, coldness, numbness, or burning, often accompany the pain.

The lower legs may be exquisitely tender to touch, with any disturbance of the hair follicles resulting in excruciating pain. Because pain can be exacerbated by repeated contact of the lower limbs with foreign objects, even basic daily activities, such as sitting at a desk, may be disrupted. Pain often occurs at the onset of the disease and is often worsened by initiation of therapy with insulin or sulfonylureas.

It may be associated with profound weight loss and severe depression, termed diabetic neuropathic cachexia. This syndrome occurs predominantly in male patients and may occur at any time in the course of both type 1 and type 2 diabetes mellitus. It is self-limiting and invariably responds to simple symptomatic treatment. Conditions such as Fabry’s disease, amyloid, human immunodeficiency viral infection, heavy metal poisoning (e.g., as with arsenic), and excess alcohol consumption should be excluded. It does overlap with the idiopathic variety of acute, painful small-fiber neuropathy that is also a diagnosis by exclusion.

Chronic Painful Neuropathy

Another variety of painful polyneuropathy is characterized by an onset occurring later (often years) in the course of diabetes mellitus, in which the pain persists for longer than 6 months and becomes debilitating. This condition may result in tolerance to narcotics and analgesics and, finally, to addiction. It is extremely resistant to all forms of intervention and is most frustrating to both patient and physician.

The mechanism of pain in DSPN is not well understood. Interacting pathophysiologic mechanisms at the peripheral and...
central nervous system may be responsible for initiation and maintenance of chronic neuropathic pain (Fig. 31-36). Hyperglycemia may be a factor in lowering the pain threshold. There is a sequence in DSPN, beginning when nerve function is good and there is no pain, hyperalgesia, hyperesthesia, or allodynia. Progression of the condition results in nerve dysfunction and pain, increased sensitivity to painful stimuli, and allodynia.

**Chronic Small-Fiber Neuropathy**

Disappearance of these symptoms may not necessarily reflect nerve recovery but rather nerve death. When patients volunteer the "apparent improvement," progression of the neuropathy must be excluded by careful examination. Pain, however, may persist even with dead nerves. The objective physical features include loss of warm thermal perception, decreased heat pain, cold pain, loss of touch pressure perception, and impairment of blood flow. A foot with these findings is at risk for repeated minor trauma, foot ulceration, infection, and gangrene. Small-fiber neuropathies have profound effects on quality of life and mortality.

**Large-Fiber Neuropathies**

Large-fiber neuropathies may involve sensory nerves, motor nerves, or both (Table 31-6). These tend to be the neuropathies of signs rather than symptoms. Large fibers subserve motor function, vibration perception, position sense, and cold thermal perception. Unlike the small nerve fibers, these are

---

**TABLE 31-5 — Clinical Manifestations of Small-Fiber Neuropathies**

1. Symptoms prominent. Pain is of the C-fiber type. It is burning and superficial and associated with allodynia, i.e., interpretation of all stimuli as painful (e.g., touch).
2. Late in the condition, hypoaesthesia.
3. Defective warm thermal sensation.
4. Defective autonomic function with decreased sweating, dry skin, impaired vasomotion and blood flow, and a cold foot.
5. Remarkable intactness of reflexes, motor strength.
7. Loss of cutaneous nerve fibers using PGP 9.5 staining.
8. Diagnosed clinically by reduced sensitivity to 1.0-g Semmes Weinstein monofilament and pricking sensation using the Waardenberg wheel or similar instrument.
9. Abnormalities in thresholds for warm thermal perception, neuro-vascular function, pain, quantitative sudorimetry, and quantitative autonomic function tests.
10. Risks are foot ulceration and subsequent gangrene.

To repeated midfoot trauma, widening of Lisfranc's joint, and foot deformity that can be relieved by Achilles tendon lengthening. The ataxia and loss of strength increase the susceptibility to falling and fractures. The tendency is increased in aging diabetic patients and requires preventive measures and exercise and strength training.

Most patients with DSPN, however, have a "mixed" variety of neuropathy, with both large-fiber and small-fiber damages. In the case of DSPN, a "glove-and-stocking" distribution of sensory loss is almost universal. Early in the course of the neuropathic process, multifocal sensory loss also might be found. In some patients, severe distal muscle weakness can accompany the sensory loss, resulting in an inability to stand on the toes or heels. Some grading systems use this as a definition of severity.
**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF DISTAL SYMMETRICAL POLYNEUROPATHY**

The 1988 San Antonio conference on DSPN and the 1992 conference of the American Academy of Neurology recommended that at least one parameter from each of the following five categories be measured to classify DSPN:

- Symptom profiles
- Neurologic examination
- Quantitative sensory test (QST)
- Nerve conduction velocity (NCV) study
- Quantitative autonomic function test (QAFT)

The diagnosis of DSPN rests heavily on a careful history for which a number of questionnaires for the neurologic symptom score and the neurologic impairment score have been developed by Boulton, Dyck, Vinik, and others. The initial neurologic evaluation should be directed toward the detection of the specific part of the nervous system affected by diabetes mellitus (Fig. 31-37). Bedside neurologic examination is quick and easy but provides nominal or ordinal measures and contains substantial interindividual and intrindividual variation. The least reliable measure is the neurologic symptom score.

For example, it is useless to measure VPT with a tuning fork other than one that has a frequency of 128 Hz. Similarly, using a 10-g monofilament is good for predicting foot ulceration, as is the Achilles reflex, but both are insensitive to the early detection of neuropathy, and a 1.0-g monofilament increases the sensitivity from 60% to 90%. Sensory function must be evaluated on both sides of the feet and hands if one wants to be sure not to miss entrapment syndromes. Tinel's sign not only is useful for carpal tunnel problems but also can be applied to the ulnar notch, the head of the fibula, and below the medial tibial epicondyle for ulnar, peroneal and medial plantar entrapments, respectively. The QST and QAFT are objective indices of neurologic functional status. Combined, these tests cover vibratory, proprioceptive, light touch, pain, thermal, and autonomic function. Developments of a number of relatively inexpensive devices allow suitable assessment of somatosensory function, including vibration, thermal, light touch, and pain perception. These types of instruments allow for cutaneous sensory functions to be assessed noninvasively, and their measurements are correlated with specific neural fiber function.

**TABLE 31-6 — Clinical Presentation of Large-Fiber Neuropathies**

1. Impaired vibration perception (often the first objective evidence) and position sense.
2. Depressed tendon reflexes.
3. A delta type deep-seated gnawing, dull, like a toothache in the bones of the feet, or even crushing or cramp-like pain.
4. Sensory ataxia (waddling like a duck).
5. Wasting of small muscles of feet with hammer toes (intrinsic minus feet and hands) with weakness of hands and feet.
7. Increased blood flow (hot foot).
8. Risk is Charcot's neuroarthropathy.

function and peripheral skin blood flow induced by autonomic neuropathy. Subclinical neuropathy is diagnosed on the basis of the following:

1. Abnormal electrodiagnostic tests with decreased NCV or decreased amplitudes;
2. Abnormal QST for vibration perception, light touch, thermal warming, and cooling thresholds;
3. QAFT revealing diminished heart rate variation with deep breathing, Valsalva maneuver, and postural testing.

Biopsy of nerve tissue may be helpful for excluding other causes of neuropathy and in the determination of predominant pathologic changes in patients with complex clinical findings as a means of dictating choice of treatment. Skin biopsy has some clinical advantages in diagnosis of small-fiber neuropathies by quantification of PGP 9.5, when all other measures, including electromyography, are negative and there are no objective physical signs. Diabetes mellitus as the cause of neuropathy is diagnosed by exclusion of various other causes of neuropathy.
MANAGEMENT OF DISTAL SYMMETRICAL POLYNEUROPATHY

Once DSPN is diagnosed, therapy can then be instituted with the goal of both ameliorating symptoms and preventing the progression of neuropathy. Successful management of these syndromes may eventually be geared to the individual pathogenic processes. At present, however, control of hyperglycemia and meticulous foot care (Table 31-7) are the mainstays of therapy.

Management Aimed at Pathogenetic Mechanisms

Control of Hyperglycemia

Retrospective and prospective studies have suggested a relationship between hyperglycemia and the development and severity of DSPN. In the Steno trial, followed 4400 diabetic patients over 25 years and showed an increase in prevalence of clinically detectable DSPN from 12% of patients at the time of diagnosis of diabetes mellitus to almost 50% after 25 years. The highest prevalence occurred in those people with poorest diabetes control.

The DCCT research group reported significant effects of intensive insulin therapy on progression of neuropathy. In type 1 diabetes, the prevalence rates for clinical or electrophysiologic evidence of neuropathy were reduced by 64% in those treated by intensive insulin therapy after 5 years of follow-up.

The results of the DCCT study support the necessity for strict glycemic control, but the effect of insulin therapy significantly reduced the prevalence of clinical neuropathy by 61% (7% in intensive insulin therapy group versus 17% in conventional therapy group). In a 12-month study of zenarestat, perception, whereas placebo-treated patients showed deterioration in most of the parameters measured.

In a placebo-controlled, double-blind study of tolrestat, 219 diabetes mellitus patients with symmetrical polyneuropathy, as defined by at least one pathologic finding, were treated for 1 year. Patients who received tolrestat showed significant improvement in autonomic function tests as well as in vibration perception, whereas placebo-treated patients showed deterioration in most of the parameters measured.

ARIs reduce the flux of glucose through the polyol pathway, inhibiting tissue accumulation of sorbitol and fructose and preventing reduction of redox potentials.

In a placebo-controlled, double-blind study of tolrestat, 219 diabetes mellitus patients with symmetrical polyneuropathy, as defined by at least one pathologic finding, were treated for 1 year. Patients who received tolrestat showed significant improvement in autonomic function tests as well as in vibration perception, whereas placebo-treated patients showed deterioration in most of the parameters measured.

ARIs reduce the flux of glucose through the polyol pathway, inhibiting tissue accumulation of sorbitol and fructose and preventing reduction of redox potentials.

In a placebo-controlled, double-blind study of tolrestat, 219 diabetes mellitus patients with symmetrical polyneuropathy, as defined by at least one pathologic finding, were treated for 1 year. Patients who received tolrestat showed significant improvement in autonomic function tests as well as in vibration perception, whereas placebo-treated patients showed deterioration in most of the parameters measured.

Alpha-Lipoic Acid

Lipoic acid (1,2-dithiolane-3-pentanoic acid), a derivative of octanoic acid, is present in food and is also synthesized by the liver. It is a natural cofactor in the pyruvate dehydrogenase complex where it binds acyl groups and transfers them from one part of the complex to another. It is effective in ameliorating both the somatic and autonomic neuropathies in diabetes mellitus.

Lipoic acid is currently undergoing extensive trials in the United States as an antidiabetic agent and as a therapy for DSPN.

Gamma-Linolenic Acid

Linoleic acid, an essential fatty acid, is metabolized to GLA, which serves as an important constituent of neuronal membrane phospholipids and also as a substrate for...
prostaglandin formation, seemingly important for preservation of nerve blood flow. In diabetes mellitus, conversion of linoleic acid to ω-linolenic acid and subsequent metabolites is impaired, possibly contributing to the pathogenesis of DSPN. A multicenter double-blind, placebo-controlled trial using GLA for 1 year demonstrated significant improvements in both clinical measures and electrophysiologic tests.

Aminoguanidine

Animal studies using aminoguanidine, an inhibitor of the formation of AGEs and a free radical scavenger, show improvement in NCV in streptozotocin-induced DSPN in rats. Controlled clinical trials to determine its efficacy in humans have been discontinued because of toxicity. However, successors to aminoguanidine and other drugs hold promise for this approach.

Human Intravenous Immunoglobulin

Immune intervention with human intravenous immunoglobulin (IVIg) has become appropriate in some patients with forms of peripheral DSPN that are associated with signs of antineuronal autoimmunity. Treatment with immunoglobulin is well tolerated and is considered safe, especially with respect to viral transmission. The major toxicity of IVIg has been an anaphylactic reaction, but the frequency of these reactions is now low and confined mainly to patients with immunoglobulin (usually immunoglobulin A) deficiency. Patients may experience severe headache due to aseptic meningitis, which resolves spontaneously. In some instances, it may be necessary to combine treatment with prednisone and/or azathioprine. Relapses may occur requiring repeated courses of therapy.

Neurotrophic Therapy

In animal models of diabetes mellitus, the evidence now suggests that decreased expression of NGF and its receptor trk A reduces retrograde axonal transport of NGF and diminishes support of small unmyelinated neurons and their neuropeptides, such as substance P and CGRP both potent vasodilators. Furthermore, recombinant human NGF (rhNGF) administration restores these neuropeptide levels toward normal and prevents the manifestations of sensory neuropathy in animals.

In a 15-center, double-blind, placebo-controlled study of the safety and efficacy of rhNGF in 250 subjects with symptomatic small-fiber neuropathy, rhNGF improved the neurologic impairment score of the lower limbs as well as small nerve fiber function cooling threshold (A delta fibers) and the ability to perceive heat pain (C-fiber) compared with placebo. These results were consistent with the postulated actions of NGF on trk A receptors present on small-fiber neurons. This finding led to two large multicenter studies conducted in the United States and the rest of the world. Regrettably, rhNGF was not found to have beneficial effects over and above placebo. The reason for this dichotomy has not been resolved, but this has somewhat dampened the enthusiasm for growth factor therapy of DSPN. Nonetheless, several new agents are able to bring about nerve growth, proliferation, and differentiation in vitro and have neurotrophic potential; these agents are now being evaluated in early phase II studies.
Management Aimed at Symptoms

Pain Control

Control of pain constitutes one of the most difficult management issues in DSPN. In essence, simple measures are tried first [Fig. 31-38]. If no distinction is made for pain syndromes, the numbers needed to treat (NNT) in DSPN to reduce pain by 50% is 1.4 for optimal-dose tricyclic antidepressants, 1.9 for dextromethorphan, 3.3 for carbamazepine, 3.4 for tramadol, 3.7 for gabapentin, 5.9 for capsaicin, 6.7 for selective serotonin reuptake inhibitors, and 10.0 for nortriptyline. If pain is divided according to its derivation from different nerve fiber type (A delta versus C-fiber), however, different types of pain respond to different therapies (see Fig. 31-38), as described next.

C-Fiber Pain

Initially, when there is ongoing damage to the nerves, the patient experiences the pain of the burning, lancinating, dysesthetic type often accompanied by hyperalgesia and allodynia. Because the peripheral sympathetic nerve fibers are also small unmyelinated C-fibers, sympathetic blocking agents (clonidine) may improve the pain. Loss of sympathetic regulation of sweat glands and arteriovenous shunt vessels in the foot creates a favorable environment for bacteria to penetrate, multiply, and wreak havoc with the foot. These fibers use the neuromodulation systems P as their neurotransmitter, and depletion of axonal substance P (capsaicin) often leads to amelioration of the pain. However, when the destructive forces persist, the individual becomes pain free and develops impaired warm temperature and pain thresholds. Disappearance of pain in these circumstances should be hailed as a warning that the neuropathy is progressing.

Capsaicin

Capsaicin is extracted from chili peppers. A simple, cheap mixture is formed by adding 1 to 3 teaspoons of cayenne pepper to a jar of cold cream and applying to the area of pain. The capsaicinoid receptor, or vanilloid receptor (VR1), is present on C and A delta fibers. When it is activated, it produces desensitization or degeneration of the sensory afferents.

VR1 is essential for selective modalities of pain sensation and for tissue injury-induced thermal hyperalgesia. Prolonged application of capsaicin depletes stores of substance P and, possibly, other neurotransmitters from sensory nerve endings. This reduces or abolishes the transmission of painful stimuli from the peripheral nerve fibers to the higher centers. Care must be taken to avoid eyes and genitals, and gloves must be worn. Because of capsaicin’s volatility, it is safer to cover the affected areas with plastic wrap. There is an initial exacerbation of symptoms that is followed by relief in 2 to 3 weeks.

Clonidine

There is an element of sympathetic-mediated C-fibertype pain that can be overcome with clonidine (α2-adrenergic agonist) or phentolamine. Clonidine can be applied topically, but the dose titration may be more difficult. Unresponsive patients are treated as outlined in Figure 31-38.

A Delta Fiber Pain

A delta fiber pain is a more deep-seated, dull, and gnawing ache, which often does not respond to the previously described measures. A number of different agents have been used for pain associated with these fibers with varying success.

Insulin

Continuous intravenous insulin infusion without resort to blood glucose lowering may be useful in some patients. A response with reduction of pain usually occurs within 48 hours, and the insulin infusion can be discontinued. If this measure fails, several medications are available that may abolish the pain.

Tramadol and Dextromethorphan

There are two possible targeted therapies. Tramadol is a nonopioid centrally acting analgesic for use in treating moderate to severe pain. It has recently been reported to provide pain relief in DSPN. Another spinal cord target for pain relief is the excitatory glutaminergic N-methyl-D-aspartate (NMDA) receptor. Blockade of NMDA receptors is believed to be one mechanism by which dextromethorphan exerts analgesic efficacy. An accomplished pharmacist can procure a sugar-free solution of dextromethorphan.

Antidepressants

Clinical trials have focused on interrupting pain transmission using antidepressant drugs that inhibit the reuptake of norepinephrine or serotonin. This central action accentuates the effects of these neurotransmitters in activation of endogenous pain-inhibitory systems in the brain that modulate pain transmission cells in the spinal cord. Side effects, including dysautonomia and dry mouth, can be troublesome. Switching to nortriptyline may lessen some of the anticholinergic effects of amitriptyline.

Carbamazepine

Several double-blind, placebo-controlled studies have demonstrated carbamazepine to be effective in the management of pain in DSPN. Toxic side effects may limit its use in some patients. However, it is useful for those patients with lightning or shooting pain.

Gabapentin

Gabapentin, which is structurally related to the neurotransmitter -aminobutyric acid, is an effective anticonvulsant whose mechanism is not well understood yet holds additional promise as an analgesic agent in painful neuropathy. In a multicenter study in the United States, gabapentin monotherapy appeared to be...
efficacious for the treatment of pain and sleep interference associated with DSPN. It also exhibited positive effects on mood and quality of life.

Transcutaneous Electrical Nerve Stimulation (TENS)

TENS occasionally may be helpful and certainly represents one of the more benign therapies for painful neuropathy. Care should be taken to move the electrodes around to identify sensitive areas and obtain maximal relief.

Analgesics

Analgesics are rarely of much benefit in the treatment of painful neuropathy, although they may be of some use on a short-term basis for some of the self-limited syndromes, such as painful diabetic third nerve palsy. Use of narcotics in the setting of chronic pain generally is avoided because of the risk of addiction.
MANAGEMENT OF LARGE-FIBER NEUROPATHIES

Patients with large-fiber neuropathies are uncoordinated and ataxic. As a result, they are more likely to fall than are non-neuropathic age-matched people. It has been demonstrated that high-intensity strength training in older people increases muscle strength in a variety of muscles. More important, the strength training results in improved coordination and balance quantifiable with backward tandem walking. Thus, it is vital to embark on a program of strength training and improvement of balance.

AUTONOMIC NEUROPATHIES

Diabetic autonomic neuropathy may involve any system in the body. Involvement of the autonomic nervous system can occur as early as the first year after diagnosis, and major manifestations are cardiovascular, gastrointestinal, and genitourinary system dysfunction (Table 31-9). Reduced exercise tolerance, edema, orthostatic supine or nocturnal hypertension, and intolerance to heat due to defective thermoregulation are a consequence of autonomic neuropathy.

Common peripheral autonomic function tests are the quantitative sudomotor axon reflex test and the sympathetic skin response, which in most hands are not reliable and sufficiently variable to be of no use clinically. Defective blood flow in the small capillary circulation is found with decreased responsiveness to mental arithmetic, cold pressor, hand grip, and heating. The defect is associated with a reduction in the amplitude of vasomotion and resembles premature aging. There are differences in the glabrous and hairy skin circulations. In hairy skin, a functional defect is found prior to the development of neuropathy and is correctable with antioxidants. The clinical counterpart is a dry, cold skin; loss of sweating; and development of fissures and cracks that are portals of entry for organisms leading to infectious ulcers and gangrene. Silent myocardial infarction, respiratory failure, amputations, and sudden death are hazards for diabetic patients with cardiac autonomic neuropathy. Therefore, it is vitally important to make this diagnosis early so that appropriate intervention can be instituted.

Management of Autonomic Neuropathy

Prevention and Reversibility of Autonomic Neuropathy

It is now become clear that strict glycemic control: a stepwise, progressive management of hyperglycemia, lipid levels, and BP; and the use of antioxidants and ACE inhibitors reduce the odds ratio for autonomic neuropathy to 0.32 (Fig. 31-39). It has also been shown that mortality is a function of loss of beat-to-beat variability with myocardial infarction. This mortality can be reduced by 35% with acute administration of insulin.

Kendall and coworkers reported that successful pancreas transplantation improves epinephrine response and normalizes hypoglycemia symptom recognition in patients with longstanding diabetes mellitus and established autonomic neuropathy. Burger and associates showed that a reversible metabolic component of cardiac autonomic neuropathy exists in patients in the early stages of the neuropathy.

and associates reported that successful pancreas transplantation improves epinephrine response and normalizes hypoglycemia symptom recognition in patients with longstanding diabetes mellitus and established autonomic neuropathy. Burger and associates showed that a reversible metabolic component of cardiac autonomic neuropathy exists in patients in the early stages of the neuropathy.

Postural Hypotension

The syndrome of postural hypotension is posture-related dizziness and syncope. Patients who have type 2 diabetes mellitus and orthostatic hypotension are hypovolemic and have sympathoadrenal insufficiency; both factors contribute to the pathogenesis of orthostatic hypotension. Postural hypotension in the patient with diabetic autonomic neuropathy can present a difficult management problem. Elevating the BP in the standing position must be balanced against preventing hypotension in the supine position.

Supportive Garments

Whenever possible, attempts should be made to increase venous return from the periphery by means of total body stockings. However, leg compression alone is less effective, presumably reflecting the large capacity of the abdomen relative to the legs. Patients should be instructed to put the stockings on while lying down and to avoid removing them until returning to the supine position.

Drug Therapy

Some patients with postural hypotension may benefit from treatment with 9-fluorohydrocortisone. Unfortunately, symptoms do not improve until edema occurs, and there is a significant risk for development of CHF and hypertension. If fluorohydrocortisone does not work satisfactorily, various adrenergic agonists and antagonists may be used. If the adrenergic receptor status is known, therapy can be guided to the appropriate agent. Metoclopramide may be helpful in patients with dopamine excess or increased sensitivity to dopaminergic stimulation. Patients with 2-adrenergic receptor excess may respond to the 2-antagonist yohimbine. Those few patients in whom receptors are increased may be helped with propranolol.

2-Adrenergic receptor deficiency can be treated with the 2-agonist, clonidine, which in this setting may paradoxically increase BP. One should start with small doses and gradually
increase the dose. If the preceding measures fail, midodrine, an \( \alpha \)-adrenergic agonist, or dihydroergotamine in combination with caffeine may help. A particularly refractory form of postural hypotension occurs in some patients postprandially and may respond to therapy with octreotide given subcutaneously in the mornings.

**Gastrophy**

Gastrointestinal motor disorders are common and widespread in patients with type 2 diabetes mellitus, regardless of symptoms. \(^{(10)}\) and there is a poor correlation between symptoms and objective evidence of functional or organic defects. The first step in management of diabetic gastroparesis consists of multiple, small feedings. The amount of fat should be decreased because it tends to delay gastric emptying. Maintenance of glycemic control is important. \(^{(33)}\) Metoclopramide may be used; when gastroparesis is severe, it is important to administer it intravenously, in liquid form, or as a suppository. When emptying becomes normal, the oral form may be resumed. Tachyphylaxis is common, and withdrawal from the drug periodically restores responsiveness.

Domperidone has been effective in some patients, \(^{(10)}\) although probably no more so than metoclopramide. Erythromycin, given as either a liquid or a suppository, may also be helpful. Erythromycin acts on the motilin receptor, “the sweeper of the gut,” and shortens gastric emptying time. \(^{(10)}\) If medications are unsuccessful and severe gastroparesis persists, jejunostomy placement into normally functioning bowel may be needed.

**Enteropathy**

Enteropathy involving the small bowel and colon can produce both chronic constipation and explosive diabetic diarrhea, making treatment of this particular complication difficult.

**Diet**

Patients with poor digestion may benefit from a gluten-free diet. The physician should be aware that certain fibers in the neuropathic patient can lead to bezoar formation because of bowel stasis in the gastroparetic or constipated state.

**Antibiotics**

Stasis of bowel contents with bacterial overgrowth may contribute to the diarrhea. Treatment with broad-spectrum antibiotics is the mainstay of therapy, including tetracycline or trimethoprim and sulfamethoxazole. Metronidazole appears to be the most effective and should be continued for at least 3 weeks.

**Cholestyramine**

Retention of bile may occur and can be highly irritating to the gut. Chelation of bile salts with cholestyramine 4 g three times daily mixed with fluid may offer relief of symptoms.

**Cholestyramine plus Atropine**

Diphenoxylate plus atropine may help control diarrhea; toxic megacolon can occur, however, and extreme care should be used.

**Somatostatin**

In refractory cases, small doses of octreotide can be helpful in controlling diarrhea.

**Cystopathy**

Patients with neurogenic bladder should be instructed to palpate the bladder, and if they cannot initiate micturition when the bladder is full, they should be advised to use Credé’s maneuver to start the flow of urine. Parasympathomimetics such asbethanechol are sometimes helpful, although often they do not help fully empty the bladder. Extended sphincter relaxation can be achieved with an \( \alpha \)-adrenergic blocker, such as doxazosin. \(^{(28)}\) Self-catheterization can be particularly useful in this setting, with the risk of infection generally being low.

**Sildenafil** (Viagra), an orally active selective inhibitor of phosphodiesterase type 5, can be used in diabetic ED. \(^{(57)}\) Most diabetic patients require 50 or 100 mg, and treatment should never be started without an evaluation of cardiac function. Patients with diabetic neuropathy are notorious for silent myocardial ischemia and poor ejection fractions. \(^{(57)}\) and cardiovascular function must be evaluated before the prescription is written. The concomitant use with nitrates or nitrates is contraindicated because of the profound hypotension that may occur. \(^{(57)}\)

**Gustatory Sweating**

Gustatory sweating is more common than previously believed, and topically applied glycopyrrolate, an antimuscarinic compound, is effective treatment in reducing both the severity and frequency of sweating of the head and neck region while eating food that triggers this reflex. \(^{(57)}\)
DIABETIC HEART DISEASE

IMPACT OF CARDIOVASCULAR DISEASE IN PATIENTS WITH DIABETES MELLITUS

It is widely underappreciated that CVD is the leading cause of mortality in patients with diabetes mellitus. Approximately 75% of the cardiovascular deaths attributed to diabetes are directly related to coronary artery disease. The economic burden of CVD in patients with diabetes far exceeds that of ESRD. Despite the well-recognized benefits of tight glycemic control in reducing the risk of microvascular complications of diabetes, as evidenced from the results of large randomized clinical trials, a similar corollary for macrovascular complications has not been firmly established.

As the treatment of diabetic microvascular disease improves, an even greater increase in the incidence and prevalence of diabetic macrovascular disease can be expected. The steady increase in both the prevalence of overt diabetes and impaired glucose tolerance in the United States further highlights the need for a comprehensive and aggressive approach to cardiovascular risk factor management in these patients. The "graying" of populations in most Westernized countries will also likely lead to a substantially larger social and economic burden from the cardiovascular complications of diabetes.
CORONARY HEART DISEASE MORBIDITY AND MORTALITY IN TYPE 1 AND TYPE 2 DIABETES

The last decades have been witness to substantial declines in coronary heart disease (CHD) mortality in the general population in the United States. However, significantly less improvement in CHD mortality has been seen in diabetic men and women during this same period. More than 90% of all patients with diabetes have type 2 diabetes, and it is this population (most middle-aged and elderly) that has been evaluated in the majority of studies of CHD risk. In these studies, the excess morbidity and mortality associated with diabetes and elevated glucose remained even after adjustment for traditional CHD risk factors.

Data from the Framingham Study showed a twofold to threefold elevation in the risk of clinically evident atherosclerotic disease in patients with type 2 diabetes compared to those without diabetes. Diabetic men in the Multiple Risk Factor Intervention Trial (MRFIT) study had an absolute risk of CHD death more than three times higher than that in the nondiabetic cohort, even after adjustment for established risk factors. Seminal work from Finland showed that patients with type 2 diabetes without a previous myocardial infarction have as high a risk of myocardial infarction over 7 years as nondiabetic patients with a previous myocardial infarction. (Fig. 31-40).

The case fatality rate following a myocardial infarction is also substantially higher in patients with diabetes. In women, diabetes mitigates the cardioprotective effects of the premenopausal period, and women with diabetes have a CHD mortality rate as high as that in diabetic men.

The risk of CHD has been evaluated in small subsets of patients with type 1 diabetes. In the Framingham study, the cumulative coronary artery disease mortality in patients with type 1 diabetes was approximately four times that of nondiabetic patients by age 55 years. Similar to patients with type 2 diabetes, the first deaths related to coronary artery disease in patients with type 1 diabetes generally occur by the fourth decade of life, and the cumulative mortality increases at a similar rate in both groups in the subsequent 20 years. The rise in coronary artery disease mortality with age in patients with type 1 diabetes is substantially higher in patients with nephropathy. In these patients, the risk of coronary artery disease development can be as much as 15 times higher than in patients without persistent proteinuria. Thus, persistent proteinuria is a strong predictor of the development of coronary artery disease in this population. These findings are consistent with a pathophysiologic viewpoint that proteinuria is a marker of generalized vascular damage that in the coronary vasculature emerges as a predisposition to CVD.
AGGREGATION OF TRADITIONAL CORONARY HEART DISEASE RISK FACTORS IN DIABETES MELLITUS

It is now well established that a number of traditional CHD risk factors (e.g., hypertension, dyslipidemia, obesity, insulin resistance) tend to occur together in patients with diabetes. Approximately 50% of patients with diabetes have hypertension, and more than 30% have hypercholesterolemia at the time of diagnosis. As in nondiabetic patients, these risk factors independently predict the risk of CVD mortality. However, even in the presence of one or more concomitant risk factors, diabetes increases the CVD death rate. It also appears that diabetes interacts synergistically with other risk factors to more sharply increase risk as the number of total risk factors increases.

Data from the UKPDS confirm the importance of risk factor aggregation in diabetic patients. In this large population of patients with newly diagnosed type 2 diabetes, the development of coronary artery disease during follow-up was significantly associated with increased concentrations of LDL cholesterol, decreased concentrations of HDL cholesterol, increased levels of Hg A1c and systolic BP, and a history of smoking as measured at baseline.
PLASMA GLUCOSE AND INSULIN RESISTANCE AS INDEPENDENT RISK FACTORS FOR ATHEROSCLEROSIS

Hyperglycemia may be responsible for the high excess risk of CHD in patients with diabetes that cannot be accounted for by the interaction of multiple risk factors alone. This association appears to be graded and continuous, without a clear threshold below which the relationship ends. One study showed that mortality from all causes, CVD, and ischemic heart disease increases progressively across quintiles of fasting blood glucose levels in patients with type 2 diabetes. [Fig. 31-42] Other data suggest a dose-response relationship between hyperglycemia and CVD mortality in diabetes, with patients with the highest levels of fasting blood glucose having a CVD mortality rate almost five times higher than patients with the two lowest levels combined. [730]

The continuum of CVD risk with rising glucose levels has also been identified in patients with type 1 diabetes [731] and in subjects without clinically overt diabetes but with varying levels of glucose tolerance. [732] In addition to its association with clinical outcomes, objective assessment of carotid artery intimal media thickness has highlighted the deleterious effects of hyperglycemia at the level of the vessel wall. [733] [734] [735] [736] [737]

Almost all patients with diabetes and the concomitant CVD risk factors of hypertension, obesity, and dyslipidemia also have insulin resistance. [738] The clustering of these risk factors in a single patient has been characterized as a syndrome, described by a variety of names such as syndrome X, insulin resistance syndrome, and cardiovascular dysmetabolic syndrome. Because insulin resistance typically precedes the development of hyperglycemia, and patients with type 2 diabetes have an elevated risk of CHD at diagnosis, it has been hypothesized that hyperinsulinemia is the underlying link between hyperglycemia and

![Figure 31-41](https://example.com/image.png)

**Figure 31-41** Age-adjusted cardiovascular disease (CVD) death rates by presence of number of risk factors for men with and without diabetes at baseline screened for the Multiple Risk Factor Intervention Trial. In the presence of diabetes the cardiovascular death rate steeply rises at any level of concomitant risk factors. SBP, systolic blood pressure. (From Stamler J, Vaccaro O, Neaton JD, et al. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. Diabetes Care 1993; 16:434-444.)

CVD in these patients [739] This has been supported by data from a number of studies showing that hyperinsulinemia is an independent predictor of CVD risk. Furthermore, in patients spanning the spectrum of glucose tolerance, from normal to hyperglycemic to diabetic, insulin resistance positively correlates with atherosclerosis as assessed by carotid intima-to-media thickness. [740]

Data from a long-term follow-up of nondiabetic men without heart disease at baseline have suggested that endogenous insulin itself, rather than insulin resistance, may directly increase CVD risk. Subjects with clinically overt CHD had significantly elevated fasting insulin levels at baseline compared with subjects without CHD, even after adjustment for the presence of traditional risk factors. [741]
THE ROLE OF GLYCEMIC CONTROL

The UKPDS confirmed the positive association between plasma glucose levels and CHD risk for Hb A1c levels above 6.2% in patients with diabetes. CHD risk increased by 11% with each 1% elevation in Hb A1c (Table 31-10). The question remains, however, whether intensive glycemic control can modify the cardiovascular risk profile of patients with diabetes.

Earlier studies, such as the DCCT and the smaller Veterans Affairs (VA) study, did not show a reduction in cardiovascular end points with intensive metabolic control. However, the conclusions that can be drawn from these studies are limited. The DCCT followed a relatively young (mean age, 27 years) population of patients with type 1 diabetes for more than 6 years. Although the study group was relatively large (n = 1441), at the end of follow-up few events had occurred. The 41% reduction between intensive and conventional therapy in the risk of cardiovascular and peripheral vascular disease was not statistically significant. In the VA study, intensive blood glucose control in patients with type 2 diabetes did not significantly reduce cardiovascular end points. Like the DCCT, this study lacked adequate power to detect a difference in macrovascular events between treatment groups, given the small number of events in each group. In addition, the patient population was small and followed for a relatively short period.

The UKPDS was larger and adequately powered to detect a difference between groups in macrovascular events. In this study, 3867 patients with newly diagnosed type 2 diabetes were randomly assigned to intensive glucose control (diet plus oral therapy or insulin) or to conventional treatment and were followed for 10 years. The study population had relatively few CHD risk factors and a low background rate of CHD. Patients treated with intensive glycemic control had a lower rate of myocardial infarction than did patients treated with conventional treatment, a finding that showed a trend for statistical significance (P = .052). As in the DCCT, intensive therapy in UKPDS significantly improved the rate of microvascular disease.
DYSLIPIDEMIA AND ITS TREATMENT IN PATIENTS WITH DIABETES MELLITUS

Dyslipidemia is the most well-characterized risk factor for increasing atherosclerosis in patients with type 2 diabetes. Moreover, there are a number of features of dyslipidemia in patients with diabetes that are uniquely associated with this metabolic derangement and that appear to increase the predisposition to atherogenesis. Although patients with diabetes tend not to have marked elevations in plasma LDL levels, this lipid fraction differs qualitatively from that in nondiabetic patients with dyslipidemia.

For example, LDL particles in patients with diabetes are generally smaller and more dense than typical LDL particles. These small, dense LDL particles are more susceptible to oxidation, particularly in the setting of poor glucose control. Other evidence suggests that glycation of LDL may be enhanced in diabetes, impairing recognition of the lipoprotein by its hepatoreceptor and extending its half-life. Conversely, levels of the cardioprotective lipid fraction, HDL cholesterol, are decreased in patients with diabetes. The HDL cholesterol of these patients may also be less effective at protecting LDL from oxidative stress, one of the proposed mechanisms for HDL’s cardioprotective effects.

Undoubtedly, the key feature of diabetic dyslipidemia is an increase in the production of VLDL by the liver in response to elevations in FFAs. Although insulin mediates the uptake of FFAs by striated muscle, reducing the levels presented to the liver, insulin resistance produces the opposite effect, increasing the levels of FFAs available to the liver. Dysmetabolic syndrome, with its characteristic abdominal obesity, also increases the delivery of FFAs to the liver. In addition, reduced lipoprotein lipase activity in type 2 diabetes leads to an accumulation of triglyceride-rich lipoproteins in the plasma of these patients. Triglyceride-rich lipoproteins also play a role in the reduced levels of HDL cholesterol, by increasing the transfer of cholesterol from these particles.

A number of landmark trials have proved that lowering lipid levels produces major clinical benefits in terms of reducing cardiovascular events in patients with and without a history of CHD at baseline. These findings have now been extended to the population of subjects with type 2 diabetes and dyslipidemia. For example, even though LDL levels are frequently within the average range in these patients, treatment with hydroxymethylglutaryl coenzyme A reductase inhibitors (statins) has been shown to improve outcomes. In the Cholesterol and Recurrent Events (CARE) trial, diabetic patients treated with pravastatin had a significant 25% reduction in the incidence of CHD death, nonfatal myocardial infarction, coronary artery bypass graft surgery, and revascularization procedures. In the Long-term Intervention with Pravastatin in Ischaemic Disease (LIPID) study, patients with diabetes experienced a 19% reduction in major CHD (fatal CHD and nonfatal myocardial infarction).

In a post hoc subgroup analysis of secondary prevention in a large cohort of patients with diabetes, impaired glucose tolerance, or normal glucose tolerance, simvastatin normalized associated elevations in total cholesterol and triglycerides across the range of glucose values. Treatment also significantly reduced major coronary events and revascularizations in patients with diabetes and major coronary events, revascularizations, and total and coronary mortality in patients with impaired glucose tolerance. Treatment with a fibrinolytic agent may also be beneficial in patients with diabetes, because these agents address the low HDL cholesterol and high triglyceride levels typically associated with diabetes.

In the VA High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT), men given gemfibrozil, many of whom had a lipoprotein profile characteristic of insulin resistance, had lower rates of coronary events and strokes. A fibrinolytic agent in combination with a statin may be the optimal approach in patients with diabetes and CHD who have hypercholesterolemia in association with elevated triglyceride and reduced HDL cholesterol levels.

The importance of dyslipidemia in contributing to cardiovascular risk in patients with diabetes is reflected in the new guidelines of the National Cholesterol Education Program Adult Treatment Panel (NCEP-ATP III). For the first time diabetes is considered a CHD risk equivalent, meaning that patients with diabetes have a risk of CHD that is similar to that in patients with clinically manifest CHD (i.e., a greater than 20% risk of an event in the following 10 years). In addition, the presence of multiple CHD risk factors, dysmetabolic syndrome, and mixed hyperlipidemia (high triglyceride and low HDL cholesterol levels) all should be taken into account when estimating a patient’s global risk.

Diabetic patients are candidates for cholesterol-lowering therapy if the LDL cholesterol level is higher than 3.36 mmol/L (130 mg/dL) (with the goal of reducing LDL cholesterol to < 2.57 mmol/L [100 mg/dL]), although many clinicians consider it prudent to approach therapy more aggressively by instituting drug treatment if the LDL cholesterol level is higher than 2.57 mmol/L (100 mg/dL). Studies are under way to determine whether even lower goals (e.g., < 2.07 mmol/L [80 mg/dL]) provide additional benefit. However, regardless of the drug regimen employed, patients with diabetes should maintain light glycemic control, which in itself can help reverse the dyslipemic profile prevalent in diabetes. As with all patients, lifestyle modification, including weight reduction and regular exercise, remains an important cornerstone of treating dyslipidemia in patients with diabetes.
SIGNATURE FEATURES AND TREATMENT OF HYPERTENSION IN DIABETIC PATIENTS

It has been estimated that up to 50% of patients with newly diagnosed diabetes also have high BP. As with dyslipidemia, hypertension interacts with diabetes to amplify the risk of cardiac mortality (see Fig. 31-41). Although the etiology of hypertension is multifactorial, the insulin-resistant state is one factor postulated to predispose patients to the development of hypertension. In addition to its negative effects on the cardiovascular system, high BP is a key contributor to the development of microvascular disease in diabetes. Based on the guidelines of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI), BP should be reduced to be less than 130/85 mm Hg in patients with diabetes and to an even lower goal, less than 125/75 mm Hg, in patients with concomitant renal insufficiency.

Results of the most recent clinical trials underscore the rewards of aggressive treatment of hypertension in patients with diabetes, although none of these studies achieved mean BP reductions to currently recommended targets. In the Systolic Hypertension in the Elderly Study, diuretic-based therapy resulted in a 34% reduction in cardiovascular events in the cohort of patients with diabetes. Use of a long-acting dihydropyridine calcium channel blocker in the Systolic Hypertension in Europe (Syst-Eur) study resulted in substantial reductions in total mortality (55%), cardiovascular mortality (76%), and cardiovascular events (69%) in the diabetic subgroup, greater benefits than were seen in the subgroup without diabetes.

In the Heart Outcomes Prevention Evaluation (HOPE) study, in which almost 40% of patients had diabetes and one other cardiovascular risk factor, ramipril reduced the primary outcome by 24% and total mortality by 25% in this cohort. Even in normotensive patients with diabetes, some benefit was seen, with a 2- to 4-mm Hg drop in BP with ACE inhibitor therapy.

Other rigorously designed studies, such as the UKPDS and the Hypertension Optimal Treatment (HOT) study, suggest even greater benefits from tight BP control in patients with diabetes. In the UKPDS, hypertensive patients with type 2 diabetes achieving BP control to a mean of 144/82 mm Hg showed a 21% reduction in the rate of myocardial infarction compared with patients achieving less tight BP control (154/87 mm Hg). A 44% reduction in the risk of fatal and nonfatal stroke was also seen in the group assigned to tight BP control. Achieving diastolic BP reduction to the low 80s in the HOT was particularly beneficial for patients with diabetes treated with felodipine-based therapy.
ACUTE CORONARY SYNDROMES IN DIABETES MELLITUS

The case fatality rate from myocardial infarction is nearly twice as high in patients with diabetes as in nondiabetic patients. This excess risk is seen both during the acute phase of myocardial infarction and in the early and late postinfarction period. A number of mechanisms have been responsible for worse outcomes in patients with diabetes, including the following:

1. Increased risk of CHF due to maladaptive remodeling of the left ventricle.
2. Increased risk of sudden death due to sympathovagal imbalance as a consequence of autonomic neuropathy.
3. Increased likelihood of early reinfarction due to impaired fibrinolysis.
4. Extensive underlying coronary artery disease.
5. Changes in myocardial cell metabolism, including a shift from glucose oxidation to FFA oxidation, with less generation of ATP at any level of oxygen consumption.
6. Associated cardiomyopathy.

Collective data provide strong evidence that a variety of treatment modalities can improve outcomes from myocardial infarction in patients with diabetes (Table 31-11). In terms of interventions, patients with diabetes experiencing an acute myocardial infarction respond as favorably to fibrinolytic therapy as do nondiabetic patients. In terms of medical therapy, excellent glycemic control is an essential component of overall management. Glucose levels at hospital admission have been independently correlated with early and late mortality after myocardial infarction in both patients with and without diabetes mellitus.

TABLE 31-11 — Management of Acute Coronary Syndrome in Patients with Diabetes

Studies such as the Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study have assessed the impact of intensive glycemic control in patients with diabetes during the acute phase of myocardial infarction. Patients in this study were randomized to either intensive insulin therapy (insulin-glucose infusion for 24 hours, followed by subcutaneous insulin injection for 3 months) or standard glycemic control. The intensive insulin regimen lowered blood glucose level during the first hour after admission and at discharge compared with conventional therapy. One-year mortality was significantly reduced with the insulin infusion compared with control, a difference that was maintained after 3.4 years of follow-up.

Although the mechanisms behind this benefit are not entirely clear, experimental data suggest that strict glycemic control may improve myocardial cell metabolism by increasing the availability of glucose as a substrate for ATP generation and reducing the formation of FFAs, thereby shifting cardiac metabolism from FFA oxidation to glycolysis and glucose oxidation. Intensive glycemic control may also reverse the impaired fibrinolysis that is typically seen in patients with diabetes.

Although widely used for glycemic control in patients with type 2 diabetes and proven to prevent microvascular complications, sulfonylureas have been implicated in an increase in cardiovascular mortality, particularly in patients undergoing revascularization for acute myocardial infarction. The UKPDS did not show a deleterious effect of these agents on the incidence of sudden death or myocardial infarction over 10 years of follow-up. Nonetheless, concerns persist surrounding the use of sulfonylureas in the setting of myocardial injury, owing to their blockade of ATP-sensitive potassium channels. In the heart, these channels are involved in ischemic preconditioning and coronary vasodilatation. Not all sulfonylureas have high specificity for vascular or myocardial channels, however, and it is not clear whether these agents as a class pose an increased material risk in patients with diabetes who experience an acute myocardial infarction.

ACE inhibitors dramatically reduce mortality following a myocardial infarction in patients with diabetes, ostensibly through their effects on reducing infarct size and limiting ventricular remodeling. In addition to these hemodynamic benefits, ACE inhibitors may improve outcomes in diabetes by improving endothelial function, improving fibrinolysis, and decreasing insulin resistance.

In a retrospective analysis of the GROPO Italian per lo Studio della Sopravvivenza nell’Infarto Miocardico (GISSI-3) study, lisinopril administration within 24 hours of hospital admission substantially reduced both 6-week and 6-month mortality in patients with diabetes compared with the nondiabetic group. Similarly, a subgroup analysis from the Trandolapril Cardiac Evaluation Study (TRACE) showed that patients with diabetes suffering an anterior myocardial infarction treated with trandolapril had greatly improved outcomes over 5 years compared with patients without diabetes, including a nearly 50% reduction in the risk of sudden death, reinfarction, and progression of CHF.

In contrast to ACE inhibitors, beta blockers are less widely accepted in the treatment of acute coronary syndrome in patients with diabetes, primarily over concerns about their effects in masking the signs of hypoglycemia and inhibiting the metabolic response to hypoglycemia. Older, noncardioselective beta blockers may also have adversely affected the lipid profile, further adding to the concerns of clinicians. More recent data with cardioselective beta blockers suggest these agents have less tendency to negatively impact metabolic indices. Clinical trial data confirm that beta blockers reduce the rates of mortality and reinfarction in patients with myocardial infarction in the presence of diabetes. In fact, their effects in patients with diabetes appear to exceed those seen in nondiabetic patients. A large review of data from more than 45,000 patients, 26% of whom had diabetes, showed that beta blocker therapy was associated with a lower 1-year mortality rate in patients with diabetes than in those without diabetes, with no evidence of an increase in diabetes-related complications.

Postulated mechanisms for the benefit of beta blockers in patients with diabetes include dampening of the sympathetic nervous system overactivity that arises as a consequence of autonomic neuropathy. Beta blockers may also reduce FFA levels and thereby reduce myocardial oxygen requirements. Carvedilol, although noncardioselective, is a beta blocker that decreases insulin resistance and also has antioxidant effects, both of which may be of particular benefit in patients with type 2 diabetes.

Aspirin is a cornerstone of therapy for the primary or secondary prevention of acute coronary syndrome in patients with type 1 and type 2 diabetes who do not have contraindications to its use. Aspirin significantly lowers the risk of myocardial infarction without increasing the risk of vitreous or retinal bleeding, even in patients with retnopathy. Enteric-coated aspirin, 81 to 325 mg/day, is currently recommended by the American Diabetes Association. The benefits of this therapy are likely associated with its effects in reversing the enhanced platelet aggregation evident in patients with either type 1 or type 2 diabetes.

Newer adjunctive therapies, such as the platelet glycoprotein IIb/IIIa receptor antagonists that antagonize platelet action, have also been assessed in patients with diabetes and insulin-glucose infusion (?).
diabetes presenting with unstable angina or non-Q-wave infarction. Overall, these agents appear to work equally well, or perhaps slightly better, in patients with diabetes as in nondiabetic patients.

In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study, the addition of tirofiban to heparin therapy reduced the 7-day composite end point compared with heparin alone. This effect was greater in patients with diabetes than in patients without diabetes.\[789\]

In one study of patients undergoing percutaneous transluminal coronary angioplasty (PTCA), glycoprotein IIb/IIIa antagonist therapy was associated with fewer acute events but a higher rate of target-vessel revascularization in the long term in the diabetic cohort compared with the nondiabetic cohort.\[790\] In another trial, however, in which stents were used, the rate of target vessel revascularization at 6 months was significantly decreased with the addition of a glycoprotein IIb/IIIa antagonist compared with placebo.\[791\]

Results of the Bypass Angioplasty Revascularization Investigation (BARI) showed that coronary bypass graft surgery provides better outcomes than PTCA in patients with diabetes, possibly as a result of addressing the extensive coronary vascular disease in these patients.\[792\] This study did not employ the use of stents or glycoprotein IIb/IIIa inhibitors, two modalities that, when used together, appear to improve outcomes after PTCA in patients with diabetes.
CARDIOMYOPATHY IN PATIENTS WITH DIABETES MELLITUS

Diabetes is associated with a fourfold increase in the risk for CHF, even after adjustment for other cardiovascular risk factors such as age, BP, cholesterol level, obesity, and history of coronary artery disease. Patients with diabetes experience higher rates of CHF than do nondiabetic patients following an acute myocardial infarction, regardless of the size of the infarct zone. These findings suggest that diabetes itself causes deleterious effects on the myocardium, leading to poorer outcomes.

A number of key structural, functional, and metabolic factors have been implicated in the increased risk of maladaptive remodeling that leads to CHF in diabetes. For example, silent myocardial infarctions, evidence of which is found in up to 40% of patients with diabetes presenting with a clinically apparent myocardial infarction, may lead to unrecognized regional and global ventricular dysfunction. As many as 50% of patients with diabetes and coronary artery disease have cardiac autonomic neuropathy, which is known to contribute to both systolic and diastolic dysfunction. Like hypertension, diabetes can cause fibrosis of the myocardium and increased collagen deposition. These effects are even more pronounced in patients with coexisting hypertension and diabetes. Enhanced endothelial dysfunction in diabetes has also been described as a pathophysiologic pathway to impaired microvascular perfusion and ischemia.

On a cellular level, both hyperglycemia and insulin resistance have direct negative effects on myocardial metabolism. Depression of myocardial GLUT 4 transporter protein levels in the setting of diabetes and ischemia inhibits glucose entry and glycolysis into the heart. As a result, intracellular metabolism shifts from glycolysis to FFA oxidation, thereby suppressing glycolytic ATP generation, a major source of energy under anaerobic (i.e., ischemic) conditions. The production of oxygen free radicals may also be enhanced in this situation, further depressing myocardial contractile function.

Collectively, these various abnormalities potentiate the characteristic left ventricular remodeling of diabetes, clinically manifested as serial wall motion changes, reduced regional ejection fraction, and increases in end-diastolic and end-systolic volumes.
THE DIABETIC FOOT

Of all the late complications of diabetes, foot problems are probably the most preventable. Thus, Joslin, who wrote in 1934 that “diabetic gangrene is not heaven-sent, but earthborn,” was correct: The development of foot ulceration mostly results from the way we care for our patients or the way in which patients care for themselves.

Increasing interest in the diabetic foot in recent years has resulted in a better understanding of the factors that interact to cause ulceration and amputation. Thus, the neuropathic foot does not spontaneously ulcerate; the combination of insensitivity with other factors, such as deformity and unperceived trauma (e.g., inappropriate footwear), leads to skin breakdown. This increase in the knowledge of pathogenesis should permit the design of appropriate screening programs for risk and preventive education. However, although much progress has been made, this has not yet resulted in a decrease in amputation rates. Indeed, in the VA system, for example, amputation rates are declining, except in diabetic patients. Thus, much research is still needed to implement strategies to reduce ulceration and amputation, and this is particularly required in the fields of behavioral and psychosocial aspects of the diabetic foot.

The year 2000 witnessed the publication of two major texts on the diabetic foot, to which, together with other major review articles, the reader is referred for detailed discussion of this topic.

EPIDEMIOLOGY AND PATHOGENESIS OF DIABETIC FOOT ULCERATION

Foot ulceration is common and occurs in both type 1 and type 2 diabetes. Approximately between 5% and 10% of diabetic patients have had past or present foot ulceration, and 1% have undergone amputation. Diabetes is the most common cause of nontraumatic lower limb amputation in the United States, with rates of 15 times those in the nondiabetic population. A recent study in the United States showed a cumulative incidence of ulceration of 5.8% in 3 years within a large health maintenance organization population of diabetic patients; 15% of ulcer patients required amputation, and, in common with other studies, foot ulcers were associated with increased mortality in the 3-year period.

Pathway to Ulceration

As stated earlier, foot ulceration results from an interaction of a number of component causes, none of which alone is sufficient to cause ulceration but, when combined, complete the causal pathway to skin breakdown. Knowledge of these component causes and their potential to interact facilitates the design of preventive foot care programs.

Diabetic Neuropathy

The three components of neuropathysensory, motor, and autonomicmay contribute to ulceration in the foot. Chronic sensorimotor neuropathy is common, affecting at least a third of older patients in western countries. Its onset is gradual and insidious, and symptoms may be so minimal that they go unnoticed by some patients. Although in some patients uncomfortable, painful, and paresthetic symptoms predominate, other patients may never experience symptoms. Clinical examination usually reveals a sensory deficit in a glove-and-stocking distribution, with signs of motor dysfunction, such as small muscle wasting in the feet and absent ankle reflexes. Thus, although a history of typical symptoms strongly suggests a diagnosis of neuropathy, absence of symptoms does not exclude the diagnosis and must NEVER be equated with a lack of foot ulcer risk. Therefore, assessment of the foot ulcer risk must always include a careful foot examination, whatever the history.

Sympathetic autonomic neuropathy affecting the lower limbs results in reduced sweating, dry skin, and development of cracks and fissures, and, in the absence of large-vessel arterial disease, there may be increased blood flow to the foot with arteriovenous shunting leading to the warm but at-risk foot.

The importance of neuropathy as a contributory cause to foot ulceration was confirmed in a large multicenter study from Europe and North America that reported a 7% annual risk of ulceration in neuropathic patients. Previous evidence had suggested that the risk in non-neuropathic patients is less than 1%.

Peripheral Vascular Disease

In the pathogenesis of ulceration, peripheral vascular disease itself in isolation rarely causes ulceration. However, the common combination of vascular disease with minor trauma may lead to ulceration. Thus, minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity, and ischemic ulceration and risk of amputation develop. Early identification of those at risk for peripheral vascular disease is essential, and appropriate investigation involving noninvasive studies, together with arteriography, often leads to bypass surgery to improve blood flow to the extremities. Distal bypass surgery is frequently performed, with good short-term and long-term results in limb salvage. Doppler-derived ankle pressure can be misleadingly high in long-standing diabetes, but the presence or absence of a dorsalis pedis or posterior tibial pulse is the simplest and most reliable indicator of significant ischemia. Long-term results with bypass grafts to the dorsalis pedis artery are excellent. In one large study, graft patency of 82% and limb salvage of 87% were observed at 5 years.
Minor Foot Ulceration

Foot ulceration is most common in those patients with a history of similar problems, and even in experienced diabetic foot clinics, more than 50% of patients with new foot ulcers give a past ulcer history.

Other Diabetic Complications

Patients with retinopathy and renal dysfunction are at increased risk for foot ulceration.

Callus, Deformity, and High Foot Pressures

Motor neuropathy, with imbalance of the flexor and extensor muscles in the foot, frequently results in foot deformity, with prominent metatarsal heads and clawing of the toes [Fig. 31-43]. In turn, the combination of the proprioceptive loss due to neuropathy and the prominence of metatarsal heads leads to increases in the pressures and loads under the diabetic foot. High pressures, together with dry skin, frequently result in the formation of callus under weight-bearing areas of the metatarsal heads. The presence of such plantar callus has been shown in cross-sectional and prospective studies to be a highly significant marker of foot ulcer risk. Conversely, removal of plantar callus is associated with a reduction in foot pressures and thus a reduction in foot ulcer risk. [809]

It is the combination of two or more of the earlier described risk factors that ultimately results in diabetic foot ulceration. In 1999, a North American/United Kingdom collaborative study[814] assessed the risk factors that resulted in ulceration in more than 150 consecutive foot ulcer cases. From this study, a number of causal pathways were identified but the most common triad of component causes was present in 63% of incident ulcers and comprised neuropathy, deformity, and trauma. Edema and ischemia were also common component causes.
PREVENTION OF FOOT ULCERATION AND AMPUTATION

That diabetic foot ulceration is largely preventable is not disputed; small, mostly single-center studies have shown that relatively simple interventions can reduce amputations by up to 80%. Thus, strategies for the earlier identification of those at potential risk of ulceration are required, and education programs that can be adapted for widespread application need to be developed. Because foot ulcers precede more than 80% of amputations, are among the most common causes of hospital admission for patients with diabetes, and account for much morbidity and even mortality, the widespread application of preventive foot care strategies is urgently required.

All patients with diabetes, whichever type and irrespective of duration, require regular review and screening of the feet for evidence of risk factors for foot ulceration. At a minimum, such screening should be carried out annually. Of all the long-term complications of diabetes, foot problems and their risk factors are probably the easiest to detect. No expensive equipment is required, and the feet can be examined for evidence of neuropathic and vascular deficits in the office setting using simple equipment. It must be remembered that neuropathy, vascular disease, and even foot ulceration may be the presenting feature of type 2 diabetes, and thus there can be no exception to the rule of screening.

A simple algorithm for the diabetic foot screen is provided in **Figure 31-44**. The most important message to practitioners is to have the patient remove the shoes and socks and to look at the feet for risk factors (e.g., presence of callus, deformity, muscle wasting, and dry skin), all of which are clearly visible on clinical inspection. A simple neurologic examination that might include a neuropathy disability score is recommended. Absence of the ability to perceive pressure from a 10-g monofilament, inability to perceive a vibrating 128-Hz tuning fork over the hallux, and absent ankle reflexes all have been shown to be predictors of foot ulceration.

**The Diabetic Foot Care Team**

Patients identified as being at high risk for foot ulceration should be managed by a team of specialists with interest and expertise in the diabetic foot. The podiatrist generally takes responsibility for follow-up and care of the skin and nails and, together with the specialist nurse or diabetes educator, provides foot care education. The orthotist, or shoe fitter, is invaluable for advising about and sometimes designing footwear to protect the high-risk feet, and these members of the team should work closely with the diabetologist and the vascular and orthopedic surgeons. The importance of wearing special shoes was demonstrated in a study in which 83% of patients wearing regular shoes experienced a recurrence of foot ulcers, whereas only 17% of those wearing special shoes did.

Patients with risk factors for ulceration require preventive foot care education and frequent review.
CLASSIFICATION OF FOOT ULCERS

Many different classification systems have been reported in the literature, but the one developed by Wagner for grading diabetic foot ulcers has been widely used and accepted. More recently, the University of Texas (UT) group has developed an alternative classification system that, in addition to depth (as in the Wagner system), takes into account the presence or absence of infection and ischemia. A prospective study from 2001 has assessed and compared these two wound classification systems and concludes that the University of Texas scheme is a better predictor of outcome than the older Wagner system.
MANAGEMENT OF DIABETIC FOOT ULCERS

Basic principles of wound healing apply equally to diabetic foot ulcers as to wounds in any other site or condition. Basically, a diabetic foot ulcer will heal if the following three conditions are satisfied:

1. Arterial inflow is adequate.
2. Infection is treated appropriately.
3. Pressure is removed from the wound and the immediate surrounding area.

Although this approach may seem simplistic, failure of healing of diabetic foot ulcers is normally due to neglect of one or more of the following considerations:

First, the most common cause of nonhealing of neuropathic foot ulcers is the failure to address the third principle (off-loading the area). Medical practitioners forget that patients advised not to put pressure over an ulcer find it difficult to adhere to such advice if peripheral sensation is lost or reduced. Pain results in protection of an injured area; the lack of pain permits pressure to be put directly onto the ulcer and results in nonhealing.

Second, the next most frequent error is inappropriate management of infection. Topical applications are generally unhelpful, and if clinical infection is present, it must be treated appropriately (see later).

Third, the presence of peripheral neuropathy, ischemic symptoms may not be typical because of altered pain sensation. The most difficult ulcer to heal is the neuroischemic ulcer, and symptoms and even signs of ischemia may be altered in the diabetic state. Thus, appropriate noninvasive investigation and arteriography are indicated in the nonhealing diabetic foot ulcer where there is any question as to the vascular status.

Fourth, a final reason for slow or nonhealing of a diabetic foot ulcer, recognized more recently, relates to inappropriate débridement of the wound. The ability of patients with neuropathy to walk putting pressure on active ulcer areas leads to an often extensive buildup of callus tissue. Appropriate débridement and removal of all dead and macerated tissues are essential in the local treatment of a diabetic foot ulcer. Indeed, Steed and colleagues have demonstrated that aggressive débridement of neuropathic foot ulcers leads to a more rapid healing of those ulcers compared with those wounds that are inadequately débrided.

The principles of management of neuropathic and neuroischemic foot ulcers are considered next. Although it is not possible to give much detail on the individual stages and grades of ulcers, we refer to both the University of Texas and the Wagner grading systems.

Neuropathic Foot Ulcer without Osteomyelitis (Wagner Grades 1, 2; University of Texas Grades 1a, 2a)

The most important feature in the management of neuropathic foot ulcers that typically occur under weight-bearing areas such as the metatarsal heads and great toe is to provide adequate pressure relief. This is usually achieved by a cast such as a total contact cast (TCC) or a removable Scotch cast boot.

The total contact cast was recognized as the gold standard for off-loading a foot wound in the 1999 consensus statement on diabetic foot wounds by the American Diabetes Association. This endorsement has now been confirmed as correct in a randomized, controlled trial in which Armstrong and colleagues comparing three off-loading techniques and found that the total contact cast was associated with the shortest healing time. When a total contact cast or any other cast device is used, regular removal of the cast is essential because occasionally the cast itself might injure the insensitive skin. Regular débridement of the wound by a podiatrist is also essential.

Theoretically, complete healing of all superficial and neuropathic ulcers should be possible without the need for amputation. In neuropathic ulcers with a good peripheral circulation, there is no indication for antibiotics unless there are clear clinical signs of infection, including prominent discharge, local erythema, and cellulitis. The presence of any of these features in Wagner's grade 1 or 2 ulcers would warrant reclassification in the University of Texas system to 1b or 2b. In such cases, deep wound swabs should be taken and broad-spectrum oral antibiotic treatment started with agents such as amoxicillin-clavulanic acid combination (Augmentin) or clindamycin. Alterations may be required when sensitivity results become available.
Neuroischemic Ulcers (Wagner Grades 1, 2; University of Texas Grades 1C, 1D)

The principles of management of neuroischemic Wagner grades 1 and 2 ulcers are similar to those for neuropathic ulcers with the following important exceptions:

1. Total contact casts are not usually recommended for the management of neuroischemic ulcers, although removable casts and air cast boots may be used.
2. Antibiotic therapy is usually recommended for all neuroischemic ulcers.
3. Investigation of the circulation (including noninvasive assessment and, when required, arteriography with appropriate subsequent surgical management or angioplasty) is indicated.
Osteomyelitis (Wagner Grade 3; University of Texas Grade 3B)

Wagner or University of Texas grade 3 ulcers are deeper and involve underlying bone, often with abscess formation. Osteomyelitis is a serious complication of foot ulceration and may be present in as many as 50% of diabetic patients with moderate to severe foot infections. If the physician can probe to bone when probing a deep ulcer, the presence of osteomyelitis is strongly suggested. Plain radiographs are indicated in any nonhealing foot ulcer and are useful in the diagnosis of osteomyelitis in more than two thirds of patients, although it should be kept in mind that the radiologic changes may be delayed. In difficult cases, further investigation, such as magnetic resonance imaging, bone scans, or an indium (111 In)-labeled white blood cell scan can be useful in the diagnosis of bony infection.

Although the treatment of osteomyelitis is commonly surgical and involves resecting the infected bone, there have been reports of successful long-term treatment with antibiotics that treat the underlying bacterium, most commonly Staphylococcus aureus. Thus, agents such as clindamycin (which penetrates bone well) or flucloxacillin are often used.
Gangrene (Wagner Grades 4, 5)

The presence of gangrene or areas of tissue death is always a serious sign in the diabetic foot. However, localized areas of gangrene, especially in the toes, without cellulitis, spreading infection, or discharge, can occasionally be left to spontaneously "autoamputate." The presence of more extensive gangrene requires (1) urgent hospital admission; (2) treatment of infection, often with multiple antibiotics; (3) control of the diabetes, usually with intravenous insulin; and (4) detailed vascular assessment. It is in this area that the team approach is most important, with close collaboration between the diabetes specialist, the vascular surgeon, and the radiologist.
NEW TREATMENTS FOR FOOT ULCERS

Platelet-Derived Growth Factors

Several controlled trials of becaplermin, a recombinant human PDGF beta chain homodimer, have confirmed the efficacy of this topically applied agent in promoting healing of neuropathic foot ulcers. In a combined analysis of randomized, controlled studies, Smiell and co-workers showed that active treatment was associated with a significant increase in the probability of complete healing compared to placebo gel.

The use of such an agent should probably be reserved for the management of difficult-to-heal neuropathic ulcers that do not respond to standard treatment, such as off-loading or regular débridement. Its widespread use is somewhat limited by its cost; when used selectively, however, this agent can accelerate the wound healing of neuropathic foot ulcers.
Living Human Skin Equivalents

The recent development of living human skin equivalents produced by tissue engineering techniques has produced new possibilities for wound healing therapies and chronic ulcers, such as those caused by venous disease or diabetic neuropathy. However, both living skin equivalents and topically applied growth factors are expensive treatments that must be seen not as a replacement but as an addition to good wound care, which must always comprise adequate off-loading and regular débridement.
Charcot's Neuroarthropathy

Charcot's neuroarthropathy is a rare and disabling condition affecting the joints and bones of the feet. Permissive features for the development of this condition include the presence of severe peripheral neuropathy, together with autonomic dysfunction, with increased blood flow to the foot; the peripheral circulation is usually intact. In the Western world, diabetes is the most common cause of a Charcot's foot and increased awareness of this condition may enable earlier diagnosis and treatment to prevent severe deformity and disability.

The actual pathogenesis of the Charcot process is poorly understood; however, the patient with peripheral insensitivity and autonomic dysfunction with increased blood flow to the foot is vulnerable to frequently unrecognized trauma that may be so trivial that the patient cannot recall the event. Repetitive trauma results in increased blood flow through the bone, increased osteoclastic activity, and remodeling of bone. In certain cases, patients may walk on a fracture that leads to continuing destruction of bones and joints in that area.

Although sometimes difficult to distinguish from osteomyelitis or an inflammatory arthropathy, the patient with neuropathy and a unilateral swollen, hot foot must be considered to have Charcot's foot until proven otherwise.

Charcot's arthropathy can be diagnosed in most patients by plain radiograph and a high index of suspicion. Radiographs may reveal bone and joint destruction, fragmentation, and remodeling, although in the early stages, the radiographic finding may be normal. In such cases, the three-phase bisphosphonate bone scan shows increased bone uptake, although the \(^{111}\)In-labeled bone scan will be negative in the absence of infection.

After diagnosis, management of the acute phase involves immobilization, usually in a total contact cast, and recent evidence suggests that treatment with bisphosphonates, which reduce osteoclastic activity, may reduce swelling, discomfort, and bone turnover markers. \[^8\]

In summary, although rare, Charcot's neuroarthropathy should be suspected in any patient with unexplained swelling and heat in a neuropathic foot, and early intervention with immobilization and possibly bisphosphonate treatment may halt progression that in the untreated state may lead to marked foot deformity and the necessity for local or major amputations.

[^8]: Additional references would be beneficial to support the statements made in this section.
ACKNOWLEDGMENT

For the section "Diabetic Nephropathy," we acknowledge Anthony J. Joseph, M.D., SUNY Downstate Medical Center, New York. M.B. would like to thank his coauthors for their gracious collaboration and for allowing editorial changes to be made in the interest of a more unified chapter.

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. In contrast, other organs oxidize fatty acids as well as glucose. Because of this unique dependence on glucose and because it cannot synthesize glucose or store more than a few minutes' supply as glycogen, the brain requires a continuous supply of glucose from the circulation. Facilitated diffusion of glucose from the blood to the brain is a direct function of the arterial plasma glucose concentration. At normal plasma glucose concentrations, the rate of blood-to-brain glucose transport exceeds the rate of brain glucose metabolism. However, as the plasma glucose concentration falls below the physiologic range, blood-to-brain glucose transport becomes limiting to brain energy metabolism and, thus, to survival. Given the immediate survival value of maintenance of the plasma glucose concentration, it is not surprising that physiologic mechanisms that prevent or rapidly correct hypoglycemia have evolved. Indeed, these mechanisms are so effective that hypoglycemia is an uncommon clinical event except in people who use drugs that lower glucose levels (e.g., insulin, sulfonylureas, or alcohol).

Insight into the physiology of glucose counterregulation—the mechanisms that normally prevent or rapidly correct hypoglycemia and its pathophysiology in the context of clinical hypoglycemia, which has been reviewed in detail, has improved the management of hypoglycemia. Nonetheless, major gaps in understanding remain. Both are discussed here.
PHYSIOLOGY OF SYSTEMIC GLUCOREGULATION

Cellular and molecular glucoregulation is discussed in Chapter 29. Glucose metabolism and systemic glucose balance and their regulation are summarized here, with emphasis on the aspects relevant to glucose counterregulation and the prevention of hypoglycemia.

Glucose Metabolism

**Origins and Fates of Glucose**

Glucose is derived from three sources: intestinal absorption that follows digestion of dietary carbohydrates; glycogenolysis, the breakdown of glycogen, which is the polymerized storage form of glucose; and gluconeogenesis, the formation of glucose from precursors including lactate (and pyruvate), amino acids (especially alanine and glutamine), and, to a lesser extent, glycerol (Fig. 32-1).

Although most tissues express the enzyme systems required to synthesize (glycogen synthase) and hydrolyze (phosphorylase) glycogen, only the liver and kidneys express glucose-6-phosphatase, the enzyme necessary for the release of glucose into the circulation, at levels sufficient to permit these organs to contribute to the systemic glucose pool. The liver and kidneys also express the enzymes necessary for gluconeogenesis (including the critical gluconeogenic enzymes pyruvate carboxylase, phosphoenolpyruvate carboxykinase, and fructose-1,6-bisphosphatase).

There are multiple potential metabolic fates for glucose that is transported into cells (external losses are normally negligible) (see Fig. 32-1). It may be stored as glycogen, or may

![Figure 32-1 Schematic representation of glucose metabolism. TCA, tricarboxylic acid.](image)

undergo glycolysis to pyruvate, which can be reduced to lactate, transaminated to form alanine, or converted to acetyl coenzyme A (CoA), which in turn can be oxidized to carbon dioxide and water through the tricarboxylic acid cycle, converted to fatty acids (and stored as triglycerides), or utilized for ketone body (acetocacetate, -hydroxybutyrate) or cholesterol synthesis. Finally, glucose may be released into the circulation. As summarized in the following paragraphs, these outcomes differ in different organs.

**Hepatic (and Renal) Glucose Metabolism**

The liver is remarkably flexible in its role in glucose homeostasis and is the major source of net endogenous glucose production (through glycogenolysis and gluconeogenesis). Under conditions of high glucose output (e.g., fasting), the energy needs of the liver are largely provided by the beta oxidation of fatty acids. Conversely, the liver can also be an organ of net glucose uptake, with glucose stored as glycogen, oxidized for energy, or converted to fat, which can either remain in the liver or be transported to other tissues as very-low-density lipoproteins. The kidneys also produce (through gluconeogenesis) and utilize glucose.

**Glucose Utilization**

Muscle can store glucose as glycogen or metabolize glucose through glycolysis to pyruvate, which either is reduced to lactate or transaminated to form alanine or is oxidized. Lactate (and pyruvate) released from muscle is transported to the liver, where it serves as a gluconeogenic precursor (the Cori or glucose-lactate cycle). It may be stored as glycogen, or may undergo glycolysis to pyruvate, which can be reduced to lactate, transaminated to form alanine, or converted to acetyl coenzyme A (CoA), which in turn can be oxidized to carbon dioxide and water through the tricarboxylic acid cycle, converted to fatty acids (and stored as triglycerides), or utilized for ketone body (acetocacetate, -hydroxybutyrate) or cholesterol synthesis. Finally, glucose may be released into the circulation. As summarized in the following paragraphs, these outcomes differ in different organs.

Although quantitatively less important than muscle, adipose tissue can also use glucose for fatty acid synthesis or formation of glyceral-3-phosphate, which can then esterify fatty acids (derived largely from circulating very-low-density lipoproteins) to form triglycerides. During a fast, adipocytes decrease their glucose utilization and satisfy energy needs from the beta oxidation of fatty acids. Other tissues, such as the formed elements of the blood and the renal medullae, do not have the capacity to decrease glucose utilization during fasting and therefore produce lactate at relatively fixed rates.

As mentioned earlier, glucose is the predominant metabolic fuel used by the brain under most conditions. Glucose undergoes terminal oxidation to carbon dioxide and water in the brain. The brain respiratory quotient is approximately 1.0. Although the adult brain constitutes only about 2.5% of body weight its oxidative metabolism accounts for approximately 25% of the basal metabolic rate under physiologic conditions. However, when ketones are plentiful in the circulation, as during prolonged fasting, they can support the majority of the energy needs of the brain and thus reduce its glucose utilization.

Systemic Glucose Balance

Normally, rates of endogenous glucose influx into the circulation and those of glucose efflux out of the circulation into tissues other than the brain are coordinately regulated largely by the plasma glucoselowering (regulatory) hormone insulin and the plasma glucosesparing (counterregulatory) hormones glucagon and epinephrine such that systemic glucose balance is maintained, hypoglycemia (as well as hyperglycemia) is prevented, and a continuous supply of glucose to the brain is assured. This is accomplished despite wide variations in exogenous glucose influx (e.g., after feeding versus during fasting) and in glucose efflux (e.g., during exercise versus during rest). Hypoglycemia occurs when rates of glucose appearance in the circulation (the sum of endogenous glucose production, from the liver through both glycogenolysis and gluconeogenesis) (see Fig. 32-1) and, to a lesser extent, from the kidneys through gluconeogenesis, and of exogenous glucose delivery from ingested carbohydrates fail to keep pace with rates of glucose disappearance from the circulation (the sum of ongoing brain glucose metabolism and of variable glucose utilization by tissues such as muscle and fat as well as the liver and kidneys, among others).

Fasting

The postabsorptive state is the interdigestive period that begins approximately 5 to 6 hours after a meal. However, the term is most commonly used to refer to data obtained after a 10- to 14-hour overnight fast. In healthy adults, the physiologic postabsorptive (fasting) plasma glucose concentration is approximately 4.0 to 6.0 mmol/L (72 to 108 mg/dL) with a mean of approximately 5.0 mmol/L (90 mg/dL). In the postabsorptive steady state, rates of glucose production and utilization are equal. They average 12 μmol/kg/minute (2.2 mg/kg/minute) and range from about 10 to 14 μmol/kg/minute (1.8 to 2.6 mg/kg/minute) in healthy adults after an overnight fast. These rates are as much as threefold higher in infants, at least in part because of their greater brain mass relative to their body weight.

Approximately 60% of basal glucose utilization is accounted for by the brain. The remainder is used by glycolyzing tissues, such as the formed elements of the blood and the renal medullae and to some extent muscle and fat. Hepatic glucose production results from both glycogenolysis and gluconeogenesis even after an overnight fast. The liver is the predominant source of net endogenous glucose production after an overnight fast. The kidneys, which both use and produce glucose, contribute little to net glucose production. However, renal, like hepatic, glucose production is regulated. It is suppressed by insulin and stimulated by epinephrine (but not by glucagon). Thus, the common practice of equating endogenous glucose production with hepatic glucose production is not precise.

The importance of gluconeogenesis in providing new glucose and supporting hepatic glycogen stores after an overnight fast becomes apparent when one considers the limited availability of preformed glucose. The glucose pool, namely free glucose in the extracellular fluid and in the cells of certain tissues (primarily in the liver but also small amounts in the kidneys, intestinal mucosa, pancreatic islet cells, brain, and blood cells), is about 83 to 111 mmol (15 to 20 g) in the normal adult. Glycogen that can be mobilized to provide circulating glucose (e.g., hepatic glycogen) contains approximately 390 mmol glucose (70 g), with a range of about 135 to 722 mmol (25 to 130 g). Thus, in an adult of average size, preformed glucose can provide as little as a 3-hour supply of glucose and less than an 8-hour supply on average, even at the diminished rate of glucose utilization that occurs in the postabsorptive state. Clearly, therefore, gluconeogenesis is important for maintenance of the plasma glucose concentration even during an overnight fast.

If fasting is prolonged to 24 to 48 hours, the plasma glucose level declines and then stabilizes, hepatic glycogen content falls to less than 55 mmol (10 g), and gluconeogenesis becomes the sole source of glucose production. Because amino acids are the main gluconeogenic precursors that result in net glucose formation, muscle protein is degraded. Glucose utilization by muscle and fat virtually ceases. As lipolysis and ketogenesis accelerate and circulating ketone levels rise, ketones become a major source of fuel for the brain. Thus, glucose utilization by the brain declines by about half, resulting in a decrease in the rate of gluconeogenesis required to maintain the plasma glucose concentration and hence in diminished protein wasting. After prolonged fasting (40 days), ketones provide an estimated 80% to 90% of the energy used by the brain and renal gluconeogenesis provides up to half of the endogenous glucose production.

Feeding

After a meal, glucose absorption into the circulation is more than twice the rate of postabsorptive endogenous glucose production, depending on the carbohydrate content of the meal and the rate of its digestion and absorption. As glucose is absorbed, endogenous glucose production is suppressed and glucose utilization by liver, muscle, and fat accelerates. Thus, exogenous glucose is assimilated and the plasma glucose concentration returns to the postabsorptive level.

Exercise

Exercise increases glucose utilization (by muscle) to rates that can be severalfold greater than those of the postabsorptive state. Endogenous glucose production normally accelerates to match the utilization so that the plasma glucose concentration is maintained.

From these examples, it is clear that the plasma glucose concentration is normally maintained within a narrow range despite wide variations in glucose flux, a homeostatic feat accomplished by hormonal, neural, and substrate glucoregulatory factors. From a mechanistic perspective, hypoglycemia could result from decreased glucose production, increased glucose utilization, or both.
Glucoregulatory Factors

Hormonal Glucoregulatory Factors

Hormones are the most important glucoregulatory factors, and the regulation of their secretion is complex. Glucose, specifically the plasma glucose concentration, is the most important determinant of the secretion of glucoregulatory hormones, including insulin, glucagon, epinephrine, growth hormone, and cortisol.

Insulin, the dominant hormone in lowering glucose levels, controls the utilization of glucose. Hormones and neural signals are sensed directly by pancreatic beta cells, resulting in decreased insulin secretion. During hypoglycemia, activated sympathetic neural and adrenomedullary systems are also released. An array of neuropeptides (glucagon-like peptides and neuropeptide Y) from sympathetic, parasympathetic, and other neurons.

Substrate Glucoregulatory Factors

Glucose per se shifts hepatic metabolism in favor of glycogen storage. Hepatic glucose autoregulation (namely hepatic glucose production as an inverse function of the plasma glucose concentration) is an important determinant of the hyperglycemic response. In addition, lower plasma glucose levels may stimulate insulin secretion. Insulin secretion is under the control of substrate (glucose), neural, and hormonal signals. Insulin secretion is regulated by substrate, neural, and hormonal signals. (see Chapter 29). Decreasing plasma glucose concentrations are sensed directly by pancreatic beta cells, resulting in decreased insulin secretion. During hypoglycemia, activated sympathetic neural and adrenergic systems further limit insulin secretion (by -adrenergic mechanisms). The mechanisms of the increase in glucagon secretion during hypoglycemia in humans are

Conversely, decreased insulin secretion causes increased hepatic (and renal) glucose production and decreased glucose utilization by insulin-sensitive tissues such as muscle and thus tends to raise the plasma glucose concentration. Insulin is therefore both glucolowering (regulatory) and glucose-raising (counterregulatory) hormone. The rate of insulin secretion is regulated by a number of factors, the most important of which is glucose. A fall in the plasma glucose concentration has an immediate inhibitory effect on insulin secretion, thereby limiting a further fall in the plasma glucose level. Insulin is a potent and critical hormone. Either profound insulin deficiency or marked insulin excess can be lethal. But it is not the only glucoregulatory hormone.

The hyperglycemic effect of the hormone epinephrine (Fig. 32-2) is more complex. Epinephrine is secreted from chromaffin cells of the adrenal medulla in response to falling plasma glucose levels and both stimulates hepatic (and renal) glucose production and limits glucose utilization. The actions of epinephrine are both direct and indirect and are mediated through both -adrenergic and -adrenergic receptors. Adrenergic (1) limitation of insulin secretion is an important indirect hyperglycemic action of epinephrine. It allows the hyperglycemic response to occur. However, the increase in insulin secretion that occurs as plasma glucose rises limits the magnitude of the glycemic response. Adrenergic (1) stimulation of glucagon secretion also occurs, but its contribution to the hyperglycemic effect of epinephrine appears to be minor under physiologic conditions.

Epinephrine acts directly (i.e., independent of changes in other hormones or substrates) to increase hepatic glycogenolysis and gluconeogenesis. In humans the hepatic effect is mediated predominantly through -adrenergic mechanisms, although a small direct -adrenergic stimulation of hepatic glucose production has been reported. Epinephrine also mobilizes gluconeogenic precursors (e.g., lactate, alanine, and glycerol) and, like glucagon, acts within minutes to produce a transient increase in glucose production and support basal rates of glucose production thereafter. In contrast to glucagon, however, epinephrine also limits glucose utilization (i.e., it reduces glucose clearance) by insulin-sensitive tissues such as skeletal muscle, predominantly through direct -adrenergic mechanisms. Because of the persistent effect on glucose utilization, sustained hyperepinephrinemia results in persistent hyperglycemia.

Long-term elevations of growth hormone and of cortisol limit glucose utilization and stimulate glucose production. Initially, however, growth hormone has a plasma glucose-lowering (insulin-like) effect; its hyperglycemic effect does not appear for several hours. Similarly, cortisol causes an increase in the plasma glucose level after 2 to 3 hours. The hyperglycemic effect of the combination of glucagon, epinephrine, and cortisol is greater than the sum of the effects of the hormones individually.

Neural Glucoregulatory Factors

The sympathetic neurotransmitter norepinephrine exerts hyperglycemic actions by mechanisms assumed to be similar to those of epinephrine, except that norepinephrine is released primarily from terminals of sympathetic postganglionic neurons. These terminals are adjacent to adrenergic receptors on target cells within the innervated tissues. Electrical stimulation of hepatic sympathetic nerves decreases glycogen content, increases glucose release, and causes hyperglycemia in animals and in humans. Parasympathetic stimulation increases the hepatic glycogen content and decreases hepatic glucose release.

Substrate Glucoregulatory Factors

Glucose per se shifts hepatic metabolism in favor of glycogen storage. Hepatic glucose autoregulation (namely hepatic glucose production as an inverse function of the plasma glucose concentration) is an important determinant of the hyperglycemic response. In addition, lower plasma glucose levels may stimulate insulin secretion. Insulin secretion is under the control of substrate, neural, and hormonal signals. Insulin secretion and glucagon secretion are regulated by substrate, neural, and hormonal signals. (see Chapter 29). Decreasing plasma glucose concentrations are sensed directly by pancreatic beta cells, resulting in decreased insulin secretion. During hypoglycemia, activated sympathetic neural and adrenergic systems further limit insulin secretion (by -adrenergic mechanisms). The mechanisms of the increase in glucagon secretion during hypoglycemia in humans are
controversial. There is considerable evidence that autonomic nervous systems (sympathetic and parasympathetic) and adrenomedullary activation play an important role in experimental animals. However, the relative role of these central nervous system (CNS)-mediated mechanisms is less clear in humans. For example, the glucagon response to hypoglycemia is not reduced substantially in adrenalectomized, spinal conduction-blocked, or vagotomized humans. Furthermore, the glucagon response is not reduced by combined adrenergic and muscarinic cholinergic blockade; however, it has been reported to be reduced by ganglionic blockade with the nicotinic cholinergic antagonist trimethaphan.

Other mechanisms may include direct alpha cell sensing of falling plasma glucose concentrations, although isolated alpha cells do not appear to release glucagon when incubated in media with low glucose concentrations.

Finally, because alpha cells are downstream of beta cells in the pancreatic islet microcirculation and insulin is known to inhibit glucagon secretion, it is conceivable that basal insulin secretion tonically inhibits glucagon secretion and that a decrease in intraislet insulin triggers glucagon secretion during hypoglycemia. Indeed, evidence that prevention of a decrease in insulin secretion during hypoglycemia virtually eliminates the glucagon response to hypoglycemia in humans suggests that this is an important mechanism.

The autonomic (adrenomedullary, sympathetic, and parasympathetic), adrenocorticotropic hormone (ACTH)-mediated cortisol and growth hormone responses to hypoglycemia are mediated through the CNS. Although sympathetic reflexes at the spinal cord level can be elicited by various stimuli in patients with spinal cord transection, sympathochromaffin responses to hypoglycemia or to cellular glucopenia produced by 2-deoxyglucose do not occur in such individuals.

The ventromedial nucleus of the hypothalamus is an important site of glucose-sensing neurons that trigger CNS-mediated neuroendocrine responses to hypoglycemia. However, there is evidence that there are widespread glucose-sensing sites within the brain and in peripheral locations, including the portal vein.
Glycemic Thresholds for Responses to Hypoglycemia

Falling plasma glucose concentrations normally elicit a typical sequence of responses. 

Arterialized venous glycemic thresholds for several of these are listed in Table 32-1 and illustrated in Figure 32-3. Insulin secretion decreases (favoring increased glucose production as well as decreased glucose utilization by tissues other than the brain) as plasma glucose levels decline within the physiologic range. Secretion of counterregulatory hormones including glucagon (which stimulates hepatic glycogenolysis and favors gluconeogenesis) and epinephrine (which stimulates hepatic glycogenolysis and, by mobilizing precursors, hepatic and renal gluconeogenesis and which limits glucose utilization by insulin-sensitive tissues) increases as plasma glucose levels fall just below the physiologic range. Lower plasma glucose concentrations cause symptoms and signs of hypoglycemia and, ultimately, brain dysfunction.

When the same methods are used, the glycemic thresholds for the various responses to falling plasma glucose concentrations in healthy subjects are quite reproducible from laboratory to laboratory (see Fig. 32-3). Nonetheless, these thresholds are dynamic rather than static. As discussed later in this chapter, they shift to higher plasma glucose concentrations in people with poorly controlled diabetes (who often have symptoms of hypoglycemia at higher than normal glucose levels) and to lower plasma glucose concentrations in people who suffer recurrent hypoglycemia, such as those with well-controlled diabetes or with an insulinoma (who often tolerate subnormal glucose levels without symptoms).
Glucose Counterregulation

The physiology of glucose counterregulation—the mechanisms that normally prevent or rapidly correct hypoglycemia—has been reviewed in detail. Early studies of the mechanisms of the correction of short-term insulin-induced hypoglycemia and of more prolonged insulin-induced hypoglycemia are summarized in Figure 32-4 and Figure 32-5, respectively. These and studies of the prevention of hypoglycemia are detailed elsewhere.

The principles of glucose counterregulation are three. First, the prevention and the correction of hypoglycemia involve both waning of insulin and activation of glucose counterregulatory factors. These are not due solely to waning of insulin. Second, although insulin is the dominant plasma glucoselowering factor, there are redundant glucose counterregulatory factors including a decrease in insulin and increases in glucagon and epinephrine. Thus, there is a fail-safe system that prevents failure of the counterregulatory process even when one, or perhaps more, of the components of the system fails. Third, there is a hierarchy among the counterregulatory factors. Some are more important than others.

The physiology of glucose counterregulation is also summarized in Table 32-1. The first defense against falling plasma glucose concentrations is decreased insulin secretion. Among the counterregulatory factors, increased glucagon secretion plays a primary role. Glucose recovery from hypoglycemia is impaired and postabsorptive plasma glucose concentrations decline but then level off when glucagon secretion is deficient. Glucagon is the second defense against falling plasma glucose concentrations. Albeit demonstrably involved, increased epinephrine secretion is not normally critical. It becomes critical when glucagon is deficient. Epinephrine is the third defense against falling plasma glucose concentrations. Hypoglycemia develops or progresses when both glucagon and epinephrine are deficient and insulin is present despite the actions of the other glucose counterregulatory factors. Thus, insulin, glucagon, and epinephrine stand high in the hierarchy of redundant glucose counterregulatory factors.

Growth hormone and cortisol, both of which tend to increase plasma glucose concentrations after several hours, are involved in defense against prolonged hypoglycemia. However, neither is critical to recovery from even prolonged hypoglycemia or, at least in adults, to prevention of hypoglycemia after an overnight fast.

There is some evidence that glucose autoregulation is involved although only during severe hypoglycemia. Other hormones, neurotransmitters, and substrates other than glucose (and fatty acids that may mediate part of the effect of epinephrine) may also be involved. If so, they play relatively minor roles.
PATHOPHYSIOLOGY OF HYPOGLYCEMIA

Clinical Manifestations of Hypoglycemia

Whipple’s triad: symptoms consistent with hypoglycemia, a low plasma glucose concentration, and relief of those symptoms when the plasma glucose concentration is raised provides compelling evidence of hypoglycemia.

Symptoms of hypoglycemia can be divided into two categories, neuroglycopenic and neurogenic (autonomic) symptoms.[1] Neuroglycopenic symptoms are the direct result of CNS neuronal glucose deprivation. They include behavioral changes, confusion, fatigue or weakness, warmth, visual changes, seizure, loss of consciousness, and, if hypoglycemia is severe and prolonged, death. Neurogenic symptoms are the result of the perception of physiologic changes caused by the autonomic nervous system discharge triggered by hypoglycemia. They include adrenergic symptoms such as palpitations, tremor, and anxiety and cholinergic symptoms such as sweating, hunger, and paresthesias. Adrenergic symptoms are mediated by norepinephrine released from sympathetic postganglionic neurons, the adrenal medulla, or both and epinephrine released from the adrenal medulla. The relative contributions of these are not known, but palpitations have been attributed to circulating epinephrine and tremor to sympathetic neural norepinephrine. Cholinergic symptoms, at least sweating, are thought to be mediated by acetylcholine released from sympathetic postganglionic neurons.

Representative neurogenic and neuroglycopenic symptoms of hypoglycemia are listed in Figure 32-6, which also illustrates that awareness of hypoglycemia is the extent to which individuals perceive that their blood sugar is low. The result

---

---

of the perception of neurogenic symptoms. The autonomic, including the sympatho-chromaffin, response to hypoglycemia is initiated by glucose-sensitive neurons, including those in the ventromedial hypothalamus, that increase firing as extracellular glucose levels fall. Thus, although both neurogenic and neuroglycopenic symptoms could be viewed as fundamentally neuroglycopenic in origin, their mechanisms are different. Some prefer the term autonomic rather than neurogenic symptoms because they may be mediated by a circulating hormone (epinephrine).

---

*Figure 32-7 Neurogenic (autonomic) and neuroglycopenic symptoms of hypoglycemia in normal humans. Among the neurogenic symptoms, "sweaty," "hungry," and "tingling" are cholinergic and "shaky/tremulous," "heart pounding," and "nervous/anxious" are adrenergic. See text for discussion. Mean (±SE) subject scores for awareness of hypoglycemia (blood sugar low) symptoms consistent with hypoglycemia, a low plasma glucose concentration, and relief of those symptoms when the plasma glucose concentration is raised provides compelling evidence of hypoglycemia.

---

as well as by a neurotransmitter. Nonetheless, the autonomic response is CNS-mediated and, therefore, the resulting symptoms are fundamentally neurogenic.

Common signs of hypoglycemia include pallor and diaphoresis. Heart rate and systolic blood pressure are typically increased, but these findings may not be prominent. To the extent that they are observable, the neuroglycopenic manifestations are often valuable, albeit nonspecific, signs. Transient neurologic defects occur occasionally. Permanent neurologic damage is rare.

The magnitude of the responses to hypoglycemia is an inverse function of the nadir plasma glucose concentration rather than the rate of decrease in plasma glucose.[2] It was once thought that neurogenic symptoms are less prominent when hypoglycemia develops gradually. However, the relative paucity of symptoms at a given low plasma glucose concentration in individuals with recurrent hypoglycemia, such as those with tightly controlled diabetes[3] or with an insulinoma[4] is attributable to a shift in glycemic thresholds for responses to lower plasma glucose concentrations. Conversely, the threshold shifts to higher plasma glucose concentrations in patients with chronic hyperglycemia result in symptoms of hypoglycemia at relatively high glucose levels.[5] The mechanism of these shifts in thresholds is unknown. Potential mechanisms are discussed later in this chapter.

---

*Figure 32-8 Representative neurogenic and neuroglycopenic symptoms of hypoglycemia are listed in Figure 32-6, which also illustrates that awareness of hypoglycemia is the extent to which individuals perceive that their blood sugar is low. The result
Diagnosis of Hypoglycemia

The manifestations of hypoglycemia are nonspecific, vary among individuals, and may change from time to time in the same individual. They are also typically episodic. Thus, although the history is of fundamental importance in suggesting the possibility of hypoglycemia, the diagnosis cannot be made solely on the basis of symptoms and signs.

The diagnosis of hypoglycemia should also not be made solely on the basis of plasma glucose measurements unless they are unequivocally subnormal. It is not possible to define a plasma glucose concentration below which neuroglycopenia invariably occurs and above which neuroglycopenia never occurs. Although symptoms commonly occur with plasma glucose levels less than 3.0 mmol/L (54 mg/dL), they can occur at higher plasma glucose levels in poorly controlled diabetes and only at lower glucose levels in well-controlled diabetes or in other conditions that result in recurrent hypoglycemia such as insulinoma. In addition, venous plasma glucose concentrations substantially less than 3.0 mmol/L (54 mg/dL) may occur in normal individuals late after glucose ingestion (arterial glucose levels are higher) and in some women and children during fasting without producing recognizable symptoms. This is not to say that distinctly low plasma glucose measurements should be ignored. Some patients with endogenous hyperinsulinism or intensively treated diabetes tolerate glucose levels that are unequivocally subnormal, as mentioned earlier. Because these patients can have hypoglycemic symptoms at other times (presumably when glucose levels are even lower), it would be inappropriate to deny that they have hypoglycemia.

In general, venous plasma glucose concentrations greater than 3.9 mmol/L (70 mg/dL) after an overnight fast are normal, those between 2.8 and 3.9 mmol/L (50 and 70 mg/dL) are suggestive of hypoglycemia, and those less than 2.8 mmol/L (50 mg/dL) indicate postabsorptive hypoglycemia. Because substantial glucose extraction occurs across the forearm under hyperinsulinemic conditions, arterial glucose concentrations (those relevant to brain function) are as much as 30% higher than venous glucose concentrations after an oral glucose load. Artifactualy low measured glucose levels can result from glycolysis in vitro (pseudohypoglycemia), particularly in the presence of leukocytosis or polycythemia, or both, or if separation of plasma from the formed elements of the blood is delayed. The diagnosis of hypoglycemia is most convincingly established when it is based on Whipple’s triad: symptoms consistent with hypoglycemia, a low plasma glucose concentration, and relief of those symptoms when the plasma glucose concentration is increased to normal levels.
Postabsorptive versus Postprandial Hypoglycemia

Reproducible hypoglycemia in the postabsorptive state implies the presence of disease and requires diagnostic explanation and therapy. This condition is commonly referred to as postabsorptive, or fasting, hypoglycemia. However, it need not be apparent initially or exclusively during prolonged fasting or after an overnight fast; it may become symptomatic during the latter portion of any interdigestive period especially with exercise. In contrast, postprandial (reactive, stimulative) hypoglycemia usually does not imply a serious underlying disorder. Thus, the distinction between postabsorptive and postprandial hypoglycemia is useful.
Mechanisms of Hypoglycemia

Hypoglycemia indicates that the rate of glucose efflux from the circulation exceeds that of glucose influx into the circulation. It can result from excessive glucose efflux (excessive utilization, external losses) or deficient glucose influx (deficient endogenous production in the absence of exogenous glucose delivery), or both. Conditions in which glucose utilization is increased include exercise, pregnancy, and sepsis; renal losses can occur at physiologic plasma glucose concentrations (e.g., renal glycosuria, pregnancy). However, because of the capacity of the normal liver (and kidneys) to increase glucose production severalfold, as discussed earlier, clinical hypoglycemia rarely results solely from excessive glucose efflux. Rather it is commonly the result of inappropriately low glucose production relative to the rate of glucose utilization.

Hypoglycemia can be caused by regulatory, enzymatic, or substrate defects. Gluoregulatory defects include excessive secretion of insulin or deficient secretion of glucose counterregulatory hormones. Enzymatic defects in glucose production may be primary or may result from hepatic disease. Substrate defects include failure to mobilize or utilize gluconeogenic substrates.
Clinical Classification of Hypoglycemia

Hypoglycemia can be classified on the basis of glucose kinetic patterns, pathogenic mechanisms, or disease groups. The last approach is used in this chapter (Table 32-2). Postabsorptive, or fasting, hypoglycemia can be the result of drugs, critical illnesses including hepatic or renal failure, hormonal deficiencies, non-beta cell tumors, endogenous hyperinsulinism (including that caused by pancreatic beta cell tumors), or metabolic disorders of infancy and childhood. Postprandial, or reactive, hypoglycemia is rarely caused by congenital enzyme defects but can follow gastric surgery and perhaps occurs rarely as an idiopathic disorder.

Most episodes of hypoglycemia result from drugs, particularly insulin, sulfonylureas, or alcohol. In one series of patients treated in an emergency room for hypoglycemia, two thirds had diabetes mellitus and two thirds had been drinking alcohol. Clearly, the combination of drug-treated diabetes and alcohol ingestion can be devastating. Nearly one fourth of the patients were septic, but diabetes or alcohol ingestion was common even in those patients. Drugs are also a common cause of hypoglycemia in inpatients. In this case, however, critical illnesses such as renal or hepatic failure, sepsis, and inanition are common. Hypoglycemia resulting from hormonal

HYPOGLYCEMIA IN DIABETES MELLITUS

Clinical Context

It is now well established that comprehensive care makes a difference for people with diabetes. A fundamentally important component of comprehensive care of diabetes is glycemic control because it prevents or delays the long-term specific complications of diabetes (retinopathy, nephropathy, and neuropathy) and may reduce its macrovascular complications. However, iatrogenic hypoglycemia is the limiting factor in the glycemic management of both type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM) both conceptually and in practice.

Conceptually, were it not for the potentially devastating effects of hypoglycemia on the brain, hyperglycemia would be rather easy to treat. Administration of enough insulin (or any effective medication) to lower plasma glucose levels to or below the normal range would eliminate symptoms of hyperglycemia; prevent diabetic ketoacidosis and hyperosmolar coma; almost assuredly prevent diabetic retinopathy, nephropathy, and neuropathy; and probably reduce atherosclerotic risk. The devastating effects of hypoglycemia are real, however, and the glycemic management of diabetes is therefore complex.

In practice, euglycemia, even near euglycemia, cannot be achieved and maintained safely in most patients with T1DM and many patients with T2DM because of the barrier of iatrogenic hypoglycemia. Because of that barrier, retinopathy, nephropathy, and neuropathy develop or progress in some patients with T1DM or T2DM despite aggressive attempts to achieve glycemic control, albeit at lower rates than during less aggressive therapy. Indeed, the inability to maintain euglycemia over time, because of the barrier of hypoglycemia, may explain the limited impact of aggressive glycemic therapy on the atherosclerotic complications of diabetes.

In T1DM, aggressive attempts to achieve glycemic control increase the risk of severe, at least temporarily disabling, iatrogenic hypoglycemia (i.e., that requiring the assistance of another individual) more than threefold. Documented in both of the controlled clinical trials with sample sizes large enough to demonstrate beneficial effects of intensive therapy on the long-term complications of diabetes, the Diabetes Control and Complications Trial (DCCT) and the Stockholm Diabetes Intervention Study, that fact was confirmed in a meta-analysis that also included 12 smaller controlled clinical trials of intensive therapy. However, it is possible to reduce the risk of hypoglycemia during aggressive therapy of T1DM. For example, the sixfold increased risk of severe hypoglycemia during intensive therapy in the feasibility phase of the DCCT was reduced by half in the full-scale trial.

Because of the interplay of therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations, as discussed later in this chapter, people with T1DM are at ongoing risk for episodes of hypoglycemia. Those attempting to achieve glycemic control suffer untold numbers of episodes of asymptomatic hypoglycemiaplasma glucose levels may be lower than 2.8 mmol/L (50 mg/dL) as much as 10% of the time and an average of two episodes of symptomatic hypoglycemia per week. They suffer an episode of severe, at least temporarily disabling hypoglycemia every year or two on average. Although seemingly complete recovery from even severe hypoglycemia is the rule, permanent neurologic deficits can result. It has been estimated that 2% to 4% of deaths of people with T1DM are caused by hypoglycemia. In addition, hypoglycemia can cause recurrent or even persistent psychosocial morbidity. The reality of hypoglycemia, the rational fear of hypoglycemia, or both can be a barrier to glycemic control.

Iatrogenic hypoglycemia is generally less frequent in T2DM. However, it occurs during treatment with sulfonylureas or other insulin secretagogues (and has been reported in patients treated with metformin) or with insulin (Table 32-4; see Table 32-3). The frequency of hypoglycemia approaches that in T1DM in those who reach the insulin-deficient end of the spectrum of T2DM. Indeed, in one series, the frequency of severe hypoglycemia was similar in patients with T2DM and T1DM matched for duration of insulin therapy.

*Taking assigned medication.*

*Comparing severe hypoglycemia (that requiring the assistance of another individual) in 65% of intensively treated patients over 6.5 years in the Diabetes Control and Complications Trial.*
Study investigators concluded that over time hypoglycemia becomes limiting in the treatment of T2DM just as it is in the treatment of T1DM. Given the now well-established long-term benefits of glycemic control and the short-term potentially devastating effects of iatrogenic hypoglycemia, it is clear that the goals of both reducing mean glycemia and minimizing hypoglycemia are important for people with diabetes. Minimizing the risk of hypoglycemia in T1DM involves both application of the principles of aggressive therapy—education and empowerment of patients, frequent self-monitoring of blood glucose, flexible insulin regimens, individualized glycemic goals, and ongoing professional guidance and support—and implementation of hypoglycemia risk reduction. As discussed later in this chapter, hypoglycemia risk reduction requires consideration of the roles of both therapeutic insulin excess and compromised physiologic and behavioral defenses against developing hypoglycemia.
Risk Factors

Insulin Excess

The conventional risk factors for iatrogenic hypoglycemia in T1DM (Table 32-5) are based on the premise that relative or absolute therapeutic insulin excess, which must occur from time to time because of the gross pharmacokinetic imperfections of all current insulin replacement regimens, is the sole determinant of risk.

Relative or absolute therapeutic insulin excess occurs when:

1. Insulin doses are excessive, ill-timed, or of the wrong type.
2. The influx of exogenous glucose is decreased (as during the overnight fast or after missed meals or snacks).
3. Insulin-independent glucose utilization is increased (as during exercise).
4. Endogenous glucose production is decreased (as after alcohol ingestion or administration or other drugs and with loss of renal parenchyma).
5. Sensitivity to insulin is increased (as after exercise; in the middle of the night; with glycemic control; with increased fitness, weight loss, or both; or with administration of certain drugs).
6. Insulin clearance is decreased (as in renal failure).

### TABLE 32-5 -- Comprehensive Risk Factors for Hypoglycemia in Diabetes

Premise: Iatrogenic hypoglycemia in type 1 diabetes is the result of the interplay of therapeutic insulin excess and compromised glucose counterregulation.

1. Absolute or relative therapeutic insulin excess (the conventional risk factors)
   a. Insulin doses excessive, ill-timed, wrong type
   b. Decreased food intake
   c. Increased glucose utilization (e.g., exercise)
   d. Decreased glucose production (e.g., alcohol)
   e. Increased sensitivity to insulin (e.g., after exercise, during the night, glycemic control, weight loss)
   f. Decreased insulin clearance (e.g., renal failure)
2. Compromised glucose counterregulation
   a. Absolute insulin deficiency (C-peptide negativity)
      - Cell destruction: No insulin in response to glucose
      - Unknown: No in glucagon in response to glucose
   b. History of severe hypoglycemia or aggressive therapy per se (lower glucose goals, lower hemoglobin A1c)

Episodes of hypoglycemia:
- Attenuated autonomic (including epinephrine) activation and symptoms in response to glucose (defective glucose counterregulation and hypoglycemia unawareness)

These are the issues with which people with diabetes and their health care providers deal routinely as they attempt to minimize iatrogenic hypoglycemia. However, it became clear early in the DCCT that these conventional risk factors explain only a minority of episodes of severe iatrogenic hypoglycemia. Indeed, in a multivariate model none was found to be statistically significant. Clearly, we must look beyond these risk factors if we are to understand the majority of episodes of severe hypoglycemia in T1DM.

Interplay of Insulin Excess and Compromised Glucose Counterregulation

Iatrogenic hypoglycemia in T1DM is more appropriately viewed as the result of the interplay of relative or absolute therapeutic insulin excess (the conventional risk factors) and compromised glucose counterregulation (see Table 32-5). Three clinically well-documented risk factors for iatrogenic hypoglycemia in T1DM are (1) absolute insulin deficiency (i.e., C-peptide negativity), (2) a history of severe hypoglycemia, and (3) aggressive glycemic therapy per se as evidenced by lower glycosylated goals or lower hemoglobin A1c levels. (Obviously, iatrogenic hypoglycemia occurs in people with diabetes who are not C-peptidenegative, have no history of severe hypoglycemia, and are not practicing aggressive glycemic therapy. Nonetheless, these are associated with a substantially increased risk of hypoglycemia.) These three risk factors are clinical surrogates of compromised physiologic and behavioral defenses against falling plasma glucose concentrations: the clinical syndromes of defective glucose counterregulation and of hypoglycemia unawareness and the pathophysiologic concept of hypoglycemia-associated autonomic failure.
Pathophysiology of Glucose Counterregulation in Diabetes

As the person with T1DM becomes absolutely insulin-deficient over the first few months or years of clinical T1DM, circulating insulin levels then simply the passive result of absorption of exogenous insulin not fall as plasma glucose levels decline. The first defense against hypoglycemia is lost.

Over the same time frame, the glucagon response to hypoglycemia is lost in T1DM. This is a selective defect; the glucagon responses to other stimuli are largely, if not entirely, intact. The mechanism of the defect is unknown, but it is tightly linked to absolute insulin deficiency. Given that and the finding that a decrease in intracellular secretion is normally a potent stimulus to the glucagon secretory response to hypoglycemia, the absent glucagon response may be a direct result of absent insulin secretion. Thus, the clinical hypoglycemia risk factor of C-peptide negativity indicates that the first defense against hypoglycemia (decreased insulin secretion) is lost and predicts accurately that the second defense against hypoglycemia (increased glucagon secretion) is lost. Therefore, patients with established (i.e., C-peptide negative) T1DM are largely dependent on the third defense against hypoglycemia, increased epinephrine secretion.

The epinephrine response to hypoglycemia is attenuated in many patients with T1DM, particularly those with the other clinical risk factors for hypoglycemia such as a history of severe hypoglycemia or aggressive glycemic therapy per se as evidenced by lower glycemic goals, lower hemoglobin A1C levels, or both. The former indicates and the latter implies recurrent episodes of prior hypoglycemia. In contrast to the absent glucagon response, the attenuated epinephrine response represents a threshold shift; an epinephrine response can be elicited, but lower plasma glucose concentrations are required. This threshold shift to lower plasma glucose concentrations is largely the result of recent antecedent iatrogenic hypoglycemia.

Recent antecedent hypoglycemia reduces autonomic (including adrenomedullary epinephrine) and symptomatic, among other, responses to a given level of subsequent hypoglycemia in nondiabetic individuals and in patients with T1DM. It shifts the glycemic thresholds for these responses to lower plasma glucose concentrations. As a result, it also impairs glycemic defense against hyperinsulinemia and developing hypoglycemia in T1DM and in patients with T1DM. In addition to this functional threshold shift, there may be an anatomic component of adrenomedullary chromaffin cells-the reduced epinephrine response in patients with classical diabetic autonomic neuropathy. Nonetheless, the epinephrine response is typically reduced in patients with no clinical evidence of classical diabetic autonomic neuropathy.

The development of an attenuated epinephrine response to falling glucose levels loss of the third defense against hypoglycemia a critical pathophysiologic event. Patients with T1DM who have combined deficiencies of glucagon and epinephrine responses have been shown in prospective studies to suffer severe hypoglycemia at rates 25-fold or more higher than those of patients with absent glucagon but intact epinephrine responses during aggressive glycemic therapy. They have the clinical syndrome of defective glucose counterregulation. The mechanisms of altered and defective glucose counterregulation are illustrated in Figure 32-12.

By reducing the autonomic, specifically the sympathochromaffin, responses to subsequent hypoglycemia, recent antecedent iatrogenic hypoglycemia also causes loss of the warning, largely if not exclusively neurogenic, symptoms of developing hypoglycemia that previously allowed the patient to recognize that glucose levels were falling and prompted the appropriate behavioral response (e.g., ingestion of food) to abort the episode. Thus, the first clinical manifestation of a hypoglycemic episode is neuroglycopenia, and it is often too late for the patient to recognize and self-treat the episode. This is the clinical syndrome of hypoglycemia unawareness. It, too, has been shown in a prospective study to be associated with a high frequency of severe iatrogenic hypoglycemia.

The concept of hypoglycemia-associated autonomic failure in T1DM, a functional disorder distinct from the fixed autonomic failure of classical diabetic autonomic neuropathy, was formulated and then verified experimentally to unify the pathogenesis of the clinical syndromes of defective glucose counterregulation and hypoglycemia unawareness.

The concept of hypoglycemia-associated autonomic failure in T1DM posits that:

1. Periods of relative or absolute therapeutic insulin excess in the setting of absent glucagon responses lead to episodes of hypoglycemia.
2. These episodes, in turn, cause reduced autonomic (including adrenomedullary epinephrine) responses to falling glucose concentrations on subsequent occasions.
3. These reduced autonomic responses result in reduced symptoms of, and therefore behavioral responses to, developing hypoglycemia (i.e., hypoglycemia unawareness) and because epinephrine responses are reduced in the setting of absent glucagon response impaired physiologic defenses against developing hypoglycemia (i.e., defective glucose counterregulation).

Thus, a vicious circle of recurrent hypoglycemia is created and perpetuated.

Perhaps the most compelling support for the concept of hypoglycemia-associated autonomic failure in T1DM is the finding, in three independent laboratories, that hypoglycemia unawareness (Fig. 32-14) and, at least in part, the reduced epinephrine component of defective glucose counterregulation are reversible after as little as 2 weeks of scrupulous avoidance of iatrogenic hypoglycemia in most affected patients. This involves a shift of glycemic thresholds for autonomic and
symptomatic responses back toward higher plasma glucose concentrations.

The basic mechanism of hypoglycemia-associated autonomic failure remains to be determined. There is evidence that it is mediated by the cortisol response to previous hypoglycemia\textsuperscript{112}, although that remains to be confirmed independently. Evidence, obtained with the Kety-Schmidt technique, that it involves increased brain glucose uptake during hypoglycemia has been reported\textsuperscript{113,114}. However, evidence that recent antecedent hypoglycemia does not increase blood-to-brain glucose transport or cerebral glucose metabolism, measured with \textsuperscript{11\textsubscript{C}}glucose and positron emission tomography, or cerebral blood flow, measured with \textsuperscript{15\textsubscript{O}}water, has been presented\textsuperscript{115}. The latter data do not exclude regional increments in blood-to-brain glucose transport. Alternatively, the alteration may lie beyond the blood-brain barrier.

Consistent with the concept of hypoglycemia-associated autonomic failure in T1DM, recent antecedent hypoglycemia also shifts glycemic thresholds for hypoglycemic cognitive dysfunction to lower plasma glucose concentrations\textsuperscript{116,117} and impairs detection of hypoglycemia in the clinical setting in patients with T1DM.\textsuperscript{118} In addition to shifting the thresholds for the adrenomedullary (plasma epinephrine) and parasympathetic (plasma pancreatic polypeptide) response to lower plasma glucose concentrations, recent antecedent hypoglycemia has been reported to reduce the sympathetic neural response to subsequent hypoglycemia,\textsuperscript{119-121} although the latter has been questioned.\textsuperscript{122}

There is also evidence that reduced sensitivity to catecholamines, measured as a reduced heart rate response to the \textsuperscript{-adrenergic agonist isoproterenol, contributes to the pathogenesis of hypoglycemia unawareness in T1DM.\textsuperscript{123} Hypoglycemia has been reported to reduce \textsuperscript{-adrenergic sensitivity, tested about 10 hours later, in T1DM (but not in nondiabetic individuals).\textsuperscript{124} Thus, it is conceivable that both reduced activation of the sympathochromaffin system and reduced sensitivity to released catecholamines might play a role in the pathogenesis of hypoglycemia unawareness and defective glucose counterregulation induced by recent antecedent iatrogenic hypoglycemia.

The extent to which these pathophysiologic concepts, developed in T1DM, apply to patients with T2DM remains to be assessed in detail. They may well apply to those approaching the insulin-deficient end of the spectrum of T2DM because hypoglycemia becomes limiting to glycemic control in such patients.\textsuperscript{126} Indeed, in one series the frequency of severe hypoglycemia was found to be similar in patients with T2DM and T1DM matched for duration of insulin therapy.\textsuperscript{127} This issue is complicated by the fact that some patients with apparent T2DM may actually have late-onset T1DM.\textsuperscript{128} Nonetheless, patients with advanced T2DM have been reported to have reduced glucagon responses to hypoglycemia\textsuperscript{129} (Table 32-6), a key feature of defective glucose counterregulation in T1DM. Furthermore, patients with T2DM have reduced epinephrine and neurogenic symptom responses to hypoglycemia after episodes of hypoglycemia, key features of defective glucose counterregulation, hypoglycemia unawareness, and hypoglycemia-associated autonomic failure in T1DM.\textsuperscript{130}

The concept of hypoglycemia-associated autonomic failure in T1DM is illustrated in Figure 32-11, and the comprehensive risk factors for iatrogenic hypoglycemia in T1DM, viewed in the context of the interplay of therapeutic insulin excess and compromised glucose counterregulation, are outlined in the Table 32-5.
Hypoglycemia Risk Reduction in Diabetes

Clearly, every effort must be made to minimize the risk of iatrogenic hypoglycemia and eliminate the risk of severe hypoglycemia while pursuing the greatest degree of glycemic control that can be achieved safely in an individual person with diabetes. Hypoglycemia risk reduction involves (1) addressing the issue of hypoglycemia in every contact with the patient, (2) applying the principles of aggressive glycemic therapy, and (3) considering each of the comprehensive risk factors for hypoglycemia.

In addition to questioning the patient about episodes of symptomatic and biochemical hypoglycemia and looking for

![Figure 32-12 Schematic representation of the pathophysiology of glucose counterregulation in people with type 1 diabetes mellitus (T1DM). See text for discussion.](image)

low values in the self-monitoring of the blood glucose (SMBG) log, it is important to assess the patient's awareness of hypoglycemia. A history of hypoglycemia unawareness identifies that clinical syndrome (and also implies defective glucose counterregulation). It is also important to determine the extent to which the patient is concerned about the reality or the possibility of hypoglycemia. Fear of hypoglycemia can be a barrier to glycemic control. If episodes of hypoglycemia are identified, their frequency, severity, timing, and clinical contexts need to be determined.

Once the problem of iatrogenic hypoglycemia is recognized, it is appropriate to review the treatment plan with respect to the principles of aggressive glycemic therapy. These include (1) education and empowerment of the patient; (2) frequent SMBG; (3) flexible insulin (or other drug) regimens; (4) rational, individualized glycemic goals; and (5) ongoing professional guidance and support. Particularly in T1DM, but also in advanced T2DM, glycemic control is achieved safely by a well-informed, thoughtful person with diabetes who must make judgments about the management of his or her diabetes several times each day. The patient must be given the resources to make those judgments.

In the context of these therapeutic principles, hypoglycemia risk reduction requires consideration of both the conventional risk factors that lead to episodes of absolute or relative insulin excess insulinsulin (or other drug) dose, timing, and type; patterns of food ingestion and of exercise; interactions with alcohol or other drugs; and altered sensitivity to or clearance of insulin and the risk factors for compromised glucose counterregulation that impair physiologic and behavioral defenses against developing hypoglycemia (see Table 32-5). The underlying principle is that iatrogenic hypoglycemia is the result of the interplay of insulin excess and compromised glucose counterregulation rather than insulin excess alone.

As discussed earlier, the clinical surrogates of risk attributable to compromised glucose counterregulation include absolute insulin deficiency, which may be apparent from a history of ketosis-prone diabetes requiring insulin therapy from diagnosis, although it is now recognized that absolute insulin deficiency can sometimes develop more gradually in late-onset T1DM or advanced T2DM and a history of recurrent hypoglycemia or, absent that, aggressive glycemic therapy per se as evidenced by lower glycosylated hemoglobin levels, lower hemoglobin A1c levels, or both. It is possible to test for defective glucose counterregulation with an insulin infusion test, but that is generally neither practical nor useful given the now recognized dynamic nature of hypoglycemia unawareness and the reduced epinephrine component of defective glucose counterregulation discussed earlier. On the other hand, a diagnosis of partial or complete hypoglycemia unawareness can be made if the patient is unaware about the requirement for therapy with insulin for an average of 5 years and reduced plasma C-peptide levels.

*In advanced type 2 diabetes, as evidenced by the requirement for therapy with insulin for an average of 5 years and reduced plasma C-peptide levels.*
complete hypoglycemia unawareness can be made from the history.

Clinical hypoglycemia unawareness (which also suggests defective glucose counterregulation) implies recurrent antecedent iatrogenic hypoglycemia whether that has or has not been documented. If such hypoglycemia is not apparent to the patient or to his or her family or in the SMBG log, it is probably occurring during the night.

Indeed, hypoglycemia occurring severe hypoglycemia occurs most commonly during the night in people with T1DM. That is typically the longest interdigestive period and time between SMBG and the time of maximal sensitivity to insulin. In addition, sleep limits the recognition of warning symptoms of developing hypoglycemia, and thus the appropriate behavioral response, and has been found to further reduce the epinephrine response to hypoglycemia and thus to further compromise the physiologic defense against developing hypoglycemia.

In addition to regimen adjustments, approaches to the problem of nocturnal hypoglycemia include use of newer insulin analogues and bedtime treatments. Substitution of a preprandial rapid-acting insulin analogue (e.g., lispro or aspart) for short-acting (regular) insulin during the day reduces the frequency of nocturnal hypoglycemia. Substitution of a long-acting insulin analogue (e.g., glargine) for neutral protamine Hagedorn (NPH) or Ultralente insulin at bedtime may also reduce the frequency of nocturnal hypoglycemia. Bedtime treatments intended to reduce nocturnal hypoglycemia include bedtime snacks, although their efficacy is largely limited to the first half of the night. Experimental approaches include bedtime administration of uncooked cornstarch, of the glucagon-releasing amino acid alanine or of the epinephrine-simulating \textsuperscript{2}adrenergic agonist terbutaline. The efficacy of uncooked cornstarch in the 5.0-g dose recommended remains to be established. Although bedtime alanine and bedtime terbutaline have been shown to prevent nocturnal hypoglycemia more effectively than a conventional bedtime snack, alanine is probably impractical and terbutaline has not been studied further in a large clinical trial.

Obviously, with a history of recurrent hypoglycemia, one should determine when it occurs and adjust the treatment regimen appropriately. With a basal-bolus insulin regimen, morning fasting hypoglycemia implicates the long-acting or immediate-acting basal insulin, daytime hypoglycemia implicates the rapid-acting or short-acting insulin, and nighttime hypoglycemia may implicate either, all in the context of the other risk factors for insulin excess. A history of severe iatrogenic hypoglycemia that requiring the assistance of another individual is a clinical red flag. Unless it was the result of an easily remediable factor, such as a missed meal after insulin administration or vigorous exercise without the appropriate regimen adjustment, a substantive change in the regimen must be made. If it is not, the risk of recurrent severe hypoglycemia is unacceptably high.

In a patient with hypoglycemia unawareness, a 2- to 3-week period of scrupulous avoidance of iatrogenic hypoglycemia is advisable and can be assessed by return of awareness of hypoglycemia. This return of awareness has been accomplished without or with minimal compromise of glycemic control, but that required substantial involvement of health professionals. In practice, it can involve acceptance of somewhat higher glucose levels over the short term. However, with the return of symptoms of developing hypoglycemia, empirical approaches to better glycemic control can be tried.

Hypoglycemia is a fact of life for people with T1DM (and some with T2DM) who attempt to achieve near-euglycemia. Because of the pharmacokinetic imperfections of all current insulin replacement regimens, it is not practical to maintain euglycemia while eliminating episodes of asymptomatic and even symptomatic hypoglycemia in T1DM. That awaits the ultimate goal of the prevention and cure of diabetes or, in the shorter term, development of clinical strategies for perfect insulin replacement (e.g., transplantation of insulin-secreting cells or development of a closed-loop insulin replacement system) or for near-perfect insulin replacement coupled with measures that prevent, correct, or compensate for compromised glucose counterregulation.
Treatment of Hypoglycemia in Diabetes

Most episodes of asymptomatic hypoglycemia (detected by SMBG) and mild to moderate symptomatic hypoglycemia are effectively self-treated by ingestion of glucose tablets or carbohydrate in the form of juices, soft drinks, milk, crackers, candy, or a meal. A commonly recommended dose of glucose is 20 g (0.3 g/kg in children). However, the glycemic response to oral glucose is transient, usually less than 2 hours in insulin-induced hypoglycemia in T1DM (Fig. 32-15). Thus, ingestion of a more substantial mixed snack or meal shortly after the plasma glucose level is raised is generally advisable.

Parenteral treatment is necessary when a hypoglycemic patient is unable or unwilling (because of neuroglycopenia) to take carbohydrate orally. Glucagon is commonly injected subcutaneously or intramuscularly by a spouse or family member. The standard dose, 1 mg (15 µg/kg in children), can cause substantial but transient hyperglycemia (see Fig. 32-15). Intranasal administration of glucagon causes a glycemic response similar to that to injected glucagon. Although glucagon can be administered intravenously by medical personnel, intravenous glucose, 25 g initially, is the standard intravenous therapy. Because the glycemic response is transient, a subsequent glucose infusion is often needed and food should be provided orally as soon as the patient is able to take it safely.
HYPOGLYCEMIC DISORDERS

Hypoglycemia is most often caused by drugs, including those used to treat diabetes, just discussed, and alcohol. Among these, insulin, sulfonylureas, and perhaps metformin, used to treat diabetes, are the common offenders as discussed earlier in this chapter. Insulin and particularly sulfonylureas are possible causative agents even when there is no history of diabetes because these are sometimes taken surreptitiously, administered with criminal intent, or taken as the result of a pharmacy or other error. Established and putative hypoglycemia-causing drugs are listed in Table 32-7.

Ethanol inhibits gluconeogenesis, possibly because its metabolism to acetaldehyde and then acetate (by alcohol dehydrogenase

7% experienced hypoglycemia. 14% experienced-induced hypoglycemia include therapy of longer duration and increased doses, previous pentamidine therapy, and renal insufficiency. 126,127

Hypoglycemia occurs commonly in severe malaria. Although associated with relative hyperinsulinemia attributed to quinine-induced insulin release in some patients, hypoglycemia can occur in the absence of quinine therapy 128 and in the absence of hyperinsulinemia in quinine-treated patients. 129 Nonetheless, quinine has been reported to cause hypoglycemia in patients not afflicted by malaria. 130 and treatment of malaria with quinine, compared with the artemisinin-derivative artesunate, has been associated with higher plasma insulin/glucose ratios and lower glucose turnover rates and reported to produce higher rates of postadministration hypoglycemia. 131 Among anilinthrugs, quinidine, disopyramide, 132 and cibenzoline 133 have been reported to cause hypoglycemia.

Hypoglycemia has been attributed to many other drugs (see Table 32-7). In many of the cases, other potential causes of hypoglycemia have been present. For example, although hypoglycemia attributed to propranolol has been reported in healthy children, 134,135 most of the reported incidents occurred in insulin-treated diabetes. Although nonselective -adrenergic antagonists such as propranolol would be expected to reduce symptoms of developing hypoglycemia and impair epinephrine-mediated glucose counterregulation, 136 compelling evidence that these drugs increase the frequency of clinical hypoglycemia in insulin-treated diabetes has not been forthcoming. Nonetheless, it would be reasonable to use a relatively selective -adrenergic receptor antagonist (e.g., metoprolol or atenolol) in such patients.

Critical Illnesses

Among hospitalized patients, drugs, particularly insulin, are still the most common cause of hypoglycemia. 137 However, serious diseases, particularly renal failure but also hepatic or cardiac failure, sepsis, or inanition are second only to drugs.

In addition to appropriate glucoregulatory signals and a sufficient supply of gluconeogenic precursors, maintenance of the postabsorptive plasma glucose concentration requires a structurally and functionally intact liver. Renal glucose production notwithstanding, total hepatectomy results in profound hypoglycemia. 138 Extensive liver disease is required to produce hypoglycemia. Hepatogenous hypoglycemia occurs most commonly when destruction of the liver is rapid and massive (e.g., toxic hepatitis). It has been reported in fulminant viral hepatitis, 139 in fatty liver attributed to alcohol repose and in cholangitis and biliary obstruction. It is unusual in common forms of cirrhosis and hepatitis, although glucose metabolism is altered demonstrably (with lower postabsorptive plasma glucose concentrations, diminished glycemic responses to glucagon, and reduced hepatic glycogen contents) in uncomplicated viral hepatitis. 140 It is also unusual in metastatic liver disease despite extensive hepatic replacement. 141 Hypoglycemia can be caused by primary malignant tumors but is the result of a glucoregulatory abnormality, insulin-like growth factor II overproduction (see "NonBeta Cell Tumors").

The pathogenesis of hypoglycemia in occasional patients with severe cardiac failure is unknown. Possibilities include hepatic congestion and hypoxia, inanition, and gluconeogenic precursor limitation. The finding of elevated blood lactate levels associated with hypoglycemia 142 raises the possibility of inhibited gluconegogenesis. Postabsorptive hypoglycemia occurs in some patients with renal failure, 143,144,145,146 and the finding of a high frequency of renal insufficiency among patients with low plasma glucose levels 147 suggests that compromised glucose counterregulation may be a feature of renal failure. However, the pathogenesis of hypoglycemia in such patients is not known; it may involve multiple mechanisms. Most patients with hypoglycemia attributed to renal failure are cachectic. One such patient had reduced glucose turnover, diminished gluconeogenesis from alanine, and reduced alanine turnover. 148 During fasting, plasma glucose levels fell, blood lactate levels did not increase, and blood alanine levels fell. Hypoglycemia was attributed to substrate limitation of gluconeogenesis. However, at least one patient did not respond to substrate (glycerol, alanine) administration. 149 Glycemic responses to glucagon have been found to be reduced, suggesting impaired glycogenolysis, in some 150,151 but not all 152 studies.

Some patients with hypoglycemia attributed to renal failure have had diabetes, 153,154 but hypoglycemia persisted or recurred after insulin or oral hypoglycemic agents were withdrawn. The kidneys are a major site of insulin clearance, and decreasing insulin requirements parallel decreasing renal function in patients with insulin-treated diabetes. In the absence of insulin or insulin secretagogue therapy, however, endogenous insulin secretion should decrease and hypoglycemia would, therefore, not be expected. The mechanism by which reduced renal glucose production contributes to hypoglycemia in end-stage renal disease is unknown. However, the capacity of the normal liver to produce substantial amounts of glucose, loss of glucose-producing renal parenchyma would not be expected to contribute to hypoglycemia in patients with glucose-6-phosphatase deficiency. 155 Thus, one functioning kidney is not sufficient to provide normal endogenous glucose production in the virtual absence of hepatic glucose production.

Sepsis is a relatively common cause of hypoglycemia. 156,157 Increased glucose utilization (by skeletal muscle 158 and by macrophage-rich tissues such as liver, spleen, and leptom 159 ) and, at least initially, glucose production characterize experimental sepsis. 160,161 Hypoglycemia develops when hepatic glucose production decreases. 162,163 The factors responsible for the increased glucose turnover and the ultimate failure of glucose production to keep pace in sepsis are not entirely clear. Cytokines such as tumor necrosis factor (TNF) and interleukin-6, among others, are thought to increase glucose utilization. 164,165,166,167 The initial increase in glucose production is at least in part mediated by increased gluconeogenesis, 168 and catecholamines 169 and catecholaminergic responses to accelerated gluconeogenesis. These may also be stimulated by cytokines. 170,171 For example, TNF-infusion increases glucose production, an effect attributable to TNF-stimulated glucagon secretion, in dogs. 172 The later decline in glucose production, which results in hypoglycemia, is not the result of glucose counterregulatory failure. Rather, it appears to be the result of decreased hepatic responsiveness to appropriate glucoregulatory stimuli, that is, low insulin and high glucagon and epinephrine levels. 173 Hepatic hyperfusion is a plausible mechanism. It has been suggested that inactivation (oxidation) of catecholamines by superoxide anions plays a role in the pathogenesis of septic shock. 174,175

Hypoglycemia caused by inanition 176 is thought to be rare in developed countries but has been reported in the United States. 177 Because hypoglycemia can persist despite high rates of glucose infusion, such patients must have high rates of glucose utilization. Beyond this, the pathogenesis of hypoglycemia is unknown. An entirely speculative suggestion is that glucose becomes the sole oxidative fuel in the setting of total body fat depletion and that high rates of glucose utilization exceed the capacity to produce glucose because of limitation of substrate (e.g., amino acids). Postabsorptive hypoglycemia (with low blood alanine levels) has been reported to produce higher rates of postadmission hypoglycemia.

Hypoglycemia in children with deficient secretion of cortisol, growth hormone, or both is generally preceded by a period of caloric deprivation. That is consistent with the observation that hypoglycemia can sometimes be provoked by 24 to 30 hours of fasting in children with hypopituitarism who do not exhibit hypoglycemia after an overnight fast. 178,179 This intolerance of fasting is largely corrected by glucocorticoids.

replacement, whereas growth hormone replacement has a lesser effect. The findings suggest that a defect in gluconeogenesis causes hypoglycemia when hepatic glycogen stores are depleted.

Cortisol supports gluconeogenesis both by increasing gluconeogenic enzyme activities and by mobilizing gluconeogenic precursors to the liver (and the kidneys). However, oral alanine administration only partially reverses hypoglycemia. Finally, because cortisol deficiency causes reduced epinephrine secretion presumably because of reduced induction of adrenomedullary phenylethanolamine N-methyltransferase by adrenocortical cortisolepinephrine deficiency might contribute to the pathogenesis of hypoglycemia in this setting. Glucagon secretion is not reduced in such patients. Thus, given the key role of glucagon in glucose counterregulation, it is not surprising that glucose recovery, at least from short-term hypoglycemia, is generally normal in children with deficient secretion of cortisol, growth hormone, or both. Adults with hypopituitarism occasionally suffer postabsorptive hypoglycemia, particularly when glucose utilization or loss is increased, as during exercise or in pregnancy, respectively, or when glucogenic acidosis is impaired, as after alcohol ingestion. Again, these observations suggest that impaired gluconeogenesis becomes limiting to glucose production in the setting of glycogen depletion resulting from caloric deprivation.

As discussed earlier (see "Glucose Counterregulation"), hypoglycemia develops or progresses when both glucagon and epinephrine are deficient and insulin is present. This TABLE 32-9 — Plasma Glucose, Insulin, C-Peptide, and Proinsulin Concentrations used by Service (1999) and by Marks and Teale (1996) to Diagnose Fasting Hypoglycemia Caused by Endogenous Hyperinsulinism (e.g., in a Patient with an Insulinoma)

combination occurs in patients with established T1DM. They must be treated with insulin, have no glucagon response to hypoglycemia, and typically have a reduced epinephrine response to hypoglycemia and are, as a result, at high risk for iatrogenic hypoglycemia as discussed earlier (see "Hypoglycemia in Diabetes Mellitus"). However, systematic studies of an unusual patient suggest that clinical postabsorptive hypoglycemia may not develop when both glucagon and epinephrine are deficient but insulin secretion decreases normally as plasma glucose levels decline. That patient, with hypopituitarism attributed to sarcoidosis involving the hypothalamus, was shown to have no glucagon or epinephrine response to insulin-induced hypoglycemia; glucose recovery from that short-term experimental hypoglycemia was impaired markedly, as expected. Plasma glucose concentrations were relatively low after overnight fasts (3.2 ± 0.5 mmol/L, 58 ± 8 mg/dL). However, during a 72-hour fast plasma insulin levels declined to about 30 pmol/L (5 µU/mL); glucose levels declined to only 2.8 mmol/L (50 mg/dL), a value indistinguishable from that of similarly fasted healthy subjects; and symptoms of hypoglycemia did not occur.

Hypoglycemia is not a feature of the epinephrine-deficient state that results from bilateral adrenalectomy if glucocorticoid replacement is appropriate. and hypoglycemia does not occur during pharmacologic blockade of catecholamine actions when other glucose counterregulatory systems are intact. Hypoglycemia has been attributed to epinephrine deficiency. For example, urinary and plasma epinephrine responses to hypoglycemia are reduced in ketotic hypoglycemia of childhood, and therapeutic responses to ephedrine, a catecholamine-releasing drug, have been reported in uncontrolled studies of such patients. Also, some patients have been reported to have diminished glycemic responses to glucagon during fasting.

Postabsorptive hypoglycemia has also been attributed to epinephrine deficiency in one member of each of three sets of twins. Compared with their unaffected twins, the hypoglycemic children had reduced, but not absent, urinary epinephrine responses to infused 2-deoxyglucose and to hypoglycemia induced by fasting. The glucagon secretory responses were not evaluated, and the affected infants had inappropriately high insulin levels while they were hypoglycemic. Finally, reduced epinephrine excretion in infants of diabetic mothers has been associated with the occurrence of neonatal hypoglycemia.

Isolated glucagon deficiency would be expected to result in lowered postabsorptive plasma glucose concentrations but not frank hypoglycemia if insulin secretion was suppressed appropriately and epinephrine secretion were intact. A seemingly convincing example of hypoglycemia attributable to isolated glucagon deficiency has been described in an abstract but the case was never published. Postabsorptive hypoglycemia has been reported in another glucagon-deficient adult, but cortisol secretion and growth hormone secretion were also deficient. Neonatal hypoglycemia has also been attributed to glucagon deficiency. However, plasma insulin levels were inappropriate high during hypoglycemia.

Elevated plasma levels of glucose counterregulatory hormones during hypoglycemia exclude deficiencies of these. Levels that are not elevated during a spontaneous episode of hypoglycemia provide a diagnostic clue that requires definitive testing. In a patient with postabsorptive hypoglycemia that is not readily explained, it is my practice to seek clinical clues of hypopituitarism or primary adrenocortical insufficiency and often assess the plasma cortisol response to cosyntropin (synthetic ACTH) and to pursue such clues with definitive testing (e.g., the responses to insulin-induced hypoglycemia). Given the evidence, just summarized, that isolated
Postabsorptive hypoglycemia is occasionally caused by nonbeta cell tumors (nonslet cell tumor hypoglycemia). The majority are large retropitoneal, intrathoracic, or extrathoracic tumors that are typically slow-growing and malignant. Epithelial tumors that can cause hypoglycemia include hepatomas, adrenocortical carcinomas, and carcinoid tumors. More common carcinomas and hemolologic or lymphoid malignancies rarely cause hypoglycemia. Affected patients often have relatively high rates of glucose utilization, a pattern resembling that of hyperinsulinemia. Reports of a few patients with hypoglycemia attributed to ectopic insulin secretion have been published, but plasma insulin and C-peptide levels are suppressed appropriately during hypoglycemia in the vast majority of patients with nonbeta cell tumor hypoglycemia.

Similarly, insulin-like growth factor I (IGF-I) levels are typically suppressed. Overproduction of insulin-like growth factor II (IGF-II), specifically an incompletely processed form ("big IGF-II") that does not complex normally with circulating binding proteins and thus more readily gains access to target tissues, is the cause of hypoglycemia in most patients. The diagnosis is usually not difficult. The tumors are often apparent clinically and plasma insulin, C-peptide, and proinsulin levels are low during hypoglycemia. Free IGF-II levels (and levels of proIGF-II [E212]) are elevated. It should be noted, however, that both of these are often elevated in patients with renal failure. Presumably because of negative feedback mediated by IGF-II, growth hormone secretion is suppressed. Thus, serum IGF-I levels are low and the ratio of IGF-II to IGF-I is distinctly elevated.

Hypoglycemia related to excessive endogenous insulin secretion can be caused by:

1. A primary pancreatic islet beta cell disorder, typically a beta cell tumor (insulinoma), sometimes multiple insulinomas, or, especially in infants or young children, a functional beta cell disorder with beta cell hyperplasia or without an anatomic correlate.
2. A beta cell secretagogue, often a sulfonylurea, theoretically a beta cell stimulating autoantibody.
3. An antibody to insulin.

None of these is common. Endogenous hyperinsulinism is more likely in an overtly well individual with postabsorptive hypoglycemia, that is, a person with no relevant drug history or critical illness and no clinical clues to hormone deficiencies or a nonbeta cell tumor. In such an individual, accidental, surreptitious, or even malicious administration of a sulfonylurea, another insulin-releasing drug, or insulin should also be considered.

The critical pathophysiological feature of endogenous hyperinsulinism is failure of insulin secretion, assessed by plasma insulin and C-peptide levels, to fall to very low rates during hypoglycemia. The plasma insulin, C-peptide, proinsulin, sulfonylurea, and insulin antibody patterns in the various diagnostic categories (including exogenous as well as endogenous hyperinsulinism) are shown in Table 32-8.

The plasma glucose, insulin, C-peptide, and proinsulin levels advocated by Service and by Marks and Teale are summarized in Table 32-9. Insulin and C-peptide levels need not be high in the absolute (i.e., relative to euglycemic postabsorptive norms) but only inappropriately high during postabsorptive hypoglycemia. The diagnostic concept of relative hyperinsulinemia is fundamentally important. Measurements of insulin and C-peptide levels when the patient is not hypoglycemic are not useful diagnostically. Plasma insulin, C-peptide, and proinsulin (and sulfonylurea) levels need to be determined when the patient is clearly hypoglycemicplasma glucose at least less than 2.8 mmol/L (50 mg/dL), preferably with symptoms in the postabsorptive state.

This determination accomplishes two diagnostic goals:

1. It generally establishes that the patient does, in fact, have postabsorptive hypoglycemia. Even during a prolonged (e.g., 48 to 72 hours) fast, plasma glucose levels rarely fall to less than 2.8 mmol/L in healthy adult men although lower levels sometimes occur in healthy adult women and children. However, healthy subjects should not have symptoms of hypoglycemia and their insulin, C-peptide, and proinsulin levels should be low.
2. It determines whether the patient has hyperinsulinemic or hypoinsulinemic hypoglycemia, the latter excluding hyperinsulinism as a diagnostic consideration.

Plasma C-peptide levels are low in endogenous hyperinsulinism, whether that is therapeutic, surreptitious, or malicious. Plasma proinsulin concentrations, like insulin and C-peptide levels, are disproportionately high in patients with insulinomas and related disorders. Sulfonylureas produce glucose, insulin, and C-peptide patterns indistinguishable from those produced by a primary beta cell disorder, but a sulfonylurea is measurable. (This potential diagnostic problem could be confounded by the availability of new nonsulfonylurea insulin-releasing drugs such as repaglinide and nateglinide.) Antibodies to insulin, plasma proinsulin, and insulin antibody patterns in the various diagnostic categories are shown in Table 32-8.

Sulfonylureas produce glucose, insulin, and C-peptide patterns indistinguishable from those produced by a primary beta cell disorder, but a sulfonylurea is measurable. (This potential diagnostic problem could be confounded by the availability of new nonsulfonylurea insulin-releasing drugs such as repaglinide and nateglinide.) Antibodies to insulin, plasma proinsulin, and insulin antibody patterns in the various diagnostic categories are shown in Table 32-8.

Figure 32-16 Diagnostic algorithm for suspected hypoglycemia. GI, gastrointestinal.

Hypoglycemia can also be caused, rarely, by insulin receptor-stimulating autoantibodies. Plasma glucose and C-peptide levels are low but insulin levels tend to be high, presumably because receptor-bound antibodies impair the clearance of insulin. Antibodies that stimulate beta-cell insulin secretion in vitro have been described in sera from patients with hypoglycemia, but a corresponding clinical syndrome has not been defined. Finally, as noted earlier, ectopic insulin secretion has been described. Nonetheless, insulin arteriovenous differences across such tumors remain to be documented.

In summary, the diagnostic strategy is to measure plasma glucose, insulin, C-peptide, proinsulin, and sulfonylureas when the plasma glucose concentration is distinctly low and the patient has symptoms in the postabsorptive state. If hypoglycemia is not demonstrable after short-term (e.g., overnight) fasting, it may be necessary to extend the fast to 48 to 72 hours. Antibodies to insulin need not be measured during hypoglycemia. The need to measure these is sometimes debated because autocrine hyperglycemia appears to be rare in the United States. But, as discussed subsequently, it occurs around the world, the presence of insulin antibodies is key to the diagnosis, and insulin antibodies cause artifactual insulin elevations in the conventional double-antibody insulin radioimmunoassays. If the plasma glucose concentration after overnight fasting is unequivocally normal (e.g., 4.0 to 6.0 mmol/L [72 to 108 mg/dL]) on several occasions, a judgment has to be made on the basis of the degree of clinical suspicion of postabsorptive hypoglycemia. It is decided that the diagnosis should be pursued or if the plasma glucose level after overnight fasting is equivocally low (e.g., 3.0 to 4.0 mmol/L [54 to 72 mg/dL]), a prolonged fast is indicated. Intermediate attempts can be made by extending the fast on an outpatient basis, but a full 48- to 72-hour fast requires hospitalization. Although there are rare exceptions, the absence of symptomatic hypoglycemia after a 72-hour fast excludes a diagnosis of endogenous hyperinsulinism caused by a primary beta-cell disorder. Indeed, some submit that a negative 48-hour fast virtually excludes that diagnosis. Other diagnostic tests, such as the tolbutamide tolerance test and the C-peptide suppression test, are not recommended. An algorithm for the approach to a patient with suspected hypoglycemia is shown in Figure 32-16.

Insulinomas, the most common cause of hypoglycemia related to endogenous hyperinsulinism in adults, are rare. The estimated incidence is one case per 250,000 patient-years. However, because approximately 90% of insulinomas are benign, they are generally a treatable cause of potentially fatal hypoglycemia.
The fetus relies on a continuous supply of glucose from the maternal circulation. After birth, the neonate must make the transition to endogenous glucose production.

In addition to changes in the level of consciousness (irritability, lethargy, stupor), tremor, seizures, and coma, signs consistent with hypoglycemia in infants include hypoglycemia levels of 2.2 mmol/L (40 mg/dL) to 1.8 mmol/L (33 mg/dL). As noted earlier, unusually low plasma glucose concentrations are required to produce symptoms of hypoglycemia in patients with an insulinoma because of the shift of glycemic thresholds to lower plasma glucose concentrations caused by recurrent hypoglycemia. Although symptomatic hypoglycemia can occur after an overnight fast, it often follows exercise. Rarely, symptomatic hypoglycemia follows meals but postabsorptive hypoglycemia is typically also demonstrable in such patients. The common symptoms in patients with an insulinoma are listed in Table 32-10.

Given convincing clinical and biochemical evidence of insulinoma, it is useful to localize the tumor if that can be done noninvasively. Percutaneous imaging-ultrasoundography, computed tomography, magnetic resonance imaging-may or may not localize an insulinoma but usually demonstrates metastases in the minority of patients with a malignant insulinoma. Thus, one of these is advisable prior to surgery. Octreotide scans localize about half of insulinomas. Arteriography has been used extensively in the past, but false-positives as well as false-negatives occur. A variation is selective regional arterial calcium injections with the end point of a sharp increase in hepatic venous insulin concentrations, but this is seldom necessary in the clinical setting. The same is true of transhepatic portal venous sampling. The other hand, intraoperative pancreatic ultrasonography almost invariably localizes insulinomas that are not readily palpable by the surgeon. Surgical resection of solitary insulinomas is generally curative. Medical therapy of unresectable insulinomas includes administration of diazoxide; the somatostatin analogue octreotide is sometimes effective. The majority of infants and young children with hyperinsulinemic hypoglycemia do not have discrete insulinomas. Other causes of hypoglycemia related to endogenous hyperinsulinism are discussed later in this chapter (see "Hypoglycemia in Infancy and Childhood").

Autoimmune hypoglycemia are thought to be quite rare. Approximately 90% of the reported cases of hypoglycemia attributed to autoantibodies to insulin have been from Japan. A history of other autoimmune disorders, particularly Graves' disease, and of treatment with sulfhydryl medications, particularly methimazole, is common. Whereas most autoantibodies against insulin receptor are antagonists and cause (type B) insulin resistance, some are agonists and cause hypoglycemia. Again, clinical or biochemical evidence of other autoimmune disorders and the finding of acanthosis nigricans are common. Finally, the finding of beta cell stimulating antibodies in the sera of patients with hypoglycemia raised the possibility of a new form of hypoglycemia. Nonetheless, a corresponding clinical syndrome has not been defined.

Causes of hypoglycemia unique to, or typically with Onset in, Infancy and Childhood

Transient Intolerance of Fasting
- Premature or small-for-gestational age infants
- Hypopituitarism, adrenal hypoplasia, congenital adrenal hyperplasia
- Ketotic hypoglycemia of childhood

Hyperinsulinism
- Infant of a diabetic mother
- Maternal drugs (sulfonylurea, 2-adrenergic agonist)
- Congenital hyperinsulinism, insulinoma
- Miscellaneous: Rh incompatibility, Beckwith-Wiedemann syndrome, exchange transfusions

Enzyme Defects
- Carbohydrate metabolism: glycogen storage disease types I, III, and VI; glycogen synthase deficiency; fructose-1,6-bisphosphatase deficiency; fructose-1-phosphate aldolase deficiency; galactose-1-phosphate uridyltransferase deficiency
- Protein metabolism: branched-chain -keto acid dehydrogenase complex deficiency
- Fat metabolism: fatty acid oxidation defects including deficiencies in the carnitine cycle, the beta oxidation spiral, the electron transport system, and the ketogenesis sequence

A corresponding clinical syndrome has not been defined.

Causes of hypoglycemia unique to, or typically with their clinical onset in, infancy and childhood include (1) transient intolerance of fasting, (2) hyperinsulinism, and (3) enzyme defects in carbohydrate, protein, or fat metabolism. Hypoglycemia in children can also be caused by the mechanisms discussed earlier. These include drugs and critical illnesses. For example, 9 (18%) of 49 children receiving resuscitative care for altered consciousness, status epilepticus, respiratory failure, cardiac failure, or cardiopulmonary arrest were hypoglycemic with plasma glucose levels ranging from 0.1 mmol/L (2 mg/dL) to 1.8 mmol/L (33 mg/dL). Four of the nine were septic. Of the 10 who died, 5 were hypoglycemic.

In addition to changes in the level of consciousness (irritability, lethargy, stupor), tremor, seizures, and coma, signs consistent with hypoglycemia in infants include apnea, cyanotic spells, hyperthermia, hypotonia, and poor feeding (especially after feeding well). The definition of neonatal hypoglycemia is controversial. Comnath and co-authors suggested the following operational plasma glucose thresholds for glucose administration: (1) less than 2.5 mmol/L (45 mg/dL) in infants with clinical manifestations compatible with hypoglycemia and (2) less than 2.0 mmol/L (36 mg/dL) in infants at risk for hypoglycemia.

The fetus relies on a continuous supply of glucose from the maternal circulation. After birth, the neonate must make the transition to endogenous glucose production with intermittent exogenous glucose delivery. Probably because of their large brains relative to their body weights, infants have rates of glucose utilization approximately threefold higher than those of adults when expressed per unit of body weight. Correspondingly high rates of endogenous glucose production are required to maintain systemic glucose balance. Because mobilizable glycogen stores are limited and feeding is intermittent, the newborn is largely dependent on

### TABLE 32-11 -- Causes of Hypoglycemia Unique to, or Typically with Onset in, Infancy and Childhood

- Transient Intolerance of Fasting
  - Premature or small-for-gestational age infants
  - Hypopituitarism, adrenal hypoplasia, congenital adrenal hyperplasia
  - Ketotic hypoglycemia of childhood

- Hyperinsulinism
  - Infant of a diabetic mother
  - Maternal drugs (sulfonylurea, 2-adrenergic agonist)
  - Congenital hyperinsulinism, insulinoma
  - Miscellaneous: Rh incompatibility, Beckwith-Wiedemann syndrome, exchange transfusions

- Enzyme Defects
  - Carbohydrate metabolism: glycogen storage disease types I, III, and VI; glycogen synthase deficiency; fructose-1,6-bisphosphatase deficiency; fructose-1-phosphate aldolase deficiency; galactose-1-phosphate uridyltransferase deficiency
  - Protein metabolism: branched-chain -keto acid dehydrogenase complex deficiency
  - Fat metabolism: fatty acid oxidation defects including deficiencies in the carnitine cycle, the beta oxidation spiral, the electron transport system, and the ketogenesis sequence

A corresponding clinical syndrome has not been defined.

Causes of hypoglycemia unique to, or typically with their clinical onset in, infancy and childhood include (1) transient intolerance of fasting, (2) hyperinsulinism, and (3) enzyme defects in carbohydrate, protein, or fat metabolism. Hypoglycemia in children can also be caused by the mechanisms discussed earlier. These include drugs and critical illnesses. For example, 9 (18%) of 49 children receiving resuscitative care for altered consciousness, status epilepticus, respiratory failure, cardiac failure, or cardiopulmonary arrest were hypoglycemic with plasma glucose levels ranging from 0.1 mmol/L (2 mg/dL) to 1.8 mmol/L (33 mg/dL). Four of the nine were septic. Of the 10 who died, 5 were hypoglycemic.

In addition to changes in the level of consciousness (irritability, lethargy, stupor), tremor, seizures, and coma, signs consistent with hypoglycemia in infants include apnea, cyanotic spells, hyperthermia, hypotonia, and poor feeding (especially after feeding well). The definition of neonatal hypoglycemia is controversial. Comnath and co-authors suggested the following operational plasma glucose thresholds for glucose administration: (1) less than 2.5 mmol/L (45 mg/dL) in infants with clinical manifestations compatible with hypoglycemia and (2) less than 2.0 mmol/L (36 mg/dL) in infants at risk for hypoglycemia.

The fetus relies on a continuous supply of glucose from the maternal circulation. After birth, the neonate must make the transition to endogenous glucose production with intermittent exogenous glucose delivery. Probably because of their large brains relative to their body weights, infants have rates of glucose utilization approximately threefold higher than those of adults when expressed per unit of body weight. Correspondingly high rates of endogenous glucose production are required to maintain systemic glucose balance. Because mobilizable glycogen stores are limited and feeding is intermittent, the newborn is largely dependent on
levels), structural and enzymatic integrity of the liver (and kidneys), and availability of sufficient gluconeogenic precursors are essential. In the setting of relatively low plasma glucose concentrations, the combination of hypoinsulinemia and activated glucose counterregulatory systems also favors lipolysis. High nonesterified fatty acid levels provide an alternative fuel for tissues other than the brain and limit glucose utilization by muscle and fat. They also drive ketogenesis, thus providing an alternative fuel for tissues other than the brain during gluconeogenesis. Impairment of any of these adaptations to extrauterine life can cause transient neonatal hypoglycemia. Persistent defects cause recurrent or persistent hypoglycemia.

Transient intolerance of fasting occurs in preterm or small-for-gestational age infants; in hypopituitarism, adrenal hypoplasia, or congenital adrenal hyperplasia; or, later, in ketotic hypoglycemia of childhood. At least in the absence of seizure or coma, neonatal hypoglycemia (that developing in the first 72 hours after birth) is usually transient. It is particularly common in preterm or small-for-gestational age infants and is thought to result from incomplete development of gluconeogenic mechanisms although glucose counterregulatory signals may be impaired. Deficiencies of cortisol, growth hormone, or both can be congenital and cause hypoglycemia through mechanisms discussed earlier.

In general, children tolerate fasting less well than adults. Indeed, hypoglycemia is the rule after 24 to 48 hours of fasting in normal children. The syndrome of ketotic hypoglycemia of childhood, which typically has its onset between ages 2 and 5 years and remits spontaneously before age 10 years, may account for the fraction of children who develop fasting hypoglycemia. Hypoglycemia can usually be elicited by fasting during an oral glucose tolerance test. It appears to involve diminished mobilization of gluconeogenic precursors including alanine. Blood alanine levels are low during hypoglycemia, and alanine infusion increases plasma glucose levels. Glycolytic and gluconeogenic mechanisms appear to be intact and, aside from low epinephrine levels, gluconeogenic signals are appropriate. Deficient epinephrine secretion might impair alanine mobilization because epinephrine stimulates alanine turnover in humans. Nonetheless, epinephrine deficiency per se does not cause hypoglycemia, as discussed earlier.

The most common cause of hyperinsulinemic neonatal hypoglycemia is maternal diabetes. Infants of diabetic mothers are hyperglycemic (in proportion to the mother's hyperglycemia) and correspondingly hyperinsulinemic. Presumably reflecting chronic stimulation of fetal insulin secretion in utero and its failure to become suppressed normally as glucose levels fall shortly after birth, transient neonatal hypoglycemia occurs. Transient hyperinsulinism also underlies neonatal hypoglycemia in infants with RH factor incompatibility or with the Beck-with-Wiedemann syndrome (macroglomia, ophthalmocele, and visceromegaly). Hypoglycemia, resulting from hyperinsulinism stimulated by glucose flush during the procedure, can also follow exchange transfusion. Neonatal hypoglycemia can be caused by drug exposure, the mother, including agents that stimulate fetal insulin secretion (e.g., a sulfonylurea) or that produce maternal and fetal hyperglycemia and thus fetal hyperinsulinism (e.g., α₂-adrenergic agonist used to delay labor). Accidental or malicious administration of a sulfonylurea or insulin is a rare cause of hyperinsulinemic hypoglycemia in children.

In contrast to these causes of transient hypoglycemia, congenital hyperinsulinism (or persistent hyperinsulinemic hypoglycemia of infancy) may persist from the neonatal period or become apparent clinically in the first year of life. Patients in that age range rarely have a discrete insulinoma, although insulinomas are found in children who develop hyperinsulinemic hypoglycemia after the first year. Although partial pancreatectomy may become necessary, patients with congenital hyperinsulinism are treated medically initially with glucose administration for stabilization; frequent feedings; and diazoxide (often with a thiazide), octreotide, and glucagon, often tried in that sequence in the anticipation of amelioration of hypoglycemia over time because there is a high frequency of diabetes late after partial pancreatectomy.

Congenital hyperinsulinism is the most common cause of nontransient neonatal hypoglycemia. It is often inherited as an autosomal recessive trait and the result of mutations of the genes that encode adenosine triphosphatase-sensitive potassium (KATP) channels, specifically the sulfonylurea receptor (SUR1) or the channel itself (Kir6.2). Homozygous mutations result in diffuse beta-cell hypersecretion; focal beta-cell hypersecretion has been attributed to loss of maternal heterozygosity and expression of the paternal KATP mutation. In general, patients with KATP channel mutations suffer from severe neonatal hypoglycemia that is unresponsive to diazoxide. Successful treatment with the calcium channel antagonist nifedipine has been reported. Other causes of congenital hyperinsulinism which typically cause less marked hypoglycemia and are more likely to be responsive to diazoxide include autosomal dominant activating mutations of the glutamate dehydrogenase gene (the hyperinsulinism-hyperammonemia syndrome) and of the glucokinase gene. Hyperinsulinemic hypoglycemia has also been reported in an infant with phosphomannose isomerase deficiency and was found to be responsive to mannose administration.

Hypoglycemia that develops in infancy or childhood persists and can be treated with effective therapy can also be caused by enzymatic defects in carbohydrate metabolism (e.g., glycogen storage disease types I, III, and IV; glycogen synthase deficiency; fructose-1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, or pyruvate dehydrogenase deficiencies; or in protein metabolism (e.g., branched-chain -keto acid dehydrogenase complex deficiency), in protein metabolism (e.g., branched-chain -keto acid dehydrogenase complex deficiency), or in fat metabolism (e.g., various defects in fatty acid oxidation). All of these disorders cause postabsorptive hypoglycemia except for hereditary fructose intolerance caused by fructose-1-phosphate aldolase deficiency and galactosaemia caused by galactose-1-phosphate uridyltransferase deficiency, which cause postprandial hypoglycemia. Although clinical features and biochemical patterns suggest a subset of diagnostic possibilities and in some instances provide a specific diagnosis, definitive diagnosis often requires either documentation of deficient enzyme activity in affected tissues or, increasingly, identification of a mutation in the relevant gene.

As first documented by Cori and Cori in 1952, deficient glucose-6-phosphatase activity causes glycogen storage disease type I (von Gierke's disease). Type I glycogen storage disease is the prototype glycogen storage disease. Because hydrolysis of glucose-6-phosphate to glucose is the common pathway for synthesis of glucose from both hepatic and nonhepatic sources, and gluconeogenesis and glycogenolysis are linked processes, they cause (1) profound post-absorptive hypoglycemia with hyperinsulinism; (2) activated glucose counterregulatory systems with elevated lactate, alanine, nonesterified fatty acid, ketone body, and triglyceride levels; and (3) metabolic acidosis with hyperuricemia. Hepatomegaly (caused by hepatocyte accumulation of fat as well as glycogen) is a universal finding. With the exception of hepatomegaly, the abnormalities can be reversed by the prevention of hypoglycemia with frequent feedings during waking hours and continuous intragastric glucose infusion during sleep or with

bedtime administration of large doses of uncooked cornstarch. Liver transplantation corrects hypoglycemia and the associated metabolic abnormalities. Adults with (presumably inadequately treated) type I glycogen storage disease have more frequency of hepatic adenomas and renal disease. Interestingly, renal cell carcinoma is a rare complication in patients with type I glycogen storage disease. The mechanism by which these patients maintain some level of endogenous glucose production is unclear.

The glucose-6-phosphatase system is complex. Most patients with type I glycogen storage disease have mutations of the gene encoding the catalytic subunit (type la). Others do not have such mutations; the defect has been attributed to mutations in the glucose-6-phosphatase translocase gene (type Ib or nontype la). Type Ib or nontype la glycogen storage disease is usually also caused by glycogen synthase deficiency, which, unlike the glycogen storage diseases, does not cause hepatomegaly. Because it blocks gluconeogenesis, fructose-1,6-phosphatase deficiency causes profound postabsorptive hypoglycemia with lactic acidosis, ketosis, and elevated alanine levels. Hyperlipidemia, hyperuricemia, and hepatomegaly (related to fat accumulation) occur as in type I glycogen storage disease. Hypoglycemia has also been attributed to phosphoenolpyruvate carboxykinase and pyruvate carboxylase deficiencies.

Finally, with respect to postabsorptive hypoglycemia and defects in glucose metabolism, CNS glucopenia occurs in patients with mutations of the GLUT-1 glucose transporter gene. Plasma glucose levels are normal but cerebrospinal glucose levels are low because of reduced GLUT-1 mediated glucose transport across the blood-brain barrier. Treatment includes the ketogenic (low-carbohydrate) diet designed to raise ketone levels and thus provide an alternative fuel to the brain. Hypoglycemia has also been attributed to GLUT-2 deficiency in the Fanconi-Bickel syndrome.

Postprandial, rather than postabsorptive, hypoglycemia can be a feature of hereditary fructose intolerance and, rarely, galactosemia. Fructose-1-phosphate aldolase deficiency, the enzymatic defect in hereditary fructose intolerance, causes vomiting and severe hypoglycemia after fructose ingestion. Fructose-1-phosphate...
accumulates and inhibits gluconeogenesis (at the phosphorylase level) and gluconeogenesis (at the mutant aldolase level). The patients are well when fructose is omitted from the diet. Galactose uridyltransferase deficiency, one of the causes of galactosemia, can also cause postprandial hypoglycemia, which has been attributed to inhibition of gluconeogenesis.  

Deficiencies of enzymes involved in protein metabolism that can cause postabsorptive hypoglycemia include that of the branched-chain keto acid dehydrogenase complex, the basis of branched-chain ketoaciduria (maple syrup urine disease).  The levels of leucine, isoleucine, and valine particularly leucine in plasma and urine are elevated. The pathogenesis of hypoglycemia is not entirely clear, although it results from defective gluconeogenesis. Hypoglycemia related to impaired gluconeogenesis also occurs in methylmalonic aciduria.  

Several defects that ultimately impair fatty acid oxidation result in postabsorptive hypoglycemia with hypoketonaemia. Normally, low-insulin, high-glucagon (and catecholamine) states such as fasting favor the mobilization of fatty acids from fat (lipolysis) and their transport to other tissues including the liver and skeletal and cardiac muscle. These regulatory conditions also favor fatty acid oxidation (with ATP formation) and ketogenesis over triglyceride, phospholipid, and cholesterol ester synthesis and peroxisomal oxidation. Mitochondrial fatty acid oxidation and ketogenesis require transport of fatty acids across the plasma membrane, formation of fatty acyl-CoA derivatives, and transport of the derivatives into mitochondria. Because the inner mitochondrial membranes are not permeable to long-chain (as opposed to medium-chain and short-chain) fatty acyl-CoA esters, the long-chain fatty acyl-CoA esters are transferred to fatty acylcarnitines at the outer surface of the membranes by carnitine palmitoyltransferase II, CPT-II, and converted to the fatty acyl-CoA esters by carnitine palmitoyltransferase I, CPT-I, at the inner surface of the membranes. Then they can be oxidized or converted to ketones.

Insulin decreases fat oxidation and ketogenesis by decreasing lipolysis and by increasing lipogenesis and the formation of malonyl-CoA, which inhibits CPT-I. Conversely, low insulin levels favor fatty acid oxidation and ketogenesis. High glucagon levels do so by decreasing malonyl-CoA. Catecholamines do so largely by stimulating lipolysis. Any defect in the sequence of events in the carnitine cycle (carnitine transport defect, CPT-I deficiency, carnitine-acylcarnitine translocase deficiency, defects in the beta oxidation spiral (long-chain acyl-CoA dehydrogenase [LCAD] deficiency, long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency, short-chain 3-hydroxyacyl-CoA dehydrogenase [SCHAD] deficiency, 2,4-dienoyl-CoA reductase deficiency, medium-chain acyl-CoA dehydrogenase [MCAD] deficiency, short-chain acyl-CoA dehydrogenase [SCAD] deficiency), several defects of electron transfer or defects in ketogenesis (hydroxymethylglutaryl [HMG]-CoA lyase deficiency, HMG-CoA synthetase deficiency) decreases fatty acid oxidation (and ketogenesis) and reciprocally increases glucose oxidation, resulting in hypoketonaemic postabsorptive hypoglycemia. Reduced plasma carnitine levels (20% to 50% of normal) are the rule in these disorders, but extremely low carnitine levels characterize the carnitine transport defect, a true carnitine deficiency state that is responsive to carnitine supplementation. CPT-I deficiency, a rare disorder, is treatable by administration of medium-chain triglycerides, which do not require the CPT system for oxidation, or by a high-carbohydrate, low-fat diet. CPT-II deficiency, which is typically seen with episodes of muscle pain and myoglobinuria but can also cause hypoglycemia, is more common.  

The child affected with a disorder of fatty acid oxidation typically presents with hypoketonicemia hypoglycemia; intravenous glucose causes prompt improvement. Some have presented with Reye's syndrome. All are at risk for sudden death, presumably from cardiac causes. Treatment includes provision of an adequate caloric intake, avoidance of fasting, and support of the plasma glucose concentration during intercurrent illnesses. The diagnosis of specific fatty acid oxidation defects is typically accomplished by blood acylcarnitine profiling, although molecular diagnosis is increasingly possible. Interestingly, the presence of a defect in fatty acid oxidation in a fetus may have implications for the mother. While carrying a fetus with a specific mutation (Glu474Gln) causing long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency, 15 (79%) of 19 mothers suffered fatty liver of pregnancy or the HELLP (hemolysis, elevated liver enzyme levels, and low platelet count) syndrome. Given the array of causes of hypoglycemia in infancy and childhood just summarized, it is reasonable to suggest an extensive biochemical assessment during a hypoglycemic episode when the hypoglycemic mechanism is obscure. In addition to the concurrent plasma glucose concentration, this might include (1) plasma insulin, C peptide, sulfonlureas, growth hormone, and cortisol; (2) plasma or blood lactate, amino acids (including alanine), nonesterified fatty acids, and -hydroxybutyrate; (3) serum liver enzymes; (4) plasma acylcarnitine profile; and (5) urine ketones and organic acid profile.
The Postprandial (Reactive) Hypoglycemias

Postprandial (reactive, stimulative) hypoglycemia occurs exclusively after meals, typically within 4 hours after food ingestion. All disorders that cause postabsorptive hypoglycemia can also result in hypoglycemia detected after a meal. However, the diagnostic and therapeutic approach is that of postabsorptive hypoglycemia in such a patient.

Congenital deficiencies of enzymes of carbohydrate metabolism, such as those that cause hereditary fructose intolerance and galactosemia discussed earlier, are rare causes of postprandial hypoglycemia that becomes apparent early in life. Postprandial hypoglycemia can occur in individuals who have undergone gastric surgery that results in rapid movement of ingested food into the small intestine. Termed alimentary hypoglycemia, this is thought to be the result of marked early hyperinsulinemia caused by rapid increments in plasma glucose, enhanced secretion of incretins (gut factors that enhance glucose-stimulated insulin secretion), or both. Hypoglycemia occurs 1.5 to 3.0 hours after food ingestion. Symptoms of hypoglycemia must be distinguished from those of the dumping syndrome (abdominal fullness, nausea, and weakness) which occur less than an hour after ingestion. Administration of an α-glucosidase inhibitor (e.g., acarbose or miglitol) is a conceptually attractive treatment for alimentary hypoglycemia, although controlled trials indicating its efficacy are lacking.

The frequency, and even the existence, of clinically relevant idiopathic (functional) postprandial hypoglycemia is a matter of debate. Idiopathic postprandial hypoglycemia is often erroneously diagnosed by patients and by physicians. For example, only 16 of 118 patients suspected of having postprandial hypoglycemia in one series had both a plasma glucose concentration lower than the 10th percentile of asymptomatic control subjects and typical symptoms after an oral glucose load; only 5 of those 16 patients had similar symptoms after their regular meals. Furthermore, most patients thought to have hypoglycemic symptoms and low glucose levels after glucose ingestion have normal glucose levels after a mixed meal. In one series in which blood glucose was measured during symptomatic episodes, only 5% of 132 episodes were associated with blood glucose levels of 2.8 mmol/L (50 mg/dL) or less. Service and colleagues reported on five adults judged to have hyperinsulinemic ("pancreatogenous") postprandial hypoglycemia. The patients were assessed thoroughly, and insulinomas were not found. Insulin levels were judged to be inappropriately high during hypoglycemia (but norms from prolonged fasts were used); antibodies to insulin were not reported. Mutations of the Kir6.2 and SUR1 genes were not found. An alternative theoretical possibility would be an attenuated resumption of glucagon secretion during the transition from the postprandial to the postabsorptive state. That would plausibly explain the pathogenesis of the postprandial syndrome including compensatory enhancement of epinephrine secretion, the production of symptoms attributable to the enhanced sympa-thochromaffin response, and the prevention of severe hypoglycemia and restoration of euglycemia.

Lower plasma glucagon levels in persons with plasma glucose nadirs less than 2.8 mmol/L (50 mg/dL) than in those with higher nadir glucose levels after an oral glucose load have been reported. However, glucagon levels were also lower at baseline and were not discernibly lower after glucose ingestion in the two individuals with the lowest plasma glucose nadirs (1.5 mmol/L [27 mg/dL] and 1.3 mmol/L [2.3 mg/dL]). On the other hand, in another report, similarly selected individuals (nadir glucose less than 2.8 mmol/L [50 mg/dL]) had normal pancreatic glucagon levels after glucose ingestion. Nonetheless, enhanced, presumably compensatory, plasma epinephrine responses have been reported in individuals with sweating, tremor, and greater heart rates temporally related to the glucose nadir late after glucose ingestion. In such individuals, the postprandial syndrome may be the result of an appropriately enhanced sympathochromaffin response to falling plasma glucose concentrations rather than hypoglycemia per se.

A diagnosis of postprandial hypoglycemia should not be made on the basis of seemingly low plasma glucose concentrations during an oral glucose tolerance test. The lower limits of normal for venous plasma glucose concentrations late after glucose ingestion can be defined statistically. For example, in 650 individuals who remained asymptomatic after ingestion of 100 g of glucose, nadir glucose concentrations were lower 5th percentile, 2.4 mmol/L (43 mg/dL); lower 10th percentile, 2.6 mmol/L (47 mg/dL); and lower 25th percentile, 3.0 mmol/L (54 mg/dL). The absence of symptoms in response to such seemingly low plasma glucose concentrations is most plausibly explained by venous sampling. Although glucose arteriovenous differences are negligible in the postabsorptive state, there is substantial glucose extraction across the forearm under hyper-insulinemic conditions. Thus, arterial glucose levels—those relevant to glucose delivery to the brain—must be lower than those measured by venous sampling. The diagnosis requires documentation of appropriate symptoms temporally related to a low plasma glucose concentration after a mixed meal and relief of those symptoms as the plasma glucose concentration rises (Whipple's triad). The diagnosis cannot be made on the basis of an oral glucose tolerance test.

Diet low in carbohydrate and high in protein are commonly recommended to patients thought to have postprandial hypoglycemia. Their efficacy has not been established by controlled clinical trials. Frequent feedings and avoidance of simple sugars are also advised. Anticholinergic drugs have been reported to be beneficial in uncontrolled studies of patients with the postprandial syndrome hypoglycemia but may cause undesirable side effects. The α-adrenergic antagonist propranolol reduces symptoms (except diaphoresis) in patients with postgastrectomy postprandial hypoglycemia, and administration of pectin is said to decrease symptoms in such patients. As mentioned earlier, to the extent that an excessive initial increase in plasma glucose plays a role in the pathogenesis of alimentary hypoglycemia, administration of an α-glucosidase inhibitor to delay carbohydrate digestion is a conceptually attractive treatment. Finally, such patients have been treated surgically with reversal of a segment of proximal jejunum.
TREATMENT OF POSTABSORPTIVE HYPOGLYCEMIA

In view of the vulnerability of the brain to prolonged hypoglycemia, the plasma glucose concentration must be raised at least to normal levels as rapidly as possible and recurrence of hypoglycemia must be prevented. Because it is self-limited, postprandial hypoglycemia rarely requires urgent treatment. In contrast, postabsorptive hypoglycemias are typically persistent or progressive and require short-term and long-term therapy.

The urgent treatment of iatrogenic hypoglycemia in individuals with diabetes with oral carbohydrate or glucose per se or with parenteral glucagon or glucose was discussed earlier under "Hypoglycemia in Diabetes Mellitus." Clinical improvement should occur within about 15 to 20 minutes after the plasma glucose level is increased and maintained provided that brain damage has not occurred. Whenever possible, the presence of hypoglycemia should be documented before therapy and the response to therapy should be followed by frequent measurements of the plasma glucose level. If these are not available and there is no clinical response within 15 minutes, the initial therapy should be repeated and access to plasma glucose monitoring and intravenous glucose infusion should be obtained as soon as possible. Even if there is a response to initial therapy, glucose monitoring is essential to ensure maintenance of the plasma glucose concentration.

Although CNS function usually recovers promptly after restoration of the plasma glucose level, recovery may be delayed, perhaps because of cerebral edema. Unconsciousness lasting more than 30 minutes after the plasma glucose concentration has been raised to normal and maintained is referred to as posthypoglycemic coma. It has been treated with intravenous mannitol (40 g as a 20% solution over 20 minutes) or glucocorticoids (e.g., dexamethasone, 10 mg), or both, along with maintenance of normal plasma glucose levels.

Definitive treatment of the postabsorptive hypoglycemia requires correction of the underlying defect whenever possible. When that is not possible, attempts must be made to increase exogenous delivery or endogenous glucose production and to limit glucose utilization by tissues other than the brain. Although the judicious use of snacks is a useful component of therapy for individuals with diabetes, frequent feedings are less than ideal for the long-term treatment of chronic hypoglycemia. One problem is weight gain. However, frequent feedings, even overnight gastric infusions, are sometimes necessary when other measures are inadequate.

Hypoglycemia caused by drugs is limited to the duration of action of the offending drug. The management is straightforward: discontinuation of the drug (at least temporarily), maintenance of the plasma glucose level while drug action continues, and adjustment of subsequent drug regimens to avoid recurrent hypoglycemia if the causative drug is known. Therapy is more difficult if the drug is used surreptitiously or given accidentally or maliciously.

As discussed earlier, postabsorptive hypoglycemia related to endogenous hyperinsulinism is often curable by the surgical removal of an insulinoma. If this is not possible because of multiple or metastatic tumors or the absence of a definable lesion, diazoxide is sometimes effective. Diazoxide (100 to 800 mg/day in adults and 5 to 30 mg/kg/day in infants) raises the plasma glucose concentration by suppressing insulin secretion. Diazoxide is bound tightly to albumin and has a plasma half-time of 20 to 30 hours. When given by rapid intravenous injection, it is a potent hypotensive drug, but when given orally or by slow intravenous infusion, it has little hypotensive action; indeed, hypertensive responses may occur. Although chemically related to the thiazide diuretics, diazoxide causes sodium retention. Coadministration of a thiazide diuretic both limits sodium retention and potentiates the hyperglycemic action of diazoxide. Both edema formation and gastrointestinal side effects (anorexia, nausea, sometimes vomiting) are dose-related. Generalized growth of lanugo hair (hypertrichosis lanuginosa) may occur during prolonged therapy. Allergic reactions, including skin rashes and agranulocytosis, are rare. Other treatments include octreotide and calcium channel antagonists.

The treatment of hypoglycemia associated with nonbeta cell tumors involves short-term measures pending effective medical, surgical, or radiotherapeutic treatment of the tumor. Administration of a glucocorticoid or growth hormone sometimes alleviates hypoglycemia. The former, but not the latter, has been reported to reduce IGF-II levels. Hypoglycemia resulting from glucocorticoid deficiency is corrected by replacement therapy. Hypoglycemia is rarely an indication for growth hormone replacement. Remissions of autoimmune hypoglycemias have been associated with immunosuppressive therapy, including glucocorticoids, but controlled trials are lacking. The treatment of hypoglycemia related to infection, hepatic or renal disease, cardiac failure, or sepsis includes short-term measures and, when possible, treatment or management of the underlying disease process. The treatment of the hypoglycemias of infancy and childhood and that of postprandial hypoglycemia were discussed earlier.
APPROACH TO THE PATIENT WITH HYPOGLYCEMIA

In addition to recognition and documentation of hypoglycemia and often urgent treatment, management of hypoglycemia requires diagnosis of the hypoglycemic mechanism leading to treatment that prevents, or at least minimizes, recurrent hypoglycemia. The differential diagnosis of hypoglycemia, discussed earlier, is summarized in Table 32-2. A diagnostic algorithm is shown in Figure 32-16. The thought process is summarized in Table 32-12.

Recognition and Documentation of Hypoglycemia

Hypoglycemia is sometimes detected serendipitously. However, a report of a distinctly low plasma glucose measurement in a person who does not have a history of corresponding symptoms raises the possibility of pseudohypoglycemia—a measured low glucose level resulting from ongoing metabolism of glucose by the formed elements of the blood after the sample is drawn. Pseudohypoglycemia is particularly common when leukocyte, thrombocyte, or erythrocyte counts are abnormally high, but it can occur in the absence of these if separation of the plasma or serum from the formed elements is delayed. Nonetheless, a report of a distinctly low plasma glucose concentration measured in a reliable laboratory cannot be ignored.

Hypoglycemia is often sought because of a history of suggestive symptoms. But the symptoms are not specific for hypoglycemia, and a normal plasma glucose concentration measured when the patient is free of those symptoms does not exclude the possibility of hypoglycemia at the time of those earlier symptoms. Convincing documentation of hypoglycemia requires demonstration of Whipple’s triads—symptoms consistent with hypoglycemia, a low plasma glucose concentration, and relief of those symptoms after the plasma glucose concentration is raised. This can be accomplished easily, by measuring the plasma glucose concentration and then administering glucose, if the patient is seen while symptomatic. When the patient is not symptomatic when seen but has a history of a previous low measured plasma glucose concentration, of previous symptoms suggestive of hypoglycemia, or both, the initial diagnostic strategy is to obtain samples from the patient under conditions in which Whipple’s triad would be expected to be demonstrable if a hypoglycemic disorder exists. In most instances, that condition would be the postabsorptive state, initially after an overnight fast but after a longer fast if necessary. If the history suggests only postprandial hypoglycemia, that condition would be after a mixed meal.

Urgent Treatment

If the patient is hypoglycemic when seen, urgent treatment is often necessary. When possible, a sample for documentation of the plasma glucose concentration by a quantitative analytical method (not a blood glucose monitor) should be obtained prior to treatment. Obviously, glucose administration based on clinical suspicion of hypoglycemia, a low monitor-measured glucose level, or both need not be delayed until the result for the initial sample is reported. The potential detrimental effects of delayed treatment of hypoglycemia far outweigh any ill effect of unnecessary treatment. In addition, if the hypoglycemic mechanism is obscure, plasma samples for insulin, C peptide, sulfonylureas, and ethanol, at a minimum, should be obtained before glucose administration.

Oral treatment, with glucose tablets or glucose-containing fluids, candy, or food, is appropriate if the patient is able and willing to take these. A reasonable initial dose is 20 g of glucose (see Fig. 32-15). If the patient is unable or unwilling (because of neuroglycopenia) to take oral feedings, parenteral therapy is necessary. Intravenous glucose, 25 g initially, is preferable. If intravenous therapy is not practical, subcutaneous, intramuscular, or even intranasal glucagon can be used.

All of these urgent treatments raise plasma glucose concentrations only transiently (see Fig. 33-15). The plasma glucose concentration, as well as the patient’s clinical status, should be monitored after treatment. Intravenous glucose infusion is often necessary, and the patient should eat as soon as that is practicable.
Diagnosis of the Hypoglycemic Mechanism

In a patient with documented hypoglycemia, a plausible hypoglycemic mechanism (see Table 32-2) is usually apparent clinically from the history, physical examination, and available laboratory data. Iatrogenic hypoglycemia is reasonably assumed in the vast majority of instances in a patient treated with insulin, a sulfonylurea, or another insulin secretagogue or metformin for diabetes. In an adult who does not have diabetes, the use of a relevant drug, including alcohol; the presence of a relevant critical illness (hepatic, renal, or cardiac failure, sepsis, or inanition); clues to deficient secretion of cortisol, growth hormone, or both; or evidence of a nonbeta cell tumor leads to a presumptive mechanistic diagnosis and guides further diagnostic evaluation. Absent such clues, one must consider medication error, endogenous hyperinsulinism, or surreptitious or malicious sulfonylurea or insulin administration (see Fig. 32-16). Congenital metabolic defects are occasionally first recognized in an adult. The same differential diagnosis should be considered for children and even infants, although the hypoglycemic disorders unique to infancy and childhood, discussed earlier, must also be considered.
Prevention of Recurrent Hypoglycemia

Prevention of recurrent hypoglycemia in the long term requires treatment that corrects or circumvents the hypoglycemic mechanism. Offending drugs can be discontinued or their doses reduced. Underlying critical illnesses can often be treated. Cortisol (and growth hormone) can be replaced. Surgical, radiotherapeutic, or chemotherapeutic reduction of a nonbeta cell tumor can alleviate hypoglycemia even if the tumor cannot be cured; glucocorticoid (or growth hormone) administration may alleviate hypoglycemia in such patients. Surgical resection of an insulinoma is often curative; medical therapy with diazoxide, octreotide, or both can be used if that is not possible and in patients with a nontumor primary beta cell disorder. The treatment of autoimmune hypoglycemia (e.g., with a glucocorticoid) is more problematic, but the disorder is typically self-limited. Failing these treatments, provision of exogenous glucose with frequent feedings, large doses of uncooked cornstarch at bedtime, or even overnight intragastric glucose infusion may be necessary.
Acknowledgments

The author acknowledges the substantive contributions of several colleagues and collaborators that shaped the views expressed in this chapter; the assistance of the nursing, dietary, laboratory, informatics, and biostatistical staffs of the Washington University General Clinical Research Center and the laboratory staff of the Washington University Diabetes Research and Training Center in the performance of the original work cited; and the help of Ms. Karen Muehlhauser in the preparation of the manuscript.

Obesity is a chronic disease that is causally related to serious medical illnesses. In the United States alone, the consequences of obesity account for an estimated 300,000 deaths per year. The medical expenses and cost of lost productivity related to obesity are greater than $100 billion per year. This chapter addresses the important clinical and pathophysiologic issues in obesity.
DEFINITION

Body Mass Index

Body mass index (BMI) is calculated by dividing weight (in kilograms) by height (in meters squared) or by dividing weight (in pounds) multiplied by 704 by height (in inches squared). There is a strong curvilinear relation between BMI and relative body fat mass. However, the current practical definition of obesity is based on the relationship between BMI and health outcome rather than BMI and body composition.

Table 33-1 summarizes the guidelines for classifying weight status by BMI, proposed by the major national and international health organizations. Large epidemiologic studies have established that there is a strong inverse relationship between BMI and mortality. Men and women with a BMI of 25.0 to 29.9 kg/m^2 are considered overweight, and those with a BMI 30 kg/m^2 or greater are considered obese. Obese persons have higher risk for adverse health consequences than those who are overweight (Fig. 33-1). These criteria for overweight and obesity represent imposed cutoff values along a continuum between mortality rate and BMI. The prevalence of obesity-related diseases, such as diabetes, begins to increase at BMI values below 25 kg/m^2 (Fig. 33-2).
Factors Affecting Body Mass Index-Related Risk

As shown in Table 33-1, several factors influence BMI-related health risk. For example, obese persons with excess abdominal fat are at higher risk for diabetes, hypertension, dyslipidemia, and ischemic heart disease than obese persons whose fat is located predominantly in the lower body. Waist circumference is highly correlated with abdominal fat mass and is therefore often used as a surrogate marker for abdominal (upper body) obesity. Waist circumference values denoting increased risk for metabolic diseases have been proposed on the basis of epidemiologic data. For men, a waist circumference greater than 102 cm (40 inches) and, for women, a waist circumference greater than 88 cm (35 inches) have been proposed as cutoff values for increased risk. However, this proposal imposes arbitrary cutoff values on the continuous relationship between waist circumference and metabolic disease risk.

Another factor that modifies the risk of obesity-related complications is weight gain during adulthood. In both men and women, weight gain of 5 kg or more since age 18 to 20 years is associated with an increased risk of diabetes, hypertension, and coronary heart disease, and the risk of disease increases with the amount of weight gained. However, this proposal imposes arbitrary cutoff values on the continuous relationship between waist circumference and metabolic disease risk.

Risks of developing obesity-associated diabetes or cardiovascular disease can also be modified by aerobic fitness. Blair and colleagues monitored more than 8000 men for an average of 6 years. Across a range of body adiposity, incidences of diabetes and cardiovascular mortality were lower in those who were fit, as defined by maximal ability to consume oxygen during exercise, than in those who were unfit.

BMI-associated health risk is also influenced by ethnicity. For example, when the subjects are matched on BMI, the risk

of diabetes is higher in Southeast Asian populations than in whites.
PATHOGENESIS

Energy Balance

Obesity is caused by an excessive intake of calories in relation to energy expenditure over a long period of time. The

Figure 33-1 Relationship between body mass index and cardiovascular mortality in adult men and women in the United States who never smoked and had no preexisting illness. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). (Adapted from Calle EE, Thun MJ, Petrelli JM, et al. Body-mass index and mortality in a prospective cohort of U.S. adults. N Engl J Med 1999; 341:1097.)

Figure 33-2 Relationship between body mass index and type 2 diabetes in adult men and women in the United States. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). The data demonstrate that the risk of diabetes begins to increase at the upper end of the lean body mass index category. (Adapted from Colditz GA, Willett WC, Rotnitzky A, Manson JE. Weight gain as a risk factor for clinical diabetes mellitus in women. Ann Intern Med 1995; 122:481-486; Chan JM, Rimm EB, Colditz GA, et al. Obesity, fat distribution, and weight gain as risk factors for clinical diabetes in men. Diabetes Care 1994; 17:981969.)

gastrointestinal tract has the capacity to absorb large amounts of nutrients. Large increases in body fat can result from even minor but chronic differences between energy intake and energy expenditure. In 1 year, the ingestion of only 5% more calories than expended can promote the gain of approximately 5 kg in adipose tissue. Over 30 years, the ingestion of only 8 kcal/day more than expended can increase body weight by 10 kg. This increase represents the average amount of weight gained by Americans during the 30-year period between ages 25 and 55 years. [20]
Genes and Environment

Body size depends on the complex interaction between genetic background and environmental factors. In humans, genetic background explains only an estimated 40% of the variance in body mass. Moreover, the marked increase in the prevalence of obesity over the last 20 years must have resulted largely from alterations in environmental factors that increase energy intake and reduce physical activity. For example, more meals are now eaten outside the home, there is greater availability of convenience and snack foods, serving sizes are larger, and daily physical activity has decreased because of sedentary lifestyle and work activities.

Environmental Effects in High-Risk Populations

Dramatic examples of the influence of environment on body weight have been reported globally and illustrate that persons of certain genetic backgrounds are especially likely to gain weight and experience obesity-related diseases when exposed to a modern lifestyle. Over the past 50 years, the striking change in the lifestyle of Pima Indians living in Arizona has led to an epidemic of obesity and diabetes. The diet of these urbanized Pimas is much higher in fat (50% of energy as fat) than their traditional diet (15% of energy as fat). In addition, these urbanized Pimas are much more sedentary than the Pimas who remain in the Sierra Madre mountains of northern Mexico and are isolated from Western influences. The rural Pimas eat a traditional diet, are physically active as farmers and sawmill workers, and have much lower incidences of obesity and diabetes than their Arizona kindred.

The aborigines of northern Australia are another high-risk population whose weight and health status has been compromised by exposure to a modern environment. Urbanized aborigines are heavier than their usually lean (BMI < 20 kg/m²) hunter-gatherer kindred and have high prevalences of type 2 diabetes and hypertriglyceridemia. The traditional hunter-gatherer lifestyle of the Aborigines involves a low-fat, low-calorie diet of wild game, fish, and plants and a high level of physical activity. Short-term (7 weeks) reexposure to the traditional lifestyle resulted in weight loss and significant improvement or normalization of glucose tolerance and fasting blood glucose, insulin, and triglyceride concentrations in urbanized Aborigines with type 2 diabetes and hypertriglyceridemia.

Influences of Childhood and Parental Obesity

The risk of becoming an obese adult is influenced both by having been obese as a child and by having one or more obese parents. The risk of adult obesity increases with increasing age and severity of obesity in childhood. For example, the risk of being obese at 21 to 29 years of age ranged from 8% for persons who were obese at 1 to 2 years of age and had nonobese parents to 75% for persons who were obese at 10 to 14 years of age and had at least one obese parent. Whereas persons who were obese at 1 to 2 years of age and had lean parents did not have an increased risk of obesity in adulthood, persons who became obese after 6 years of age had more than a 50% chance of becoming obese adults.
Monogenic Causes of Obesity

Since the discovery of the adipose tissue protein leptin, much progress has been made in understanding the molecular basis of body fat regulation. It has nonetheless been disappointing that a genetic cause of obesity has been identified in only a few individuals. Several rare, monogenic causes of obesity have been described.

Leptin Gene Mutations

The pathophysiologic relevance of leptin was established in two extremely obese cousins with hyperphagia who belonged to a consanguineous family of Pakistani origin.[26] These cousins were homozygous for a single nucleotide deletion at position 398 of the leptin gene. This mutation resulted in a frameshift of the leptin-coding region and a premature termination of leptin synthesis. The parents of the cousins were heterozygous for this mutation. Another mutation, this time involving a homozygous single nucleotide transversion in the leptin gene that resulted in an Arg Trp substitution in the mature peptide and low serum leptin levels, was discovered in three extremely obese individuals. Two of these persons are adults. Both the adult man and woman were hyperinsulinemic.[27] The man exhibited hypothalamic hypogonadism and dysfunction of the sympathetic nervous system, and the woman had primary amenorrhea.

Leptin treatment has successfully reversed the obesity of leptin-deficient patients. Treatment with recombinant human leptin resulted in weight loss of 1 to 2 kg per month over a 12-month period. Loss of fat mass accounted for 95% of this weight loss.[28]

The possibility that leptin levels are reduced in obesity has been investigated in large groups of subjects. However, serum leptin levels increase exponentially with fat mass, suggesting that most obese persons are resistant or insensitive to body weight regulation by endogenous leptin.[29]

Leptin Receptor Mutation

Three extremely obese sisters from a consanguineous family were found to have markedly high serum leptin levels and were homozygous for a single nucleotide substitution at the splice site of exon 16 of the leptin receptor gene.[30] This mutation resulted in a truncated protein that lacked both the transmembrane and intracellular domains of the receptor. The sisters displayed hypogonadotropic hypogonadism, failure of pubertal development, growth delay, and secondary hypothyroidism. This finding confirms the endocrine abnormalities in leptin-deficient subjects and implies a role for the leptin/leptin receptor system in the central regulation of energy balance and hypothalamic endocrine functions in humans.

Prohormone Convertase 1 Gene Mutation

A mutation in the prohormone convertase 1 (PC1) gene was identified in a 43-year-old obese woman with a history of severe childhood obesity.[31] The woman had impaired glucose tolerance, postprandial hypoglycemia, low plasma cortisol levels, and hypogonadotropic hypogonadism. In addition, she had increased plasma concentrations of proinsulin and pro-opiomelanocortin (POMC) but low plasma insulin concentrations. She was a compound heterozygote for two mutations in the PC1 gene, which resulted in loss of the autocatalytic cleavage ability of PC1. Melanocortins, including -melanocortin-stimulating hormone, are formed through the processing of POMC by PC1. Therefore, reduced production of melanocortin may have been responsible for obesity in this patient.

Pro-opiomelanocortin Gene Mutation

A mutation in the POMC gene was described in two obese children with hyperphagia.[32] The children also had red hair pigmentation and were deficient in adrenocorticotropic hormone. The mutations resulted in complete loss of the ability to synthesize -melanocortin-stimulating hormone and adrenocorticotropic hormone. The red hair pigmentation and obesity are thought to be due to deficiency of -melanocortin-stimulating hormone.

Melanocortin 4 Receptor Mutation

Although rare, melanocortin 4 receptor mutations are the most common monogenic cause of obesity.[33] Moreover, melanocortin 4 receptor mutations are characterized by both dominant and recessive modes of inheritance, in contrast to the other monogenic forms of obesity, which involve recessive modes of inheritance. Persons with melanocortin 4 receptor mutations have no apparent phenotypic abnormalities other than obesity.

SIM1 Gene Mutation

A de novo balanced translocation between chromosomes 1 and 6 was found in a severely obese girl who weighed 47 kg at 67 months of age.[34] The mutation caused a disruption in the SIM1 gene, which encodes a transcription factor involved in the formation of the paraventricular and supraoptic nuclei. It is likely that this abnormality altered energy balance by stimulating food intake because measured resting energy expenditure was normal.
Polygenic Causes of Obesity

In contrast to the small number of single-gene mutations that clearly cause obesity, a large number of human genes have been identified that show variations in deoxyribonucleic acid (DNA) sequences and may also contribute to obesity. In large population surveys, more than 250 genes, markers, and chromosomal regions have been linked to human obesity. Some of these associations will undoubtedly prove to be more important than others. It remains a major challenge to identify genes that contribute to human obesity because of the potential interactions between multiple genes and the interaction between genes and environment that can lead to expression of an obesity phenotype.
ENERGY METABOLISM

The components of daily total energy expenditure (TEE) are:

1. Resting energy expenditure (REE), accounting for approximately 70% of TEE.
2. Energy expended in physical activity, accounting for approximately 20% of TEE.
3. The thermic effect of food (TEF), accounting for approximately 10% of TEE.

REE represents the energy expended for normal cellular and organ function under postabsorptive resting conditions. Energy expended in physical activity includes the energy costs of both volitional activity, such as exercise, and nonvolitional activity, such as spontaneous muscle contractions, maintaining posture, and fidgeting. The thermic effect of food represents the energy expended in digestion, absorption, and sympathetic nervous system activation after ingestion of a meal.

Cross-sectional studies have investigated whether alterations in energy metabolism are involved in obesity. Obese individuals usually have greater rates of REE than lean individuals of the same height because obese individuals have a greater amount of lean and adipose tissue cell mass. Defects in REE or TEE have not been detected in diet-resistant patients who maintain their weight despite the claim of strict adherence to a low-calorie diet. Instead, such patients appear to underestimate their food intake and actually consume twice as many calories as they record in food intake diaries.

It is not known whether obese individuals expend less total energy in daily physical activity because they are less active than lean individuals. During nonweight-bearing activity (e.g., cycling), obese individuals expend the same amount of energy as lean individuals to perform the same amount of work. During weight-bearing activities, however, obese individuals expend more energy than lean individuals because more work is required to carry their greater body weight. Evidence from studies of obese and lean subjects, matched for either fat mass or lean body mass, suggests that obese subjects have a small (75 kcal/day) but potentially important reduction in the thermic effect of food. This reduction in the thermic effect of food may arise from the insulin resistance and blunted sympathetic nervous system activity that occur in obesity.

Although extensive research has not revealed significant defects in the energy metabolism of individuals who are already obese, the possibility remains that inherent abnormalities in energy metabolism contribute to the development of obesity. However, today's research technology has only limited ability to detect small, but possibly clinically significant, chronic defects in energy metabolism. Moreover, it is difficult to establish a causal relationship between energy expenditure and the development of obesity because energy metabolism measurements capture only a brief point in time and may not reveal abnormalities that emerge during specific life stages.

Most studies do not support the involvement of a defect in metabolic rate in the development of obesity. In one longitudinal study, daily TEE at 3 months of age was 21% lower in infants who later became overweight than in those who maintained a normal weight. However, larger subsequent studies have not confirmed this finding. In a longitudinal study of 126 Pima Indians, those in the lowest tertile of REE at baseline had the highest cumulative incidence of a 10-kg weight gain 1 to 4 years later. In contrast, the Baltimore Longitudinal Study on Aging, which monitored 775 men for an average of 10 years, did not detect a relationship between initial REE and weight change.

When energy intake exceeds energy expenditure, weight gain usually occurs. However, genetic factors may influence the amount of weight gained with overfeeding. Bouchard and colleagues observed variable weight gain among 12 monozygotic twin pairs who were chronically overfed 1000 kcal/day. However, the members of each twin pair gained similar amounts of weight. In another study, the increase in body fat after 8 weeks of overfeeding was inversely related to changes in nonvolitional energy expenditure (e.g., fidgeting). Therefore, in some individuals, nonvolitional energy expenditure during periods of overingestion could be a mechanism that limits weight gain through the dissipation of excess ingested energy.

Diet-induced weight loss decreases REE, which promotes weight regain. This observation underlies the set-point theory, which posits that body weight is predetermined so that weight loss (or gain) promotes a decrease (or increase) in metabolic rate that acts to restore body weight to a preset level. In both lean and obese persons, hypocaloric feeding reduces REE by 15% to 30%. This reduction in REE cannot be completely accounted for by the accompanying decrease in body size or lean body mass and is considered a normal part of the physiologic adaptation to energy restriction. The reduction in REE that occurs with negative energy balance is transient and does not persist during maintenance of a lower body weight.

As reported in several studies, long-term maintenance of weight loss is not associated with an abnormal decrease in REE or TEE when adjustments are made for changes in body composition. In a meta-analysis of 15 studies, the REE of subjects who were formerly obese was found to be similar to that of subjects who were never obese. Although the decrease in energy metabolism with weight loss is largely appropriate for the concomitant changes in body composition, this decrease may nonetheless promote weight regain.
ADIPOSE TISSUE AND TRIGLYCERIDE METABOLISM

Triglycerides stored within adipose tissue constitute the body's major energy reserve. (Table 33-2) Triglycerides are a much more compact fuel than glycogen because of their energy density and hydrophobic nature. Triglycerides yield 9.3 kcal/g upon oxidation and are compactly stored as oil inside the fat cell, accounting for 85% of adipocyte weight. Glycogen, in contrast, yields only 4.1 kcal/g upon oxidation and is stored intracellularly as a gel containing approximately 2 g of water for every gram of glycogen.

Adipose tissue is an effective storage mechanism for transportable fuel that allows mobility and survival when food is scarce. During starvation, the duration of survival is determined by the size of the adipose tissue mass. Lean persons die after only approximately 60 days of starvation when more than 35% of body weight is lost. In contrast, obese persons, have tolerated therapeutic fasts for more than a year without adverse effects. In the longest reported fast, a 207-kg man ingested only noncaloric fluids, vitamins, and minerals for 382 days and lost 126 kg, or 61% of his initial weight.

Triglyceride Storage

The major function of adipocytes is the storage of triglycerides for future use as energy substrate. Lipogenesis from glucose makes only a limited contribution to triglyceride storage in the adipocyte. Most of the triglyceride in adipocytes is derived from chylomicrons and very-low-density lipoprotein (VLDL) triglycerides that originate, respectively, from dietary and hepatic sources. These plasma triglycerides are hydrolyzed by lipoprotein lipase (LPL), a key regulator of fat cell triglyceride uptake from circulating triglycerides. LPL is synthesized by adipocytes and transported to the endoluminal surface of endothelial cells. The interactions of LPL with chylomicrons and VLDL release fatty acids from plasma triglycerides, which are then taken up by local adipocytes. Plasma free fatty acids themselves can also be taken up by adipose tissue, independent of lipoprotein lipolysis.

Insulin and cortisol are the principal hormones involved in regulation of LPL activity and expression. The activity of LPL within individual tissues is a key factor in partitioning triglycerides among different body tissues. Insulin influences this partitioning through its stimulation of LPL activity in adipose tissue. Insulin also promotes triglyceride storage in adipocytes through other mechanisms, including inhibition of lipolysis, stimulation of adipocyte differentiation, and increasing glucose uptake. The importance of cortisol in fat distribution is supported by the clinical appearance of patients with Cushing’s syndrome. The obesity-promoting effect of cortisol may involve a synergistic effect of cortisol and insulin on the induction of LPL in adipose tissue, which has been demonstrated in vitro. Testosterone, growth hormone, catecholamines, and tumor necrosis factor (TNF) and other related cytokines inhibit LPL activity.
Lipolysis

The balance between triglyceride storage and lipolysis is regulated by complex hormonal and neuronal mechanisms. To become available as an energy substrate, triglycerides stored within adipocytes must be hydrolyzed by hormone-sensitive lipase into fatty acids. These fatty acids can be released from adipocytes into the circulation.

The circulating half-life of plasma fatty acids is only 3 to 4 minutes. The excess availability of fatty acids in plasma provides a ready supply of oxidizable substrate to respond to sudden changes in energy requirements, such as are induced by exercise. These fatty acids are the major precursors of hepatic VLDL triglyceride synthesis. In turn, VLDL triglycerides are secreted by the liver and redistributed throughout the body, depending on tissue-specific factors such as the activity of LPL. These observations imply that there is continuous redistribution of triglycerides between adipose tissue and the rest of the body.

There is considerable variation in the rate of lipolysis and, consequently, plasma fatty acid level both within and between subjects. Insulin and catecholamines are the major circulating hormones that influence lipolysis in adipocytes. Insulin inhibits lipolysis through its effect on hormone-sensitive lipase, whereas catecholamines stimulate lipolysis. Small changes in plasma concentrations of insulin and catecholamines may have major effects on lipolytic rate. Half-maximal suppression of lipolysis occurs at postabsorptive insulin levels, and maximal suppression of lipolysis occurs at insulin levels within the range observed after a regular meal. Only minor increases in resting catecholamine levels stimulate lipolysis. Other factors modulate the rate of lipolysis. For example, growth hormone and cortisol stimulate lipolysis. In general, the effects of these other factors are less potent than the effects of insulin and catecholamines.

In contrast to the tight feedback regulation of insulin secretion by glucose levels, insulin and catecholamine concentrations are not regulated by lipolysis or fatty acid levels. Although free fatty acid levels affect glucose-stimulated insulin release, there is no feedback between insulin release and rate of lipolysis. The wide physiologic variation in plasma free fatty acid concentrations between individuals can be explained, in part, by the finely tuned dose-response effects of insulin and catecholamines on lipolysis in combination with the absence of tight feedback regulation of insulin and catecholamine levels by free fatty acids.

Basal plasma fatty acid concentrations are often increased in obese persons, particularly those with abdominal (upper body) obesity. An increased rate of free fatty acid release into plasma because of an increased rate of lipolysis from upper body subcutaneous fat is responsible for the higher levels of circulating fatty acids. The excess free fatty acid availability in plasma may lead to increased hepatic free fatty acid uptake, VLDL triglyceride synthesis, intramuscular triglyceride formation, and insulin resistance.
ADIPOSE TISSUE AS AN ENDOCRINE ORGAN

Traditionally, adipocytes have been viewed as energy depots that store triglycerides during feeding and release fatty acids during fasting to provide fuel for other tissues. However, it has become evident that adipose tissue has major integrative physiologic functions and secretes numerous proteins. In part, these factors participate in autocrine and paracrine regulation within adipose tissue. In addition, these factors have profound effects on the function of distant organs, such as muscle, pancreas, liver, and brain. The realization that adipose tissue functions as an endocrine organ has important implications for understanding the pathophysiologic relationship between excess body fat and pathologic states, such as insulin resistance and type 2 diabetes mellitus.

Leptin

Adipocytes produce leptin and secrete it into the blood stream. Leptin has pleiotropic effects on food intake, hypothalamic neuroendocrine regulation, reproductive function, and energy expenditure. There is a direct relationship between plasma leptin concentrations and BMI or percent body fat. However, there can be considerable variability in leptin concentrations among persons with the same BMI, suggesting that leptin production is also regulated by factors other than adipose tissue mass per se.

Leptin levels decrease rapidly within 12 hours after the start of starvation; conversely, they increase in response to overfeeding. Therefore, plasma leptin concentrations reflect adipose tissue mass and are influenced by energy balance. In this perspective, leptin is a bidirectional signal that switches physiologic regulation between fed and starved states. Plasma leptin concentrations increase with increasing fat mass and decrease rapidly during early fasting. At present, the relative importance of the central versus peripheral effects of leptin remains to be elucidated.
Resistin

Resistin is another signaling polypeptide secreted by adipocytes. Resistin levels are increased in mice with diet-induced and genetic forms of obesity and insulin resistance. Administration of recombinant resistin to normal mice impaired glucose tolerance and insulin action. Neutralization of resistin reduced hyperglycemia in obese, insulin-resistant mice, in part by improving insulin sensitivity. It has therefore been proposed that resistin is a hormone that links obesity to diabetes by inducing insulin resistance.
Estrogens

Adipose tissue has aromatase activity. This enzyme is important for transforming androstenedione into estrone. Estrone is the second major circulating estrogen in premenopausal women and the most important estrogen in postmenopausal women. The rate of conversion of androstenedione to estrone increases with age and obesity and is higher in lower body than in upper body obesity. In addition to a role in endocrine regulation, the effects of P450 aromatase on estrogen metabolism may have a role in autocrine or paracrine action because estrogen receptors are present in adipose tissue.
Tumor Necrosis Factor

Adipocytes secrete TNF-α, and TNF-α expression is increased in the enlarged adipocytes of obese subjects. However, plasma TNF-α levels are generally at or below the detection limit of available assays, which suggests that the TNF-α produced within adipose tissue has paracrine rather than endocrine functions. The multiple effects of TNF-α on adipocytes include impairment of insulin signaling. Therefore, it has been proposed that TNF-α may partially contribute to insulin resistance in obesity.\ref{23}
ADIPOCYTE BIOLOGY

Obesity is associated with an increased number of adipocytes. A lean adult has about 35 billion adipocytes, each containing about 0.4 to 0.6 µg of triglyceride; an extremely obese adult can have four times as many adipocytes (125 billion), each containing twice as much lipid (0.8 to 1.2 µg of triglyceride).

Our understanding of adipocyte differentiation is largely derived from studies of preadipocytes in culture. The current concept is that adipocytes are derived from fibroblast precursor cells after the concerted actions of extracellular signals and intrinsic transcription factors and coactivators. Many extranuclear factors and intracellular transduction pathways influence the adipogenic potential of cells in vitro and in vivo.

Although in the future it may be possible to regulate adipogenesis in vivo, decreasing adipogenesis without altering energy balance may result in the deposition of triglycerides in other tissues. Excessive triglycerides in nonadipose tissues can have deleterious effects, as suggested by the liver steatosis, dyslipidemia, and diabetes observed when adipogenesis was prevented in mice.

The cornerstone of obesity therapy is to increase the utilization of endogenous fat stores as fuel by reducing energy intake below energy expenditure. With dieting, weight loss is composed of approximately 75% to 85% fat and 15% to 25% fat-free mass (FFM). An energy deficit of approximately 3500 kcal is required to oxidize 1 pound of adipose tissue. However, because of the oxidation of lean tissue and associated water losses, a 3500-kcal energy deficit reduces body weight by more than 1 pound. The distribution of fat loss is characterized by regional heterogeneity. Particularly in men and women with initially increased intra-abdominal fat, there are greater relative losses of intra-abdominal fat than of total body fat mass. A decrease in the size (triglyceride content) of existing adipocytes accounts for most, if not all, of the fat loss. In humans, there is also evidence that the number of adipocytes is reduced with large, long-term fat loss. However, it is possible that this perception of decreased fat cell number is false because standard cell-counting techniques may fail to detect adipocytes that have undergone marked shrinkage.

There are two possible mechanisms through which weight loss can eliminate fat cells: (1) dedifferentiation, the morphologic and biochemical reversion of mature adipocytes to preadipocytes, and (2) apoptosis. Adipocyte dedifferentiation has been observed in vitro, but there is no evidence that it occurs in vivo. Adipocyte apoptosis has been induced in vitro and has been shown to occur in vivo in some patients with cancer. To date, it is not known whether diet-mediated weight loss induces adipocyte apoptosis.
PREVALENCE OF OBESITY

The worldwide prevalence of obesity has increased dramatically over the last several decades. In the United States alone, an estimated 61% (110 million) of adults 20 to 74 years of age are now considered overweight or obese. According to national population surveys conducted since 1960, the prevalence of overweight in the United States increased only slightly from 30.5% to 34.0% but the prevalence of obesity (BMI >30 kg/m²) more than doubled, from 12.8% to 27%. In the United States, the prevalence of obesity increases progressively from 20 to 50 years of age but then declines after 60 to 70 years of age.

The prevalence of obesity has also risen in children and adolescents. As defined by a BMI greater than the 95th percentile for age and gender from the revised National Center for Health Statistics growth charts, 10% to 15% of 6- to 17-year-old children and adolescents in the United States are overweight. These data indicate that overweight prevalence rates for children and adolescents, reported by earlier surveys, have doubled. Diseases commonly associated with obesity in adults, such as type 2 diabetes mellitus, hypertension, hyperlipidemia, gallbladder disease, nonalcoholic steatohepatitis, sleep apnea, and orthopedic complications, are now increasingly observed in children.
CLINICAL FEATURES AND COMPLICATIONS OF OBESITY

Obesity is strongly associated with many serious medical complications that impair quality of life and lead to increased morbidity and premature death (Fig. 33-4).

The complications associated with obesity have been reviewed in detail previously. 9

Endocrine and Metabolic Disease

The Metabolic or Insulin Resistance Syndrome

In the metabolic or insulin resistance syndrome, also known as syndrome X, the specific phenotype of upper body or abdominal obesity is associated with a cluster of metabolic risk factors for coronary heart disease (CHD). Features of this syndrome include:

1. Insulin resistance, including hyperinsulinemia, impaired glucose tolerance, impaired insulin-mediated glucose disposal, and type 2 diabetes mellitus.
2. Dyslipidemia, characterized by hypertriglyceridemia and low serum high-density lipoprotein (HDL) cholesterol levels.
3. Hypertension.

Abdominal obesity has also associated with the metabolic risk factors of (1) increased serum levels of apolipoprotein B; (2) small, dense low-density lipoprotein (LDL) particles; and (3) plasminogen activator inhibitor 1 with impaired fibrinolysis. 14 15 16 The metabolic syndrome does not affect only those with frank obesity; it has also been reported in persons of normal weight, who presumably have an increased amount of abdominal fat. 17

The metabolic syndrome was originally identified and defined on the basis of epidemiologic associations. The underlying pathogenesis and the interrelationships between the individual features have not been completely elucidated. Insulin resistance has been hypothesized to be the common underlying pathogenic mechanism. 18 However, according to a factor analysis of data from nondiabetic subjects in the Framingham Offspring Study, insulin resistance may not be the only precedent condition and more than one independent physiologic process may be involved. 19 Abdominal obesity is clearly associated with insulin resistance. It is not clear whether the visceral (omental and mesenteric) or subcutaneous depots of abdominal fat are more closely related to insulin resistance because data from different studies are contradictory. In addition, it is difficult to define the relationship between each abdominal adipose tissue depot and insulin resistance because the size of the depots is closely correlated. Furthermore, it is not known whether visceral fat and abdominal fat actually participate in the pathogenesis of the metabolic syndrome or merely serve as markers of increased risk for the metabolic complications of obesity. 20

There is increasing evidence that the ectopic distribution of triglycerides in nonadipose tissue may be involved in the complications of obesity. In cross-sectional studies, insulin resistance was highly correlated with the intramyocellular concentration of triglyceride. 21 It is not known whether triglycerides per se interfere with insulin action or whether triglycerides serve as a surrogate marker for some other fatty acid-derived entity from plasma or intracellular sources that impairs insulin signaling. 22

Type 2 Diabetes Mellitus

The marked increase in the prevalence of obesity has played an important role in the 25% increase in the prevalence of diabetes that has occurred in the United States. 23 According to data from the Third National Health and Nutrition Examination Survey (NHANES III), two thirds of the adult men and women in the United States with a diagnosis of type 2 diabetes had a BMI of 27 kg/m² or greater. 24 The risk of diabetes increases linearly with BMI; the prevalence of diabetes increased from 2% in those with BMI 25 to 29.9 kg/m², to 6% in those with 30 to 34.9 kg/m², and finally to 13% in those with BMI greater than 35 kg/m². 25 In the Nurses Health Study, the risk of diabetes began to increase when BMI exceeded the "normal" value of 22 kg/m² (see Fig. 33-2). 26 27 In addition, the risk of diabetes increases with increments in abdominal fat mass, waist circumference, or ratio of waist to hip circumference at any given BMI value. 28 29 30

The risk of diabetes also increases with weight gain during adulthood. Among men and women 35 to 60 years of age, the risk of diabetes was three times greater in those who gained 5 to 10 kg after the age of 18 to 20 years than in those who maintained their weight within 2 kg. 31 32

Dyslipidemia

Obesity is associated with several serum lipid abnormalities, including hypertriglyceridemia, reduced HDL cholesterol levels, and an increased proportion of small, dense LDL particles. 33 34 35 This association is especially strong in persons with abdominal obesity. In addition, most studies suggest that serum concentrations of total cholesterol and LDL cholesterol are elevated in obesity. 36 Data from NHANES III showed that in men there was a progressive increase in the prevalence of hypercholesterolemia (total blood cholesterol >240 mg/dL or 6.21 mmol/L) with increasing BMI. 37 In women, by contrast, the prevalence of hypercholesterolemia was highest at BMI of 25 to 27 kg/m² and did not increase further at higher BMI values. The serum lipid abnormalities associated with obesity are important risk factors for CHD. 38 39 40
Cardiovascular Disease

Hypertension

There is a linear relationship between hypertension and BMI. In NHANES III, the age-adjusted prevalence of hypertension (defined as systolic blood pressure > 140 mm Hg, diastolic blood pressure > 90 mm Hg, or the need for antihypertensive medication) in obese men and women was 42% and 38%, respectively. These prevalence rates are more than twice as high as the prevalence rates of hypertension in lean men and women (15% prevalence rate in both men and women).

The risk of hypertension also increases with weight gain. Among subjects in the Framingham Study, there was an increase of 6.5 mm Hg in blood pressure with every 10% increase in body weight.

Coronary Heart Disease

The risk of CHD is increased in obese persons, particularly those with increased abdominal fat distribution and those who gained weight during young adulthood. Moreover, CHD risk starts to increase at the normal BMI levels of 23 kg/m$^2$ in men and 22 kg/m$^2$ in women. In the Nurses Health Study, the risk of fatal and nonfatal myocardial infarctions was greater in women with the lowest BMI but highest ratio of waist to hip circumference than in women with the highest BMI but lowest ratio of waist to hip circumference. At any BMI level, the risk of CHD increases with the presence of increased abdominal fat. The risk of fatal and nonfatal myocardial infarction also increases when 5 kg or more is gained after 18 years of age.

Obesity-related CHD risk factors, particularly hypertension, dyslipidemia, impaired glucose tolerance, and diabetes, are largely responsible for the increase in CHD. However, even after adjustments for other known risk factors, several long-term epidemiologic studies found that overweight and obesity increased the risk of CHD. As a result, the American Heart Association classified obesity as a major preventable risk factor for CHD.

Cerebrovascular and Thromboembolic Disease

The risk of fatal and nonfatal ischemic stroke is approximately twice as great in obese as in lean persons and increases progressively with increasing BMI. The risks of venous stasis, deep vein thrombosis, and pulmonary embolism are also increased in obesity, particularly in persons with abdominal obesity. Lower extremity venous disease may result from increased intra-abdominal pressure, impaired fibrinolysis, and the increase in inflammatory mediators.
Pulmonary Disease

Restrictive Lung Disease

Obesity increases the pressure placed on the chest wall and thoracic cage, which restricts pulmonary function by decreasing respiratory compliance, increasing the work of breathing, restricting ventilation (measured as decreased total lung capacity, forced vital capacity, and maximal ventilatory ventilation), and limiting ventilation of lung bases.\[116\]

Obesity-Hypoventilation Syndrome

In obesity-hypoventilation syndrome, the partial pressure of carbon dioxide (P$_{\text{CO}_2}$) is less than 50 mm Hg because of decreased ventilatory responsiveness to hypercapnia or hypoxia, or both, and inability of respiratory muscles to meet the increased ventilatory demand imposed by the mechanical effects of obesity. Alveolar ventilation is reduced because of shallow and inefficient ventilation related to decreased tidal volume, inadequate inspiratory strength, and elevation of the diaphragm. Symptoms increase when patients are lying down because of increased abdominal pressure on the diaphragm. The resulting increase in intrathoracic pressure further compromises lung function and respiratory capacity.

The pickwickian syndrome is a severe form of the obesity-hypoventilation syndrome. Named after an obese character in Charles Dickens' *Pickwick Papers*, this syndrome involves extreme obesity, irregular breathing, somnolence, cyanosis, secondary polycythemia, and right ventricular dysfunction.

Obstructive Sleep Apnea

In patients with obstructive sleep apnea (cessation of breathing), excessive episodes of apnea and hypopnea during sleep are caused by partial or complete upper airway obstruction despite persistent respiratory efforts. Daytime sleepiness and cardiopulmonary dysfunction result from the interruption in nighttime sleep and arterial hypoxemia. In general, patients with sleep apnea are characterized by a BMI greater than 30 kg/m$^2$, abdominal fat distribution, and a large neck girth (>17 inches in men and >16 inches in women).\[117\], \[118\], \[119\]
Musculoskeletal Disease

Gout

Both hyperuricemia and gout are associated with obesity.\textsuperscript{120, 121}

Osteoarthritis

The risk of osteoarthritis of weight-bearing joints is increased in overweight and obese persons.\textsuperscript{122} The knees are most often involved because much more body weight is exerted across the knees than across the hips during weight-bearing activity.\textsuperscript{122} There is a stronger relationship between body size and osteoarthritis in women than in men, and even small increases in body weight in women can promote osteoarthritis. In a study of twins, symptomatic or asymptomatic lower extremity osteoarthritis was found in individuals who were only 3 to 5 kg heavier than their twin sibling.\textsuperscript{123}
Cancer

Overweight and obesity increase the risk of cancer of the esophagus, gallbladder, colon, breast, uterus, cervix, and prostate gland. Most but not all epidemiologic studies have found a direct relationship between BMI and colon cancer in both men and women. The risks of mortality from breast and endometrial cancer increase with obesity and weight gain after age 18 years. The risk of breast cancer appears to increase with increasing BMI only in postmenopausal women, in premenopausal women, increased BMI may actually protect against breast cancer. Obesity is often correlated with ingestion of a high-fat, high-calorie diet, which is another risk factor for cancer. Therefore, it is difficult to distinguish how much of the relation between obesity and cancer is attributable to obesity per se and how much is attributable to dietary factors.
Genitourinary Disease in Women

Obese women are often affected by irregular menses, amenorrhea, and infertility. Pregnant obese women are at increased risk for gestational diabetes and hypertension, delivery complications, and congenital malformations. The risk of urinary incontinence is also increased in obese women, even after adjustments are made for age and parity. In extremely obese patients, incontinence usually resolves after considerable weight loss, usually achieved by bariatric surgery.
Neurologic Disease

As described earlier, the incidence of ischemic stroke is increased in obesity. Obesity is also associated with idiopathic intracranial hypertension (IIH), also known as pseudotumor cerebri. This syndrome is manifested by headache, vision abnormalities, tinnitus, and sixth nerve paresis. Although the prevalence of IIH increases with increasing BMI, the risk of IIH is increased even in persons who are only 10% above ideal body weight. The observation that weight loss in extremely obese patients with IIH decreases intracranial pressure and resolves most associated clinical signs and symptoms suggests that there is a causal relationship between obesity and IIH.
Cataracts

Overweight and obesity are associated with an increased prevalence of cataracts. Moreover, persons with abdominal obesity are at greater risk than those with lower body obesity, suggesting that insulin resistance may be involved in the pathogenesis of cataract formation.
Gastrointestinal Disease

Gastroesophageal Reflux Disease

The relationship between gastroesophageal reflux disease and obesity is unclear because of conflicting data from different studies. A higher incidence of reflux symptoms in obese than in lean persons has been found in most but not all large epidemiologic studies. In addition, studies that evaluated gastroesophageal acid reflux by 24-hour pH monitoring have reported the presence of a significant relationship and no relationship between BMI and pathologic reflux, defined as the occurrence of esophageal pH less than 4 more than 5% of the time.

Gallstones

The risk of symptomatic gallstones increases linearly with BMI. The Nurses Health Study found that the annual incidence of symptomatic gallstones was 1% in women with a BMI greater than 30 kg/m² and 2% in women with a BMI greater than 45 kg/m². The risk of gallstones increases during weight loss, particularly when weight loss is rapid. This increased risk is related to increased bile cholesterol supersaturation, enhanced cholesterol crystal nucleation, and decreased gallbladder contractility. When the rate of weight loss exceeded 1.5 kg (1.5% of body weight) per week, the risk of gallstone formation increased exponentially.

In obese patients who underwent rapid weight loss with a very-low-calorie diet (<600 kcal/day), a low-fat diet (1 to 3 g/day), or gastric surgery, the respective incidence of new gallstones was approximately 25%, 33%, and 38%. Gallstone formation was also promoted by the low fat content of very-low-calorie diets because more than 4 to 10 g of fat in a meal was needed to stimulate maximal gallbladder contractility. Therefore, increasing the fat content of a very-low-calorie diet can prevent the development of new gallstones. However, increasing dietary fat content may not be as important in preventing gallstones in patients consuming a low-calorie diet as in those consuming a very-low-calorie diet. Administration of ursodeoxycholic acid (600 mg/day) during weight loss markedly decreased gallstone formation.

Pancreatitis

Although obese patients would be expected to be at increased risk for gallstone pancreatitis because of their increased prevalence of gallstones, few studies have addressed this issue. Several studies have shown that overweight and obese patients with pancreatitis have a higher risk of local complications, severe pancreatitis, and death than lean patients. It has been hypothesized that the increased deposition of fat in the peripancreatic and retroperitoneal spaces predisposes obese patients to the development of peripancreatic fat necrosis and subsequent local and systemic complications.

Liver Disease

Obesity is associated with a spectrum of liver abnormalities, which are now referred to as nonalcoholic fatty liver disease (NAFLD). These abnormalities include hepatomegaly, abnormal liver biochemistry, steatosis, steatohepatitis, fibrosis, and cirrhosis. Alanine aminotransferase and aspartate aminotransferase are the most commonly elevated liver enzymes, but elevations of these enzymes generally do not exceed two times the upper limit of normal. Moreover, enzyme levels often do not correlate with the severity of histologic abnormalities. Most of the available data suggest that steatosis affects approximately 75%, steatohepatitis approximately 20%, and cirrhosis approximately 2% of obese patients.

The presence of NAFLD is associated with the presence of abdominal obesity and the metabolic syndrome. However, the factors underlying the development of NAFLD in obese persons are not clear. NAFLD has been hypothesized to result from two or more insults to the liver. The first of these events is steatosis, caused by obesity-induced alterations in lipid metabolism: (1) increased lipolysis of adipose tissue triglycerides, which increases the delivery of free fatty acids to the liver; (2) increased de novo lipogenesis; and (3) possibly inadequate hepatic fatty acid oxidation. The second insult may involve peroxidation of hepatic lipids and injury-related cytokines, which can promote direct cellular injury, inflammation, and fibrosis.

Obese patients with NAFLD are usually advised to lose weight, but it is not known whether weight loss alters the progression of the disease. With a gradual weight loss of 10% or more, abnormalities in liver chemistry resolve and liver size, hepatic fat content, and features of steatohepatitis decrease.
BENEFITS OF INTENTIONAL WEIGHT LOSS

Effect on Mortality

Intentional weight loss improves many of the medical complications associated with obesity. Moreover, many of these beneficial effects have a dose-dependent relationship with the amount of weight lost and begin after only a modest weight loss of 5% of initial body weight. In addition, weight loss can decrease the risk of new obesity-related diseases, such as diabetes.

Type 2 Diabetes Mellitus

In obese patients with type 2 diabetes mellitus, weight loss improves insulin sensitivity and glycemic control. A 1-year study of obese patients with type 2 diabetes treated with oral hypoglycemic agents showed that even a 5% weight loss decreased fasting blood glucose, insulin, and hemoglobin A\textsubscript{1c} concentrations and the required dosage of medication. Loss of 15% or more of their body weight decreased or eliminated the need for hypoglycemic medication. In patients with severe obesity who underwent gastric bypass surgery, the average loss of about 30% of initial body weight promoted marked long-term improvements in glucose homeostasis. In this study, normal fasting blood glucose, insulin, and glycoylated hemoglobin concentrations were achieved by 83% of the patients who had type 2 diabetes and 99% of the patients who had impaired glucose tolerance. However, a subset of obese patients with severe diabetes may not experience improved glycemic control with weight loss.

In obese patients with mild type 2 diabetes mellitus, both energy restriction and weight loss have important beneficial effects on insulin action and glycemic control. The initial negative energy balance associated with dieting acutely improves insulin sensitivity before there is a significant change in body weight. Subsequent weight and fat losses further improve glycemic control and insulin-mediated glucose uptake.

Sustained weight loss can prevent the development of new cases of diabetes. For example, the Swedish Obese Subjects (SOS) Study found that in severely obese patients (initial BMI 41 kg/m\textsuperscript{2}) who underwent gastric surgery, a 16% weight loss reduced the risk of diabetes fivefold over an 8-year period. Data from the Finnish Diabetes Prevention Study demonstrated that changes in lifestyle that resulted in modest (5%) weight loss decreased the 3-year incidence of diabetes by 58% in subjects with impaired glucose tolerance.

Several studies have found that weight loss is more difficult in obese patients with type 2 diabetes than in patients without diabetes. Moreover, successful weight loss may be inversely related to the duration and severity of diabetes. The reasons obese patients with diabetes are less responsive to weight loss therapy are not known but may involve the energy-conserving effects of improved glycemic control (e.g., reduced glycogenesis) and the tendency for weight gain associated with most drug treatments for diabetes.

Dyslipidemia

Weight loss usually decreases serum triglyceride, total cholesterol, and LDL-cholesterol concentrations and increases serum HDL cholesterol concentrations. In serum triglyceride, total cholesterol, and LDL cholesterol concentrations are generally greatest during the first 4 to 8 weeks of a weight loss program. Serum HDL cholesterol concentrations decrease during active weight loss but tend to increase when body weight stabilizes. A greater reduction in LDL cholesterol is observed when weight loss is induced by a program of diet plus exercise than with either treatment alone.

Hypertension

Systolic blood pressure and diastolic blood pressure decrease with weight loss, independent of sodium restriction. In the Trials of Hypertension Prevention, phase II (TOHP II), which is one of the largest intervention studies to date, approximately 1200 overweight and obese patients were randomly assigned to dietary weight loss intervention or usual care. This study showed a dose-response relationship between weight loss and change in blood pressure at 36 months. During the first 6 months, patients who lost weight experienced a marked reduction in blood pressure. Among patients who regained most or all of their lost weight, however, blood pressure steadily increased to near baseline values.

The marked weight loss induced by gastric surgery improved or completely resolved hypertension in about two thirds of extremely obese hypertensive patients. However, data compiled by the SOS Study indicate that the beneficial effect of weight loss on blood pressure may not persist. Much of the improvement in blood pressure observed at 1 and 2 years after gastric surgery disappeared by 3 years. Over the next 5 years, both systolic and diastolic blood pressures gradually increased. These findings imply that current energy balance and the direction of weight change are also important in blood pressure control.

A decreased incidence of hypertension with weight loss has been reported by several large prospective epidemiologic and intervention studies. For example, TOHP II found that persons who maintained a weight loss of at least 4.5 kg at 36 months had a 65% decrease in the risk of hypertension compared with the control group who gained 1.8 kg. The Nurses Health Study observed a direct correlation between the risk of developing hypertension and changes in body weight among normotensive women, who were monitored for 12 to 15 years. With weight losses of 5.0 to 9.9 kg and 10 or more kg, the risk of developing hypertension decreased by 15% and 26%, respectively.

Data from the SOS Study also question the ability of weight loss to prevent development of hypertension. In that study, the preventive effect of weight loss on the development of hypertension, which was observed 2 years after gastric surgery, disappeared at 3 years. In contrast, the SOS Study found a marked effect of weight loss on the incidence of other obesity-related diseases. For example, long-term maintenance of major weight loss after gastric surgery was associated with a marked and persistent reduction in the risk of diabetes.

Cardiovascular Disease

Modest weight loss can simultaneously affect the entire cluster of cardiovascular risk factors associated with obesity. In the Framingham Offspring Study, a weight loss of 5 pounds (2.25 kg) or more over 16 years was associated with 48% and 40% reductions in the sum of risk factors (defined as the highest quintile of systolic blood pressure, serum triglyceride, serum total cholesterol, fasting blood glucose, and BMI) and the lowest quintile of HDL-cholesterol) in men and women, respectively. Improvements in cardiovascular structure and function associated with weight loss included reductions in blood volume and hemodynamic demands on the heart, left ventricular mass and chamber size, and septal wall thickness. Such improvements in cardiac function may be responsible for the reduced frequency of chest pain and dyspnea reported by patients who lost weight after bariatric surgery.

Weight loss may also delay the progression of atherosclerosis. In one study, the progression of carotid artery intimal wall thickening over 4 years was three times higher in untreated obese subjects who did not lose weight than in obese subjects who lost weight after gastric surgery.

Pulmonary Disease

Weight loss results in improved pulmonary function, obstructive sleep apnea, and obesity-hypoventilation syndrome. Even modest weight loss resulted in reduced severity of sleep apnea, improved sleep patterns, and decreased daytime hypersomnolence. More marked weight loss, induced by bariatric surgery, has been
shown to improve obesity-hypoventilation syndrome by correcting resting room air arterial blood gases, lung volume, and cardiac filling pressure. These improvements in sleep apnea and obesity-hypoventilation syndrome are maintained with sustained weight loss; however, pulmonary symptoms recur with weight regain.

Reproductive and Urinary Tract Function in Women

Marked weight loss (>20% of initial body weight) has been shown to result in correction of urinary overflow incontinence, resolution of amenorrhea, and improved fertility.
Effect on Mortality

To date, there is no conclusive evidence that weight loss itself in obese persons reduces mortality. In fact, most epidemiologic studies indicate that weight loss or weight fluctuation increases mortality. However, these studies did not distinguish between intentional and unintentional weight loss, and their results may have been confounded by unintentional weight loss caused by concomitant rather than preexisting illness.

The effect of intentional weight loss on mortality has been addressed in three studies, which obtained baseline data between 1959 and 1960 and follow-up data for an average of 12 years. The composite results of these studies suggest that intentional, and possibly transient, weight loss may increase survival among overweight and obese persons who have type 2 diabetes mellitus. However, these data are not conclusive because weight loss was self-reported and occurred at any time before the initial interview, and possible changes in weight that might have occurred during follow-up were not determined. Therefore, long-term prospective trials are needed to determine the true relationship between intentional weight loss and survival in obese persons.
OBESITY THERAPY

Many obese persons can achieve short-term weight loss by dieting alone, but successful long-term weight maintenance is much more difficult to achieve. Weight cycling and yo-yo dieting are terms used popularly to describe repetitive cycles of weight loss and subsequent regain. 165 Although some adverse consequences have been associated with weight cycling, 166 available data on the health effects of weight cycling are inconclusive and should not deter obese persons from attempting to lose weight. 167 Currently available weight loss treatments include (1) dietary intervention, (2) increased physical activity, (3) behavior modification, (4) pharmacotherapy, and (5) surgery.

Dietary Intervention

For most obese people, negative energy balance is more readily achieved by decreasing food intake than by increasing physical activity. Therefore, dietary intervention is considered the cornerstone of weight loss therapy. Weight loss diets generally involve modifications of energy content and macronutrient composition. However, the degree of weight loss achieved depends primarily on the energy content, rather than the relative macronutrient composition, of the diet.

Energy Content

Weight loss diets can be classified according to their energy content:

1. Balanced-deficit diets of conventional foods usually contain more than 1500 kcal/day and an appropriate balance of macronutrients.
2. Low-calorie diets (LCDs) contain 800 to 1500 kcal/day and are consumed as liquid formula, nutritional bars, conventional food, or a combination of these items.
3. Very-low-calorie diets (VLCDs) contain less than 800 kcal/day and are generally high in protein (70 to 100 g/day) and low in fat (<15 g/day). Such diets may be consumed as a commercially prepared liquid formula and may include nutritional bars. VLCDs consumed as regular foods (mostly lean meat, fish, or fowl) are known as protein-sparing modified fasts.

According to treatment guidelines issued by the National Institutes of Health (NIH), 168 persons who are overweight (BMI of 25.0 to 29.9 kg/m²) and have two or more cardiovascular disease risk factors and persons with class I obesity (BMI of 30 to 34.9 kg/m²) should decrease their energy intake by approximately 500 kcal/day. This deficit in energy intake generally promotes weight loss of 1 pound (0.45 kg) per week and results in about a 10% reduction of initial weight at 6 months. The NIH guidelines recommend a more aggressive energy deficit of 500 to 1000 kcal/day for persons with more severe obesity (BMI of 35.0 kg/m² or higher). In such individuals, this energy deficit generally produces weight loss of 1 to 2 pounds/week and results in a 10% weight loss at 6 months.

Total daily energy requirements can be estimated by using standard equations (e.g., the Harris-Benedict equation 169 or the World Health Organization equation 170), which are based on the patient's size, age, gender, and activity level. However, the use of standard equations is cumbersome and may be unreliable in obese persons. Use of the simple dietary guidelines outlined in Table 33-4 is suggested as an alternative to a specific energy deficit diet based on the individual's daily energy requirements. Patients who follow these guidelines generally lose weight. Because many patients do not fully adhere to their prescribed diet, the energy content of the diet should be regularly adjusted according to the patient's weight loss response.

More than 30 prospective randomized clinical trials have investigated the effectiveness of LCDs for weight loss. 171 The composite results of these trials indicate that an LCD providing 1000 to 1500 kcal/day induces about an 8% weight loss after 16 to 26 weeks of treatment. However, these results may not be typical of the results obtained when an LCD is prescribed in routine clinical practice because trial participants volunteered to enroll in a weight loss study and most study protocols included some form of behavior modification therapy.

The use of VLCDs induced a weight loss of about 15% to 20% in 12 to 16 weeks of treatment, but this weight loss was not usually maintained. 172 In fact, several randomized trials have shown that weight regain is greater after VLCD than LCD therapy. 173 174 175 176 Therefore, 1 year after treatment, weight loss with a VLCD is often similar to that obtained with an LCD. In addition, initial weight losses with a VLCD and an LCD are similar when the diets are consumed in the same manner. For example, the weight loss observed in patients given a liquid diet providing 420 kcal/day was not significantly greater than that observed in persons who consumed a liquid diet providing 800 kcal/day. 177 This finding suggests that patients treated with VLCDs are either less compliant with the diet or sustain a greater decline in energy expenditure than those treated with LCDs. With VLCDs, there is a greater risk of the medical complications associated with dieting, such as hypokalemia, dehydration, and gallstone formation. Patients treated with a VLCD therefore require closer medical supervision than those treated with an LCD.

| TABLE 33-4 – Suggested Energy and Macronutrient Composition of Initial Reduced-Calorie Diet |
|-------------------------------------------------|----------------------------------|
| Body Weight (lb) | Suggested Energy intake (kcal/day) |
| 150199 | 1000 |
| 200249 | 1200 |
| 250299 | 1500 |
| 300349 | 1800 |
| 350 | 2000 |

Macronutrient Composition

| Total fat | 20%-30% of total calories |
| Saturated fatty acids | 8%-10% of total calories |
| Monounsaturated fatty acids | Up to 15% of total calories |
| Polyunsaturated fatty acids | Up to 10% of total calories |
| Cholesterol | <300 mg/day |
| Protein | 15%-20% of total calories |
| Carbohydrate | 55%-65% of total calories |

Macronutrient Composition

Alterating the macronutrient composition of the diet does not induce weight loss unless total energy intake is reduced. Lowfat diets have traditionally been prescribed for weight loss because such diets facilitate energy restriction. Triglycerides, the principal component of dietary fat, increase the palatability and energy density of food. The results of epidemiologic and diet intervention studies suggest that increased dietary fat intake is associated with increases in total energy intake and body...
Conversely, data from a large number of studies suggest that decreasing fat intake is associated with spontaneous decreases in total energy intake and body weight even when carbohydrate and protein intakes are not restricted.

A direct relationship between changes in dietary fat intake and body weight was found in a meta-analysis of 37 intervention studies involving the Step I or Step II low-fat (<30% kcal as fat) diet recommended by the National Cholesterol Education Program to lower cardiovascular risk. Data from another meta-analysis suggest that the amount of weight loss induced by a low-fat diet is directly related to the severity of obesity.

The weight loss effects of a low-fat diet may be related to the effect of dietary fat on energy density. Energy density is defined as the energy (i.e., calories) present in a given weight (grams) of food. Because the energy density of fat is so high, there is a high correlation between dietary fat content and dietary energy density. According to short-term studies lasting up to 14 days, energy intake is regulated according to the weight of ingested food rather than its fat or energy content. For example, the weight of food ingested was the same when lean and obese subjects were given either an ad libitum high-fat, high-energy-density (1.5 kcal/g) diet or a low-fat, low-energy-density (0.7 kcal/g) diet. As a result, energy intake with the high-fat, high-energy-density diet (3000 kcal/day) was nearly double the intake with the low-fat, low-energy-density diet (1570 kcal/day). In other studies, the weight of food ingested also remained the same when subjects were given liquid diets that had the same energy density but varied in fat content (20% to 60%) and when energy density was varied but fat content remained constant.

The results of these short-term studies show that dietary fat content itself does not affect total energy intake, apart from its effects on dietary energy density and food palatability. Whether diets of low energy density can help induce and maintain weight loss remains to be confirmed by long-term studies in obese subjects.

The weight loss effects of varying dietary carbohydrate content have also been investigated. For example, several short-term (<12 weeks) trials have compared the effects of low-carbohydrate and high-carbohydrate diets on weight loss when energy intake was kept constant. These studies suggest that, despite equal energy intakes, initial weight loss during the first 4 weeks may be greater with a low-carbohydrate than with a high-carbohydrate diet because a low-carbohydrate diet induces greater water loss; however, weight loss between 6 and 12 weeks was the same with either diet. Many currently popular low-carbohydrate diets restrict carbohydrate intake (e.g., the Atkins diet restricts carbohydrate intake to 20 g/day) but allow unlimited intake of fat and protein.

Some potentially valid explanations for promotion of weight loss by low-carbohydrate diets, despite unlimited fat and protein intakes, include (1) initial diuresis associated with ketone and urea nitrogen excretion, (2) losses of up to 100 kcal/day in urinary ketones, and (3) most important, decreased energy intake, which may be related to ketosis, diet monotony, or other unknown mechanisms.

Although it has been suggested that the high-fat and high-protein intakes associated with such diets may cause dehydration, electrolyte imbalance, hyperuricemia, calciumuria, kidney stones, glycogen depletion with easy fatigue, and hyperlipidemia potential adverse effects of long-term ingestion of such diets have not been carefully investigated. No serious adverse effects were reported in a 6-month trial involving 41 subjects receiving the Atkins diet. These subjects, in fact, showed a 43% decrease in plasma triglycerides, an 18% increase in plasma HDL-cholesterol, and a 7% decrease in plasma LDL-cholesterol. However, the safety and efficacy of low-carbohydrate diets need to be evaluated in long-term studies using randomized controlled trials.
Physical Activity

Metabolic Rate

Although there is a profound increase in energy expenditure during an actual episode of exercise, the addition of regular exercise to a weight loss program has negligible effects on REE. In a meta-analysis of prospective controlled trials in which obese subjects were randomly assigned to treatment with diet alone or diet plus exercise, the addition of exercise did circumvent the expected decline in REE when REE was adjusted for body mass.\[219\]

Body Composition

The composition of weight loss can be influenced by the addition of exercise to a diet program. Pooled data from two meta-analyses indicated that exercise can reduce the loss of FFM that occurs with weight loss.\[220\] When diet-induced weight loss was about 10 kg, regular exercise of low or moderate intensity reduced the percentage of weight lost as FFM from approximately 25% to 12%. Although the difference in weight lost as FFM was large on a percentage basis, it nonetheless represented only a small (1 kg) difference in the absolute amount of FFM lost. This preservation of FFM with exercise may not necessarily reflect preservation of muscle protein but may instead involve increased retention of body water and muscle glycogen. Indeed, nitrogen balance studies have not been able to detect any nitrogen-sparing effect of exercise during diet-induced weight loss in women.\[221\] Whether there is a difference between the effects of endurance and resistance exercise on FFM conservation is not clear because the available data are limited and conflicting.

Diabetes and Coronary Heart Disease

Endurance exercise increased insulin sensitivity\[223\] and was associated with a decreased risk of development of diabetes\[224\] and death from cardiovascular disease.\[225\]  

Weight Loss

Increasing physical activity alone is not an effective strategy for promoting initial weight loss. Most studies have shown that moderate endurance exercise, such as brisk walking for 45 to 60 minutes, four times a week, for up to 1 year, usually induces only minor weight loss.\[226\] In obese persons, the energy deficit created by exercise is usually much less and requires more effort than the energy deficit created by a reduced-calorie diet. For example, to lose 1 pound of fat, an obese patient would have to walk or run approximately 4.5 miles/day for 1 week or to consume a 500 kcal/day deficit diet for 1 week.\[227\]

Although exercise is not an effective strategy for inducing initial weight loss, increasing physical activity is an important component of successful long-term weight management. Several large-scale, cross-sectional case studies have shown that obese subjects who were successful in maintaining weight loss for 1 year or more engaged in regular exercise.\[228\] In several prospective randomized studies, subjects treated with diet plus exercise who continued to exercise sustained significantly larger long-term weight losses than subjects who stopped exercising or subjects treated with diet alone.\[229\] However, when data were analyzed on an intention-to-treat basis, most prospective randomized trials did not find that exercise had a statistically significant effect on the long-term maintenance of weight loss, presumably because adherence to the exercise program was often poor.\[230\]

It has been reported that obese patients need to expend approximately 2500 kcal/week to maintain weight loss.\[231\] This level of energy expenditure can be accomplished through vigorous activity (aerobics, cycling, or jogging) for approximately 30 minutes/day or more moderate activity (brisk walking) for 60 to 75 minutes/day. Most obese persons cannot easily achieve this level of activity. Therefore, prescribed activity goals should be initially modest and increased gradually over time.
Behavior Modification

Principles

Behavior modification therapy attempts to enable obese patients to recognize and subsequently alter eating and activity habits that promote their obesity. Behavior modification is derived from the classical conditioning principle that behaviors are often triggered by an antecedent event. The association between the antecedent event, such as watching television, and the behavior, such as eating, is strengthened by repetition so that the more often the two are paired, the stronger the association between them.

Behavior modification for the treatment of obesity usually involves multiple strategies to modify eating and activity habits. These strategies include:

1. Stimulus control (avoiding the cues that prompt eating).
2. Self-monitoring (keeping daily records of food intake and physical activity).
3. Problem-solving skills (developing a systematic manner of analyzing a problem and identifying possible solutions).
4. Cognitive restructuring (thinking in a positive manner).
5. Social support (cooperation from family members and friends in altering lifestyle behaviors).
6. Relapse prevention (methods to promote recovery from bouts of overeating or weight regain).

Effectiveness

Treatment by a comprehensive group behavior therapy approach generally results in about a 9% loss of initial weight in 20 to 26 weeks. When treatment ends, weight regain is commonly observed. Although patients generally regain about 30% to 35% of their lost weight in the year after treatment, most patients sustain a clinically significant weight loss of more than 5% of initial body weight. Increasing the duration of behavior therapy programs has only marginally improved total weight loss, but it probably prevents the weight regain that usually occurs when treatment is stopped.
Pharmacotherapy

Overview

Conventional obesity therapy is associated with a high rate of recidivism. Therefore, the most important goal of pharmacotherapy is to maintain long-term weight loss. Pharmacotherapy should not be considered a short-term approach for weight loss because patients who lose weight with drug therapy usually regain weight when the therapy is discontinued. 

Some obese patients do not respond to drug therapy, and long-term success is unlikely if weight loss does not occur within the first 4 weeks of drug treatment. Moreover, weight loss usually levels off by 6 months of treatment and weight begins to increase after 1 year. This observation implies that the efficacy of weight loss medications declines with time or obesity is a progressive disease, or both.

Treatment outcomes are less successful when pharmacotherapy is administered alone than when it is administered as part of a comprehensive weight loss program that includes diet, exercise, and behavior modification (Fig. 33-5). The use of obesity pharmacotherapy alone exposes patients to the full risks of the drug without the full medical benefits of more comprehensive treatment.

Table 33-5 lists the drugs currently approved by the United States Food and Drug Administration for the treatment of obesity. All such approved weight loss drugs act as anorexigens, with the exception of orlistat, which inhibits the absorption of dietary fat. Three anorexigent drugs have been withdrawn from the market because of the increased incidence of either valvular heart disease (fenfluramine and dexfenfluramine) or hemorrhagic stroke (phenylpropanolamine) associated with their use.

All anorexigent drugs, except mazindol, are derived from -phenylethylamine, the amphetamine precursor. The structures of these drugs have been chemically altered to reduce the potential for abuse. Anorexigent medications affect the monoamine (norepinephrine, serotonin, and dopamine) system in the hypothalamus and thereby enhance satiety (level of fullness during consumption of a meal, which influences the amount of food consumed), satiety (level of hunger after consumption of a meal, which influences the frequency of eating), or both. Monoamine neurotransmitters are synthesized from tyrosine and stored in granules that release their contents to presynaptic nerve terminals into the interneuronal cleft between presynaptic and postsynaptic nerves. Only a small portion of the monoamines released into the interneuronal cleft actually bind to postsynaptic receptors and thus transmit a signal from one nerve to the other. Most of the released monoamines are taken back up into the presynaptic nerve terminal, where they are either degraded or repackaged into granules for future release. Weight loss pharmacotherapy is approved for patients with no contraindications to therapy who have BMI greater than 30 kg/m² or a BMI between 27 and 29.9 kg/m² and an obesity-related medical condition. Because a comprehensive review of drug therapy for obesity has been published, we review only data from long-term (>6 months) prospective, randomized, controlled trials that investigated the weight loss efficacy and safety of sibutramine and orlistat, the only drugs currently approved for long-term use in the management of obesity.

Sibutramine

Sibutramine inhibits the neuronal reuptake of norepinephrine, serotonin, and, to a lesser degree, dopamine. It enhances satiety rather than satiety. In humans, sibutramine also appears to promote a small increase in metabolic rate several hours after its administration. The currently recommended initial dose of sibutramine is 10 mg/day. This daily dose can be decreased or increased by 5 mg if tolerance is poor or weight loss is inadequate. Administration of sibutramine at doses between 1 and 30 mg/day for 24 weeks resulted in a dose-dependent weight loss; the weight loss ranged from 0.9% of initial body weight with placebo to 7.7% with sibutramine at 30 mg/day.

Results from two 1-year, randomized, controlled trials of the effectiveness of sibutramine treatment in producing and maintaining weight loss have been reported. The results of one trial have appeared only in abstract form, and the other trial involved only obese subjects with medication-controlled hypertension. In both trials, all participants received minimal adjunctive weight management therapy and the placebo group lost less weight than usually observed in placebo groups from other trials. Subjects treated with sibutramine (10 to 20 mg/day) lost more weight than those treated with placebo. In the first study, 39% of patients randomly assigned to sibutramine therapy lost 10% or more of their initial body weight compared with 9% of those randomly assigned to receive placebo. In the second study of hypertensive obese patients, 13% of patients who received sibutramine therapy lost 10% or more of their body weight compared with 4% of those who received placebo.

Results have also been reported from two prospective, randomized, controlled trials that evaluated the efficacy of sibutramine therapy in long-term weight management after a predetermined amount of weight was lost. In the first trial, obese subjects who lost at least 6 kg after a 4-week VLCD resumed a regular diet with diet counseling and were randomly assigned to 1 year of treatment with placebo or sibutramine.
the year after randomization, sibutramine-treated subjects lost an additional 5.2 kg while placebo-treated subjects gained 0.5 kg. Total weight losses in the study were 12.9 kg in sibutramine-treated subjects and 6.9 kg in subjects treated with placebo. The initial weight loss achieved with the VLCD was maintained or increased in 74% of sibutramine-treated subjects compared with only 41% of placebo-treated subjects.

In the second trial, obese subjects who lost more than 5% of their initial weight after 6 months of treatment with sibutramine (10 mg/day) and a 600 kcal/day deficit diet were randomly assigned to treatment with either sibutramine (increased to 15 or 20 mg/day) or placebo. All subjects received dietary counseling. Nearly half of the subjects who entered the study failed to complete the 18-month treatment program. Among subjects who completed the study, 43% of those treated with sibutramine but only 16% of those treated with placebo maintained 80% or more of their original 6-month weight loss. On average, subjects who continued sibutramine maintained their weight loss for 1 year and then experienced a slight and progressive increase in weight; subjects who were switched to placebo experienced a progressive increase in weight as soon as sibutramine therapy was stopped.

The most common side effects of sibutramine therapy are dry mouth, headache, constipation, and insomnia. Sibutramine also causes small increases in blood pressure (2 to 4 mm Hg) and heart rate (4 to 6 beats/min). However, some patients experience much larger increases in blood pressure or heart rate and require dose reduction or discontinuation of therapy.

**Orlistat**

Orlistat is synthesized from lipstatin, a product of *Streptomyces toxytricini* mold, which inhibits most mammalian lipases. Orlistat binds to lipases in the gastrointestinal tract and thereby blocks the digestion of dietary triglycerides. This inhibition of fat digestion reduces micelle formation and, subsequently, the absorption of long-chain fatty acids, cholesterol, and certain fat-soluble vitamins. The degree of fat malabsorption is directly related in a curvilinear fashion to the dose of orlistat administered. Excretion of about 30% of ingested triglycerides, which is near the maximum plateau value, occurs at a dose of 360 mg/day (120 mg three times a day with meals). Orlistat has no effect on systemic lipases because less than 1% of the administered dose is absorbed.

Many clinical trials of orlistat included treatment with low doses (30 and 60 mg three times a day) that were not effective. Therefore, only data obtained with the standard recommended dose of 120 mg three times a day are reviewed here. The effectiveness of orlistat therapy (120 mg three times a day) in promoting and maintaining weight loss has been evaluated in several prospective, randomized, controlled trials more than 1 year in duration. At 1 year, about one-third more patients treated with orlistat than treated with placebo lost 5% or more of initial body weight; about twice as many patients treated with orlistat than treated with placebo lost 10% or more of initial weight. Subjects who were enrolled in a trial conducted within a primary care practice setting, which did not include behavior therapy or interaction with a dietitian, did not do as well as those enrolled in trials that provided formal behavior modification and dietary counseling.

Successful weight loss was also more difficult to achieve in patients with type 2 diabetes mellitus. The long-term efficacy of orlistat in maintaining initial weight loss after 1 year has been evaluated in several randomized, controlled trials, including second-year extensions of the 1-year trials just discussed. During the second year of these trials, more liberal energy intake was allowed with a goal of preventing weight regain rather than promoting additional weight loss. About half of the initially randomly assigned subjects completed the second year. After 1 year, both placebo-treated and orlistat-treated groups in all trials regained weight. However, at the end of 2 years, relative weight loss was greater with orlistat than with placebo treatment.

The results of several randomized clinical trials suggest that orlistat administration is associated with a reduction of serum cholesterol concentrations that is independent of the effect of weight loss alone. Even after adjusting for percent weight loss, these studies found that subjects treated with orlistat sustained a greater reduction in serum LDL-cholesterol concentrations than those treated with placebo. The mechanism responsible for this effect may be related to orlistat-induced inhibition of dietary cholesterol absorption.

The most common side effects associated with orlistat therapy are gastrointestinal complaints. Approximately 70% to 80% of subjects treated with orlistat experienced one or more gastrointestinal events, compared with approximately 50% to 60% of those treated with placebo. These gastrointestinal events were induced by fat malabsorption, usually occurred within the first 4 weeks of treatment, and were of mild or moderate intensity. Subjects rarely reported more than two episodes despite continued orlistat treatment. Orlistat treatment can also affect fat-soluble vitamin status and the absorption of some lipophilic medications. Therefore, it is recommended that all patients treated with orlistat also receive a daily multivitamin supplement and that orlistat not be taken for at least 2 hours before or after the ingestion of vitamin supplements or lipophilic drugs.
Surgical Therapy

Overview

Gastrointestinal surgery is the most effective approach for inducing major weight loss in extremely obese patients. In 1991, guidelines for the surgical treatment of obesity were established by an NIH consensus conference. According to these guidelines, eligible candidates for surgery include patients with a BMI of 40 kg/m² or higher or those with a BMI of 35.0 to 39.9 kg/m² and one or more severe medical complications of obesity (e.g., hypertension, heart failure, type 2 diabetes mellitus, or sleep apnea). Additional eligibility criteria are inability to maintain weight loss with conventional therapy, acceptable operative risks, absence of active substance abuse, and the ability to comply with the long-term treatment and follow-up required.

Current surgical procedures for obesity can be categorized as those that primarily cause gastric restriction and those that primarily cause nutrient malabsorption and malabsorption. All procedures have been performed laparoscopically, but the laparoscopic approach is technically challenging and usually requires more operating room time.

Types of Surgical Procedures

Gastric Bypass Procedure

The gastric bypass procedure (GBP), also known as Roux-en-Y gastric bypass, involves creating a small (10 to 30 mL) proximal gastric pouch that empties into a segment of jejunum that is anastomosed as a Roux-en-Y limb. The size of the patient determines the length of the Roux-en-Y limb (Fig. 33-6 A) (Figure Not Available). In patients with a BMI less than 50 kg/m², a 45- to 60-cm limb is generally used, but in patients with a BMI of 50 kg/m² or higher, a 150-cm limb (long-limb gastric bypass) promotes better weight loss without increasing the risk of nutrient deficiencies. Although the gastric bypass is primarily a restrictive procedure, some malabsorption does occur as a result of the bypassed stomach, duodenum, and upper jejunum.

Specific complications associated with the gastric bypass procedure

Data from four prospective, randomized trials showed that weight loss several years after surgery was consistently greater with the gastric bypass procedure (loss of 65% of excess weight) than with gastroplasty (loss of 40% of excess weight) (Fig. 33-6 B) (Figure Not Available). Specific complications associated with gastroplasty include staple line disruption, stomal stenosis, and gastroesophageal reflux.

Gastric Bypass versus Gastroplasty

In the laparoscopically inserted adjustable silicone gastric band (LASGB) procedure, a silicone band is placed around the upper stomach, just below the gastroesophageal junction. The band's circumference can be adjusted by inflating or deflating a balloon connected to a subcutaneously implanted port with percutaneous access.

This operation is currently the most popular bariatric surgical procedure performed in Europe and has been approved for use in the United States. The degree of weight loss achieved with this procedure has been similar to that achieved with vertical banded gastroplasty but on average has been much less than that achieved with the gastric bypass procedure.

Associated complications include esophageal dilatation, erosion of the band into the stomach, band slippage, band or port infections, and balloon or system leaks that lead to inadequate weight loss. Esophageal dilatation and dysphagia can result from the placement of the band at the gastroesophageal junction. Although loosening the band usually relieves the dilatation, removal of the band is sometimes necessary. In some patients, the band erodes into the stomach and must be surgically removed. When the posterior stomach wall herniates through the band, band slippage occurs. Band slippage can cause gastric obstruction and necessitates surgical revision.

Partial Bilipancreatic Bypass Procedures

The partial bilipancreatic bypass and the partial bilipancreatic bypass with duodenal switch result in both gastric restriction and maldigestion or malabsorption. Both procedures involve a partial gastrectomy and bypassing a considerable amount of small intestine from biliary and pancreatic secretions. Partial bilipancreatic bypass induces malabsorption of protein, fat, fat-soluble vitamins, iron, calcium, and vitamin B₁₂ and thus promotes more nutritional deficits than gastric restrictive procedures. The incidence of protein deficiency is probably less common and gastrointestinal side effects are not as severe after partial bilipancreatic bypass with duodenal switch than after partial bilipancreatic bypass with distal gastric resection. Presumably, these procedures cause greater weight loss (75% of excess weight) than a standard gastric bypass, but they have never been compared directly in a prospective randomized trial.

Jejunoileal Bypass

Jejunoileal bypass was first described in 1969. This procedure was designed to bypass the major portion of the small intestine and thereby promote weight loss by inducing the malabsorption of ingested nutrients. The procedure is no longer performed because of an unacceptable incidence of serious side effects. The serious side effects of jejunoileal bypass result from protein-calorie malnutrition, bacterial overgrowth and translocation, and excess oxalate absorption (e.g., colitis, interstitial nephritis, migratory arthritis, bypass enteritis, erythema nodosum, oxalate urolithiasis, hypocalcemia, and electrolyte imbalances). Oral metronidazole is effective in treating the complications of jejunoileal bypass related to bacterial overgrowth (e.g., migratory arthritis, elevated liver enzymes, bleeding from inflammation in the bypassed intestine).
About 15% of patients fail to lose more than 40% of their excess weight (10% to 15% of total weight) after a gastric bypass procedure. The percentage of patients who cannot lose this amount of weight after a gastropasty procedure is even greater. The major cause of inadequate weight loss after gastric bypass is the frequent ingestion of high-calorie soft foods and liquids (e.g., ice cream, cookies, milk shakes, and sodas) and high-fat snacks and fried foods (e.g., potato chips and fried potatoes). In patients who have undergone either a stapled gastropasty or gastric bypass, increased food intake may be related to staple line disruption, particularly if the patient is able to eat much larger quantities of food at a time.

**Perioperative Mortality**

The perioperative mortality rate after open surgical procedures for obesity reported in studies involving large numbers of patients was usually less than 1.5%. Approximately 75% of the deaths were due to anastomotic leaks and peritonitis, and 25% were due to pulmonary embolism.

*Pharmacotherapy should be considered only in patients who are not able to achieve adequate weight loss with available conventional therapy (diet, physical activity, and behavior therapy) and who do not have any absolute contraindications for drug therapy.

Bariatric surgery should be considered only in patients who are unable to lose weight with available conventional therapy and do not have any absolute contraindications for surgery.
TREATMENT GUIDELINES

A practical guide to the management of overweight and obesity was developed by the North American Association for the Study of Obesity in conjunction with the NIH. An overview of these guidelines is shown in Table 33-6. According to these guidelines, all overweight or obese patients who have type 2 diabetes should attempt to modify diet and physical activity behaviors. Certain behaviors are common among patients who have achieved successful long-term weight loss without bariatric surgery. Therefore, these four behaviors should be a goal for all patients:

1. Consume a diet that is low in calories (1300 to 1400 kcal/day) and fat (25% kcal as fat).
2. Engage in high levels of regular physical activity (expending about 2800 kcal/week equivalent to walking about 4 miles/day).
3. Monitor food intake and physical activity.
4. Check weight regularly.

Weight management is a key component in the treatment of overweight or obese patients with type 2 diabetes. Even a modest weight loss of 5% of initial body weight improves glycemic control and reduces the need for hypoglycemic medication. Moreover, modest weight loss improves other diabetes-related risk factors for CHD.

Unfortunately, successful weight management is more difficult to achieve in obese patients with type 2 diabetes than in those without diabetes. In fact, treatment of diabetes itself is usually associated with an increase in body weight. Therefore, the first principle of weight management in patients with diabetes is to use hypoglycemic therapy that is associated with the least amount of weight gain. Metformin is the preferred oral hypoglycemic agent because it produces minimal weight gain or slight weight loss. In addition, providing long-acting insulin at night is associated with less weight gain than more frequent dosing.

References

Lipids are hydrophobic molecules that are insoluble or minimally soluble in water. They are found in cell membranes, which maintain cellular integrity and allow the cytoplasm to be compartmentalized into specific organelles. Lipids function as a major form of stored nutrients (triglycerides), as precursors of adrenal and gonadal steroids and bile acids (cholesterol), and as extracellular and intracellular messengers (e.g., prostaglandins, phosphatidylinositol). Lipoproteins provide a vehicle for transporting the complex lipids in the blood as water-soluble complexes and deliver lipids to cells throughout the body.

Classes of Lipids: Structure and Function

**Fatty Acids**

Fatty acids vary in length and in the number and position of double bonds. Saturated fatty acids lack double bonds (all carbon atoms have a full complement of hydrogen), and unsaturated fatty acids have one or more double bonds. Monounsaturated fatty acids have one double bond, and polyunsaturated fatty acids have two or more. The major fatty acids and their sources in foods are listed in Table 34-1.

Fatty acids are a readily available source of energy. In tissues, they can be esterified to other organic molecules to form complex lipids (e.g., triglycerides). In the blood, they may be transported on lipoproteins as complex lipids, or they may be transported in the nonesterified state as free fatty acids bound to albumin.

**Cholesterol**

Cholesterol is a four-ring hydrocarbon with an eight-carbon side chain. It plays a critical role as a major component of cell membranes and as a precursor of steroid hormones (adrenal and gonadal hormones). Cholesterol is also a precursor of bile acids, which are formed in the liver, stored in the gallbladder, and secreted in the intestine to participate in the absorption of fat. In the blood, about two thirds of the cholesterol is esterified (i.e., has a fatty acid esterified to the hydroxyl group at position 3).

*The numeral after the C indicates the number of carbon atoms; the numeral after the colon indicates the number of double bonds. Carbon number 1 is the carboxylic acid carbon, and the carbon atom is the carbon most distant from the carboxyl group. The placement of the double bonds is shown by the designations (e.g., 9 indicates a double bond between carbons 9 and 10). In omega-6 fatty acids the first double bond occurs after the sixth carbon atom from the carbon atom (indicated by 6), and in omega-3 fatty acids it occurs after the third carbon atom from the carbon atom (3).
Triglycerides consist of three fatty acid molecules esterified to a glycerol molecule (see Fig. 34-1). Diglycerides (diacylglycerols) contain two fatty acids, and monoglycerides have only one fatty acid per glycerol molecule. Triglycerides serve to store fatty acids and form large lipid droplets in adipose tissue. They are also transported as a component of certain lipoproteins. When triglycerides are hydrolyzed in adipocytes or on lipoprotein particles, free fatty acid molecules are released to be used as a source of energy.

Phospholipids

Phospholipids have fatty acids esterified at two of the three hydroxyl groups of glycerol (see Fig. 34-1). The third hydroxyl group is esterified to phosphate (this complex lipid is referred to as phosphatidic acid). Typically, in mammalian tissue, the phosphatidic acid is esterified to the hydroxyl group of a hydrophilic molecule, such as choline, serine, or ethanolamine, to form phosphatidylcholine (commonly called lecithin), phosphatidylserine, or phosphatidylethanolamine, respectively. Lysolecithin is phosphatidylcholine from which one of the fatty acids has been removed. The combination of hydrophobic and hydrophilic regions in phospholipids enables them to be miscible at the water-lipid interface and makes them ideal components of membranes and of surface coats of lipoproteins. They are the most hydrophilic of the complex lipids.
Cholesterol Biosynthesis and the Low-Density Lipoprotein Receptor Pathway

Cholesterol is either absorbed from the diet or synthesized by cells in the body. All dietary cholesterol is of animal origin (i.e., from meats, dairy products, and eggs). Plants do not produce cholesterol; plant membranes contain sitosterol, which, except in a rare genetic disease, is not absorbed. Cholesterol is produced in many tissues (e.g., liver, skin, adrenals, gonads, brain, intestine). In most mammals, including humans, about 10% to 20% of the total synthesis of cholesterol occurs in the liver.

Cholesterol Biosynthesis

Cholesterol synthesis, illustrated schematically in Figure 34-2A, begins with acetate. Three molecules of acetate are condensed to form 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA), which is then converted to mevalonic acid by the enzyme HMG-CoA reductase. Through a series of steps, mevalonic acid is converted to cholesterol. The key (rate-limiting) step regulating cholesterol biosynthesis involves HMG-CoA reductase. Competitive inhibitors of this enzyme (the statins) reduce cholesterol biosynthesis and lower plasma cholesterol levels. Increased cholesterol content of cells feeds back on the HMG-CoA reductase and decreases its activity, thereby decreasing cholesterol biosynthesis. Conversely, a deficiency of intracellular cholesterol increases reductase activity and increases cholesterol biosynthesis (see later discussion).

Cholesterol cannot be eliminated by catabolism to carbon dioxide and water; it must be either excreted as free cholesterol in the bile or converted to bile acids and secreted into the intestine. About 50% of the cholesterol entering the intestine is reabsorbed and recirculates to the liver; the remainder is eliminated in the feces. Almost all of the secreted bile acids (97%) are reabsorbed from the intestine and transported back to the liver. This recirculation of cholesterol and bile acids from the intestine to the liver is called the enterohepatic circulation (Fig. 34-2B). The reabsorbed cholesterol and bile acids regulate de novo cholesterol and bile acid synthesis in the liver. For example, if the amount of bile acids returning to the liver is decreased (as occurs in the intestine during treatment with bile acidbinding resins), bile acid synthesis is increased, enhancing the amount of cholesterol being converted to bile acids.

Cholesterol 7-hydroxylase

This enzyme of about 57 kDa (503 amino acids), known as CYP7A (formerly P450 7A1), converts free cholesterol to 7-hydroxycholesterol. This is the rate-limiting step in bile acid synthesis, and it is under feedback regulation by recirculated bile acids. The interruption of bile acid recirculation increases cholesterol 7-hydroxylase activity. This enzyme and HMG-CoA reductase are closely coupled, and their activities usually change in parallel (for a review see references 13 and 17). In this way, the intracellular cholesterol level for bile acid production remains rather constant.

Low-Density Lipoprotein Receptor

Cholesterol levels in the blood are controlled primarily through the low-density lipoprotein (LDL) receptor pathway. This receptor is present on the surface of all cells throughout the body, including hepatocytes, and mediates the uptake of cholesterol-rich lipoproteins (e.g., LDL) from the blood. Specific proteins on the surface of certain lipoproteins (apolipoprotein [apo] B100 and apo-E) interact with the LDL receptor and facilitate lipoprotein internalization by cells. By this mechanism, cells that require cholesterol can obtain the preformed sterol. The LDL receptor also allows the liver (the principal site for LDL catabolism) to take up LDL and eliminate cholesterol from the body (discussed in "Lipoprotein Receptors Controlling Lipoprotein Metabolism").

The number of LDL receptors on the cell surface is tightly regulated. If the cholesterol content of a cell is elevated, fewer receptors are synthesized (i.e., receptor expression is down-regulated). On the other hand, if a cell requires cholesterol, expression of LDL receptors is up-regulated and synthesis increases. This system keeps the intracellular cholesterol concentration relatively constant and prevents excessive and possibly toxic accumulation. Within the cell, cholesterol can be esterified by the enzyme acyl-CoA:cholesterol acyltransferase (ACAT).

Acyl-CoA:Cholesterol Acyltransferase

ACAT is an enzyme of the endoplasmic reticulum (ER) (about 45 to 50 kDa, 550 amino acids) that catalyzes the formation of cholesteryl esters from long-chain fatty acyl-CoA (e.g., oleoyl-CoA) and free cholesterol substrates. When lipoproteins enter the cell by receptor-mediated endocytosis and are degraded within the lysosomes, the free cholesterol released can be transported to the ER, where it is esterified by ACAT. There are two ACAT enzymes. ACAT1 is present in macrophages, steroidogenic tissues, and sebaceous glands, and its action in macrophages has been implicated in foam cell formation and atherogenesis. ACAT2 acts to promote the absorption of dietary cholesterol. Agents that inhibit intestinal ACAT activity may provide a means to limit cholesterol absorption by the intestine.

Cholesteryl ester hydrolysis by cholesterol ester hydrolase generates free cholesterol, either for efflux from the cells or to serve as a biosynthetic substrate (e.g., for steroid hormones and cell membranes) within the cells. The pool of intracellular cholesterol and cholesteryl esters is dynamic.
Metabolism of Dietary Lipids

The digestion of dietary fats begins in the stomach and continues in the proximal small intestine. Triglycerides are hydrolyzed to free fatty acids and small amounts of monoglycerides and diglycerides, cholesteryl esters are hydrolyzed to free cholesterol, and phospholipids are converted primarily to lysophosphatidylcholine. Bile salt micelles disperse and partially solubilize water-insoluble lipids; this facilitates the intestinal transport and delivery of lipids to the unstirred water layer of intestinal epithelial cells, where they can be taken up by the cells. Bile acids also activate pancreatic lipase, which participates in the hydrolysis of triglycerides. Long-chain fatty acids are taken up primarily by the enterocytes of the duodenum and proximal jejunum, reesterified into triglycerides, and used in the biosynthesis of intestinal lipoproteins (chylomicrons), which are delivered to the mesenteric lymph and enter the general circulation with the thoracic duct lymph. Medium-chain fatty acids (10 carbons) are absorbed into the portal blood without being esterified and are cleared directly from the blood by the liver. Bile acids are reabsorbed primarily from the ileum, enter the portal blood, and are taken up by the liver.
Triglyceride and Free Fatty Acid Metabolism

Storage and Use

Free fatty acids are released from triglycerides of chylomicrons and very-low-density lipoproteins (VLDLs) through the action of lipoprotein lipase (LPL). LPL is bound to the capillary endothelial cells adjacent to adipose, muscle, and breast tissue, where it liberates free fatty acids from lipoprotein triglyceride. The level of LPL in tissues differs under different physiologic circumstances so that free fatty acids are directed to tissues requiring them as substrates or energy sources. During fasting, for example, LPL activity decreases in adipose tissue and increases in heart muscle. In the breast, LPL levels are low until parturition, when they increase 10-fold to promote milk formation.

Figure 34-3 Triglyceride synthesis and the DGAT reaction. A, Two major pathways of triglyceride synthesis have been described: the glycerol-phosphate pathway and the monoglyceride pathway, which is prominent in the small intestine. B, DGAT catalyzes a reaction in which 1,2-diacylglycerol and fatty acyl-CoA react to form triacylglycerol at the surface of the endoplasmic reticulum. (From Farese RV Jr, Cases S, Smith SJ. Triglyceride synthesis: insights from the cloning of diacylglycerol acyltransferase. Curr Opin Lipidol 2000; 11:229-234.)

In adipose tissue, high levels of glucose and insulin promote the conversion of free fatty acids to triglyceride for storage. Insulin stimulates LPL activity and fatty acid esterification through the formation of glycerol phosphate and decreases free fatty acid release through the inhibition of hormone-sensitive lipase. Insulin deficiency, as in diabetes mellitus, is associated with decreased LPL activity. Insulin and glucose also stimulate the biosynthesis of free fatty acids in the liver and, to a lesser degree, in adipocytes when dietary fat is replaced by carbohydrates. As a result, hepatic free fatty acids are converted to triglyceride and packaged into VLDL particles (discussed in the section on plasma lipoproteins).

Acyl-Coenzyme A:Diacylglycerol Acyltransferase

Triglyceride (triacylglycerol) synthesis is catalyzed by the enzyme acyl-CoA:diacylglycerol acyltransferase (DGAT) (Fig. 34-3). A DGAT gene, which is expressed in all tissues, has been identified. Interestingly, the inactivation of this gene in mice has revealed that multiple pathways exist for triglyceride synthesis. These alternative mechanisms might include a second DGAT or fatty acyl-CoA-independent mechanisms. The gene inactivation study also revealed that DGAT plays an important role in energy metabolism.

Fatty Acid Release from Adipose Tissue

The net release of free fatty acids and glycerol from adipose triglyceride stores occurs during various physiologic conditions, including stress, exercise, fasting, and uncontrolled diabetes mellitus. This release occurs in response to hormones (Table 34-2), most of which act by means of cyclic adenosine monophosphate to activate a hormone receptor-coupled protein kinase that in turn activates a hormone-sensitive lipase (Fig. 34-4). In contrast to numerous hormones, insulin inhibits rather than stimulates hormone-sensitive lipase in adipose tissue. Growth hormone liberates free fatty acids by a different mechanism, which requires enhanced synthesis of hormone-sensitive lipase.

After triglyceride hydrolysis in adipose tissue, the released free fatty acids bind to albumin and circulate in the plasma. Released glycerol is taken up by the liver and kidney for triglyceride synthesis or for gluconeogenesis. The fate of the free fatty acid-albumin complexes is determined in part by the blood flow. With intense exercise and diminished blood flow to the splanchnic bed, free fatty acids are targeted to muscle. Depending on the metabolic state, free fatty acids taken up by the liver are reused for triglyceride or phospholipid synthesis (exported on VLDL), oxidized to carbon dioxide, or converted to ketone bodies.

Fatty Acid Oxidation and Ketogenesis

Both oxidation and ketogenesis of fatty acids take place in the mitochondria, except for very-long-chain fatty acids (C-24 and C-26), which are oxidized in peroxisomes. Because free fatty acids and their CoA derivatives can penetrate only the outer leaflet of the mitochondrial membrane, they are converted to carnitine...
derivatives within the mitochondrial membrane to allow transport across the inner membrane. Once inside the mitochondria, they are reconverted to CoA derivatives and undergo beta oxidation, which produces acetyl-CoA and the reduced forms of nicotinamide-adenine dinucleotide (NADH) and flavin-adenine dinucleotide (FADH).

With a normal flux of free fatty acids, the NADH and FADH enter the electron transport system, resulting in the formation of adenosine triphosphate and water. The condensation of acetyl-CoA with oxaloacetic acid yields citrate, which can enter the citric acid cycle, where it is oxidized to carbon dioxide or is transported out of the mitochondria and converted again to free fatty acids. If free fatty acid flux to the liver is massively increased, as in insulin-deficient states such as prolonged fasting or uncontrolled diabetes mellitus, the production of VLDL triglyceride from free fatty acids is limited. As a result, NADH, FADH, and acetyl-CoA accumulate in the mitochondria and give rise to the products of ketogenesis: acetoacetate, -hydroxybutyrate, and acetone.

Ketogenesis occurs in several steps. Initially, acetyl-CoA condenses in two steps to form acetoacetyl-CoA and then HMG-CoA. The latter is cleaved to acetoacetate and acetyl-CoA, which leads to the liberation of CoA and its use in beta oxidation of free fatty acids. Acetoacetate can be reduced by NADH to form -hydroxybutyrate; the NAD produced can be used for continued beta oxidation of fatty acids. Alternatively, the acetoacetate can decompose to form acetone. The ketones are released into the plasma and, if they accumulate, cause ketoacidosis.

Fatty Acid Biosynthesis

Under normal conditions, the diet supplies sufficient fatty acids through the ingestion of fat. However, increases in the ratio of carbohydrate to fat in the diet stimulate fatty acid synthesis by the liver and adipose tissue. Fatty acids are synthesized from two carbon units of acetyl-CoA. Because acetyl-CoA is produced in the mitochondria, it must first be converted to citrate by condensation with oxaloacetate and then transported into the cytosol, where it is reconverted to acetyl-CoA and oxaloacetate. Eight acetyl-CoA units are condensed to form palmitic acid (16 carbon atoms) in a series of reactions involving the enzymes fatty acid synthase and acetyl-CoA carboxylase. Longer fatty acids, such as stearic acid (18 carbon atoms) or oleic acid (18 carbon atoms with a single double bond), are synthesized from palmitic acid by chain extension. In this way, fatty acid synthesis can meet most of the body's requirements.

Certain essential polyunsaturated fatty acids cannot be synthesized in humans and must be supplied in the diet. These include linoleic acid (18 carbon atoms with two double bonds) and linolenic acid (18 carbon atoms with three double bonds). Essential fatty acids are required for a number of special functions, including prostaglandin synthesis.
PLASMA LIPOPROTEINS: APOLIPOPROTEINS, RECEPTORS, AND ENZYMES

General Structure and Major Classes of Lipoproteins

Lipoproteins function as vehicles to transport lipids in the blood in the form of soluble complexes of lipids and proteins. The lipids include triglycerides, cholesteryl esters, free cholesterol, and phospholipids. About 10 different protein moieties, called apolipoproteins, are associated with various lipoproteins and are given letter designations (Table 34-3). Lipoproteins also transport fat-soluble vitamins (A, D, and E), drugs (e.g., probucol, cyclosporine), some viruses, and certain antioxidant enzymes (e.g., paraoxonase and platelet-derived activating factor hydrolase).

Lipoproteins are spherical particles with a core of mostly hydrophobic lipids (triglycerides and cholesteryl esters) and a surface layer of more hydrophilic constituents, namely protein, free cholesterol, and phospholipids (Fig. 34-5). Six major classes of lipoproteins play different roles in lipid transport (Table 34-4), and the specific apolipoproteins on the surface determine the fate of the lipoproteins. To understand lipoprotein metabolism and the diseases associated with lipid abnormalities, it is necessary to consider the roles of the individual apolipoproteins in regulating lipid metabolism. Some of their properties are summarized in Table 34-4 and Figure 34-6.

Major Apolipoproteins Regulating Lipoprotein Metabolism

Apolipoprotein B

In human plasma, apo-B occurs in two forms, apo-B100 and apo-B48, which are derived from a single gene **B100** on the short arm of chromosome 2. The human apo-B gene comprises 29 exons and 28 introns and is approximately 45 kilobases in length. A unique ribonuclease acid (RNA) editing mechanism is responsible for the synthesis of apo-B100 and apo-B48 from the apo-B messenger RNA (mRNA) (Fig. 34-7) for a review see references 51 and 57. An editing protein (or proteins) interacts with the apo-B mRNA in the human intestine to change a single nucleotide, resulting in the synthesis of a truncated form of apo-B (apo-B48). In humans, this modification of the apo-B mRNA occurs only in the intestine and not in the liver; therefore, the liver produces the full-length apo-B100. Apo-B100 (but not apo-B48) is also expressed in the yolk sac of mammals.

The editing of apo-B mRNA results in the change of cytosine-6666 in the apo-B100 mRNA to a uracil. This cytosine is part of the codon CAA, which encodes a glutamine at amino acid residue 2153 in apo-B100, whereas the codon UAA is a stop codon and terminates translation of the protein chain (see Fig. 34-7). Therefore, apo-B48 possesses only 2152 amino acids, compared with the 4536 in apo-B100. Apo-B100, a 513-kd protein, is synthesized in the liver; it serves as a structural protein of VLDL and of intermediate-density lipoproteins (IDLs) and is the exclusive protein constituent of LDL. Each VLDL, IDL, and LDL particle contains one molecule of apo-B100. The primary structure of apo-B contains many hydrophobic and amphipathic sequences, forming alpha helices and beta strands, that occur throughout the molecule and appear to function as lipid-binding domains. In addition to its structural role, apo-B100 functions as a ligand for the LDL receptor.

Apo-B48, a 241-kd protein, is a structural constituent of chylomicrons. Each chylomicron appears to possess one or two apo-B48 molecules. The apo-B48 is a 17-kd protein, which is derived from apo-B100 by the selective chemical modification of the apo-B100 mRNA in the human intestine to change this single nucleotide, resulting in the synthesis of the truncated form of apo-B (apo-B48) (see Fig. 34-7).

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

*Small, partially lipolyzed VLDL and IDL are often called VLDL remnants.*

Possibly two molecules of apo-B48. Because it lacks the carboxyl-terminal domain of apo-B100, apo-B48 cannot bind to the LDL receptor. The carboxyl-terminal domain of apo-B100 in the region of amino acids 3000 to 3700 is critical for the binding of apo-B100 to the LDL receptor (Fig. 34-8). Selective chemical modification of the apo-B100 of LDL demonstrated that the positively charged (basic) amino acids arginine and lysine are important in the interaction of LDL with its receptor. When apo-B100 was sequenced, several regions enriched in arginines and lysines became candidates for receptor binding. It is now apparent that the basic residues in the region of amino acids 3359 to 3369 are critical for receptor binding. However, it is also clear that the carboxyl-terminal region of apo-B100 in the vicinity of amino acid 3500 can modulate receptor-binding activity. Patients expressing apo-B48 have hypercholesterolemia and high LDL levels. This genetic disorder, familial defective apo-B100 (see later discussion), is caused by the substitution of glutamine for arginine at amino acid 3500.

Role of Apolipoprotein B in Lipid Metabolism

Apo-B100 and apo-B48 play critical roles in the biosynthesis of apo-B-containing lipoproteins (for a review, see references 51 and 57). In addition, the apo-B100 in VLDL interacts with the LDL receptor. Although it is also a constituent of VLDL and IDL, apo-B100 does not play a major role in the binding of these lipoproteins to LDL receptors. Apo-E is responsible for most of the receptor-mediated clearance of VLDL and IDL; presumably, the lipid or apolipoprotein content of the VLDL and IDL masks or alters the conformation of the receptor-binding domain of the apo-B100 on these particles. Apo-B100 is, however, the major (or exclusive) protein moiety of LDL and is responsible for directing the clearance of these lipoproteins through the LDL receptor pathway.
Overexpression of apo-B in transgenic mice increases the levels of LDL and other apo-B-containing lipoproteins, resulting in increased susceptibility to diet-induced atherosclerosis. Knockout

**Apolipoprotein E**

Apo-E mediates the interaction of apo-E-containing lipoproteins with the LDL receptor and with the chylomicron remnant (apo-E) receptor, presumably the LDL receptor-related protein (LRP). As a consequence, apo-E plays a critical role in determining the metabolic fate of several classes of lipoproteins and is of central importance in cholesterol metabolism. In addition, apo-E appears to participate in cholesterol transport to cells undergoing proliferation and repair and may modulate lymphocyte response and smooth muscle cell proliferation (see references 77 and 78). Apo-E, a 34-kDa protein composed of 299 amino acids, circulates in the plasma both as a constituent of chylomicrons, chylomicron remnants, VLDL, and LDL and as a component of a minor subclass of high-density lipoproteins (HDLs), referred to as HDL with apo-E or HDL-E (see Fig. 34-8). Normal plasma apo-E levels range from 30 to 70 µg/mL, approximately half of which is associated with HDL and serves as a reservoir of apo-E for redistribution to chylomicrons and VLDLs as they enter the plasma. In lymph and interstitial fluid, apo-E is associated with lipid complexes (phospholipid-apo-E discs) or with HDL.

Approximately 75% of plasma apo-E is synthesized by hepatocytes, and the remainder is synthesized in a variety of tissues. Macrophages can synthesize and secrete the protein, especially when they are loaded with cholesterol, and are responsible for a portion of the apo-E found in interstitial fluid. Smooth muscle cells of arteries and keratinocytes in the skin also synthesize apo-E (see Table 34-3). The tissue with the second highest level of apo-E mRNA (after the liver) is the brain, where apo-E is synthesized primarily by astrocytes. Cerebrospinal fluid contains apo-E derived from the brain (approximately 0.3 mg/dL, or 5% to 10% of plasma apo-E levels). Apo-E appears to play a key role in cholesterol transport in both the central and peripheral nervous systems and may be involved in the pathogenesis of Alzheimer's disease (for a review, see references 77 and 78).

The apo-E gene is located on chromosome 19 and is part of a gene cluster that includes the genes for apo-CI and apo-CII. The apo-E gene locus has multiple alleles, and the three major forms of apo-E—apo-E2, apo-E3, and apo-E4—are encoded by three different alleles, referred to as epsilon2, epsilon3, and epsilon4, that occur in several populations with a frequency of about 8%, 77%, and 15%, respectively (see Fig. 34-9). There are three homoyzous (E2/2, E3/3, and E4/4) and three heterozygous (E3/2, E4/2, and E4/3) phenotypes. About 60% of individuals are homozygous for apo-E3.

These genetic polymorphisms are caused by amino acid differences at two sites in the protein (see Fig. 34-9). Apo-E3 has cysteine at position 112 and arginine at position 158, whereas apo-E2 has cysteine at both positions and apo-E4 has arginine. In addition, apo-E displays a second type of polymorphism, post-translational glycosylation. Carbohydrate attachment at threonine-194 and the presence of multiple sialic acid residues give rise to minor acidic isoforms.

Apo-E functions in both receptor binding and lipid binding, and the different isoforms have different activities. Apo-E3 and apo-E4 are equally capable of interacting with LDL receptors, but the binding of apo-E2 to LDL receptors is impaired and is associated with the development of type III hyperlipoproteinemia under certain conditions. Apo-E isoforms also interact differently with specific types of lipids and lipoproteins. Apo-E binds preferentially to large, triglyceride-rich lipoproteins (e.g., VLDL), whereas apo-E3 and apo-E2 bind preferentially to smaller, phospholipid-rich HDL.

The apo-E primary translational product is a 317-amino-acid protein; an 18-amino-acid signal peptide is cleaved before the mature protein (299 amino acids, relative molecular mass 32,000).
34 kDa) is secreted into plasma. The molecule has two domains (Fig. 34-10). The amino-terminal domain (residues 1 to 191) contains the receptor-binding region, and the carboxyl-terminal domain (residues 192 to 299) appears to have three amphipathic alpha helices (one face being hydrophilic and the other hydrophobic) and is responsible for lipid binding. Residues 242 to 272 are key in the binding of apo-E to lipoproteins. Paradoxically, the lipid-binding region of apo-E resides in the carboxyl-terminal domain, but the amino acid differences that distinguish the three major apo-E isoforms are in the amino-terminal domain (residues 112 and 158). The fact that the isoforms display different specificities for different types of lipoproteins (i.e., apo-E4 for VLDL and apo-E3 and apo-E2 for HDL) suggests that the amino-terminal and carboxyl-terminal domains interact so that specific residues in the amino terminus alter the conformation and specificity of the lipid-binding domain in the carboxyl terminus for certain types of lipoproteins (for a more complete discussion, see references 23 and 24).

The amino acids of apo-E that mediate its binding to the LDL receptor are in the vicinity of residues 134 to 160 (Fig. 34-11). Positively charged arginines and lysines between amino acids 136 and 150 may interact with the negatively charged glutamyl and aspartyl acids in the ligand-binding region of the LDL receptor. As shown by x-ray crystallography, the amino-terminal domain of apo-E (residues 1 to 191) forms a four-helix bundle (Fig. 34-12). The fourth helix encompasses residues 130 to 165, the area envisioned to contain the receptor-binding region. The basic residues in the vicinity of amino acids 134 to 150 are oriented away from the surface of the molecule and are probably involved in the direct interaction of apo-E with the LDL receptor. 25 26

The identification of naturally occurring defects of apo-E that are defective in receptor binding has provided key insights into the specific residues involved (see Fig. 34-11). The most common variant that is defective in binding is apo-E2 (Arg-158 Cys). This substitution appears to impair receptor binding secondarily by altering the conformation of residues in the 136 to 150 region of apo-E. Other variants that are defective in binding involve single amino acid substitutions: Arg-136 Ser, Arg-142 Cys, Arg-145 Cys, and Lys-146 Gln or Glu. Site-directed mutagenesis showed that Arg-150 also plays a key role in receptor binding. A rare apo-E mutation, apo-E Leiden, involves a duplication of seven amino acids (residues 121 to 127) inserted in tandem at the junction between helices 3 and 4. This insertion probably disrupts receptor binding by altering the conformation of the 136 to 150 receptor-binding region.

Apo-E also binds to heparin and to heparan sulfate proteoglycans (HSPGs). As discussed later, binding of apo-E to HSPG is important in the clearance of remnant lipoproteins by the LDL pathway. Residues in the 136 to 150 region of apo-E are responsible for the ionic interaction with the sulfate groups of heparin-like molecules and for binding to the LRP.

Apolipoprotein E in Lipid Metabolism

Apo-E functions in two aspects of lipid and cholesterol transport. The first, involving chylomicron and VLDL metabolism, provides a global transport role for apo-E. The knockout of apo-E by gene targeting in mice results in marked hyperlipidemia and the development of severe atherosclerosis, confirming the importance of this protein in cholesterol homeostasis and lipid transport. The second aspect involves the redistribution of lipids (including cholesterol) among cells within a tissue or organ. This local transport role redistributes lipids from cells with excess cholesterol to those requiring cholesterol, phospholipids, and other lipids for repair, proliferation, or other purposes. This pathway may involve lipid-laden HDL and apo-E that can acquire tissue lipids or apo-ElpId complexes formed in the interstitial fluid. As stated previously, apo-E is synthesized and secreted by a variety of cells and is available in interstitial fluid to transport lipids. Cells requiring cholesterol up-regulate their LDL receptors, and apo-E targets the apo-E-containing HDL or lipid complexes to cells deficient in necessary lipids. For example, the local transport pathway for apo-E is involved in lipid redistribution within a liver after injury and during regeneration.

Apolipoprotein A-I

Apo-A-I is a 29-kDa protein encoded by a gene on the long arm of chromosome 11, part of a cluster that includes genes for apo-CII and apo-AIV. The apo-A-I gene is 1863 base pairs in length, and its mRNA encodes a 267-amino-acid protein that includes an 18-amino-acid prepeptide and a 6-amino-acid prepeptide. The prepeptide is cleaved extracellularly to yield the mature circulating form of 243 amino acids (Table 34-3).

Apo-A-I is synthesized by the human intestine and liver and is a constituent of chylomicrons and HDL. It binds to lipids of these lipoproteins, mainly through a series of 22-amino-acid amphipathic alpha helices separated by helix-breaking proline residues. The polar face of the amphipathic helix is exposed to the aqueous environment, whereas the nonpolar face binds to the lipid (primarily phospholipids) on the surface of the particle. There are eight complete 22-amino-acid amphipathic helices and two 11-amino-acid repeats in apo-A-I.

In addition to its role as a structural protein in HDL, apo-A-I activates lecinthin:cholesterol acyltransferase (LCAT), which esterifies free cholesterol on HDL particles. It may facilitate the interaction of LCAT with phosphatidylcholine, the substrate of LCAT, and activate the enzyme. The specific regions of apo-A-I involved in LCAT activation have been identified, including the amino acids responsible for catalytic activity. Other apolipoproteins, such as apo-AIV and apo-CI, which have similar lipid-binding properties, can also activate LCAT (discussed in detail in a later section).

Apolipoprotein A-II

Apolipoprotein A-II is a 34-kDa protein encoded by a gene on the long arm of chromosome 1. The mRNA encodes a 100-amino-acid protein, but the mature circulating form of apo-A-II is 77 amino acids in length. In the plasma, human apo-A-II exists primarily as a homodimer. A cysteine at residue 6 of apo-A-II forms a disulfide bond with a second apo-A-II molecule. Heterodimers of apo-A-I and apo-E occur only in persons with apo-E2 and apo-E3, which possess free cysteine residues. Heterodimer formation interferes with the function of the individual proteins.
with the ability of apo-E to bind to the LDL receptor.

Apo-AII is synthesized primarily in the liver. It is found together with apo-AI on a subfraction of HDL referred to as LpAI/AII particles. Apo-AII may play a role in the activation of hepatic lipase and the inhibition of LCAT. The genetic absence of apo-AII in two sisters did not produce any obvious phenotypic effects and did not cause low HDL levels.

Overexpression of apo-AII in mice leads to an increased susceptibility to atherosclerosis, possibly because apo-AII displaces apo-AI from HDL. This could interfere with the normal ability of apo-AI-containing HDL to transport cellular cholesterol to the liver for excretion. Therefore, apo-AII is considered a proatherogenic apolipoprotein.

C Apolipoproteins

The genes for apo-CI and apo-CII reside on chromosome 19 near the gene that encodes apo-E, whereas the apo-CIII gene is part of the apo-AI and apo-AIV gene cluster on chromosome 11 (for a review, see references 8 and 45). The C apolipoproteins (see Table 34-3 and Fig. 34-6) readily exchange among various lipoproteins and are synthesized primarily by the liver. (Apo-CI is also produced by macrophages and, in small amounts, by the intestine.) HDLs appear to serve as a reservoir for the C apolipoproteins, which can then be transferred to triglyceride-rich lipoproteins. The C apolipoproteins appear to regulate triglyceride metabolism and to influence the inverse relation between triglyceride levels and HDL cholesterol (HDL-C). Apo-CI (6.6 kDa) modulates the uptake of triglyceride-rich lipoprotein (chylomicron remnants, VLDL, and IDL) by interfering with the ability of apo-E to mediate binding to lipoprotein receptor pathways. Similarly, apo-CIII (8.8 kDa) may prevent the normal interaction of triglyceride-rich, apo-E-containing lipoproteins with receptors and cell-surface HSPG. Apo-CI and apo-CIII may displace apo-E from the particles. Apo-CII (8.9 kDa) is a cofactor for LPL, and mutations in the apo-CII gene result in a marked hypertriglyceridemia (discussed later).

Overexpression of apo-CI, apo-CII, or apo-CIII in transgenic mice results in hypertriglyceridemia (for a review, see references 45 and 110). In the case of apo-CI and apo-CIII, the resulting hyperlipidemia appears to be caused by displacement of apo-E from triglyceride-rich particles, which results in impaired receptor-mediated uptake, displacement of apo-CII, and impaired lipolytic processing. A polymorphism of the apo-CIII gene promoter region in mice is also associated with increased levels of apo-CIII and hypertriglyceridemia.

The hypertriglyceridemia that follows the overexpression of apo-CII was initially puzzling because apo-CII is a cofactor that activates LPL-mediated hydrolysis of triglycerides. However, the triglyceride-rich lipoproteins that accumulate in the plasma are poor in apo-E and do not interact well enough with cell-surface HSPG to allow lipase activity to occur or with receptors in the proteoglycan-rich matrices of the cell surface to allow uptake. Therefore, either overproduction or underproduction of apo-CII can cause hypertriglyceridemia.
Lipoprotein Receptors Controlling Lipoprotein Metabolism

Low-Density Lipoprotein Receptor Gene Family

Mammalian members of this gene family, in addition to the LDL receptor itself, include the LRP, the glycoprotein 330 (gp330)/megalin receptor, the VLDL receptor, and the apo-E receptor. Non-mammalian members include the chicken vitellogenin receptor, a Caenorhabditis elegans receptor, and the Y1 protein in the fruit fly Drosophila melanogaster. These receptors share common structural motifs, including a single transmembrane domain, a short cytoplasmic tail, and an extracellular ligand-binding domain that contains various numbers of cysteine-rich repeats of approximately 40 amino acids each. It has become apparent that the functions of this gene family extend far beyond mediating lipid uptake by cells and include serving as transducers of extracellular signals involved in normal brain development.

Low-Density Lipoprotein Receptor

The LDL receptor, a glycoprotein with an apparent molecular weight of 160,000, is expressed on the surface of most cells and especially in liver. It functions in the uptake of apo-B and apo-E-containing lipoproteins, including LDL, chylomicron remnants, VLDL, VLDL remnants, IDL, and HDL. Most HDL particles lack apo-E and do not interact with the LDL receptor. Cells can acquire cholesterol from the plasma by taking up these lipoproteins through the LDL receptor. The LDL receptor gene was first identified in 1973, and its gene was characterized in 1985 in the laboratory of Nobel laureates Joseph L. Goldstein and Michael S. Brown. Two proteins on the lipoprotein surface, apo-B100 and apo-E, bind to the LDL receptor, which for this reason is sometimes referred to as the apo-B100/apo-E receptor.

After the lipoprotein binds to the LDL receptor, the resulting complex becomes localized to a specialized area of the cell membrane called a coated pit. The “coat” contains a protein complex called clathrin, which clusters the receptors in a region of the cell membrane that can invaginate and form an intracellular vesicle to contain the lipoprotein. As these internalized vesicles, or endosomes, move into the cytoplasm, the internal environment becomes progressively more acidic, causing the receptor and the lipoprotein to dissociate. The lipoproteins are degraded in the lysosomes, and the unoccupied receptors recycle to the cell surface.

The LDL receptor is synthesized in the ER as a protein of 839 amino acids with an apparent molecular weight of 120,000. Glycosylation of the protein in the ER and in the Golgi apparatus increases its weight to about 160,000. The LDL receptor has five distinct structural and functional domains. Mutations within these domains disrupt the normal function of the receptor in lipoprotein metabolism and cause the genetic disorder familial hypercholesterolemia (FH).

Ligand-Binding Domain

The ligand-binding domain of the LDL receptor consists of the 292 amino acids at the amino terminus. This region of the molecule is rich in cysteines and contains glutamic and aspartic acids that mediate the binding to apo-B and apo-E. It is composed of seven repeats of approximately 40 amino acids each. Each repeat contains six cysteines that form three intrarepeat disulfide bonds, resulting in a very stable structure. In addition, each repeat contains a Ser-Asp-Glu triple that mediates the interaction of apo-B and apo-E-containing lipoproteins with the LDL receptor. The ligand-receptor binding is an ionic interaction between positively charged arginines and lysines in apo-B100 and apo-E and negatively charged aspartic and glutamic acids in the ligand-binding domain of the LDL receptor.

Site-directed mutagenesis and analysis of naturally occurring mutants of the LDL receptor associated with FH have provided insights into the roles of specific repeats and residues in ligand binding. Ligand-binding domain repeat 1 does not play a major role in the binding of either apo-B-containing (LDL) or apo-E-containing (VLDL) lipoproteins. The deletion of repeats 2 through 7, however, markedly impairs the binding of LDL. The binding of -VLDL is mediated by apo-E and is impaired only if repeat 5 is deleted. Therefore, the requirements for the binding of LDL are more stringent than those for the binding of -VLDL.

Single amino acid substitutions of critical residues in the ligand-binding repeats also impair binding activity. For example, in patients with FH Puerto Rico, in which the second of the ligand-binding triplet (Ser-Asp-Glu) in repeat 4 is changed to a leucine, the LDL fails to bind, although apo-E-containing -VLDL binds with near-normal affinity. In FH Heterozygote, in which lysine is substituted for the glutamic acid of the ligand-binding triplet of repeat 5, neither LDL nor -VLDL binds normally.

The defect in the Watanabe heritable hyperlipidemic (WHHL) rabbit with hypercholesterolemia and accelerated atherosclerosis involves a deletion of four amino acids in repeat 4. Although this defect is associated with a reduced number of receptors reaching the cell surface, those that do reach the surface retain the ability to bind -VLDL (apo-E) but not LDL (apo-B).

As demonstrated in the WHHL rabbit, mutations in the ligand-binding domain can also disrupt the normal transport of the LDL receptor to the cell surface. The decreased transport of the receptor from the ER to the Golgi apparatus and to the cell surface is undoubtedly caused by improper folding of the molecule and increased intracellular degradation. For example, FH Afrikaner, which is caused by the presence of a glutamic acid rather than aspartic acid in the triplet of repeat 5, results in defective transport and lack of normal expression of the receptor on the cell surface.

Epidermal Growth Factor Precursor Homology Domain

This region is composed of 400 amino acids and is about 33% identical to the sequence of the human EGF precursor. It contains three cysteine-rich repeats (A, B, and C), each approximately 40 amino acids in length. The repeats are not homologous to the 40-amino-acid repeats of the ligand-binding domain but...
are related to the EGF. Repeat A is involved in the binding of LDL, and its deletion markedly inhibits LDL binding (-VLDL binding is retained). The EGF precursor domain also plays a role in allowing the LDL receptor or receptors to dissociate from the lipoproteins and recycle to the cell surface. Detection of the EGF precursor homology domain allows normal binding and internalization of -VLDL but prevents dissociation of the ligand and receptor. As a result, receptors do not recycle to the cell surface. The role of the EGF precursor domain was established by site-directed mutagenesis studies, and FH Osaka was subsequently found to have the same deletion.

**O-Linked Sugar Domain**

This domain is composed of 58 amino acids, primarily serines and threonines, many of which are sites for the attachment of O-linked carbohydrate chains. No functional role for this domain has been described, and its deletion has no functional consequences.

**Membrane-Spanning Domain**

The 22 amino acids in this domain are hydrophobic and serve to anchor the receptor within the plasma membrane. Truncation mutations that exclude this region are characteristic by secretion of the receptor from the cell so that lipoproteins are not internalized.

**Cytoplasmic Domain**

The carboxyl-terminal region of the LDL receptor is composed of 50 amino acids and contains the sequence NPXY (N, asparagine; P, proline; X, any amino acid; Y, tyrosine), which is responsible for clustering the receptors in coated pits and mediating internalization of the receptors by the cells. One of the early mutations associated with FH (J.D. allele, FH Ban) provided insights into the role of a critical residue for directing internalization. In the mutant form of the receptor, tyrosine-807 is changed to a cysteine. Site-directed mutagenesis demonstrated that this position must be occupied by an aromatic amino acid (tyrosine, phenylalanine, or tryptophan) for normal internalization. The tetrameric sequence Asn-Pro-Val-Tyr, in which tyrosine-807 occurs, is the signal directing the receptors to the coated pit.

**Regulation of the Low-Density Lipoprotein Receptor Gene**

The LDL receptor gene is 45 kilobases in length and is located on the distal portion of the short arm of chromosome 19. Synthesis of the LDL receptor is regulated by deoxyribonucleic acid (DNA) sequences in the 5'-flanking region of the LDL receptor gene. A sequence of approximately 10 bases in this region, called the sterol regulatory element (SRE), and two other repeats that bind the transcription factor Sp1 are necessary for the regulation of the LDL receptor mRNA levels. If intracellular sterol levels are high, LDL receptor mRNA is not transcribed. When the sterol content of the cells decreases, the expression of LDL receptors on the cell surface increases, causing increased uptake of apo-B-100-containing lipoproteins and increased delivery of cholesterol to the cells. The LDL receptor gene "senses" the sterol level of the cell and appropriately controls receptor mRNA production and protein biosynthesis to meet the needs of the cell.

The control mechanism of LDL receptor expression has been elucidated in considerable detail. Currently, there are three structurally related transcription factors, SRE-binding proteins (SREBPs) 1α, 1c, and 2, which regulate the level of LDL receptors and other genes encoding enzymes involved in the biosynthesis of cholesterol, unsaturated fatty acids, and triglycerides. SREBP-1a and SREBP-1c arise from the same gene but use different promoters and have different first introns; SREBP-2 arises from a separate gene. The intact 125-kDa SREBPs are three-domain integral membrane proteins containing two membrane-spanning regions. The amino-terminal domain of SREBPs represents transcription factors of the loop-helix leucine zipper family and contains sequences that recognize the SREs on the genes that they control.

To become active transcription factors, the intact SREBPs must be cleaved in the correct order by two proteases in a post-ER compartment and then translocated to the nucleus to interact with the SREs. The first protease, designated site-1 protease (S1P), cleaves the loop connecting the amino-terminal and carboxyl-terminal domains, both of which remain membrane bound after cleavage. The second protease, site-2 protease (S2P), further cleaves the amino-terminal domain just within the first membrane-spanning region, releasing the transcription factor to enter the nucleus and interact with the SREs. Sterol control is exerted through a two-domain regulatory protein, SREBP cleavage activating protein (SCAP), that is required for S1P cleavage of the SREBP. SCAP is membrane associated (eight transmembrane regions) and is tightly complexed to the SREBPs through its carboxyl-terminal domain. Five of the eight membrane-spanning segments serve as a sterol-sensing domain. It is not clear whether the sensing domain interacts directly or indirectly with sterols. What is known is that sterols regulate the ability of SCAP to transport SREBPs to the post-ER compartment where S1P is located. SCAP cycles between the ER and Golgi apparatus, and whether SCAP transports the SREBPs to the S1P compartment is dependent on the processing of its N-linked carbohydrates by the Golgi apparatus. In sterol-depleted cells, SCAP cycles to the Golgi apparatus and its N-linked carbohydrates are modified; the modified SCAP returns to the ER to transport the SREBPs. Sterol blocks the movement of SCAP from the ER to the Golgi apparatus, preventing carbohydrate modification and the ability of SCAP to transport the SREBPs for S1P cleavage.

**Low-Density Lipoprotein Receptor-Related Protein**

The LRP is an integral membrane receptor composed of two components: a 515-kDa amino-terminal extracellular domain and an 85-kDa cytoplasmic and membrane-spanning domain (the precursor protein, composed of 4525 amino acids, is cleaved after synthesis). This large protein is equivalent structurally to approximately four LDL receptors and possesses 31 ligand-binding domains. The LRP contains the four structural motifs characteristic of other members of the LDL receptor gene family: multiple ligand-binding repeats, EGF repeats and EGF precursor homology domains, a single membrane-spanning region, and two NPXY internalization signals. The LRP is expressed primarily in liver (parenchymal cells), brain (neurons), and placenta (syncytiotrophoblast cells).

The LRP interacts with approximately 18 ligands and has several functions. With respect to lipoprotein metabolism, the LRP binds with high affinity to apo-E-rich chylomicron remnants and VLDL remnants and internalizes them. Interaction of these lipoproteins with the LRP requires the addition of multiple apo-E molecules per particle, which serves as ligands. Initial binding of the lipoprotein to cell-surface HSGLP is necessary to facilitate the interaction or transfer of the apo-E-rich remnants to the LRP (discussed further in "Chylomicron Remnant Receptors in Remnant Catabolism"). The LRP does not bind LDL.

The LRP can also interact with LPL and hepatic lipase. This interaction could mediate the hepatic binding and uptake of remnant lipoproteins possessing these enzymes on their surface. Other ligands for the LRP that are not directly related to lipid metabolism include 2-macroglobulin, plasminogen activators and inhibitors, and bacterial toxins. Knockout of the LRP in mice is lethal, demonstrating its critical importance, but the reason for the lethality remains to be elucidated.

A receptor-associated protein (RAP) of 39 kDa can be isolated along with purified LRP and effectively competes with all the ligands for the LRP binding. This protein also binds to the gp330 and VLDL receptors (described later) and blocks ligand binding to these receptors as well. However, RAP does not appear to be secreted from the cells, and it may serve as an intracellular chaperone that occupies the ligand-binding sites for transport of the LRP to the cell surface. The knockout...
of RAP by gene targeting in mice markedly reduces the expression of LRP in both liver and brain, further suggesting an intracellular transport role for this protein. Alternatively, it may participate in the intracellular recycling of the receptors. Regardless of its physiologic role, RAP inhibits the interaction of LRP and its ligands both in cultured cells and in intact animals.

Glycoprotein 330

The gp330/megalin receptor, also referred to as the major Heymann nephritis antigen, is a large protein (about 600 kDa) that possesses many of the structural motifs of the LDL receptor. It is expressed in the proximal tubules of the kidney and the ependymal cells in the brain and is not present in liver. Although gp330 binds apo-E containing lipoproteins and LDL, its role in lipoprotein metabolism is unknown. The knockout of gp330 by gene targeting does not have an obvious effect on lipoprotein metabolism, but it causes developmental abnormalities of the central nervous system (holoprosencephaly).

Very-Low-Density Lipoprotein Receptor

The VLDL receptor closely resembles the LDL receptor except that it has an eighth ligand-binding repeat. The VLDL receptor (about 130 kDa) binds apo-E containing lipoproteins and is present primarily in muscle, fat, and brain. In the nervous system, it is present in the choroid plexus and in some neurons. It is absent from liver, and its role in lipoprotein metabolism remains to be determined. It has been suggested, because the receptor is present in tissues that metabolize VLDL-derived fatty acids, that it may function to deliver triglyceride-rich lipoproteins to target tissues.

Apolipoprotein E Receptor 2

The apo-E receptor 2 (106 kDa) is the newest member of the LDL receptor family to be described; it is expressed primarily in the brain and to a lesser extent in the placenta and can be expressed as various splice variants. Although this receptor, like the LDL receptor, contains seven cysteine-rich repeats in the ligand-binding domain, the repeats are more closely related structurally to the VLDL receptor. Because the receptor is primarily expressed in the brain, it is likely to play a role in lipoprotein metabolism in the central nervous system. In addition to its roles in lipoprotein metabolism, the apo-E receptor 2 and the VLDL receptor have been implicated in normal brain development by transducing extracellular signals.

Scavenger Receptors

Originally, it was thought that a single scavenger receptor existed on macrophages. Also known as the acetyl-LDL receptor, this receptor was characterized by its ability to interact with chemically modified LDL but not with native LDL. LDL particles that had been modified by acetylation, acetoacetylation, or malondialdehyde were taken up by high-affinity cell-surface receptors on macrophages, resulting in marked cholesterol accumulation. As a result of cloning efforts, it became apparent that the scavenger receptor actually represented a large family of receptors with specificities for a broad range of unrelated ligands and involvement in a spectrum of physiologic processes, including atherosclerosis, host defense, and central nervous system disorders.

Currently, there are five subclasses (A to E) of the scavenger receptor family. Class A receptors include types I, II, and III and MARCO. The type I and type II receptors are generated by alternative splicing of the mRNA encoded by a gene on chromosome 8. The predicted structure is that of a trimer (220 kDa) composed of three identical subunits (each about 77 kDa). The type I receptor contains six domains: a cytoplasmic, amino-terminal domain (50 amino acids); a transmembrane domain (26 amino acids); a spacer (74 amino acids); an alpha-helical coiled-coil domain (121 amino acids); a collagen-like domain (72 amino acids with a Gly-X-Tyr repeat); and a cysteine-rich domain (110 amino acids). The type II scavenger receptor is identical to the type I receptor except that it lacks the carboxyl-terminal cysteine-rich domain; its collagen-like domain is responsible for ligand binding. Clusters of positively charged residues (lysines) appear to mediate the interaction with the chemically modified lipoproteins (see section on the LDL receptor and oxidized lipids for a discussion of the role of the scavenger receptor in atherogenesis). In addition to binding acetylated LDL, class A scavenger receptors bind anionic proteins, polynucleotides, and bacterial endotoxins (lipopolysaccharides). Their main function appears to involve the clearance of microbial pathogens, senescent cells, and altered lipoproteins.

Class B scavenger receptors include CD36 and murine SR-BI (human homologue CLA-1). These receptors possess two membrane-spanning regions and bind both oxidized and native lipoproteins. CD36 is expressed on the surface of platelets, capillary endothelial cells, adipose cells, circulating monocytes, and other cell types. The role of the SR-BI as a receptor for HDL and its involvement in reverse cholesterol transport are discussed in the section "Transport Facilitated by a Cell-Surface Binding Protein." CD36 is also implicated in platelet adhesion and aggregation, phagocytosis of apoptotic cells, and clearance of Plasmodium falciparum-infected cells for a review, see reference 112).

Class C is represented by a single member, SR-C from D. melanogaster. It contains domains that are homologous to the vertebrate complement control protein and a mucin-like domain. Class D and E scavenger receptors are also represented by single members, Lox-1 and endothelial scavenger receptor, respectively. Lox-1 is characterized by a C-type lectin structure and the endothelial scavenger receptor by multiple EGF repeats. Regardless of the class, all scavenger receptors share the common property of binding oxidized or modified LDLs, or both.
Enzymes and Transfer Proteins Involved in Lipid and Lipoprotein Metabolism

Lipoprotein Lipase

Human LPL is a protein composed of 448 amino acids (approximately 50 kDa). It is synthesized by adipocytes, by myocytes in skeletal and cardiac muscle, and by macrophages but is not produced by hepatocytes. After secretion from adipocytes and myocytes, LPL is transported to the surface of capillary endothelial cells of these tissues, where it attaches to HSPG and interacts with chylomicrons and VLDL in the circulation and mediates the hydrolysis of their triglycerides to release free fatty acids for use by the tissues. The fatty acids are stored as triglyceride in adipocytes and used as a source of energy in muscle and for triglyceride synthesis in the formation of hepatic VLDL.

The active form of LPL is a dimer. Although its crystal structure is not known, LPL has a high degree of homology with another serine esterase, pancreatic lipase, whose structure is known. Based on similarities between LPL and pancreatic lipase, a model for LPL function has been suggested (Fig. 34-16), and five functional domains have been identified in LPL on the basis of structural and mutational studies.

Contrasting Lipoprotein Lipase and Hepatic Lipase

"Metabolic Pathways Involving High-Density Lipoproteins."

Hepatic Lipase

Hepatic lipase has several roles in lipoprotein metabolism. First, it hydrolyzes triglycerides and possibly excess surface phospholipids in the final processing of chylomicron remnants. As suggested, this enzyme may be active in the space of Disse. It binds heparan sulfate and facilitates the interaction of remnant lipoproteins with the LRP, thereby delivering these lipoproteins to the receptor for internalization by hepatocytes. Second, it completes the processing of IDL to LDL (discussed in the section on IDL). Third, it participates in the conversion of HDL to HDL₂ by the removal of triglyceride and phospholipid from HDL₁ (discussed in "Metabolic Pathways Involving High-Density Lipoproteins"). High levels of hepatic lipase activity decrease total HDL levels.

LPL requires apo-C-II as a cofactor to stimulate its catalytic activity, but apo-C-II is not a cofactor for hepatic lipase. In contrast, apo-E may facilitate both triglyceride binding and uptake of lipoproteins associated with the enzyme.

Heparin-Binding Site

The heparin-binding site mediates the interaction of LPL with HSPG on endothelial cells. Clusters of positively charged arginines and lysines on one face of LPL, particularly those in the carboxyl terminus, appear to mediate this interaction.

Lipid-Binding Site

The domain of the protein that allows the enzyme to interact with the surface of the chylomicron lies in the carboxyl terminus, particularly around residues 245 to 253.

Apolipoprotein CII-binding Site

Apo-C-II, an essential cofactor for LPL, binds to the carboxyl terminus at a site that has not been identified precisely.

Catalytic Site

This site mediates the hydrolysis of triglycerides, primarily to fatty acids and monoglyceride, and is postulated to involve serine-132, aspartic acid-156, and histidine-241, which are at the bottom of a hydrophobic channel that is covered by a flap or catalytic lid. The lid may mediate the interaction with the lipid substrate by assuming an open or closed conformation. LPL is a serine esterase with triglyceride hydrolase activity and, to a lesser extent, phospholipase activity.

LRP-Binding Site

The LRP-binding site is distinct from the heparin-binding site and involves the carboxyl-terminal domain. Through its interaction with the LRP, LPL can facilitate the binding and uptake of lipoproteins associated with the enzyme.

LPL is synthesized by adipocytes and is present primarily on liver endothelial cells and on HSPG in the space of Disse. Hepatic lipase is transported from the liver to the capillary endothelium of the adrenals, ovaries, and testes, where it functions in the release of lipids from lipoproteins for use in these organs. Its activity is increased by androgens and reduced by estrogens. Little is known about the structural domains of hepatic lipase except by analogy to similar domains within LPL, but the catalytic triad includes serine-145, aspartic acid-171, and histidine-256.

Hepatic lipase has several roles in lipoprotein metabolism. First, it hydrolyzes triglycerides and possibly excess surface phospholipids in the final processing of chylomicron remnants. As suggested, this enzyme may be active in the space of Disse. It binds heparan sulfate and facilitates the interaction of remnant lipoproteins with the LRP, thereby delivering these lipoproteins to the receptor for internalization by hepatocytes. Second, it completes the processing of IDL to LDL (discussed in the section on IDL). Third, it participates in the conversion of HDL to HDL₂ by the removal of triglyceride and phospholipid from HDL₁ (discussed in "Metabolic Pathways Involving High-Density Lipoproteins"). High levels of hepatic lipase activity decrease total HDL levels.

Contrasting Lipoprotein Lipase and Hepatic Lipase

LPL requires apo-C-II as a cofactor to stimulate its catalytic activity, but apo-C-II is not a cofactor for hepatic lipase. In contrast, apo-E may facilitate both triglyceride binding and phospholipid hydrolysis by hepatic lipase and may be a cofactor for its enzymatic activity. In other respects, the enzymes are similar. After intravenous injection of heparin, both enzymes are released from endothelial cells of the liver and peripheral tissues and are referred to as postheparin lipase. Therefore, measurements of total plasma lipolytic activity after heparin injection reflect the activities of both enzymes.

Mutations that impair or inactivate LPL cause hypertriglyceridemia (discussed later). Likewise, deficiency of apo-C-II prevents normal activation of LPL and also causes hypochondylidemia. Hepatic lipase deficiencies result in a variable and diverse pattern of lipoprotein changes, including the accumulation of remnant lipoproteins, IDL, and LDL. These changes are predictable on the basis of the functional roles of hepatic lipase. Knockout of the LPL gene in mice causes a particularly severe hypertriglyceridemia that becomes evident as soon as the newborns begin to suckle and causes death within the first 24 hours. On the other hand, knockout of the hepatic lipase gene causes less severe manifestations, including changes in HDL and increased plasma phospholipid levels. In the mouse, LPL may take on some of the functions subserved by hepatic lipase in other species. Overexpression of human hepatic lipase in transgenic mice markedly decreases HDL and IDL.

Lecithin:Cholesterol Acyltransferase

LCAT circulates in association with HDL in the plasma and functions to esterify free cholesterol. In humans, most of the cholesteryl esters in plasma lipoproteins are formed by the action of LCAT. The major substrate for LCAT is the small HDL particle; to a lesser extent, LDL is also a substrate. The enzyme catalyzes the transfer of long-chain fatty acids from phosphatidylcholine (linoleic acid at position 2 of lecithin preferred) to the hydroxyl group at position 3 on cholesterol. The
structure and function of LCAT are discussed more thoroughly in the context of HDL metabolism.

Cholesteryl Ester Transfer Protein

The cholesteryl ester transfer protein (CETP) transfers cholesteryl esters from the larger HDL to VLDL, IDL, and remnant lipoproteins. In return, triglyceride from these lipoproteins is transferred to HDL. LCAT and CETP function in concert in HDL metabolism, and the structure and function of CETP are discussed further in the section on HDL.
PLASMA LIPOPROTEINS: STRUCTURE, FUNCTION, AND METABOLISM

Chylomicrons

Characteristics

Chylomicrons (density [d] < 0.95 g/mL) are the largest of the plasma lipoproteins (> 1000 Å in diameter) and readily float after ultracentrifugation of plasma. They are composed of 98% to 99% lipid (85% to 90% triglyceride) and 1% to 2% protein (see Table 34.4). Chylomicrons are present in post-prandial plasma (but absent after an overnight fast) and contain several apolipoproteins, including apo-B48, apo-Al, apo-AIV, apo-E, and the C apolipoproteins (see Fig. 34-6). The distinctive apolipoprotein is apo-B48, a form of apo-B that has an apparent molecular mass 48% that of apo-B100. Because it is the only form of apo-B synthesized by the intestine, apo-B48 is a marker for human lipoproteins produced by the intestinal epithelium.

Origin

Chylomicrons are produced by the epithelial cells of the small intestine (duodenum and proximal jejunum) when dietary fat and cholesterol are presented to the brush border of the epithelial cell membranes as bile acid micelles. Free fatty acids and monoglycerides taken up by the intestinal epithelial cells are synthesized into triglycerides in the ER in the apical region of the intestinal cells. Triglycerides, phospholipids, and cholesterol (absorbed or synthesized by the intestinal cells) are used for chylomicron formation in the Golgi apparatus, where some of the apolipoproteins undergo final carbohydrate processing, and the chylomicrons are secreted into the space along the lateral borders of the intestinal cells. From there, they enter the mesenteric lymph and proceed through the thoracic duct lymph to the general circulation. Newly synthesized chylomicrons possess apo-B48, apo-Al, and apo-AIV (intestinally synthesized apolipoproteins); they acquire apo-E and C apolipoproteins in the lymph and blood, primarily from HDL.

Metabolic Fate

In the circulation, LPL catalyzes the release of free fatty acids from chylomicron triglycerides and converts them into triglyceride-poor, cholesterol-enriched chylomicron remnants (Fig. 34-17). The free fatty acids are taken up by various tissues to be stored as triglyceride, oxidized as an energy source, or reutilized in hepatic lipoprotein triglyceride synthesis. Hepatic lipase, acting primarily as a phospholipase and secondarily as a glyceride hydrolase, also plays a role in the final preparation of chylomicron remnants for uptake by hepatocytes. Chylomicron remnants are cleared rapidly from the plasma by the liver.

Sequestration of chylomicron remnants within the space of Disse (see Fig. 34-18) appears to involve binding of the remnant lipoproteins to HSPG mediated by apo-E (or possibly LPL or hepatic lipase). The microvilli-covered surface of hepatocytes is coated with HSPG, which is abundant in the space of Disse. HSPGs bind apo-B48 by an ionic interaction between negatively charged sulfate groups of HSPG and basic amino acids within the 136 to 150 region of apo-E. The absence of proteoglycans on the cell surface impairs uptake of the particles. Apo-E secreted by the hepatocytes appears to be bound to the cell-surface HSPG and further enhances the apo-E-mediated binding of remnant lipoproteins.

Chylomicron remnants may be further processed by lipases or other enzymes in the space of Disse. LPL is carried into the space of Disse on chylomicron remnants, and hepatic lipase produced by the liver may be localized there. These lipases facilitate the binding and uptake of remnants by interacting with the LRP.

The actual uptake of the particles by hepatocytes may involve two or more receptors (see Fig. 34-18), the LDL receptor, which interacts with lipoproteins containing apo-B100 and apo-E, and possibly a unique apo-E or chylomicron remnant receptor, now known to be the LRP.

Whereas remnant particles with LPL or hepatic lipase on their surfaces may interact by means of these molecules with the HSPG in the space of Disse and facilitate binding and uptake by the LRP, apo-E mediates interactions with HSPG and the LRP or the LDL receptor are critical in remnant metabolism. Patients with apo-E mutations that prevent interaction with HSPG or lipoprotein receptors develop hyperlipidemia characterized by remnant lipoprotein accumulation despite having normal lipase activity. In addition, knockout of apo-E by gene targeting in mice causes a massive accumulation of remnant lipoproteins.
or chylomicron remnants in patients with absent or defective LDL receptors could reflect the fact that remnant clearance requires several steps, as described. For example, sequestration of the particles in the space of Disse (HSPG binding) is normal in patients with defective LDL receptors and could prevent the accumulation of remnants in plasma. Furthermore, the HSPG/LRP pathway can compensate for deficiency of LDL receptors. Both receptors probably function in the uptake of the remnants, and in the absence of one the other continues to function.

### Chylomicron Remnant Receptors in Remnant Catabolism

Evidence suggests that the LRP is the chylomicron remnant (apo-E) receptor, which belongs to the LDL receptor gene family (discussed previously). As noted earlier, the LRP binds with high affinity to apo-E-enriched lipoproteins but does not bind LDL to a significant extent. Apo-E must be added to remnant lipoproteins before they bind to the LRP with high affinity. Apo-E exists in the space of Disse in high concentration, probably because it is secreted by hepatocytes and binds to HSPG in the space of Disse. The HSPG may serve as a reservoir for apo-E, allowing enrichment of the remnants with this apolipoprotein. These and other observations have led to the hypothesis that apo-E functions in a process called secretion-capture. It is envisioned that apo-E combines with lipids or lipoproteins and directs them to cells expressing LDL receptors or the LRP. In the liver, the LRP and apo-E could interact in this way to capture chylomicron remnants. The LRP is also present in other tissues, including brain, and may function locally in the uptake of lipids. The secretion-capture role of apo-E functions in peripheral nerve injury and repair and in the normal maintenance of neurons.

As already stated, LRP-mediated uptake of remnants requires the initial interaction of apo-E-containing lipoproteins with cell-surface HSPG. HSPGs are hydrolyzed by treating cells with heparinase in vitro or by infusing heparinase into the portal vein of mice, apo-E-rich remnants do not bind to the cell surface and do not interact with the LRP even though the receptor is present. After the lipoproteins interact with HSPG, the remnants may be transferred to the LRP for internalization by the cells, or the HSPG/LRP complex may be internalized. This two-step process involving cell-surface proteoglycans and receptors is referred to as the HSPG/LRP pathway, a similar two-step process has also been described for growth factors. It is also possible that HSPG alone can mediate remnant uptake directly without the LRP.

The LRP interacts not only with apo-E-containing lipoproteins but also with an unrelated protein, 2-macroglobulin, a broad-spectrum endopeptidase inhibitor that is involved in clearing of proteases from the plasma by the liver. The binding of protease activates 2-macroglobulin, which then binds to the LRP. Activated 2-macroglobulin competes with remnants for binding to the LRP. Radiolabeled chylomicron remnants are rapidly cleared from the plasma of mice, but the injection of 2-macroglobulin along with the chylomicron remnant impairs remnant clearance. This finding indicates that 2-macroglobulin and the remnants are binding to the same receptor, the LRP.

Herz and colleagues demonstrated that the LRP is the chylomicron remnant (apo-E) receptor and documented its importance in remnant catabolism. These studies used RAP, which blocks the interaction of all ligands with the LRP, to demonstrate the role of the LRP in remnant clearance in mice. Knockout of RAP in mice results in a loss of LRP expression in the liver. Double-knockout mice, in which both RAP and the LDL receptor are missing, develop hyperlipidemia characterized by the accumulation of remnant lipoproteins in the plasma.

In summary, the catabolism of chylomicron remnants involves several steps and several components: sequestration, further lipolytic processing, and receptor-mediated endocytosis utilizing both the LDL receptor pathway and the HSPG/LRP pathway.
Very-Low-Density Lipoproteins

Characteristics
VLDLs are particles 300 to 700 Å in diameter that float on ultracentrifugation at a density of less than 1.006 g/mL (see Table 34-4). They are composed of 85% to 90% lipid (about 55% triglyceride, 20% cholesterol, and 15% phospholipid) and 10% to 15% protein. The distinctive apolipoprotein is apo-B100, the hepatic form of apo-B. VLDLs also contain apo-E and C apolipoproteins (see Fig. 34-8). VLDLs have pre- or pre-electrophoretic mobility and were previously called pre-lipoproteins.

Origin
VLDLs are synthesized by the liver, and their production is stimulated by increased delivery of free fatty acids to the hepatocytes, either from a high intake of dietary fat or from the mobilization of fatty acids from adipose tissue with fasting or uncontrolled diabetes mellitus. Triglycerides and phospholipids to be used in the formation of VLDL are synthesized in the liver, whereas VLDL cholesterol can be synthesized de novo or remobilized from LDL cholesterol (LDL-C). The VLDL particles are first visible at the junction of the rough ER and the smooth ER (transitional elements) before they enter the Golgi apparatus. Several of the apolipoproteins undergo carbohydrate processing within the Golgi apparatus. Large Golgi secretory vesicles migrate to the brush border surface of the hepatocytes, fuse with the plasma membrane, and release the VLDL particles into the space of Disse, where they enter the plasma (Fig. 34-20). The major protein constituents of the newly synthesized VLDLs are apo-B100, apo-E, and small amounts of the C apolipoproteins. In plasma, VLDLs acquire additional C apolipoproteins and apo-E, primarily from HDL.

Control of Very-Low-Density Lipoprotein Secretion Rate
The quantity of VLDL secreted from the liver is not controlled by changes in apo-B100 mRNA levels. Apo-B100 is constitutively expressed and is not highly variable. Newly synthesized apo-B100 is subject to two fates: (1) It can be combined with lipid to form VLDL particles, or (2) it can be degraded, in which case a VLDL particle is not secreted. If there is a stimulus for VLDL production, such as the delivery of free fatty acids to the liver, the balance is shifted away from apo-B100 degradation to the formation and secretion of apo-B100 containing VLDL.

Biosynthesis of Very-Low-Density Lipoproteins
Newly synthesized apo-B100 is translocated across the rough ER membrane. If not sufficiently lipidated as it is translocated, apo-B100 is destined to be degraded. If sufficient lipid is available, the apo-B100 binds the lipid as it enters the ER and forms triglyceride-rich particles. These particles can increase in size, enter the secretory pathway, and exit from the cell as mature VLDLs (see Fig. 34-20). MTP, phospholipid transfer protein (PLTP), and additional triglyceride, cholesterol, and phospholipid may be added as the VLDL precursor passes through the lumen of the rough ER. At the junction of the rough and smooth ER, lipid-rich particles lacking apo-B have been identified in rat liver, and these particles may fuse with the apo-B containing VLDL precursors to form the mature particle. However, because rat liver synthesizes both apo-B100 and apo-B48 containing VLDLs, the fusion step may apply only to apo-B48 VLDL and may be more relevant to apo-B48 containing chylomicron synthesis by the intestine.

Microsomal Triglyceride Transfer Protein
MTP is produced in the liver at sites where apo-B100 containing VLDLs are synthesized and in the intestine at sites where apo-B48 containing chylomicrons are synthesized. MTP (97 kDa) occurs as a heterodimer complex with the 58-kDa protein disulfide isomerase, an association required for MTP activity. Protein disulfide isomerase reshuffles disulfide bonds of cysteine residues and therefore may play a role in altering the conformation of apo-B for lipidation. In addition to transferring triglycerides to these lipoprotein particles, MTP transfers cholesterol esters and phospholipids.

More than a dozen mutations of MTP interfere with its activity. Defective MTP is responsible for the lipid disorder abetalipoproteinemia, a condition in which patients essentially lack apo-B containing lipoproteinemia in plasma. Therefore, MTP is critical for the biosynthesis of both apo-B100 VLDLs in the liver and apo-B48 chylomicrons in the intestine.

The luminal surfaces of the hepatocytes express LDL receptors and the LRP, and VLDLs possess both apo-B100 and apo-E that can react with these receptors. How then do VLDLs traverse the space of Disse and enter the blood? First, lipids such as phosphatidylethanolamine on the surface of the newly secreted VLDLs may alter the reactivity of the lipoproteins with the receptors. Newly secreted VLDLs are rich in phosphatidylethanolamine, but VLDLs in the circulation are poor in phosphatidylethanolamine. This phospholipid may prevent the particle from interacting with the receptors (i.e., specific lipids may mask the receptor-binding domains of apo-B100 and apo-E).

Second, other apolipoproteins may mask the receptor-binding domains of the VLDL apo-B100 and apo-E. Although they are present in small amounts on newly secreted VLDLs, the C apolipoproteins may alter the conformation or availability of apolipoproteins that interact with lipidoprotein receptors. Specifically, when VLDLs are formed in the liver and acquire apo-E, the C apolipoproteins may be positioned so as to mask the apo-E and thereby block its ability to react with the receptor or with proteoglycans in the space of Disse. Alternatively, apo-E associated with the particles intracellularly may not be available to bind to the receptors; only newly acquired apo-E obtained from HDL may have the appropriate conformation for receptor binding.

Metabolic Fate
VLDL triglycerides are hydrolyzed by the actions of LPL and hepatic lipase. They are converted to smaller and smaller particles that become increasingly rich in cholesterol (see Fig. 34-17). The products of VLDL catabolism are IDLs (d = 1.006 to 1.019 g/mL). IDLs retain apo-B100 and apo-E but have lost most of the C apolipoproteins. IDLs are processed to LDLs (d = 1.019 to 1.063 g/mL) by LDL with final processing by hepatic lipase. Approximately half of VLDLs are converted to LDLs, and the remainder are cleared directly by the liver as VLDL remnants (small VLDL) and IDLs (see Fig. 34-17). The uptake of VLDL remnants and IDLs by liver parenchymal cells is mediated by apo-E, and the uptake of LDL by the LDL receptor is mediated by apo-B100.
Intermediate-Density Lipoproteins

IDLs (d = 1.006 to 1.019 g/mL) are normally present in low concentrations in the plasma and are intermediate in size and composition between VLDL and LDL. Their primary proteins are apo-B100 and apo-E. The IDLs are precursors of LDLs and represent metabolic products of VLDL catabolism in the plasma by the action of lipases. As shown in Figure 34-17, IDLs may be further processed by hepatic lipase or removed from the plasma by the LDL receptor. IDLs are often considered to be VLDL remnants and to be atherogenic.
Low-Density Lipoproteins

Characteristics

LDLs (\(a = 1.019\) to 1.063 g/mL), which are about 200 Å in diameter, are the major cholesterol-carrying lipoproteins in the plasma; about 70% of total plasma cholesterol is in LDL. LDLs are composed of approximately 75% lipid (about 35% cholesteryl ester, 10% free cholesterol, 10% triglyceride, and 20% phospholipid) and 25% protein (see Table 34-4). Apo-B100 is the principal protein in these particles, along with trace amounts of apo-E (see Fig. 34-6). LDLs have -electrophoretic mobility and were previously referred to as lipoproteins.

Origin

LDLs are the end products of lipase-mediated hydrolysis of VLDLs (see Fig. 34-17). Moreover, as the triglyceride-rich core of the larger VLDL particles is removed, the surface lipids and proteins are remodeled and excess surface constituents are transferred to HDL, resulting in the formation of a small, cholesterol-rich LDL devoid of almost all apolipoproteins except apo-B100.

Metabolic Fate

About 75% of LDL is taken up by hepatocytes. Other tissues take up smaller amounts of LDL. Approximately two thirds of the uptake is mediated by the LDL receptor, and the remainder is mediated by a poorly defined process that does not involve receptors. LDLs are considered to be atherogenic.

Apolipoproteins B and E Determine Rate of Plasma Lipoprotein Clearance

The rate of clearance of lipoproteins from the plasma is determined by the apolipoprotein that mediates the interaction with the receptor and by the number of receptors expressed on the cell surface (primarily in the liver). VLDL and IDL are rapidly cleared from the plasma (their half-lives are measured in minutes to a few hours). Apo-E mediates their binding to the LDL receptors. Multiple apo-E molecules per lipoprotein can interact with more than one receptor or with multiple sites on a receptor. Multiple interactions enhance binding affinity and increase the clearance of these particles from the plasma. The clearance of LDL is mediated by apo-B100. The affinity of apo-B100 for the LDL receptor is lower than that of apo-E, and clearance of LDL is much slower (with a half-life of 2 to 3 days). Compared with apo-B100-containing LDLs, apo-E-containing lipoproteins have 20-fold greater affinity for the LDL receptor.

Role for Lipoprotein Cholesterol in Cellular Metabolism

All cells can synthesize cholesterol de novo. However, LDL serves as a source of cholesterol for many cells. Cholesterol taken up by the liver has several fates: membrane biosynthesis, VLDL biosynthesis, excretion as cholesterol in the bile, and conversion to bile acids. Cholesterol is used as a precursor for steroid hormone production in the adrenals, ovaries, and testes. In other peripheral tissues, cholesterol is used in membrane biosynthesis for cell repair and proliferation.

Factors Affecting Low-Density Lipoprotein Levels in the Blood

Plasma LDL levels can be increased through two primary mechanisms: (1) increased VLDL biosynthesis and secretion caused by increased flux of free fatty acids to the liver from dietary fats or from mobilization from adipose tissue and (2) decreased LDL catabolism. Decreased catabolism can result from (1) decreased LDL receptor levels in hepatic and extrahepatic tissues (LDL receptor expression is down-regulated when cells have enough cholesterol for their metabolic needs or when diets are high in saturated fat and cholesterol), (2) increased numbers of high-affinity apo-E-containing lipoproteins that compete with LDL for receptor interaction (as discussed previously), (3) defective LDL receptors incapable of normal interaction with apo-B100, and (4) defective apo-B100 incapable of normal interaction with LDL receptors.
High-Density Lipoproteins

Characteristics

HDLs are small particles (70 to 120 Å in diameter) that float at densities of 1.063 to 1.21 g/mL. They are somewhat arbitrarily divided into two major subclasses: HDL2 (d = 1.063 to 1.125 g/mL) and HDL3 (d = 1.125 to 1.21 g/mL). HDLs contain about 50% lipid (25% phospholipid, 15% cholesteryl ester, 5% free cholesterol, and 5% triglyceride) and 50% protein (see Table 34-4). Their major apolipoproteins are apo-AI (65%), apo-AII (25%), and smaller amounts of the C apolipoproteins and apo-E (see Fig. 34-4). Apo-E is a minor component of a subclass of HDL referred to as HDL-E, but about 50% of total plasma apo-E is in this HDL fraction. The major classes of HDLs lack apo-E and therefore do not interact with the LDL receptor. HDLs serve as a reservoir for apo-E and the C apolipoproteins to be distributed to other lipoproteins when they enter the plasma (e.g., chylomicrons, VLDLs). Subclasses of HDL may contain only apo-AI (called LpAI) or apo-AI and apo-AII (called LpAII). Although LpAI and LpAII do not correspond directly to the ultracentrifugal fractions, LpAI corresponds primarily to HDL3 and LpAII to HDL2. The HDLs as a class have -electrophoretic mobility and were previously referred to as lipoproteins.

Origin

HDLs originate from three major sources (Fig. 34-21). First, the liver secretes an apo-AI-phospholipid disc called nascent or precursor HDL. Second, the intestine directly synthesizes a small apo-AI-containing HDL particle. Third, HDLs are derived from surface material (primarily apo-AI and phospholipid) that comes from chylomicrons and VLDLs during lipolysis. As chylomicrons and VLDLs become depleted of cholesterol and triglyceride, excess material is shed from the surface of the particle in combination with apo-AI to form small HDL discs. The phospholipid transfer protein facilitates the shedding of the surface material during lipolysis of triglyceride-rich lipoproteins to generate the HDL precursors.

Maturation of High-Density Lipoproteins

The nascent or precursor HDL particles exist as apo-AI-phospholipid discs. Designated pre-1, pre-2, and pre-3, these discs are excellent acceptors of free cholesterol from cell membranes with excess cholesterol or from other lipoproteins. The pre-phospholipid discs can accommodate only a limited amount of free cholesterol. However, esterification of the cholesterol with a long-chain fatty acid increases its hydrophobicity, and the newly formed cholesteryl ester moves away from the surface of the disc, beginning the process of forming a cholesteryl ester-rich core and converting the disc to a sphere. The enzyme in plasma that converts free cholesterol to cholesteryl ester is LCAT.

The small, spherical, mature HDL particles (HDL3) also serve as acceptors for free cholesterol; as more free cholesterol is acquired and esterified, the particles increase in size, forming HDL2. These HDL subclasses can include LpAI, or they can be converted to LpAII particles by the addition of apo-AI.

In some animals and to a lesser extent in humans, HDL4 can be further enriched in cholesteryl ester and at the same time acquire apo-E (Fig. 34-22). These apo-E-containing HDL4 are a minor but metabolically active subclass of HDL. The presence of apo-E targets the HDL4 to cells expressing the LDL receptor. Typical HDLs lack apo-E and do not interact with the LDL receptor. The HDL4 represent a major HDL class in many lower species and in humans with abetalipoproteinemia or CETP deficiency.

HDL4 can also arise from a precursor particle that displays -electrophoretic mobility and is called LpE. This particle is approximately 80% protein and 20% lipid (primarily sphingomyelin).

Acquisition of Cholesterol by High-Density Lipoproteins

HDLs, especially HDL3, precursors of mature HDL, and lipid-poor apo-AI, can acquire cholesterol from cells by two mechanisms: aqueous transfer from cells and transport facilitated by a cell-surface binding protein.

Aqueous Transfer from Cells

The HDLs come in close contact with cells having excess cholesterol and acquire free cholesterol (not cholesteryl ester) from the cell surface. Free cholesterol follows a physicochemical concentration gradient from the cell to the HDL particle, from a high concentration of free cholesterol in the membranes of cells with excess cholesterol to a low concentration at the surface of the HDL. This process is referred to as passive desorption.

Transport Facilitated by a Cell-Surface Binding Protein

At least two cell-surface proteins facilitate the efflux of free cholesterol from cells possessing excess cholesterol. The class B, type I scavenger receptor (SR-BI) binds HDL particles to the cell surface. This receptor may alter the organization of the cell membrane lipids facilitating the efflux of free cholesterol from the membrane to the lipoprotein. The HDLs are not internalized by the cell and are released into the circulation when the particle is enriched in cholesterol. The second receptor that participates in the efflux of cholesterol from cells is the ATP binding cassette transporter A1 (ABCA1). It appears to bind apo-AI or a pre-HDL disc to the cell membrane and facilitate the transfer of free cholesterol and phospholipid from the cell to enrich the HDL precursors in these lipids. Mutations in ABCA1 prevent the efflux of cholesterol from cells, resulting in absence of mature HDL and rapid catabolism of apo-AI and causing the lipid disorder called Tangier disease.
HDLs function in the redistribution of lipids among lipoproteins and cells by a process called reverse cholesterol transport. In exchange for the function of cholesterol esters to the liver, HDLs acquire cholesterol from cells and transport it to the liver for excretion or to other cells that require cholesterol. The scheme is shown in Figure 34-22.

The mechanism for the transfer of the fatty acid to cholesterol has not been well defined. LCAT has two different enzymatic activities. First, lecithin cleavage (phospholipase activity) involves the ester bond of the fatty acid in position 2 of lecithin, which is usually linoleic acid (C18:2), yielding lyssolecithin and the fatty acid. The fatty acid becomes covalently linked to serine-181 in the LCAT molecule. Second, transesterification (transacylase activity) involves the transfer of the fatty acid attached to LCAT to the 3-hydroxyl position of cholesterol, forming a cholesteryl ester. The mechanism for the transfer of the fatty acid to cholesterol has not been well defined.

Much has been learned about the normal function of HDL in lipoprotein metabolism by studying patients who have low or undetectable activity of this enzyme in plasma. HDL deficiency can be caused by mutations that affect the structure of LCAT or of apo-AI. The disorder is manifested by low levels of cholesterol esters, low levels of HDL, and clinical features ranging from mild symptoms such as corneal clouding (caused by accumulation of free cholesterol in the cornea) to severe disorders such as renal failure (see "Lecithin:Cholesterol Acyltransferase Deficiency").

**Metabolic Pathways Involving High-Density Lipoproteins**

HDLs function in the redistribution of lipids among lipoproteins and cells by a process called reverse cholesterol transport. In exchange for the function of cholesterol esters to the liver, HDLs acquire cholesterol from cells and transport it to the liver for excretion or to other cells that require cholesterol. The scheme is shown in Figure 34-22. HDLs acquire cholesterol from cells and transport it to the liver for excretion or to other cells that require cholesterol. The scheme is shown in Figure 34-22.

The channels appear to represent flaps of cell-surface membrane that form a 150- to 250-Å-wide cleft in which the lipoproteins are trapped at least transiently. Within these channels, cholesterol ester and free cholesterol can be extracted from HDLs without the lipoprotein particle entering the cell or being degraded. The SR-BI can facilitate the transfer of cholesteryl esters from HDLs to cells without the lipoprotein particle entering the cell or being degraded. The SR-BI appears to function by transferring cholesteryl ester through a hydrophilic channel formed in the cell membrane. Hepatic lipase may be involved in the selective uptake of cholesterol from the HDL by hydrolyzing the phospholipids on the particles and creating a chemical gradient that promotes the transfer of cholesterol from the particle to the cell. Recall that hepatic lipase is localized in the space of Disse of the liver and in the adrenal glands and ovaries. In the kidneys, apo-AI is removed in preference to cholesterol; this apo-AI may be dissociated from the HDL particle, filtered, and degraded. Ultimately, intact HDL can be taken up by hepatocytes and degraded. Although HDL, represents a small fraction of total HDL, it is taken up directly by LDL receptors and degraded in the liver through the LDL pathway.

The catabolism of HDL is not entirely understood. Specific lipid moieties of HDL can be taken up by cells without removal of the intact particle from the plasma compartment. For example, cholesterol esters are removed from the particle by selective uptake and preferentially delivered to the liver, adrenal glands, and gonads. The SR-BI can facilitate the transfer of cholesteryl esters from HDLs to cells without the lipoprotein particle entering the cell or being degraded. The SR-BI appears to function by transferring cholesteryl ester through a hydrophilic channel formed in the cell membrane. Hepatic lipase may be involved in the selective uptake of cholesterol from the HDL by hydrolyzing the phospholipids on the particles and creating a chemical gradient that promotes the transfer of cholesterol from the particle to the cell. Recall that hepatic lipase is localized in the space of Disse of the liver and in the adrenal glands and ovaries. In the kidneys, apo-AI is removed in preference to cholesterol; this apo-AI may be dissociated from the HDL particle, filtered, and degraded. Ultimately, intact HDL can be taken up by hepatocytes and degraded. Although HDL, represents a small fraction of total HDL, it is taken up directly by LDL receptors and degraded in the liver through the LDL pathway.

**Selective Uptake of Cholesterol by Steroidogenic Cells**

HDL is more efficient than LDL in delivering cholesterol to steroidogenic cells of the adrenal, ovary, and testis. In these organs, the lipoproteins concentrate on the surface of cells in micellar structures. The channels appear to represent flaps of cell-surface membrane that form a 150- to 250-Å-wide cleft in which the lipoproteins are trapped at least transiently. Within these channels, cholesterol ester and free cholesterol can be extracted from HDLs without the lipoprotein particle entering the cell or being degraded. The SR-BI appears to function by transferring cholesteryl ester through a hydrophilic channel formed in the cell membrane. Hepatic lipase may be involved in the selective uptake of cholesterol from the HDL by hydrolyzing the phospholipids on the particles and creating a chemical gradient that promotes the transfer of cholesterol from the particle to the cell. Recall that hepatic lipase is localized in the space of Disse of the liver and in the adrenal glands and ovaries. In the kidneys, apo-AI is removed in preference to cholesterol; this apo-AI may be dissociated from the HDL particle, filtered, and degraded. Ultimately, intact HDL can be taken up by hepatocytes and degraded. Although HDL, represents a small fraction of total HDL, it is taken up directly by LDL receptors and degraded in the liver through the LDL pathway.

**Cholesteryl Ester Transfer Protein**

CETP facilitates the transfer of cholesteryl esters from HDL to the lower density, triglyceride-rich lipoproteins (primarily VLDL, IDL, and remnants). CETP plays a pivotal role in lipid metabolism and may affect susceptibility or resistance to the development of atherosclerosis. For example, humans, nonhuman primates, and rabbits have significant amounts of CETP activity in their plasma. As a consequence, they form only small amounts of HDL,; they dispose of most of their HDL cholesterol esters by delivering them to lower density lipoproteins. Ultimately, most of the cholesteryl esters leave the plasma by the LDL pathway. These species are susceptible to atherosclerosis and tend to have higher levels of LDL. On the other hand, rats, mice, and dogs have no CETP activity, readily form HDL, and can deliver the cholesterol directly to the liver by the apo-E-mediated pathway. These animals have very low levels of LDL and are resistant to the development of atherosclerosis. These observations suggest that high levels of CETP activity accelerate atherosclerosis and that inhibition of CETP may be beneficial in treating certain types of hyperlipidemia.

However, this concept has been brought into question by the observation that Japanese Americans with a deficiency of CETP have increased HDL but nevertheless develop CHD. The HDL in these subjects tends to be the large HDL, and levels of the smaller HDL, are decreased. If these data concerning the atherogenicity of low CETP activity are confirmed, it may mean that low levels of HDL, which serves as the most potent acceptor of cellular cholesterol, are a major risk factor for...
CHD in these subjects; alternatively, high levels of the large apo-E-containing HDL may be atherogenic.

Data obtained through overexpression of CETP in transgenic mice do not clarify whether high levels are protective or detrimental. In one study, overexpression of CETP led to accelerated atherogenesis, but in a study in which CETP was overexpressed in hypertriglyceridemic mice expressing high levels of apo-CIII, there was less atherosclerosis even though the mice were hyperlipidemic and had low HDL levels. The potential therapeutic value of lowering CETP to retard atherogenesis must be questioned until these inconsistencies are sorted out.

High-Density Lipoproteins as Antiatherogenic Lipoproteins

Numerous studies have demonstrated that high levels of HDL-C are associated with a lower incidence of CHD. Conversely, low levels of HDL-C are associated with a higher incidence of CHD. The protective mechanism involving HDL may be related to its role in reverse cholesterol transport, which results in redistribution of cholesterol away from the artery wall. Although low HDL-C is a major CHD risk factor, it must be kept in mind that the HDLs are a heterogeneous group of molecules having different metabolic roles. Some may be protective (e.g., LpAI, HDL₂), and others may not be (e.g., LpAI/AII). As the complex nature of HDL is unraveled, it may be possible to define an antiatherogenic spectrum of HDL particles and determine the metabolic and therapeutic measures needed to alter these HDLs selectively.
LIPIDS AND ATHEROSCLEROSIS

Atherosclerosis causes a reduction of blood flow and insufficient delivery of oxygen and nutrients to affected organs. Insufficient oxygen results in ischemia or infarction, leading to angina or myocardial infarction in the case of restricted blood flow to the heart muscle, to stroke with reduced blood flow to the brain, or to intermittent claudication with restricted blood flow to the lower extremities. CHD is the leading cause of death in the United States and in western Europe.

The restricted arterial blood flow in atherosclerosis is caused by changes in the vessel wall characterized by lipid deposition and cell proliferation. Narrowing of the vessel lumen may lead to obstruction and, more important, to unstable plaques susceptible to ulceration or fissure formation causing thrombosis. The deposited lipids are derived from plasma lipoproteins, and elevated plasma cholesterol represents a major risk factor. Other important risk factors include low HDL levels, cigarette smoking, hypertension, male sex, diabetes mellitus, obesity, stress, and lack of exercise. The discussion here focuses on plasma lipoproteins and the cholesterol-diet-heart hypothesis.

Cholesterol-Diet-Heart Hypothesis

For the last 40 years, evidence linking high plasma cholesterol concentrations with an increased risk for CHD has been accumulating, and the evidence is now overwhelming and indisputable. The cholesterol-diet-heart hypothesis states (1) that increased plasma cholesterol concentrations increase the risk of CHD, (2) that diets high in fat (especially saturated fat) and cholesterol result in increased levels of plasma cholesterol, and (3) that lowering plasma cholesterol levels results in a decreased risk of CHD.

Animal Models

Numerous animal models have demonstrated that diets enriched in cholesterol and saturated fat elevate plasma cholesterol levels and lead to atherosclerosis with many features of the human disease.

Studies in monkeys are particularly relevant. Feeding monkeys a diet that approximates the typical Western diet (500 mg cholesterol per day and 20% of calories as saturated fat) resulted in elevation of plasma LDL concentrations and atherosclerotic lesions almost identical to those seen in humans. Eliminating the saturated fat and cholesterol from the diet reduced LDL levels and caused lesions to regress. In addition to elevations in LDL concentrations, cholesterol-fat feeding in animals caused accumulation of VLDL. These cholesterol-enriched remnant lipoproteins are derived from lipoproteins secreted by the intestine and liver and also accumulate in type III hyperlipoproteinemia (discussed later). Single-gene mutations in animals have also demonstrated the link between hypercholesterolemia and atherosclerosis. The WHHL rabbit is a model of FH in which the deposited cholesterol from LDL is increased in the vessel walls and the aorta of these animals develops severe spontaneous atherosclerosis, even when fed a low-fat diet.

Epidemiologic Evidence

Several epidemiologic studies have demonstrated a relation between the plasma cholesterol level and the risk of CHD. For example, the Multiple Risk Factor Intervention Trial (Fig. 34-23) showed that there is increased risk at levels above 5.2 mmol/L (200 mg/dL). The Seven Countries Study also demonstrated a relation between an increased incidence of CHD and high plasma cholesterol levels (Fig. 34-24). The causal relationship between elevated plasma cholesterol levels and accelerated atherosclerosis is established. Epidemiologic studies have linked the intake of high levels of dietary fat, especially saturated fats, with increased plasma cholesterol levels. Likewise, diets high in cholesterol also tend to increase plasma cholesterol levels. Therefore, restriction of saturated fat and cholesterol is the cornerstone of dietary therapy to reduce elevated blood cholesterol levels.

Familial Hypercholesterolemia

Some of the most compelling evidence for the deleterious effects of elevated plasma cholesterol has come from studies of FH. This genetic disorder results from a series of mutations in the LDL receptor that cause LDL to accumulate in the plasma as a result of defective clearance of LDL by the receptors. These studies conclusively demonstrate that increased plasma concentrations of LDL cause atherosclerosis.

Experimental Evidence in Humans

Final compelling evidence supporting the cholesterol-diet-heart hypothesis came from several human clinical trials examining the efficacy of several lipid-lowering drugs in reducing CHD (reviewed in the section on treatment of lipid disorders, clinical trials). In all groups examined, including patients with and without preexisting
CHD over a range of initial plasma cholesterol levels, the results unequivocally demonstrated that lowering plasma cholesterol levels reduces the risk of CHD.

In summary, the current evidence overwhelmingly supports the cholesterol-diet-heart hypothesis and upholds the conclusion of the Cholesterol Consensus Conference on Lowering Blood Cholesterol to Prevent Coronary Heart Disease organized by the National Heart, Lung, and Blood Institute that the cause-and-effect relation between cholesterol and CHD is clearly established.
Atherogenic Lipoproteins

In addition to LDL, almost all classes of lipoproteins that contain apo-B (VLDL, -VLDL, IDL, Lp(a), and oxidized LDL) are considered to be atherogenic. A common feature of these atherogenic lipoproteins is that they contain various amounts of cholesterol esters and either apo-B-100 or apo-B-48. In addition, Lp(a) contains apo(a), a protein that is disulfide-linked to apo-B and is homologous to plasminogen; apo(a) may contribute to atherogenesis by mechanisms related to thrombosis. Furthermore, the atherogenic potential of LDL differs among the various LDL size and density subclasses, with the small, dense LDL subclass being the most atherogenic.

Apo-B-containing remnant lipoproteins appear to be especially atherogenic because -VLDLs, which accumulate in the plasma of cholesterol-fed animals and in patients with type III hyperlipoproteinemia, are associated with accelerated formation of atherosclerotic lesions. These particles, representing chylomicron remnants and VLDL remnants (IDL), are taken up by macrophages, including, presumably, macrophages in the artery wall, in a nonsaturable manner. This uptake results in massive intracellular accumulation of cholesteryl esters in the form of lipid droplets. The lipid-engorged macrophages resemble the foam cells of the early fatty streak (discussed subsequently).

Another related class of potentially atherogenic apo-B-containing lipoproteins is triglyceride-rich lipoproteins, which are associated with postprandial lipemia after ingestion of a fatty meal. Whereas chylomicrons and large, triglyceride-rich VLDLs are not believed to be atherogenic, remnants derived from these particles are.

The Low-Density Lipoprotein Paradox and Oxidized Lipids

Because LDL-C levels are a strong predictor of CHD and atherosclerosis, it was expected that LDL would be taken up avidly by macrophages, leading to the formation of foam cells. However, in vitro experiments showed that only low levels of normal plasma LDL are taken up by macrophages. This low uptake presumably occurred because of the highly regulated LDL receptor pathway; the delivery of LDL-C to macrophages down-regulates LDL receptor expression, thereby protecting the cells from overaccumulation of LDL-C. These results led to the so-called LDL paradox: How do LDLs contribute to atherosclerosis if only limited quantities are taken up by macrophages? The explanation turned out to be that LDLs that have been modified are taken up by macrophages in an unregulated manner through receptors unrelated to the LDL receptor. These receptors for modified LDL were originally referred to as acetyl-LDL receptors but are now commonly referred to as scavenger receptors (discussed in "Scavenger Receptors").

In vitro experiments have demonstrated that a number of chemical modifications, including acetylation, acetoacetylation, and reaction with malondialdehyde, circumvent the LDL receptor pathway and cause massive amounts of modified LDL to enter macrophages by means of scavenger receptors. Furthermore, macrophages can alter LDL so that these particles can be taken up by macrophages in an unregulated manner. Other cells, including smooth muscle cells, can also modify LDL.

The physiologically important LDL modification probably involves oxidation and results in lipid peroxidation. The oxidized-LDL hypothesis proposes that unsaturated lipids on the particle undergo oxidative modification, which subsequently leads to oxidation of apo-B, which alters the protein's affinity for cell-surface receptors. As a corollary, antioxidant vitamins (such as A, C, and E), drugs (such as probucol), and enzymes (such as paraoxonase) may limit these oxidative processes. It appears that production of reactive oxygen species (i.e., free radicals) is an integral part of the modification and may be related to the general aging process, in which lipid peroxidation may be a component. Two products of lipid peroxidation, 4-hydroxynonenal and malondialdehyde, modify amino acids of apo-B100, resulting in its fragmentation. Modification is inhibited by antioxidants. Phospholipase and lipoxigenases have also been implicated in LDL modification. In addition to macrophage uptake, oxidized LDLs may participate directly in atherogenesis because they are cytotoxic and may serve as chemoattractants for circulating monocyte-macrophages and are immunogenic.

The role of oxidized LDL as a major contributor to atherosclerosis remains to be proved in vivo. However, what appear to be oxidatively modified forms of LDL have been identified in atherosclerotic lesions and inflammatory fluid. Also, epitopes of malondialdehyde- and 4-hydroxynonenal-modified apo-B100 have been observed in lesions. Furthermore, the formation of oxidized LDL, which may contribute to atherogenesis in a number of ways, is an attractive solution to the LDL paradox.

The most probable mechanism by which oxidized or modified LDLs are taken up by macrophages is by one or more of the scavenger receptors (see "Scavenger Receptors"). The roles of the various scavenger receptors and their relative importance in atherogenesis are still being clarified (for a review, see reference ). However, the receptor whose primary function is to take up oxidized or modified LDL within the artery wall and to contribute to the development and progression of atherosclerosis may well remain to be identified.
Overview of Atherogenesis

Until the last several years, two theories of atherogenesis prevailed. The first, referred to initially as the lipid infiltration hypothesis, proposed that excess blood lipids in the form of lipoproteins infiltrate into the arterial wall. This theory was supported by epidemiologic evidence and the identification of atherogenic lipoproteins. The second theory was the endothelial injury hypothesis, which proposed that injury to the endothelial surface is required and results in removal of these cells, exposing a thrombogenic surface to which platelets adhere. Platelet adherence was suggested to result in the release of platelet-derived growth factor, which would stimulate the smooth muscle cell proliferation and migration that are characteristic of early lesion formation. Endothelial denudation would also remove the endothelial barrier, allowing lipoproteins to enter the vessel wall more readily. The current view of atherosclerosis development combines features of both hypotheses. However, loss of endothelial cells is not required for an atherosclerotic lesion to develop, and atherogenic lipoproteins can and do penetrate intact endothelium to enter the artery wall.

A unifying modification of this general view of atherogenesis is the response-to-retention hypothesis. According to this view, one key event in atherosclerosis is the retention of atherogenic, cholesterol-rich lipoproteins bound to arterial proteoglycans in the arterial subendothelium. Oxidation and other modifications of the retained lipoproteins could initiate a series of responses that lead to the transformation of healthy, normal arteries into diseased, lesioned arteries. An important component of the artery wall involved in the retention is chondroitin 6-sulfate proteoglycans, which are known to bind LDL. Although oxidation may be a major fate of the retained lipoproteins, it is not the only possibility. Nonpancreatic secretory phospholipase A₂ has been proposed to generate proinflammatory modified lipid components from aggregated but nonoxidized lipoproteins. Also, induction of cell-adhesion molecules such as vascular cell adhesion molecule 1, leading to recruitment of inflammatory cells, appears to be triggered by nonoxidized, retained lipoproteins.

Consistent with a prominent role for inflammation, atherosclerotic lesions share many features with wound healing or inflammation: (1) proliferation of smooth muscle cells and accumulation of macrophages; (2) formation, by smooth muscle cells, of a connective tissue matrix composed of elastic fibers, collagen, and proteoglycans; and (3) deposition of lipid, primarily cholesterol, both intracellularly and extracellularly. The pattern of lesion formation does not occur randomly within the arterial tree but is focal in nature. Susceptible regions are more permeable to plasma components, and endothelial cell turnover is greater, although the endothelial surface appears to be intact. The focal nature of atherosclerosis suggests that local hemodynamic factors are involved.

Normally, the endothelium forms a relatively impermeable barrier. The endothelial cells and the relatively narrow region beneath them (subendothelial space), which contains an occasional smooth muscle cell, constitute the intima of the artery wall (Fig. 34-25A). Beneath the intima is a layer of many smooth muscle cells, the media, which constitutes the bulk of the arterial wall. The adventitia is the outermost layer of the artery wall and is composed of loose connective tissue.

A current model of atherogenesis is depicted in Figure 34-25B through E. The major cell types involved include endothelial cells, smooth muscle cells, and inflammatory mononuclear cells, such as macrophages and possibly lymphocytes. One of the initial events is the focal attachment of circulating monocytes to the endothelial surface (see Fig. 34-25B). It is not entirely clear which factors are responsible for the adherence of monocytes, although oxidized or modified LDLs or other atherogenic lipoproteins retained in the subendothelium are probably a major initiating factor; areas of micronjury may contribute as well. The monocytes modify the endothelial surface and induce the expression of leukocyte adhesion molecules such as vascular cell adhesion molecule 1. Once adhered, the monocytes migrate between endothelial cells, enter the subendothelial space, and differentiate into macrophages (see Fig. 34-25B). In addition, LDLs and other atherogenic lipoproteins can enter this space. Within the wall, LDLs may become entrapped in the matrix and undergo oxidation or further chemical modifications. The macrophages take up the oxidized or modified LDLs and begin to take on the appearance of foam cells as lipid accumulates. These initial steps set in motion a chain of events that includes the expression of growth factors (mediators of cell proliferation and chemotaxis) and cytokines (mediators involved in inflammation and immunity).

Monocyte chemoattractant protein 1 (MCP-1), produced by endothelial and smooth muscle cells, plays a role in further monocyte recruitment into lesions and may be induced by the presence of oxidized LDL. The role of MCP-1 in macrophage recruitment in the early stages of lesion development was established in MCP-1-deficient mice. MCP-1 stimulates monocyte chemotaxis, and the absence of MCP-1 results in a substantial decrease in monocyte infiltration into lesions of apo-E-deficient mice. When the MCP-1-deficient mice were crossed with apo-E-deficient mice, a common mouse model of atherosclerosis, and fed a high-fat Western-type diet for 5 weeks, fewer macrophages were present in the aortas of the double transgenic mice than in the apo-E-deficient control mice. After 5 to 26 weeks of the diet, the double transgenic mice displayed significantly smaller lesions. These results establish a role for MCP-1 in the recruitment of macrophages into the artery wall at an early stage of lesion formation and establish MCP-1 as an important factor for atherogenesis.

Other growth factors that have been implicated in atherosclerosis include platelet-derived growth factor, basic fibroblast growth factor, insulin-like growth factors, interleukin-1, tumor necrosis factor, and transforming growth factor. These mitogenic factors, which can stimulate smooth muscle cell proliferation, are not expressed in the normal artery wall but are present in developing lesions. Several of these mitogens are also chemoattractants with the potential to attract smooth muscle cells or monocytes-macrophages into a developing lesion. Inflammatory response cytokines include interleukin-1, interferon, tumor necrosis factor, interleukin-2, and the colony-stimulating factors. It is unlikely that the various factors act in isolation from each other, but they probably act through a network of cellular interactions operating in a paracrine or autocrine manner.

The first grossly visible atherosclerotic lesion is referred to as a fatty streak (see Fig. 34-25C). Macrophages accumulate in abundance in the subendothelial space and are converted to foam cells, presumably through the uptake of oxidized LDLs or remnant lipoproteins. The recruitment of monocytes continues, and smooth muscle cells begin to migrate into the intima. Fatty streaks probably come and go, depending on the local stimuli present in the artery wall.
As the cycle of interactions continues, the fatty streak matures into a proliferative or fibrous plaque, which is raised and begins to extend into the lumen of the vessel (see Fig. 34-25D). The foam cells begin to necrose, probably because of the cytotoxicity of the accumulated lipid; as the lesion progresses, cholesterol crystals develop. The death of foam cells leads to extracellular lipid deposition, accompanied by collagen synthesis and smooth muscle cell migration and proliferation. In the continued presence of factors that promote atherogenesis (e.g., high plasma concentrations of atherogenic lipoproteins), the plaque progresses to the complicated lesion stage (see Fig. 34-25E).

The surfaces of complicated lesions may become thrombogenic as endothelial cells are lost and the subendothelial space is exposed. Platelets can adhere to this exposed surface, promoting thrombus formation. Alternatively, a fissure forms in the unstable plaques and blood actually dissects into the artery wall, leading to the formation of a large thrombus. At late stages in complicated lesions, T lymphocytes infiltrate the lesion and there is evidence of an autoimmune response characterized by lymphocyte infiltration of the adventitia. Calcification is also a feature of late lesions. Advanced lesions can weaken the elasticity and integrity of the artery wall, with the potential to lead to an aneurysm of the vessel. As experiments in humans have shown, removal or reduction of the atherogenic stimulus can result in plaque regression, leaving a remnant devoid of lipid that resembles a wound scar.
HYPERLIPIDEMIA: DEFINITIONS AND OVERVIEW

Plasma lipid levels vary among individuals of different populations owing to genetic and dietary factors. For example, the mean plasma cholesterol concentration for Western men is 5.4 mmol/L (210 mg/dL), whereas for Japanese men it is 4.3 mmol/L (165 mg/dL). Historically, hyperlipidemia has been arbitrarily defined from population distributions as the upper 5% to 10% of values (i.e., the 90th to 95th percentile). For Western adults, cholesterol concentrations higher than 6.2 mmol/L (240 mg/dL) or triglyceride concentrations higher than 2.3 mmol/L (200 mg/dL) constitute significant hyperlipidemia.

In agreement with these definitions, guidelines from the 2001 National Cholesterol Education Program (NCEP) suggest that plasma cholesterol levels less than 5.2 mmol/L (200 mg/dL) are desirable, that those between 5.2 and 6.2 mmol/L (200 to 240 mg/dL) are borderline elevated, and that levels greater than 6.2 mmol/L (240 mg/dL) are high. Because plasma lipid levels increase with age, cutoff values for hyperlipidemia in children are lower (5.2 mmol/L [200 mg/dL] and 1.6 mmol/L [140 mg/dL], respectively, for cholesterol and triglycerides). Conversely, hypolipidemia can be defined as plasma cholesterol concentrations less than 3.4 mmol/L (130 mg/dL). Although these boundaries are arbitrary, the designation of plasma cholesterol concentrations higher than 6.2 mmol/L (240 mg/dL) as hyperlipidemic has support from clinical observations indicating that the risk for atherosclerotic CHD increases markedly when the cholesterol concentration reaches or exceeds this level.

Hyperlipidemia is caused by increased concentrations of plasma lipoproteins. One or more classes of lipoproteins may accumulate in the blood stream because of increased production or secretion into the circulation or because of decreased clearance or removal from the circulation; in some cases, both processes coexist. Alterations in metabolic processes are often related to alterations in the proteins involved in lipoprotein metabolism (see "Plasma Lipoproteins: Apolipoproteins, Receptors, and Enzymes"). Alterations resulting from genetic defects are classified as primary disorders of lipid metabolism. Alternatively, other factors that alter lipoprotein metabolism, such as diabetes mellitus or hypothyroidism, lead to increased plasma lipoprotein concentrations; these are classified as secondary disorders of lipid metabolism. Often, hyperlipidemia results from mixed primary and secondary causes, such as when diabetes mellitus occurs in a subject who has an inherited defect in one of the proteins involved in lipoprotein metabolism. In cases in which no known cause of hyperlipidemia can be identified, the disorder is classified as sporadic or possibly polygenic in origin.

When considering the causes of hyperlipidemia, it is useful to classify the various possibilities by the pattern of plasma lipoprotein elevation (or the lipoprotein phenotype). This was once commonly done by performing plasma electrophoresis to separate and determine the relative concentrations of the plasma lipoproteins (Table 34-5). Although such a classification is still useful in some instances, it has generally lost utility because it has been recognized that certain disorders can manifest different phenotypes at different times in the same person and that different phenotypes may occur in different family members with the same disorder. Furthermore, classification based on electrophoresis is not necessary to determine a therapeutic plan. Nevertheless, many of the terms still used to describe lipoprotein disorders (e.g., hypopalphalipoproteinemia, hypobetalipoproteinemia, abetalipoproteinemia, type III hyperlipoproteinemia, dysbeta1lipoproteinemia) are derived from the patterns observed on plasma electrophoresis gels.

It is also possible to create a differential diagnosis on the basis of whether the concentration of plasma cholesterol, triglycerides, or both is elevated. Table 34-6 illustrates such a diagnostic strategy. More extensive lists of primary and secondary disorders are given in Table 34-7 and Table 34-8. Although it is often not essential to diagnose a genetic disorder in a hyperlipidemic subject for treatment purposes, the understanding of genetic causes may have important implications for family members. The recognition of secondary disorders is of great importance because therapy should be directed, at least in part, toward correcting the underlying disorder.
PRIMARV DISORDERS OF HYPERLIPIDEMIA

Familial Hypercholesterolemia

FH is a relatively common disorder caused by mutations in the LDL receptor gene that result in LDL receptor malfunction or absence in cells of the liver and peripheral tissues, leading to elevation of plasma LDL and total cholesterol concentrations. Heterozygous subjects typically have plasma cholesterol concentrations that are twofold to threefold above average, and homozygous subjects have cholesterol concentrations that are elevated threefold to sixfold.

Clinical Features

Heterozygosity for FH occurs with a frequency of about 1 in 500 in the population and is found in many ethnic groups. Typically, the plasma cholesterol concentration is higher than 7.8 mmol/L (300 mg/dL), and the LDL-C concentration is higher than 6.5 mmol/L (250 mg/dL). Plasma triglyceride concentrations are not elevated. The typical plasma lipid abnormalities are characterized by increased plasma cholesterol, slightly increased triglyceride, and decreased HDL cholesterol concentrations. FH is associated with a type IIa pattern, reflecting increased concentrations of -migrating LDLs.

The characteristic physical finding in approximately 75% of affected subjects is the presence of tendon xanthomas (Fig. 34-26C and D). Xanthomas of the Achilles tendon can cause recurrent episodes of Achilles tendinitis. These xanthomas may be subtle and apparent only as a thickening of the tendon (see Fig. 34-26C). Other common physical findings include xanthelasma (see Fig. 34-26A; see color section) and premature arcus corneae (i.e., in persons younger than 40 years). A minority of affected subjects have no physical findings. Premature coronary artery disease is common, the average age of onset of coronary disease is 45 years in men and 55 years in women.

Homozgyosity for FH is rare, occurring at a frequency of about 1 in 10^6 in the population (i.e., 250 persons in the United States population). These subjects come to clinical attention early in life because of marked hypercholesterolemia or premature CHD. Typical plasma cholesterol concentrations range from 15.5 mmol/L (600 mg/dL) to 25.9 mmol/L (1000 mg/dL), and LDL-C concentrations range from 14.2 mmol/L (550 mg/dL) to 24.6 mmol/L (950 mg/dL). In addition to the xanthelasma and tendon xanthomas found in heterozygotes, FH is associated with a type IIa pattern, reflecting increased concentrations of -migrating LDLs.

Homozygous individuals frequently have planar xanthomas, which are almost unique to this disorder and almost always noticed by age 6. These xanthomas are raised plaques of cholesterol deposits that occur in the skin at areas of trauma, such as the elbows and knees. Symptoms of CHD may occur before age 10, and, if not treated, these homozygous individuals usually die from myocardial infarction by age 20. Myocardial infarction has been reported as early as age 18 months. Homozygotes are also susceptible to both valvular and supravalvular aortic stenosis.

**Origin and Pathogenesis**

FH is an autosomal dominant disorder caused by mutations in the LDL receptor gene. Many different types of mutations have been described, including null mutations or nonsense mutations that affect the production of a functional protein, mutations that affect the ability of the receptor to bind to its ligands on lipoproteins, and mutations in which receptors bind LDL normally but are unable to internalize the lipoprotein. A milder phenotype occurs when the ability to bind LDL is impaired but not absent. Different LDL receptor mutations occur in different ethnic groups; for example, there is an increased prevalence (about 60%) of a large deletion mutation in French Canadians with heterozygous FH.

The lack of LDL receptors impairs the clearance of lipoproteins that rely on the LDL receptor for this purpose; these include LDLs, in which apo-B100 is the ligand, and remnant lipoproteins (IDLs) that are cleared by apo-E. This results in a twofold to threefold increase in the plasma cholesterol concentration in heterozygotes and in a threefold to sixfold increase in homozygotes. The high levels of LDL in the plasma are taken up by scavenger receptors on macrophages in a nonsaturable manner, possibly after the LDL undergoes oxidative modification.

In one study, heterozygous FH accounted for 4% of men who survived myocardial infarction before age 60. The differential diagnosis includes familial defective apo-B100, which has many of the same phenotypic characteristics, including tendon xanthomas. The pattern of isolated high LDL-C also occurs in the more common disorder of polygenic hypercholesterolemia, but tendon xanthomas are not usually a feature of the latter.

The diagnosis of FH is primarily a clinical diagnosis because tests to detect one of the many LDL receptor gene mutations or to demonstrate diminished LDL receptor function are performed only in specialized research laboratories. The diagnosis can be confirmed in the laboratory by culturing skin fibroblasts and demonstrating a reduced ability of LDL to bind to receptors on the cells. As a consequence, cholesterol accumulates in tissue macrophages in the arterial wall, tendons, and skin and causes the pathologic processes observed in these tissues.

**Diagnosis**

The diagnosis of heterozygous FH is suggested by the presence of high plasma levels of total cholesterol and LDL-C, normal plasma triglycerides, tendon xanthomas, and a family history of premature CHD. Up to 25% of subjects do not have xanthomas. Heterozygous FH should be suspected in any person with premature heart disease. In one study, heterozygous FH accounted for 4% of men who survived myocardial infarction before age 60. The differential diagnosis includes familial defective apo-B100, which has many of the same phenotypic characteristics, including tendon xanthomas. The pattern of isolated high LDL-C also occurs in the more common disorder of polygenic hypercholesterolemia, but tendon xanthomas are not usually a feature of the latter.

The diagnosis of FH is primarily a clinical diagnosis because tests to detect one of the many LDL receptor gene mutations or to demonstrate diminished LDL receptor function are performed only in specialized research laboratories. The diagnosis can be confirmed in the laboratory by culturing skin fibroblasts and demonstrating a reduced ability of LDL to bind to receptors on the cells. As a consequence, cholesterol accumulates in tissue macrophages in the arterial wall, tendons, and skin and causes the pathologic processes observed in these tissues.

**Treatment**

Treatment of heterozygous FH consists of a diet low in total and saturated fat (approximately 20% and 6% of calories, respectively) and low in cholesterol (<2.6 mmol/day [100 mg/day]) and drug therapy. Dietary modifications usually result in only minor decreases in the plasma cholesterol levels (5% to 15%). With the development of more potent HMG-CoA reductase inhibitors, adequate cholesterol lowering in these patients can sometimes be achieved by a single therapeutic drug. However, combinations of two or three drugs are often needed to reduce plasma cholesterol to desired levels. Effective drug combinations usually include
low doses of bile acid sequestrants together with HMG-CoA reductase inhibitors or niacin or all three agents combined. Bile acid sequestrants and HMG-CoA reductase inhibitors both work by depleting cholesterol from hepatic cells (see later discussion), thereby causing increased expression of functional LDL receptors (from the normal allele) on cells, which in turn lowers the plasma cholesterol.

Because high Lp(a) concentrations appear to be an adverse risk factor for patients with heterozygous FH, the plasma Lp(a) level should be determined; if it is elevated, niacin should be considered in the drug regimen because this agent can lower plasma Lp(a) levels. On the basis of studies in animal models of FH, antioxidant agents may be of therapeutic benefit for preventing CHD, but this has not been demonstrated directly in humans. Probucol treatment has resulted in xanthoma regression, ileal bypass surgery, which, like bile acid sequestrants, causes decreased reabsorption of bile acids from the gut, may be considered in patients who cannot tolerate lipid-lowering drugs.

The age at which treatment should begin in heterozygous FH is somewhat controversial. On the one hand, development of atherosclerosis in these subjects is a long process that begins early in life, and one could argue that treatment should begin during the early stages of lesion development. On the other hand, CHD is usually not symptomatic until the third or fourth decade of life in men and 10 years later in women. Because established CHD is reversible, one could argue that medicines can be withheld until after age 25 in men or age 35 in women. A rational approach may be to use diet therapy and bile acid sequestrants, which do not have systemic toxicity, in the early years and to add more potent drug combinations later. The presence of additional risk factors (e.g., high plasma Lp(a) levels, low plasma HDL-C levels, smoking) in an affected subject is an indication for more aggressive treatment at a young age.

Unless the causative mutation is such that there is some residual LDL binding, drug therapy for FH homozygotes is usually ineffective for lowering plasma cholesterol, except with high doses of atorvastatin and simvastatin. However, the most effective means of therapy in these patients is selective removal of LDL from the plasma by extracorporeal pheresis combined with LDL immunoadsorption performed every 1 to 3 weeks. Experimental therapies include liver transplantation, which provides functional LDL receptors, portacaval shunting, and gene therapy.
Familial Defective Apolipoprotein B100

Familial defective apo-B100 is a relatively common disorder caused by a mutation in apo-B100, the ligand for the LDL receptor, that results in high plasma LDL and total cholesterol levels and increased susceptibility to CHD. It is phenotypically similar to FH.

Clinical Features

This disorder occurs with a frequency of 1 in 500 to 1 in 750 in white persons with hypercholesterolemia. The prevalence of familial defective apo-B100 was 0.08% in an ethnically diverse, unselected population. Familial defective apo-B100 had not been described in nonwhite populations until 1993, when it was detected in an individual of Chinese ancestry. The clinical features of heterozygous familial defective apo-B100 overlap extensively with those of heterozygous FH and include isolated elevations of plasma LDL-C (type IIa pattern), tendon xanthomas, xanthelasmas, and premature CHD.

Although there is extensive overlap, familial defective apo-B100 is usually milder in its manifestations than FH. Subjects who are homozygous for the familial defective apo-B100 mutation also appear to have a milder clinical phenotype than FH homozygotes. In one report, a 66-year-old man and his 69-year-old sister with homozygous familial defective apo-B100 had total plasma cholesterol levels of 9.6 mmol/L (370 mg/dL) and 11.9 mmol/L (460 mg/dL), respectively, and only the man had evidence of CHD. Presumably, the less severe phenotype is related to the fact that the binding of apo-B to LDL receptors is defective but not totally absent in familial defective apo-B100, whereas the apo-E-mediated clearance of remnant particles, which is impaired in FH, is normal in persons with familial defective apo-B100.

Origin and Pathogenesis

Familial defective apo-B100 is caused by a mutation in apo-B100 that impairs its ability to bind to the LDL receptor. To date, a single mutation, the substitution of glutamine for arginine at amino acid 3500, accounts for almost all cases of familial defective apo-B100. Apo-B allele haplotype analysis of DNA from affected subjects has indicated that almost all cases can be traced back to an original founder. Only after extensive screening was this mutation detected in persons with a different apo-B haplotype for the allele carrying the mutation, one of whom was of Chinese ancestry and one in a kindred from Germany.

The mutation located at apo-B amino acid 3500 disrupts the conformation of the protein in the receptor-binding domain and reduces receptor binding of LDL from heterozygotes to levels that are about one third of normal in tissue culture assays. Isolation of the binding-defective LDL from affected subjects demonstrated that it binds with 4% to 9% of normal activity to LDL receptors. Decreased affinity of the defective apo-B100 for its receptor delays the clearance of LDL from the plasma (by about 50%) and leads to elevation of plasma LDL-C levels. Defective LDL particles accumulate in the plasma in increased proportions relative to normal LDL. A second mutation at amino acid 3500 (tryptophan for arginine) has been reported.

Another mutation located near the receptor-binding region of the apo-B molecule (a substitution of cysteine for arginine at amino acid 3531) also impairs binding of apo-B to the LDL receptor. This mutation decreases LDL binding to LDL receptors by 35% to 40% in tissue culture assays and is associated with moderate elevations in plasma LDL-C levels.

Diagnosis

As in heterozygous FH, the diagnosis of familial defective apo-B100 is suggested by the presence of increased plasma LDL-C and normal triglyceride levels, especially in the presence of tendon xanthomas and a family history of premature CHD. Without specialized testing, however, familial defective apo-B100 is clinically indistinguishable from FH. Because familial defective apo-B100 is caused primarily by one mutation, in contrast to the many mutations that cause FH, it is possible to screen easily for the familial defective apo-B100 mutation using a polymerase chain reaction-based assay of genomic DNA isolated from blood. This test is available only in specialized laboratories.

Treatment

Treatment of familial defective apo-B100 is similar to that of heterozygous FH and consists of a low-fat, low-cholesterol diet and a combination drug regimen. Drugs that either decrease LDL production (e.g., niacin) or increase the expression of LDL receptors to facilitate clearance of the normal apo-B100-containing particles effectively lower the plasma LDL-C level. In two patients with homozygous familial defective apo-B100 whose LDL had receptor-binding affinities 10% to 20% of normal, treatment with HMG-CoA reductase inhibitors markedly reduced plasma cholesterol levels.

Family members at risk should also be screened for the dominant mutation.
Familial Combined Hyperlipidemia

Originally described in 1973, familial combined hyperlipidemia is a common disorder of unknown genetic cause associated with elevations of plasma cholesterol and triglyceride levels and increased susceptibility to CHD. It is inherited as an autosomal dominant trait. The phenotype of familial combined hyperlipidemia overlaps with and may be the same as that in familial hyperapobetalipoproteinemia, in subjects with plasma elevations of small, dense LDL particles, and in subjects with syndrome X or the metabolic syndrome, a disorder that includes insulin resistance, increased plasma levels of small, dense LDL, elevated plasma triglycerides, and low plasma HDL levels.

Clinical Features

The features of familial combined hyperlipidemia include moderate elevations of plasma cholesterol, triglycerides, or both within subjects of an affected kindred, corresponding to lipoprotein pattern type IIa, IIb, or IV on plasma electrophoresis. The predominant lipid abnormality may vary in a single person over time or among affected family members; the variable phenotype in this disorder led in part to the decreased utility of pattern typing of hyperlipoproteinemia by plasma electrophoresis in the clinical evaluation. Levels of HDL-C are often moderately decreased, especially in the setting of increased plasma triglycerides.

Although it was originally thought that lipid abnormalities usually develop after puberty, it is now known that the phenotype can be detected in children. Neither xanthomas nor xanthelasma is a feature of familial combined hyperlipidemia. Associated metabolic disturbances may include glucose intolerance, obesity, and hyperuricemia. Premature CHD is a common feature; in one study of male survivors of myocardial infarction, familial combined hyperlipidemia was found in 11.3% of those younger than 60 years of age. CHD is often present in men by age 50.

Origin and Pathogenesis

Although familial combined hyperlipidemia is a common disorder (estimated prevalence, 0.5% to 2.0%), neither its genetic cause nor its metabolic pathogenesis is clear. Given the dominant pattern of inheritance, it was initially presumed that familial combined hyperlipidemia is caused by a single gene defect. Now it is believed that multiple genes may be involved, with one or two genes playing a large role and other genes acting as modifiers. A candidate gene locus was identified in syntenic chromosomal regions in mice and humans, suggesting that an important contributing gene may reside at this locus. The phenotype of this disorder has also been mapped to loci on chromosomes 11, and 19, and several different loci may underlie the expression of the phenotype. Heterozygous LPL deficiency may constitute a subset of familial combined hyperlipidemia.

A significant problem with mapping this disorder is the difficult task of assigning phenotypes to individuals because of the fluctuating and indistinct clinical features. Familial hyperapobetalipoproteinemia, a disorder characterized by high plasma levels of apo-B and normal plasma cholesterol levels, overlaps with the phenotype of familial combined hyperlipidemia, as do both the familial syndrome characterized by small, dense LDL and syndrome X characterized by insulin resistance and other metabolic abnormalities. The metabolic defect that leads to the hypercholesterolemia or hypertriglyceridemia, or both, is also unclear, but overproduction of apo-B may be a contributing factor; apo-B overproduction can result in elevations in plasma VLDL, LDL, or both. Similarly, the pathogenesis of the low HDL in this disorder remains unclear. Low HDL-C is commonly associated with hypertriglyceridemia. This finding could be related either to decreased substrate for HDL formation because of impaired catabolism of the apo-B-containing lipoproteins or to enhanced CETP-mediated cholesteryl ester transfer from HDL to the apo-B-containing lipoproteins.

Diagnosis

Familial combined hyperlipidemia should be suspected in subjects with moderate hypertriglyceridemia or moderate hypercholesterolemia (lipoprotein type IIa, IIb, or IV), or both, especially in the setting of a family history of premature CHD. Xanthomas are not a feature of this disorder. Low plasma HDL-C, obesity, insulin resistance, and hyperuricemia are often present. The diagnosis is a clinical one; it requires demonstration of the clinical phenotype in the affected subject and family members and exclusion of other primary or secondary disorders. Secondary disorders that produce a similar phenotype include diabetes mellitus, nephrotic syndrome, and occasionally hypothyroidism. Many patients with diabetes mellitus and combined hyperlipidemia may have a genetic susceptibility related to inheritance of familial combined hyperlipidemia.

Treatment

Weight reduction and dietary treatment can help correct metabolic abnormalities, such as obesity and insulin resistance, that contribute to the hyperlipidemia. Drug therapy should be directed at the predominant lipid abnormality. For example, plasma elevations of total cholesterol and LDL-C can be treated with HMG-CoA reductase inhibitors, niacin, or bile acid sequestrants. Of these, HMG-CoA reductase inhibitors may be preferable because niacin can cause or worsen glucose intolerance and hyperuricemia and bile acid sequestrants can cause hypertriglyceridemia. Gemfibrozil can lower triglyceride and raise HDL-C levels, and it reduced the incidence of coronary events in the Helsinki Heart Study. Low HDL-C levels can be treated with niacin, gemfibrozil, or HMG-CoA reductase inhibitors. Because familial combined hyperlipidemia is associated with premature CHD, affected family members should be identified.
Type III Hyperlipoproteinemia (Familial Dysbetalipoproteinemia)

Type III hyperlipoproteinemia, or familial dysbetalipoproteinemia, is an uncommon disorder of lipoprotein metabolism characterized by moderate to severe hypertriglyceridemia and hypercholesterolemia caused by the accumulation of cholesterol-rich remnant particles in the plasma. Premature peripheral vascular disease and coronary artery disease are common. The cause is mutations in apo-E that result in defective binding to lipoprotein receptors. The disorder is associated with the apo-E2 isoform (described previously) and in most instances is inherited as an autosomal recessive trait that requires a secondary exacerbating metabolic factor (either genetic or environmental) for expression of the phenotype. Several rare apo-E mutations result in the dominant expression of the disorder.

Clinical Features

Type III hyperlipoproteinemia is usually diagnosed in adulthood and is rarely detected in persons younger than 20 years, with the exception of those with the rare autosomal dominant apo-E mutations. The disorder is more common in men and is usually not manifested in women until after menopause. It is characterized by moderately severe elevations in plasma triglyceride and cholesterol levels; typically, these values range from 3.4 to 4.5 mmol/L (300 to 400 mg/dL) and 7.8 to 10.3 mmol/L (300 to 400 mg/dL), respectively. Concentrations of HDL-C are normal, and LDL-C is almost always reduced.

Xanthomas are present in more than half of affected subjects. The presence of palmar xanthomas, which are planar xanthomas in the palmar creases (see Fig. 34-26F), is virtually pathognomonic for this disorder. Tuberous or tuberoeruptive xanthomas (see Fig. 34-26E; see color section) are also common but are less specific for this disorder. Tendon xanthomas and xanthelasma occur in some patients. Premature vascular disease is common, and peripheral vascular disease occurs in about 10% of patients with type III hyperlipoproteinemia. Type III hyperlipoproteinemia accounts for 0.2% to 1.0% of lipid disorders associated with myocardial infarction in persons younger than 60 years. Coexisting metabolic conditions that exacerbate the phenotype of type III hyperlipoproteinemia, such as obesity, alcohol consumption, diabetes mellitus, and hypothyroidism, are often present.

Origin and Pathogenesis

Type III hyperlipoproteinemia is caused by the plasma accumulation of cholesterol-rich remnants of VLDL, IDL, and chylomicrons. The clearance defect is caused by mutant apo-E that binds defectively to remnant receptors, including LDL receptors (discussed in “Roles of Apolipoprotein E in Lipid Metabolism”). The remnants that accumulate have lost much of their triglyceride through LPL-mediated triglyceride hydrolysis and therefore are cholesterol rich. The predominant remnant particles are termed -VLDL and can be isolated in the VLDL ultracentrifugation density range (<1.006 g/mL). In contrast to normal VLDLs, which migrate as pre-particles, these remnants are characterized by -migration on agarose gel electrophoresis.

Homozygosity for the apo-E2 isoform occurs at a frequency of about 1 in 100 in the general population. Despite this high frequency, the type III hyperlipoproteinemia phenotype is relatively rare: the dyslipidemia develops in about 1 in 10 to 1 in 100 apo-E2 homozygotes (overall prevalence of 1 in 10,000). Manifestation of the dyslipidemia appears to require the presence of a secondary factor, such as a metabolic condition that contributes to the phenotype of impaired remnant clearance. Such conditions can be caused by lipoprotein overproduction syndromes, such as obesity, diabetes mellitus, or alcohol consumption, or by conditions that further impair lipoprotein clearance, such as hypertriglyceridemia. In conditions characterized by VLDL overproduction, the increased generation of remnant particles through catabolism of VLDL overwhelms the ability of the remnant receptors to clear them from the plasma. Because the manifestations are so sensitive to conditions that increase hepatic lipoprotein production, this disorder is also one of the most sensitive to therapeutic modalities directed at decreasing hepatic lipoprotein production, such as dietary modifications, weight loss, and alcohol cessation.

In addition to homogygosity for the apo-E2 isoform, six mutations in the apo-E gene are known to lead to the type III hyperlipoproteinemia phenotype in an autosomal dominant fashion. In these dominant disorders, the phenotype is present at an early age and does not require a coexisting metabolic condition as an exacerbating factor. These rare dominant disorders are of great interest because they show that different mutations in a single protein can give rise to either recessively or dominantly inherited phenotypes.

When a given apo-E mutation interacts with the HSPG/LRP pathway is believed to determine whether the mutation gives rise to a dominant or recessive phenotype. For example, in recessive expression of the disorder, as occurs with apo-E2 homozygosity, apo-E2 interacts poorly with the LDL receptor but almost normally with the HSPG/LRP pathway so that in the absence of exacerbating secondary factors remnant lipoproteins are cleared efficiently. However, in the presence of a secondary factor that overwhelms or even slightly impairs the normal pathways, apo-E2 cannot clear remnants efficiently. In dominant expression of the disorder, apo-E interacts poorly with both the LDL receptor and the HSPG/LRP pathway, and remnant lipoprotein clearance is impaired even in the heterozygous state. Another contributing factor is the particular lipoprotein fraction with which the apo-E molecule preferentially associates (discussed in “Roles of Apolipoprotein E in Lipid Metabolism”).

The accumulation of cholesterol-rich remnant lipoproteins in the plasma leads to the deposition of cholesterol in tissue macrophages, which avidly bind and take up -VLDL. The deposition of -VLDL-derived cholesterol in macrophages leads to foam cell formation and accumulation, manifested as skin xanthomas and as atherothrombotic vascular disease. In addition to the frequent occurrence of CHD, -VLDL hyperlipidemia appears to cause a disproportionately high incidence of peripheral vascular disease. The onset of premature CHD occurs at about 40 years of age in men and at about 50 years of age in women.

Diagnosis

The diagnosis of type III hyperlipoproteinemia should be suspected in persons with moderately severe elevations in both plasma triglyceride and cholesterol concentrations. Typically the cholesterol and triglyceride levels are in the range of 3.4 to 4.5 mmol/L (300 to 400 mg/dL) and 7.8 to 10.3 mmol/L (300 to 400 mg/dL), respectively. Because this disorder is most commonly recessive, there is often no family history of hyperlipidemia or premature CHD. The presence of palmar or tuberous xanthomas makes the diagnosis highly likely. In the absence of palmar or tuberous xanthomas, the specific diagnosis is more difficult and requires specialized testing. If available, a measurement of the VLDL cholesterol level allows detection of cholesterol-rich remnant particles. The VLDL cholesterol/triglyceride ratio is a useful screen; in type III hyperlipoproteinemia, this ratio is usually greater than 0.3 (when hyperlipidemia is present). The normal VLDL cholesterol/triglyceride ratio is typically about 0.2 (i.e., the VLDL cholesterol concentration is about 20% of the plasma triglyceride level, as estimated by the Friedewald formula; see later discussion). The ratio is elevated because -VLDL remnants are rich in cholesterol and cause the VLDL fraction to be cholesterol rich. Electrophoresis of plasma samples on agarose gel typically demonstrates a broad band in the migrating lipoprotein region (type III pattern), hence the names broad- disease, dysbetalipoproteinemia, and type III hyperlipoproteinemia. Patients suspected of having type III hyperlipoproteinemia can be evaluated for apo-E2 homozygosity either by isoelectric focusing of plasma (see Fig. 34-9) or by apo-E genotyping of DNA obtained from leukocytes. The other rare dominant mutations in apo-E can be diagnosed only in specialized laboratories.

Treatment

Because type III hyperlipoproteinemia is greatly influenced by coexisting metabolic conditions, a vigorous search should be made to identify and treat obesity, alcohol consumption, diabetes mellitus, and hypothyroidism. If such conditions can be identified and treated successfully, the lipid abnormalities can often be resolved and plasma lipids returned to normal without the use of drug therapies. Type III hyperlipoproteinemia associated with hypothyroidism, in particular, responds dramatically to thyroid hormone replacement therapy. Dietary therapy should be aimed at restricting total fat, saturated fat, and cholesterol (Step 1 or Step 2 American Heart...
Association diet) and at caloric restriction to reduce weight if appropriate. Treatment with estrogen should be considered in postmenopausal women because it can dramatically diminish the hyperlipidemia, probably by stimulating LDL receptor-mediated remnant particle clearance.

If dietary therapy and treatment of coexisting metabolic conditions yield unsatisfactory results, drug therapy should be initiated using either niacin, fibric acid derivatives, or HMG-CoA reductase inhibitors, all of which are effective in the treatment of this disorder. By decreasing VLDL synthesis and secretion, niacin lowers triglyceride and VLDL cholesterol levels by about 40% and LDL-C levels by 20% and can raise HDL-C concentrations by 20%. The fibric acid derivatives, gemfibrozil and clofibrate, can also lower triglyceride and VLDL cholesterol levels. Through their ability to increase LDL receptor levels, the HMG-CoA reductase inhibitors can also lower the plasma cholesterol levels. Cases that are refractory to treatment with individual drugs can be treated with combinations of fibric acid derivatives and HMG-CoA reductase inhibitors, although this combination should be used cautiously because of the risk of myopathy. Because the disorder is associated with premature vascular disease, first-degree relatives such as siblings (or offspring if the affected person's spouse has an apo-E2 allele) should be screened.
Lipoprotein Lipase Deficiency

LPL deficiency is a rare, recessive disorder that results from mutations in the LPL gene. These abnormalities cause LPL deficiency and severe hypertriglyceridemia by blocking the clearance of triglyceride-rich lipoproteins from the plasma. Massive accumulations of these proteins in the plasma, known as the chylomicronemia syndrome, can be accompanied by severe clinical manifestations, including pancreatitis.

Clinical Features

LPL deficiency is usually recognized in infancy or childhood as a chylomicronemia syndrome, which consists of marked hypertriglyceridemia associated with recurrent abdominal pain or pancreatitis, which can be life-threatening. A syndrome of recurrent abdominal pain and severe hypertriglyceridemia but without overt pancreatitis or elevated serum amylase concentrations also exists. The pain syndrome is associated with triglyceride levels of more than 22.6 mmol/L (2000 mg/dL) and abates with triglyceride lowering. When plasma triglyceride levels exceed 22.6 mmol/L (2000 mg/dL), the findings include eruptive xanthomas and lipemia retinalis. The plasma may be visibly lipemic; plasma that has been refrigerated overnight can demonstrate chylomicrons (type I pattern) with a cream-like layer on the top, VLDL (type IV pattern) with a turbid plasma infranatant, or both (type V pattern).

Chylomicrons can be assumed to be present if the fasting triglyceride concentration is greater than 11.3 mmol/L (1000 mg/dL). The degree of fasting chylomicronemia is, in large part, determined by the dietary fat intake. Accumulation of chylomicrons in tissue reticuloendothelial cells can lead to hepatomegaly and splenomegaly. Chylomicronemia can also cause neurologic manifestations and dyspnea. CHD is not a prominent feature. Massive triglyceride elevations can occupy significant plasma volume and lead to artificially low measurements of serum electrolytes, such as sodium (pseudohyponatremia), if the electrolyte measurements are not corrected for serum water.

Subjects who are heterozygous for LPL deficiency may have reduced LPL activity and often have milder hypertriglyceridemia, increased VLDL cholesterol levels, and decreased HDL-C levels. This phenotype, which may constitute a subset of familial combined hyperlipidemia, is exacerbated by age and obesity.

Origin and Pathogenesis

Complete LPL deficiency results from homozygosity or compound heterozygosity for mutations in the LPL gene that lead to the absence or inactivation of the LPL protein. A variety of mutations have been described. The combined frequency of homozygosity and compound heterozygosity is approximately 1 in 10^5 persons. Patients who are heterozygous for LPL deficiency have half-normal LPL activities and hypertriglyceridemia may develop in the presence of secondary factors. Heterozygous LPL deficiency occurs at a frequency of 1 in 500 persons in the general population but as high as 1 in 40 in areas of Quebec. In the absence of functional LPL, triglyceride-rich lipoproteins accumulate in the plasma. Because of the impaired clearance of these lipoproteins, plasma triglyceride levels are especially sensitive to dietary fat intake. Whereas chylomicrons are normally cleared from the plasma within 8 hours after eating, clearance in patients with this disorder may take days. The triglyceride-rich particles infiltrate organs, where they are taken up by reticuloendothelial cells. The accumulation of these lipoproteins in the pancreas can cause pancreatitis, presumably resulting from chemical irritation by fatty acids and lyssolecithin liberated by the action of pancreatic lipases.

Diagnosis

LPL deficiency should be suspected in children with pancreatitis or recurrent abdominal pain. Eruptive xanthomas are often present. LPL deficiency should also be suspected in any person who has lipemic serum after a 12-hour fast. Plasma triglyceride levels are usually higher than 11.3 mmol/L (1000 mg/dL) and may be considerably higher, depending on the dietary fat intake. Eruptive xanthomas, lipemia retinalis, and pancreatitis are usually apparent only when triglyceride levels are greater than 22.6 mmol/L (2000 mg/dL). Because LPL deficiency is a recessive disease, family history is usually uninformative except in siblings.

The definitive diagnosis is established by demonstrating the absence of lipase activity in plasma after heparin administration. Heparin, when infused intravenously, displaces LPL from its binding sites on HSPI in capillary endothelium and releases it into plasma, which can be assayed for lipase activity. LPL deficiency must be distinguished from deficiency of apo-CII, a cofactor for LPL, which is another cause of chylomicronemia. Because multiple mutations can result in LPL deficiency, specific mutations can be identified only by specialized laboratories.

Treatment

During the initial stages of treatment, a fat-free diet is provided until plasma triglycerides reach a safe level (e.g., <11.3 mmol/L [1000 mg/dL]). After the acute chylomicronemia syndrome has resolved, the mainstay of treatment is a diet that contains very small amounts of fat (e.g., <10% of calories or 20 to 25 g/day). Because medium-chain triglycerides, in contrast to long-chain triglycerides, are absorbed directly into the portal circulation and do not rely on chylomicron formation for hepatic uptake, they can provide a source of fat in the diet; however, these agents may cause hepatic toxicity. Fatsoluble vitamins should be supplemented. The goal of therapy is to maintain the plasma triglyceride level at less than 11.3 mmol/L (1000 mg/dL), which prevents further episodes of pancreatitis.

Drug therapy for primary LPL deficiency is largely ineffective; however, clofibrate, gemfibrozil, or niacin may lower VLDL production and prevent severe hypertriglyceridemia. Secondary causes of hypertriglyceridemia, such as diabetes mellitus or hypothyroidism, should be screened for and treated if present.
Apolipoprotein CII Deficiency

Apo-CII deficiency is a rare autosomal recessive disorder that occurs in fewer than 1 in 10^6 persons and causes a chylomicronemia syndrome similar to that in LPL deficiency. As in LPL deficiency, the features include pancreatitis or recurrent bouts of abdominal pain in children or young adults and lipemic serum after a 12-hour fast. Plasma triglyceride levels are usually severely elevated (>11.3 mmol/L [1000 mg/dL]), reflecting the accumulation of chylomicrons (type I pattern), VLDL (type IV pattern), or both lipoproteins (type V pattern) in the plasma. This hyperlipoproteinemia results from the lack of apo-CII, an activating cofactor for LPL, which causes a functional LPL deficiency. More than 10 mutations are known to cause apo-CII deficiency. The accumulation of triglyceride-rich particles results in a pathophysiologic process that is nearly identical to that described for LPL deficiency. Heterozygotes may have slightly elevated triglyceride concentrations, but they do not develop pancreatitis.

The diagnosis requires specialized testing to demonstrate that apo-CII is absent on electrophoresis of the plasma apolipoproteins or that the plasma is incapable of activating LPL in vitro. The treatment of apo-CII deficiency is identical to that of primary LPL deficiency with the exception that severe hypertriglyceridemia and pancreatitis in apo-CII-deficient patients can be treated with transfusions of plasma, which contains apo-CII.
Familial Hypertriglyceridemia

Familial hypertriglyceridemia is characterized by increased plasma concentrations of triglyceride-rich VLDLs, which cause elevations of plasma triglycerides but not plasma cholesterol levels.

Clinical Features

Subjects with familial hypertriglyceridemia typically have plasma triglyceride levels in the range of 2.3 to 5.6 mmol/L (200 to 500 mg/dL) and normal LDL-C levels. As the level of LDL-C considered to be normal has declined, the prevalence of individuals with isolated elevations of plasma triglycerides has also diminished. The hypertriglyceridemia is often associated with low plasma HDL-C levels. The elevated triglyceride levels are usually not evident until adulthood and may be exacerbated by secondary factors, including hypothyroidism, estrogen therapy, or alcohol ingestion. Such exacerbations can be associated with severe elevations of triglycerides (>11.3 mmol/L [1000 mg/dL]), placing subjects at risk for eruptive xanthomas and pancreatitis. However, xanthomas are usually not present. Obesity and insulin resistance are common. Although familial hypertriglyceridemia was originally thought to be associated with increased risk for CHD, this relation has been questioned. The association of decreased HDL-C levels with hypertriglyceridemia may contribute to increased CHD risk.

Origin and Pathogenesis

Familial hypertriglyceridemia appears to be caused by overproduction of VLDL triglycerides in the presence of near-normal apo-B production, which leads to the secretion of large, triglyceride-rich VLDL. Secondary disorders (e.g., insulin resistance) that lead to VLDL overproduction can exacerbate the syndrome. The low plasma HDL levels commonly found in hypertriglyceridemia are associated with enhanced fractional catabolism of apo-AI. The genetic defect in familial hypertriglyceridemia is unknown. It is likely that the genetic loci involved in causing hypertriglyceridemia in familial combined hyperlipidemia are also involved in causing isolated hypertriglyceridemia. Whether the large, triglyceride-rich VLDLs are atherogenic is unclear; an enhanced risk for premature CHD may be related to whether concomitant decreases in HDL-C occur.

Diagnosis

Familial hypertriglyceridemia should be suspected in individuals with increased plasma triglyceride levels and normal plasma cholesterol. The disorder can be diagnosed only if hypertriglyceridemia is found in half of the first-degree relatives at risk, and it can be difficult to distinguish from familial combined hyperlipidemia, which may also occur as isolated hypertriglyceridemia related to increased plasma VLDL (type IV pattern). Measurement of plasma lipid levels in children does not help to distinguish these disorders because lipid abnormalities are usually not present until after puberty in either disorder. The elevated VLDL levels can be observed as a cloudy appearance of the plasma after overnight refrigeration.

Treatment

In addition to dietary fat restriction, secondary disorders such as diabetes mellitus, estrogen administration, or alcohol intake should be screened for and treated. Drugs that lower triglyceride levels (e.g., niacin, gemfibrozil) may be useful. Because niacin can impair glucose tolerance, it should be used cautiously in patients with underlying insulin resistance.
Elevated Plasma Lp(a)

This disorder consists of elevations of modified LDL particles in the plasma, in which the apo-B protein of LDL is covalently bonded to apo(a). Apo(a) is a protein of unknown function that shares high sequence homology with plasminogen but is not catalytically active. Some studies suggest that elevated plasma Lp(a) concentrations are associated with an increased risk for CHD.

Clinical Features

There are no characteristic physical findings or lipoprotein patterns to suggest elevated plasma Lp(a) levels. Elevated Lp(a) (>30 mg/dL) may be suspected, however, in patients with premature CHD. Plasma Lp(a) concentrations are influenced by heredity and vary among different ethnic populations. For example, African populations have higher levels. Some data suggest that elevations of plasma Lp(a) may be atherogenic only in the presence of high concentrations of LDL. In support of this, elevated Lp(a) concentrations are a risk factor for development of CHD in subjects with FH. Thus, high Lp(a) levels may be viewed as a potent risk factor for CHD in predisposed individuals.

Origin and Pathogenesis

Apo(a) is found only in humans, nonhuman primates, and hedgehogs. Its function from an evolutionary perspective is unclear. Nevertheless, the presence of high plasma levels of apo(a) appears to have been selected for in certain populations. Apo(a) is attached by disulfide bonds to the apo-B protein of LDL. Plasma Lp(a) levels are in large part determined by heredity and appear to be related to the number of repeats of a so-called kringle motif in the protein. The larger isoforms that contain more kringle repeats are found in lower concentrations in the plasma, possibly related to impaired processing of these large forms for secretion by hepatocytes. The factors that control the production and clearance of Lp(a) are largely unknown. An increased susceptibility to atherosclerosis associated with high plasma levels of Lp(a) could be related to impaired fibrinolysis caused by competition for plasminogen receptors, to effects on smooth muscle proliferation, or to unknown factors.

Diagnosis

The diagnosis of high plasma Lp(a) levels is made by specific assays of plasma for apo(a) or intact Lp(a) particles; care should be taken to ensure that samples are collected and stored appropriately and that the assay does not detect plasminogen. Lp(a) levels greater than 30 mg/dL are considered high.

Treatment

Of the hypolipidemic drugs currently available, only niacin appears to lower plasma Lp(a) levels. Treatment with niacin (4 g/day) lowers Lp(a) levels by 35% to 40%. In postmenopausal women, estrogen therapy lowers Lp(a) levels by about 20%.
Polygenic Hypercholesterolemia

Hypercholesterolemia is defined as a cholesterol value that exceeds the 95th percentile for the population. A study by Goldstein and co-workers suggested that about 10% of patients with hypercholesterolemia have familial combined hyperlipidemia and about 5% have FH. In a large proportion of the remaining 85%, the cause of the hypercholesterolemia is unknown but probably largely involves combinations of genetic and environmental factors. Other genetic factors that contribute to hypercholesterolemia may involve physiologic processes that influence cholesterol absorption, bile acid metabolism, or intracellular cholesterol metabolism. Polygenic hypercholesterolemia is diagnosed by excluding other primary genetic causes, by the absence of tendon xanthomas, and by demonstrating that hypercholesterolemia is present in no more than 10% of first-degree relatives. The hypercholesterolemia is treated according to NCEP guidelines (described later).
Sporadic Hypertriglyceridemia

As with high plasma cholesterol, unknown genetic and environmental factors can result in elevated plasma triglyceride levels. This so-called sporadic hypertriglyceridemia can be distinguished from familial syndromes by the absence of hypertriglyceridemia in relatives. The condition is treated with dietary fat restriction, treatment of secondary conditions that exacerbate hypertriglyceridemia, and drugs that lower triglyceride levels, such as niacin or gemfibrozil.
PRIMARY DISORDERS OF HIGH-DENSITY LIPOPROTEIN METABOLISM

Several genetic disorders can result in decreased or increased plasma levels of HDL-C (Table 34-9).

**Familial Hypoalphalipoproteinemia**

The autosomal dominant disorder familial hypoalphalipoproteinemia is manifested by low plasma HDL-C levels and an increased risk for premature CHD. The diagnosis is suggested by HDL-C levels that are less than the 10th percentile (<0.8 mmol/L [30 mg/dL] in men or 1.0 mmol/L [40 mg/dL] in premenopausal women). There are no characteristic physical findings, but there is often a family history of low HDL-C levels and premature CHD. The genetic and metabolic defects that lead to low plasma HDL levels are unknown, but it appears that up to 50% of low HDL-C levels can be linked to the hepatic lipase or apo-AI/apo-CIII/apo-AIV gene locus. The lack of HDL in the plasma accelerates the development of atherosclerosis, presumably because reverse cholesterol transport or other protective effects of HDL are impaired.

**Drug therapy** should be aimed at raising the plasma HDL concentration or lowering the plasma LDL concentration, or both. Treatments to raise HDL levels include estrogen therapy for postmenopausal women, aerobic exercise, and the drug niacin or gemfibrozil. Because increasing HDL-C is difficult with current therapies, lowering the LDL-C concentration may be the most effective approach, with the premise that the lowering of atherogenic LDL particles can overcome some, if not all, of the effects of low HDL.

Low HDL levels have been found in specific ethnic groups. For example, Southeast Asians, specifically people from the Indian subcontinent, have very low HDL levels in the context of insulin resistance. In Turks, however, low HDL levels are associated with elevated hepatic lipase activity without insulin resistance. Apo-AI Mutations

Mutations in the apo-AI gene can decrease HDL formation and result in low plasma HDL-C levels. Apo-AI deficiency can be caused by point mutations in the apo-AI gene or by deletions or gene rearrangements at the apo-AI/apo-CIII/apo-AIV gene locus. Apo-AI deficiency typically results in plasma HDL-C levels less than 0.3 mmol/L (10 mg/dL). Manifestations include a predisposition to premature CHD, xanthomas, and corneal opacities. The molecular diagnosis can be made only by specialized analysis, including electrophoresis of the plasma apolipoproteins and DNA analysis to identify the mutation. Inasmuch as it is difficult to raise the plasma apo-AI or HDL-C levels in these disorders, the treatment should be directed toward lowering the levels of plasma nonHDL-C.

Other rare variants of apo-AI exist, including apo-AI insufficiency, which is caused by a substitution of cysteine for arginine at amino acid 173 and results in lower plasma HDL-C levels. This mutation is inherited as an autosomal dominant trait and has not been associated with premature CHD. Whether the mutation protects against the development of atherosclerosis or whether this kindred has mitigating genetic or environmental factors is not known. Other apo-AI variants are associated with amyloidosis.

*Clinical manifestations also include orange tonsils.*
Cholesteryl Ester Transfer Protein Deficiency

CETP deficiency is a hereditary syndrome in which plasma HDL-C levels are increased because of diminished activity of plasma CETP. Once thought to be rare, the disorder is not uncommon in the Japanese population. Its features include marked elevations of plasma HDL-C in homozygotes (usually >2.6 mmol/L [100 mg/dL]) and possible protection against development of CHD. Heterozygotes have moderately elevated HDL-C levels. The diminished activity of CETP results in diminished transport of cholesteryl esters from HDL to the apo-B-containing lipoproteins. As a result, more cholesteryl esters are found in HDL, and the ratio of total cholesterol to HDL-C is markedly reduced. Presumably, the combination of reduced amounts of atherogenic LDL and increased antiatherogenic HDL decreases susceptibility to atherosclerosis.

Studies in transgenic mice have confirmed this relation between CETP and atherosclerosis. Although mice normally do not have significant plasma CETP activity and have high plasma HDL-C levels, transgenic mice that express CETP have increased plasma LDL-C, decreased HDL-C, and increased susceptibility to atherosclerosis. Nevertheless, as discussed previously, subjects who are heterozygous for CETP deficiency experience CHD despite high plasma HDL, and it remains to be determined whether lowering CETP activity in humans would have therapeutic value. The molecular diagnosis of CETP deficiency requires the measurement of plasma CETP activity in vitro or identification of the DNA mutation. At present, there is no specific treatment.
Lecithin:Cholesterol Acyltransferase Deficiency

LCAT deficiency is a rare autosomal recessive disorder that causes corneal opacities, normochromic anemia, and renal failure in young adults. About 30 kindreds of LCAT deficiency and a number of mutations have been described. LCAT deficiency results in decreased esterification of cholesterol to cholesteryl esters on HDL particles. As a result, free cholesterol accumulates on lipoprotein particles and in peripheral tissues such as the cornea, red blood cell membranes, and renal glomeruli, presumably because reverse cholesterol transport is impaired. Plasma cholesterol levels in LCAT deficiency are variable, HDL-C levels are reduced, and the ratio of free cholesterol to esterified cholesterol in the plasma is increased. Normally, free cholesterol accounts for about one third of the total cholesterol in the plasma; in LCAT deficiency, free cholesterol accounts for most of the plasma cholesterol. The accumulation of free cholesterol in vascular tissues can lead to premature CHD. At present, there is no means to increase the plasma activity of LCAT; therefore, the treatment is preventive (by dietary fat restriction) and symptomatic (e.g., renal transplantation).

A variant of LCAT deficiency is called fish-eye disease. Although this disorder is also caused by mutations of the LCAT gene, the phenotype is less severe than that seen in complete LCAT deficiency. Fish-eye disease is characterized by low plasma HDL-C levels and corneal opacities; anemia, renal disease, and premature atherosclerosis are not present. The phenotypic differences between LCAT deficiency and fish-eye disease have been attributed to whether LCAT activity is absent from both HDL and apo-B-containing lipoproteins (LCAT deficiency) or from HDL only (fish-eye disease); however, one subject with phenotypic fish-eye disease had normal HDL-associated LCAT activity.
Tangier disease is a rare autosomal recessive disorder associated with hypolipidemia, including decreases in both plasma HDL and LDL-C levels, and the presence of orange tonsils. Other features include corneal opacities, hepatosplenomegaly, peripheral neuropathy, and premature CHD. Metabolic studies have demonstrated that the disorder is associated with enhanced catabolism of plasma HDL. Mutations in ABCA1 have been causally linked to Tangier disease. ABCA1 appears to promote cholesterol efflux from cells such as macrophages, the loss of this function apparently accounts for the impaired efflux of cholesterol from Tangier cells. As a result, massive amounts of cholesteryl esters accumulate in macrophages of the reticuloendothelial system. The orange tonsils observed in this disorder are caused by cholesterol deposits. There is currently no specific treatment. The degree to which heterozygosity for ABCA1 mutations contributes to inherited low-HDL syndromes remains to be determined.
PRIMARY GENETIC HYPOLIPIDEMIAS

Familial Hypobetalipoproteinemia

Familial hypobetalipoproteinemia, an autosomal dominant disorder of apo-B metabolism, is associated with plasma cholesterol and LDL-C levels that are less than one half of normal in heterozygotes and with marked hypocholesterolemia (<1.3 mmol/L [50 mg/dL]) in homozygotes.\(^{12,13}\)

Clinical Features

Heterozygous subjects, about 1 in 500 persons, are usually asymptomatic but come to attention because of the detection of low plasma cholesterol levels. Typically, the total plasma cholesterol level is less than the fifth percentile, and it may be less than 2.6 mmol/L (100 mg/dL). Plasma LDL-C levels are also reduced by one half or more, and HDL-C levels are normal or slightly increased.\(^{14}\) Plasma triglyceride levels are reduced in some kindreds. Although heterozygotes are usually asymptomatic, fat malabsorption has been reported.\(^{15}\) Plasma triglyceride levels are reduced in some kindreds. Although heterozygotes are usually asymptomatic, fat malabsorption has been reported.\(^{15}\)

Subjects who are homozygotes or compound heterozygotes for these apo-B mutations are rare, about 1 in 10\(^5\) persons. Homozygotes may be detected at a young age because of fat malabsorption and decreased plasma cholesterol levels. Fat malabsorption is caused by inability to form chylomicrons in the intestine and subsequent failure to absorb fats and fat-soluble vitamins. Fat malabsorption may be accompanied by retinitis pigmentosa, acanthocytosis, and a progressive neurologic degenerative disease resulting from vitamin E deficiency. The acanthocytosis is caused by alterations in red blood cell membrane lipids. Despite the low plasma cholesterol levels, steroidogenesis appears to be normal except when demands are quite high.\(^{16,17}\) Homozygous subjects who produce enough of a truncated isoform of apo-B to facilitate some fat absorption may have a milder phenotype.

Origin and Pathogenesis

Most cases of known origin result from mutations in the apo-B gene.\(^{18}\) More than 30 mutations have been described;

most are either nonsense or frameshift mutations that lead to the formation of truncated apo-B proteins.\(^{19}\) Metabolic turnover studies indicate that these apo-B gene mutations impair the synthesis of apo-B-containing lipoproteins in some cases\(^{20}\) and enhance the clearance of apo-B-containing lipoproteins from the plasma in others.\(^{21}\) The decreased levels of apo-B-containing lipoproteins in the plasma cause low plasma cholesterol and triglyceride levels. Although most known cases of hypobetalipoproteinemia involve apo-B mutations, additional undefined genetic factors can result in low cholesterol levels.\(^{22}\)

In homozygous subjects, the absence of apo-B leads to impaired intestinal chylomicron formation, which in turn leads to impaired absorption of fats and fat-soluble vitamins. Cholesterol absorption is probably also impaired, as demonstrated in transgenic mice lacking intestinal apo-B expression and chylomicron formation.\(^{23}\) As noted, vitamin E malabsorption results in low tissue stores of tocopherol and a degenerative neurologic disease. Retinal degeneration may also be related to deficiencies of fat-soluble vitamins.\(^{24}\)

Diagnosis

The diagnosis of familial hypobetalipoproteinemia is suggested by low plasma total and LDL cholesterol levels inherited as an autosomal dominant trait. The homozygous condition is suggested by extremely low plasma cholesterol and triglyceride levels in an infant or child with fat malabsorption. The differential diagnosis of the homozygous state includes abetalipoproteinemia (see later discussion) and Anderson’s disease (chylomicron retention disease).\(^{25,26}\) The molecular diagnosis of hypobetalipoproteinemia can be performed only in specialized laboratories by gel electrophoresis of plasma apo-B or by DNA analysis to identify specific mutations.

Treatment and Prognosis

Because heterozygous subjects are almost always asymptomatic, no specific treatment is indicated, but dietary supplementation of fat-soluble vitamins (especially vitamin E) is reasonable. Heterozygotes should be informed that if their spouse also has a very low plasma cholesterol level, their children could have homozygous or compound heterozygous hypobetalipoproteinemia; in this scenario, subjects should be referred to a lipid clinic for genetic counseling.

Subjects with homozygous hypobetalipoproteinemia (phenotypic abetalipoproteinemia) should be treated with large doses of vitamin E orally (100 to 300 mg/kg/day), which can raise the tissue vitamin E concentrations and prevent the neurologic complications.\(^{27}\) It is imperative to make the diagnosis and begin treatment at an early age to prevent nutritional deficiencies. Fat should be provided in the diet up to a level that symptoms allow (usually 15% to 20% of calories). Supplementation with medium-chain triglycerides is probably contraindicated because of reports of liver toxicity.\(^{28}\)
Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disorder caused by a deficiency in MTP, which results in a virtual absence of apo-B-containing lipoproteins in the plasma. The clinical features include malabsorption of fat and fat-soluble vitamins from the intestine, which can lead to neurologic disease related to vitamin E deficiency. The disorder is frequently detected in infancy because of fat malabsorption associated with marked decreases in plasma cholesterol and triglyceride levels.

Clinical Features

Abetalipoproteinemia occurs in fewer than 1 in 10^6 persons and has the same phenotype as homozygous hypobetalipoproteinemia (described previously), including malabsorption of fat and fat-soluble vitamins from the intestine, which can lead to neurologic disease related to vitamin E deficiency. The disorder is frequently detected in infancy because of fat malabsorption associated with marked decreases in plasma cholesterol and triglyceride levels.

Origin and Pathogenesis

Abetalipoproteinemia is caused by a deficiency of MTP, a protein that transfers triglycerides or phospholipids onto nascent apo-B-containing lipoproteins during their formation in the ER. Insufficient lipidation of nascent particles impairs the synthesis and secretion of these particles by the intestine and the liver, and little if any apo-B is found in the plasma. Several mutations in the MTP gene have been described. The lack of MTP in the intestine leads to impaired chylomicron formation and malabsorption of fats and fat-soluble vitamins.

Diagnosis

The diagnosis is suggested by fat malabsorption associated with extremely low levels of plasma cholesterol (usually <1.3 mmol/L [50 mg/dL]) and triglyceride in an infant or young child. Cholesterol levels in the parents, who are obligate heterozygotes, are normal. The demonstration of the molecular defect requires a specialized laboratory for detection of low or absent MTP in intestinal biopsy specimens or DNA analysis to identify specific mutations. The differential diagnosis of abetalipoproteinemia includes homozygous hypobetalipoproteinemia, in which the obligate heterozygote parents have low plasma lipid levels, and Anderson's disease. Also called chylomicron retention syndrome, the latter disorder is a rare condition that is phenotypically similar to abetalipoproteinemia. Subjects with Anderson's disease cannot secrete chylomicrons from the intestine owing to an as yet undefined recessive mutation.

Treatment

Abetalipoproteinemia is treated in the same way as homozygous hypobetalipoproteinemia. Large doses of vitamin E are given by mouth to prevent the neurologic sequelae of vitamin E deficiency.
Hepatic Lipase Deficiency

Hepatic lipase deficiency is a disorder associated with lack of hepatic lipase activity in the plasma. Its features include combined hyperlipidemia, with elevated levels of plasma cholesterol (6.5 to 38.8 mmol/L [250 to 1500 mg/dL]) and triglyceride (4.5 to 92.6 mmol/L [395 to 8200 mg/dL]); palmar and tuberous xanthomas; and premature arcus corneae. VLDL levels are increased (however, the VLDL cholesterol/triglyceride ratio is <0.3, in contrast to type III hyperlipoproteinemia), and there is a threefold to fivefold enrichment of triglyceride in the LDL and HDL fractions. HDL-C levels are normal or slightly increased. Susceptibility to atherosclerosis is thought to be increased. The demonstration of hepatic lipase deficiency requires specialized in vitro assays of hepatic lipase activity in plasma or DNA analysis to identify mutations. Dietary restriction of fat and cholesterol can lower the plasma lipid levels.
Sitosterolemia

In this rare disorder, dietary sitosterol and other plant sterols, which are not normally absorbed in significant quantities in the intestine, are absorbed in large amounts, resulting in their accumulation in the plasma and in peripheral tissues. Premature atherosclerosis can occur. The molecular defect was mapped to chromosome 2p21 and was identified as mutations in the genes encoding ABCG8 and ABCG5. Clinically, affected children have tendon xanthomas and normal to high plasma levels of LDL-C; the differential diagnosis includes FH and cerebrotendinous xanthomatosis. The diagnosis can be confirmed by gas-liquid chromatography of plasma lipids to demonstrate the abnormal sterols. Treatment consists of restriction of plant sterols in the diet.
Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis is a rare disorder of sterol metabolism associated with neurologic disease, tendon xanthomas, and cataracts in young adults. Neurologic manifestations include cerebellar ataxia, dementia, spinal cord paresis, and subnormal intelligence. Premature atherosclerosis is common. Osteoporosis has been reported and is presumably caused by alterations in vitamin D metabolism. The disorder results from mutations that cause deficiencies of 27-hydroxylase, a key enzyme in cholesterol oxidation and bile acid synthesis. As a result, high levels of cholesterol and cholestanol, a 5-dihydro derivative of cholesterol, accumulate in the plasma, tendons, and tissues of the nervous system. Treatment is with chenodeoxycholic acid, often in combination with an HMG-CoA reductase inhibitor.
Acid Cholesteryl Ester Hydrolase Deficiency

Acid cholesteryl ester hydrolase deficiency is an autosomal recessive disorder caused by deficiency of a lysosomal esterase, which results in massive accumulation of cholesteryl esters and triglycerides in lysosomes. In the variant called Wolman's disease, which is usually fatal in the first year of life, there is a complete deficiency of the lysosomal esterase. Cholesteryl ester storage disease is a milder variant in which there may be some residual esterase activity; affected subjects can survive past childhood but may develop premature CHD.
Familial Isolated Vitamin E Deficiency

Familial isolated vitamin E deficiency is a rare disorder characterized by low plasma levels of vitamin E in association with progressive neurologic degenerative disease.\cite{490,491} It is caused by lack of hepatic -tocopherol transfer protein, \cite{492} which is thought to facilitate the incorporation of -tocopherol onto nascent VLDLs during their formation in the liver. In the absence of the protein, there is a lack of vitamin E on VLDL, which is a major transport mechanism for delivery of vitamin E to peripheral tissues. Treatment consists of daily supplementation with high doses of oral vitamin E.
SECONDARY DISORDERS OF LIPID METABOLISM

A number of metabolic diseases and drug therapies influence plasma lipids. The secondary disorders of hyperlipidemia

HDL, high-density lipoproteins; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

are listed in Table 34-8 . Factors that affect HDL levels are listed in Table 34-10 .

Diabetes Mellitus

Of the common diseases, diabetes mellitus exerts some of the most profound effects on plasma lipid metabolism. Hypertriglyceridemia is found in up to one third of all diabetic patients and is related to the critical role of insulin in the production and clearance of triglyceride-rich lipoproteins from the plasma. In addition, diabetic patients frequently have high plasma levels of atherogenic lipoproteins and low plasma HDL, predisposing them to premature CHD, a leading cause of death in diabetes.

In type 1 diabetes, insulin deficiency and poor glycemic control are associated with increases in the plasma levels of triglycerides and of apo-B-containing lipoproteins because of effects on plasma lipid metabolism in peripheral tissues and the liver. In peripheral tissues, insulin deficiency results in impaired LPL activity and diminished clearance of triglyceride-rich particles. Insulin deficiency also causes enhanced lipolysis, which results in increased free fatty acid flux to the liver. In the liver, increased free fatty acid flux drives triglyceride synthesis and VLDL triglyceride synthesis and secretion. Plasma LDL-C levels may also be increased, possibly because insulin stimulates LDL receptor-mediated degradation of LDL and this is diminished in type 1 diabetes.

In its most severe form, insulin deficiency can cause a chylomicronemia syndrome known as diabetic lipemia. In this disorder, massive increases in plasma triglyceride levels (>22.6 mmol/L [2000 mg/dL]) can result in lipemia retinalis, eruptive xanthomas, fatty liver, and pancreatitis. This disorder arises from an acquired LPL deficiency and is relatively rare in the modern era of insulin therapy. The acquired lack of LPL activity results in accumulation of chylomicrons in the plasma (type I pattern), similar to that seen in primary genetic LPL deficiency. The disorder may result from the occurrence of diabetes melitus in combination with some underlying disorder of triglyceride metabolism. The hyperlipidemia related to insulin deficiency and type 1 diabetes is reversible with intensive insulin therapy. Persistent lipid abnormalities in patients with type 1 diabetes with excellent glycemic control suggest that another disorder of lipid metabolism is present.

In type 2 diabetes, which accounts for more than 90% of cases, the metabolic defect is related to insulin resistance and relative insulin deficiency. The insulin resistance appears to be caused by both genetic and acquired factors; metabolic abnormalities that accompany the insulin resistance include obesity, hyperglycemia, hypertension, plasma lipid abnormalities, and hyperuricemia, which are referred to as syndrome X or the metabolic syndrome. One of the most common lipid abnormalities in type 2 diabetes is a moderate hyperlipidemia characterized by an increase in VLDL (type IV pattern), which can be accompanied by various degrees of chylomicronemia (type V pattern), depending on the dietary fat intake. This disorder is characterized by the accumulation of apo-B-containing lipoproteins, which are likely to be proatherogenic, in the plasma. The plasma triglyceride and cholesterol levels are often moderately elevated, the HDL-C concentration may be low, and IDLs, or remnants, which are probably atherogenic, are also often increased. Plasma levels of LDL are increased in some but not all subjects. However, the hypertriglyceridemia in type 2 diabetes is often characterized by an increase in the small, dense LDLs (LDL subclass pattern B), which are particularly atherogenic; this increase occurs even in the absence of hyperglycemia. In addition, a portion of the plasma LDL undergoes glycosylation, which may increase susceptibility to oxidation. Xanthomas are usually absent in this disorder.

Factors that contribute to the lipoprotein abnormalities in type 2 diabetes include decreased LPL activity in muscle and adipose tissue and increased free fatty acid flux to the liver from peripheral adipose tissue stores. Combined with hepatic overproduction of apo-B, which occurs in insulin resistance, the free fatty acid flux drives triglyceride synthesis and VLDL production in the liver. The lipid abnormalities associated with VLDL overproduction may be exacerbated by a primary genetic disorder of lipid metabolism.

The mainstay of therapy for patients with type 2 diabetes with hyperlipidemia is glycemic control through diet, oral hypoglycemic agents, or insulin therapy. Periodic monitoring of the glycosylated hemoglobin is helpful in assessing the glycemic control. However, in contrast to the situation in type 1 diabetes, the hyperlipidemia in type 2 diabetes may be difficult to eradicate even with excellent glycemic control because these subjects have accompanying genetic and acquired metabolic abnormalities that are not resolved by returning blood sugar levels to normal. Decreasing insulin resistance through weight loss can, however, have dramatic effects on both the hyperglycemia and the hyperlipidemia. Metformin, a hypoglycemic agent, may lower plasma glucose levels and produce a modest lowering of plasma lipid levels. In addition to glycemic control, drugs for diabetic hyperlipidemia include gemfibrozil and HMG-CoA reductase inhibitors. Niacin should be used with caution as it can impair or worsen glucose tolerance. Treatment with insulin can lower plasma LDL-C levels in both type 1 and type 2 diabetes mellitus.
Hypothyroidism

Alterations in thyroid function can have profound effects on plasma lipids. and all patients with significant hyperlipidemia should be screened for hypothyroidism. The classical manifestation of hypothyroidism is an elevation of the plasma LDL-C level (6.5 to 15.5 mmol/L [250 to 600 mg/dL]), but this disorder can also be associated with high plasma triglyceride levels. Levels of HDL-C are usually unchanged or slightly lower in hypothyroidism and may be reduced in hyperthyroidism, the latter effect may be related to alterations in hepatic lipase activity. The elevations of plasma LDL-C in hypothyroidism are associated with impaired clearance of LDL, probably reflecting decreased LDL receptor expression. The high LDL-C levels in hypothyroidism are associated with an increased risk for atherosclerosis, but risk for myocardial infarction is not necessarily increased, perhaps because hypothyroidism decreases myocardial oxygen demand. Subclinical hypothyroidism, in which metabolic abnormalities are present without symptoms, can also cause hypercholesterolemia that responds to treatment with thyroid hormone. Hypothyroidism is also associated with low LPL activity, predisposing to increased plasma triglyceride levels. Hyperlipidemia with hypothyroidism may be more marked in those with an underlying genetic susceptibility, but it responds dramatically to thyroid hormone replacement. In elderly patients with CHD or significant risk factors, thyroid hormone should be replaced cautiously because rapid replacement can exacerbate underlying ischemic heart disease.
Estrogen Therapy

Estrogen therapy increases plasma triglyceride levels and can occasionally cause marked hypertriglyceridemia, especially in predisposed individuals. The hypertriglyceridemia appears to be dose-related. Although most women taking either oral contraceptives or postmenopausal estrogens maintain triglyceride levels in the normal range, massive hypertriglyceridemia can on occasion cause pancreatitis. For this reason, triglyceride levels should be measured in women before estrogen therapy is initiated. Estrogens appear to cause hypertriglyceridemia through increased production of VLDL. LPL activity in adipose tissue is not altered.

Estrogen therapy also enhances the clearance of LDL from the circulation and lowers plasma LDL-C. Enhanced LDL clearance probably results from increased hepatic LDL receptor expression. Treatment of postmenopausal women with estrogen can lower LDL-C by 15%. Estrogens can also reduce the hyperlipidemia of type III hyperlipoproteinemia.

Estrogens have significant effects on HDL metabolism, increasing HDL-C in postmenopausal women by more than 15%, primarily by increasing the HDL subfraction. Women have higher HDL-C levels than men at all ages after puberty. This is presumably a result of the effects of androgens because HDL-C levels decrease at puberty in men but remain constant in women. The mechanism by which gonadal hormones alter the HDL-C levels is uncertain but may involve differences in hepatic lipase activity. The effects of estrogen, which raises HDL and lowers LDL-C levels, can be offset if estrogens are combined with progestational agents, which lower HDL and raise LDL cholesterol levels. Because estrogens tend to lower LDL and raise HDL-C, estrogen therapy in postmenopausal women appears to decrease CHD risk significantly. However, more recent studies have brought this into question.
Alcohol Consumption

The regular consumption of large amounts of alcohol can significantly affect plasma triglyceride metabolism. Alcohol metabolism results in increased NADH levels, which inhibit fatty acid oxidation in the liver. This inhibition leads to increased triglyceride synthesis, fatty liver, and enhanced VLDL production. The enhanced VLDL production raises plasma triglycerides and occasionally causes massive hypertriglyceridemia and pancreatitis, especially in persons with an underlying genetic susceptibility. Plasma electrophoresis reveals an accumulation of VLDL in the plasma (type IV pattern) and occasionally a superimposed chylomicronemia (type V pattern) as these particles compete for saturable clearance mechanisms. Subjects with type III hyperlipoproteinemia are particularly sensitive to the effects of alcohol consumption because the alcohol-induced overproduction of VLDL and associated remnant particles occurs in the setting of impaired remnant clearance. Hypertriglyceridemia can be an important contributor to pancreatitis associated with alcohol consumption.

Alcohol consumption is also associated with higher plasma levels of HDL-C, which in turn may explain why moderate alcohol consumption may protect against CHD. Indeed, moderate consumption of alcohol in the form of wine may be inversely correlated with CHD mortality.
Nephrotic Syndrome

Hyperlipidemia, which almost always accompanies the nephrotic syndrome, is caused predominantly by elevation of LDL (type IIa pattern) but can also be caused by high VLDL levels (type IV pattern). Total cholesterol, VLDL, LDL-C, total triglycerides, and plasma apo-B are all elevated. The ratio of total cholesterol to HDL-C is increased, consistent with an atherogenic phenotype. Plasma Lp(a) levels can also be elevated. The pathogenesis of the hyperlipidemia appears to be related to increased rates of production of LDL or VLDL or both. The cause of VLDL overproduction is unclear, but it may be related to a generalized hypersecretion phenomenon in the liver. Because myocardial infarction ranks second only to renal failure as the cause of death in subjects with nephrotic syndrome, the hyperlipidemia should be treated vigorously. HMG-CoA reductase inhibitors appear to be particularly effective.
Protease Inhibitor Use in Human Immunodeficiency Virus Infection

Combination therapy with protease inhibitors for human immunodeficiency virus infection has been associated with metabolic changes, including hyperlipidemia, lipodystrophy, and insulin resistance, in many patients. The cause of this syndrome is currently unknown. With the improved life expectancy in patients receiving protease inhibitor regimens, there is increased concern about the risk of CHD related to the metabolic side effects. Although data concerning CHD risk and treatment guidelines are lacking, many affected subjects are currently treated with regimens similar to those used in patients with insulin resistance or diabetes not associated with human immunodeficiency virus infection.
Other Drugs

In addition to estrogens, other therapeutic agents can cause hyperlipidemia. These agents include glucocorticoids and antihypertensive agents such as thiazide diuretics and α-adrenergic blockers. Exogenous androgens can reduce HDL-C levels.
TREATMENT OF LIPID DISORDERS

Clinical Trials Providing Rationale for Treating Hyperlipidemia

In addition to proving the cholesterol-diet-heart hypothesis, clinical trials in humans demonstrated that lowering plasma lipid levels reduces the incidence of symptomatic CHD in patients at risk. The Lipid Research Clinics Coronary Primary Prevention Trial was the first of the trials and followed approximately 3800 men (ages 35 to 59) with plasma cholesterol concentrations higher than 7.7 mmol/L (290 mg/dL) and with no prior evidence of CHD. The men were divided into two groups. The control group was given a placebo and minimal dietary advice, while the experimental group was given the lipid-lowering drug cholestyramine and dietary management. Over the 7-year study, reductions of 19%, 19%, and about 25% were seen in total and LDL cholesterol concentrations, in the incidence of fatal and nonfatal myocardial infarction, and in the incidence of angina, respectively. At high doses of cholestyramine, the results were even more dramatic, with 35% and 50% reductions in LDL-C levels and in the incidence of symptomatic CHD, respectively.

The Familial Atherosclerosis Treatment Study took the cholesterol-diet-heart hypothesis a step further. In this study, 120 high-risk men were treated aggressively with lipid-lowering protocols for 2.5 years. All subjects had plasma cholesterol and LDL concentrations higher than 7.0 mmol/L (270 mg/dL) and 4.7 mmol/L (180 mg/dL), respectively, and had all angiographically documented CHD. Digitized quantitative coronary arteriography was used for documentation. Men receiving either drug treatment (lovastatin and colestipol or niacin and colestipol) displayed dramatic reductions in plasma LDL concentrations and in the progression of coronary atherosclerosis. More importantly, established atherosclerotic lesions actually regressed.

Despite the impressive results of these intervention trials, critics continued to question recommendations for diet and drug therapy to reduce the risk of CHD on the basis of the fact that the trials, although they clearly demonstrated a marked reduction in CHD-related events, did not conclusively prove that lowering cholesterol prolonged life. Concern was expressed that an increased risk of death from other causes could result from the treatment. Two important prospective studies have addressed these concerns: the Scandinavian Simvastatin Survival Study (4S), conducted in high-risk patients with preexisting coronary disease (a so-called secondary prevention study), and the West of Scotland Coronary Prevention Study (WOSCOPS), conducted in men without preexisting coronary disease (a so-called primary prevention study).

The 4S trial included 4444 patients, of whom 19% were women, with angina pectoris or a previously documented myocardial infarction and with elevated plasma cholesterol concentrations (5.5 to 8.0 mmol/L [214 to 311 mg/dL]). The subjects, who previously received a lipid-lowering diet, were randomly divided into placebo and treatment groups; the drug tested was simvastatin, an HMG-CoA reductase inhibitor. The groups were observed for an average of 5.4 years (the time interval at which 10% of the study participants died). The mean changes in total plasma cholesterol, LDL-C, and HDL-C in the drug group compared with the placebo group were -25%, -35%, and 8%, respectively. The placebo group had 256 (12%) deaths, and the simvastatin group had 182 (8%), for a relative risk of death of 0.70. Deaths from CHD-related events were 189 in the placebo group and 111 in the simvastatin group, for a relative risk of death of 0.58 in the drug group. There were no differences in noncardiovascular deaths between the two groups (49 versus 46, respectively). In addition, the relative risk for one or more coronary events was 0.66 for the drug group, and there was a 37% reduction in the need for myocardial procedures. In this study, cholesterol lowering prolonged life in persons with established CHD.

The results from the WOSCOPS trial were equally impressive. This trial was designed to test the effect of another HMG-CoA reductase inhibitor (pravastatin) in men (6595 subjects, 45 to 65 years old) with elevated plasma cholesterol concentrations (average 7.0 ± 0.6 mmol/L [272 ± 23 mg/dL]) but with no prior history of cardiac disease. The dosage of pravastatin was 40 mg/day, and the subjects were followed for an average of 4.9 years. Drug treatment lowered plasma cholesterol and LDL-C concentrations by 20% and 26%, respectively, whereas the placebo group had no changes in these levels. The placebo group had 248 documented coronary events (either nonfatal myocardial infarction or death from CHD) compared with 174 for the drug group, representing a 31% reduction in risk with treatment. The drug group had a 32% reduction in death from all cardiovascular causes and a 22% reduction in the risk of death from any cause. Furthermore, reduction in clinical cardiac events was evident within 6 to 12 months. Again, cholesterol lowering in men at high risk for CHD reduced death from cardiovascular events without increasing the risk of noncardiovascular death.

The efficacy and safety of treatment with statins were further demonstrated in subsequent trials. In the Cholesterol and Recurrent Events (CARE) trial and the Long-term Intervention with Pravastatin in Ischemic Disease (LIPID) study, subjects with established CHD at baseline were studied for 5 years. In CARE the average baseline plasma cholesterol was 209 mg/dL (139 and 39 mg/dL for LDL-C and HDL-C, respectively), and in LIPID it was 218 mg/dL (150 and 36 mg/dL for LDL-C and HDL-C, respectively). Treatment with pravastatin (40 mg/day) reduced LDL-C by 25% in CARE and by 28% in LIPID. These decreases were associated with a 24% reduction in CHD in LDL and 29% and 28% reductions in nonfatal myocardial infarctions in LIPID and CARE, respectively.

The CARE and LIPID studies along with 4S demonstrate that patients with CHD and LDL-C levels above 130 mg/dL benefit from lipid-lowering therapy. Although patients in these studies with LDL-C levels between 100 and 130 mg/dL did not display a consistent benefit from treatment, the Veterans Affairs High Density Lipoprotein Intervention Trial demonstrated that CHD patients with LDL-C of 104 mg/dL did benefit from gemfibrozil therapy. Thus, the results from these four trials clearly suggest that treatment of CHD patients with LDL-C higher than 100 mg/dL with hypolipidemic drugs is of benefit and that the target of treatment of CHD patients should be to reduce LDL-C to less than 100 mg/dL.

Like the WOSCOPS trial, the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) targeted men and women without CHD but with moderately elevated LDL-C (average, 156 mg/dL) who were also at risk because of age (men older than 45 years; women older than 55 years) coupled with low HDL-C levels (average, 37 mg/dL). In this trial, lovastatin reduced LDL-C by 26% and primary end-point events, including fatal and nonfatal myocardial infarction and unstable angina pectoris, by 37%.

In addition to proving the diet-cholesterol-heart disease hypothesis, the clinical trials confirm and extend the recommended guidelines for treatment of dyslipidemic patients established by the NCEP, which are discussed in a later section.
Approach to the Hyperlipidemic Patient

Individuals come to attention for evaluation for a lipid disorder because of the presence of atherosclerotic vascular disease, pancreatitis, xanthomas, or xanthelasma or because of detection of a high plasma cholesterol or triglyceride level. The initial evaluation of these patients includes a history and physical examination, including assessment of CHD risk factors, and measurement of plasma lipids.

Risk Factors

The initial examination should include an assessment of risk factors for atherosclerotic CHD. Table 34-11 lists the risk factors, as specified by the NCEP in 2001. Diabetes mellitus is considered to be a disorder equivalent to established CHD with regard to risk. In addition, data indicate that obesity is an independent risk factor for CHD. Particular emphasis should be placed on obtaining a detailed history of all first-degree relatives to identify cholesterol disorders or premature CHD.

*Diabetes is regarded as a CHD equivalent, that is, >20% risk of a CHD event within 10 years.

### Physical Examination

A thorough physical examination should be performed with emphasis on the cardiovascular system and the manifestations of hyperlipidemia. Elevated plasma lipids (cholesterol or triglycerides) can accumulate in macrophage reticuloendothelial cells in certain tissues, particularly skin, tendons, eye, liver, and spleen. Deposits in the skin or tendons are manifest as xanthomas or xanthelasmas. In almost all cases, these tissue lipid deposits are reversible with lipid-lowering therapy. Several of the clinical findings are illustrated in Figure 34-26.

Xanthelasmas (see Fig. 34-26A) are small, raised, yellowish macules that typically appear on or near the eyelids above and around the medial canthus. They are seen in FH, familial defective apo-B100, and type III hyperlipoproteinemia. Xanthelasmas occasionally occur in patients with normal plasma cholesterol levels, possibly as the result of enhanced uptake of oxidized or modified lipoproteins by tissue macrophages. Xanthelasmas typically regress with cholesterol lowering and can often be treated effectively in the setting of normal cholesterol levels with low doses of probucol, an antioxidant drug. Lipemia retinalis (see Fig. 34-26B), a condition in which lipemic plasma can be visualized by routine ophthalmologic examination of the fundi, is typically seen only when the triglyceride levels are 22.6 mmol/L (2000 mg/dL) or higher.

Tendon xanthomas (see Fig. 34-26C and D) are nodular deposits of cholesterol that accumulate in tissue macrophages in the Achilles and other tendons, including the extensor tendons in the hands, knees, and elbows. Tendon xanthomas are often present in FH (approximately 75% of subjects), in familial defective apo-B100, and sometimes in type III hyperlipoproteinemia. Small tendon xanthomas can be overlooked if not specifically sought. The examination of the Achilles tendon should include an assessment for thickness and for irregularities of contour (see Fig. 34-26C). Achilles tendon xanthomas can also be detected by xeroradiography.

Tuberous or tuberoeruptive xanthomas (see Fig. 34-26F) are subcutaneous nodules that develop in the skin over areas susceptible to trauma such as the elbows and knees. They may be singular or multiple and may range from pea-sized to lemon-sized. Tuberous xanthomas are most often seen in type III hyperlipoproteinemia and also occur in FH. Palmar xanthomas (see Fig. 34-26F) are cutaneous deposits in the palmar and digital creases of the hands. This type of xanthoma is almost pathognomonic for high plasma levels of VLDL and type III hyperlipoproteinemia.

Eruptive xanthomas (see Fig. 34-26G) are cutaneous xanthomas that appear as small, yellowish, round papules that contain a pale center and an erythematous base. They can be mistaken for acne. The distribution of eruptive xanthomas includes the abdominal wall, the back, the buttocks, and other pressure contact areas. They are caused by accumulation of triglyceride in dermal histiocytes and generally occur when the plasma triglyceride level is 11.3 to 22.6 mmol/L (1000 to 2000 mg/dL) or more. They can disappear rapidly with lowering of the plasma triglyceride level.

### Screening for Secondary Disorders

The history and physical examination should be directed toward uncovering secondary disorders of lipid metabolism (e.g., diabetes mellitus, hypothyroidism, or the nephrotic syndrome) and toward identifying agents that could cause hyperlipidemia (e.g., estrogens, alcohol, or -adrenergic blockers). In addition, laboratory studies should be performed to measure fasting blood sugar or glycosylated hemoglobin or both and to assess renal and hepatic function and urinary protein. To screen for hypothyroidism, the plasma thyroid-stimulating hormone (thyrotropin) level should be assessed because the prevalence of hypothyroidism is increased in dyslipidemic subjects.

### Measurement of Plasma Lipids

Ideally, plasma lipids should be measured at least twice under fasting steady-state conditions before therapeutic decisions are made. Although plasma lipids are usually measured after a 12-hour fast, the plasma lipid response in the postabsorptive state, which may include significant elevations in atherogenic remnant lipoproteins, may be important in atherogenesis. Because cholesterol is a minor component of chylomicrons, plasma cholesterol can be measured in either the fasting or nonfasting state. Of note, plasma lipids can be decreased in the setting of acute myocardial infarction, and follow-up measurements are essential in these cases.
patients.

Most clinical laboratories measure plasma levels of total triglycerides, total cholesterol, and HDL-C; the last analysis is performed after apo-B-containing lipoproteins are precipitated from the plasma with an agent such as heparin. The plasma LDL-C concentration is then calculated from these measurements by the Friedewald formula:\[\text{LDL cholesterol} = \text{total cholesterol} - \text{HDL cholesterol} - \frac{\text{triglycerides}}{5}\]

This formula relies on an estimate of the VLDL cholesterol that is about 20% of the plasma triglyceride level and is reliable for triglyceride levels of 4.5 mmol/L (400 mg/dL) or less. Plasma LDL concentrations calculated by this formula may be inaccurate in the setting of severe hypertriglyceridemia. Specialized lipid laboratories separate the plasma into different density fractions (e.g., VLDL, LDL, and HDL) by sequential ultracentrifugation of the plasma and then measure the lipid concentrations in each fraction. The main advantage of the latter technique is that VLDL cholesterol, which can reflect atherogenic remnant lipoproteins, is measured directly.

Because the plasma lipids can be divided roughly into the proatherogenic apo-B-containing lipoproteins and the antiatherogenic HDL, assessment of the relative proportions of cholesterol in these two fractions can be valuable in the individual lipid profile. One method is to assess absolute levels of HDL and non-HDL cholesterol.\[\text{Another method is to determine the ratio of total cholesterol to HDL-C; it is desirable for the ratio to be about 4.5 or lower (i.e., to have at least 25% of the plasma cholesterol in the HDL fraction). Both methods allow incorporation of the potentially atherogenic apo-B-containing lipoproteins in the assessment of cardiovascular risk from hyperlipidemia by including VLDL cholesterol levels in the assessment.}\]

Several caveats for interpretation of the plasma triglyceride level deserve mention. First, a triglyceride level higher than 11.3 mmol/L (1000 mg/dL) usually signifies the presence of two or more abnormalities of lipid metabolism (e.g., estrogen therapy in the presence of underlying familial hypertriglyceridemia).\[\text{Second, elevated plasma triglyceride levels can fluctuate markedly in a single person over short periods. The fluctuation occurs because the LPL-mediated clearance mechanisms for triglyceride-rich particles become saturated at plasma triglyceride concentrations of approximately 5.6 mmol/L (500 mg/dL), and above this level plasma triglyceride levels largely reflect dietary influences. In this range, the plasma triglyceride levels may rise precipitously with high dietary fat intake and fall rapidly with dietary fat restriction.}\]

In some instances, visual inspection of plasma after it has been refrigerated overnight can be helpful in understanding a disorder of lipoprotein metabolism. To accomplish this, plasma should be collected in a tube containing ethylenediaminetetraacetic acid (EDTA) and refrigerated overnight. A cream-like layer on the top signifies the presence of chylomicrons (type I hyperlipoproteinemia), which are less dense than plasma and float to the surface. A turbid plasma infranatant signifies high levels of VLDL (type IV hyperlipoproteinemia). Plasma can also be analyzed by electrophoresis on paper or agarose gels and stained for neutral lipids to analyze the amount of lipids in the various lipoprotein classes.\[\text{This type of analysis is now rarely used because it has little utility in the classification or treatment of lipid disorders.}\]

Nevertheless, much of the terminology used to describe lipoprotein disorders is derived from the originally described patterns in Table 34-12.

Specialized tests used to assess plasma lipid disorders include measurements of plasma Lp(a) levels and plasma apolipoproteins and screening of genomic DNA for mutations. Plasma Lp(a) levels can be determined by enzyme-linked immunosorbent assays, if warranted. The Lp(a) assay must distinguish the apo(a) protein from plasminogen, which is highly homologous. Plasma Lp(a) measurement may be helpful in assessing CHD risk, and high levels of Lp(a) may suggest the use of niacin as a therapeutic agent.\[\text{Plasma apo-B and apo-AI levels may be of great value in predicting CHD risk; however, because the assays for these apolipoproteins are difficult to perform and add minimal information to that obtained from plasma cholesterol measurements, they are not routinely used. Specialized tests such as in vitro assays for enzyme activities (e.g., LPL, CETP) or DNA screening for mutations (e.g., the familial defective apo-B100 mutation) are currently performed in specialized laboratories.}\]

Selection of Patients for Plasma Lipid Measurements

Guidelines published by the NCEP in 2001 recommend that a complete plasma lipid profile (total cholesterol, LDL-C, HDL-C, and triglycerides) be measured in all adults 20 years of age and older at least once every 5 years.\[\text{The classification of plasma lipid levels is shown in Table 34-12. An analysis of large, long-term cohort studies has provided evidence that young men with hypercholesterolemia are at substantially}

HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

Increased risk for morbidity and mortality from CHD.\[\text{Others have suggested that cost-benefit analyses of the impact of such screening programs on health care and the potential reversibility of atherosclerosis make it questionable whether to screen young, healthy people without significant risk factors for development of premature coronary artery disease; these researchers recommend delaying plasma lipid screening until an older age.}\]

Plasma triglycerides should be measured in all patients with pancreatitis. The lipemic plasma seen in hypertriglyceridemia can interfere with some assays for serum
Selection of Patients for Treatment

The 2001 NCEP treatment guidelines are based on measurements of plasma cholesterol levels and risk factor assessment. The first step in risk assessment is to determine whether CHD or a CHD equivalent (e.g., diabetes mellitus) is present, as these disorders confer more than 20% risk of a CHD event within 10 years. Framingham risk scores (Table 34-13) are used to identify additional subjects with multiple risk factors conferring a 10-year risk of more than 20%. Treatment options, based on risk stratification, are discussed below. Other criteria for assessing risk in primary prevention have been proposed, including an assessment that places more emphasis on age. Guidelines for managing dyslipidemia based on risk assessment were also published by the European Atherosclerosis Society in 1998.

Treatment decisions can be divided into two major categories: treatment of hyperlipidemia in patients with established CHD and treatment of patients for the primary prevention of CHD. Subjects with hyperlipidemia and established CHD should be aggressively treated to lower plasma cholesterol to NCEP treatment guideline levels. The rationale for this recommendation is that lowering of plasma cholesterol in patients with established CHD decreases subsequent risk for cardiac events and decreases mortality from cardiac events. One study demonstrated a reduction in CHD-related and overall mortality in treated patients: this benefit extended to elderly patients as well. In subjects with established CHD, lipid-lowering therapy causes atherosclerotic lesions to stabilize or regress. However, despite the overwhelming evidence demonstrating the benefits of lipid-lowering treatment, many people with hypercholesterolemia and CHD remain untreated.

The use of lipid-lowering therapies in subjects with hypercholesterolemia and no known CHD (i.e., therapy for primary prevention) has been more controversial. This issue arises in part because there is no easy noninvasive test for assessing the degree of atherosclerosis in human coronary arteries. Therefore, treatment recommendations for asymptomatic persons have been based largely on studies of hypercholesterolemic populations. Primary prevention trials showed that lipid lowering in such patients decreased cardiac events and CHD-related mortality but not overall mortality. However, the WOSCOPS trial (discussed previously) showed that lipid-lowering treatment for 5 years decreased both CHD-related mortality and overall mortality in middle-aged hypercholesterolemic men. This study also established that lipid-lowering therapy improves survival in asymptomatic hypercholesterolemic men. Because the costs of such treatment are high, a noninvasive test to evaluate the coronary arteries and identify which hypercholesterolemic patients are at the highest risk would be useful.

The treatment of hypercholesterolemia in persons older than 65 years is controversial, and few prospective studies have addressed the benefits of treatment in this population. Nevertheless, CHD accounts for a high proportion of deaths in this age group, and the 4S trial demonstrated the survival benefits of treatment in elderly individuals who have established CHD.

Patients with type 2 diabetes mellitus have at least a twofold increase in the risk for CHD, and diabetics without diagnosed CHD have the same risk as nondiabetics with established CHD. In post hoc analyses, clinical trials with HMG-CoA reductase inhibitors (e.g., 4S, CARE, APEX/TexCAPS, and LIPID) demonstrated 20% to 55% reductions in CHD events. For these reasons, the American Heart Association and American Diabetes Association have recommended that guidelines for treatment of hyperlipidemia in diabetics be the same as for patients with CHD. Accordingly, the latest NCEP guidelines recommend considering diabetes mellitus as a CHD equivalent, with identical treatment goals. HMG-CoA reductase inhibitors have been recommended as a first-line treatment. Severe hypertriglyceridemia (>11.3 mmol/L [1000 mg/dL]) should be treated aggressively because it is associated with a high risk for pancreatitis, a potentially fatal disease.

Treatment Goals

The treatment goals of the 2001 NCEP guidelines, based on LDL-C and risk assessment, are summarized in Table 34-14. For patients with clinical CHD, the treatment goal for LDL-C should be a level less than 2.6 mmol/L (100 mg/dL). A useful rule is to lower total cholesterol to roughly 4.1 mmol/L (160 mg/dL) and LDL-C to 2.6 mmol/L (100 mg/dL). These values are similar to the average cholesterol levels in the Japanese population, in which CHD is much less prevalent. In general, LDL-C levels should be lowered to less than 4.1 mmol/L (160 mg/dL) for patients with minimal risk (10-year risk <10%) and to less than 3.4 mmol/L (130 mg/dL) in those with moderate risk (10-year risk 10-20%). It is also useful to monitor the ratio of total cholesterol to HDL-C, which should be 4.5 or less.

CHD, coronary heart disease; LDL-C, low-density lipoprotein cholesterol.

If severe hypertriglyceridemia is present, the goals for triglyceride lowering are to lower the plasma triglyceride level to less than 4.5 mmol/L (400 mg/dL), which markedly reduces the risk for development of pancreatitis. The 2001 NCEP guidelines reflect the fact that even moderate hypertriglyceridemia (>1.7 mmol/L, or 150 mg/dL) is associated with increased CHD risk. If plasma triglycerides remain above 2.3 mmol/L (200 mg/dL) after the LDL-C goal is reached, further reduction may be achieved by increasing the drug therapy.
Treatment of Hyperlipidemia

The treatment of hyperlipidemia is directed primarily at lowering plasma cholesterol levels to prevent morbidity and mortality from CHD. The rationale and the use of diet or drugs for this purpose have been reviewed. Treatment modalities recommended by the NCEP include therapeutic lifestyle changes, which include diet, weight management, and physical activity recommendations, and drug therapy. A major goal in the treatment of hypertriglyceridemia is to prevent pancreatitis. Patients with CHD or CHD equivalent should immediately start appropriate lipid-lowering therapy. Patients

| Blood pressure   | 130/85 mm Hg      |
| Fasting glucose  | 110 mg/dL         |

HDL-C, high-density lipoprotein cholesterol.

*Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index. Therefore, the simple measurement of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased, for example, 94-102 cm (37-40 in). Such patients may have a strong genetic contribution to insulin resistance and, like men with categorical increases in waist circumference, they should benefit from changes in life habits.

Dietary Treatment

All patients should receive instruction about restriction of dietary saturated fat and cholesterol. On average, the Western diet contains 35% to 40% of calories as fat (about 15% to 20% saturated fat, 10% polyunsaturated fat, and 10% monounsaturated fat) and approximately 380 mg of cholesterol per day. In contrast, the average diet in many underdeveloped countries is closer to 10% of calories as fat. The American Heart Association has recommended a single diet, termed Step 1 Dietary Therapy by the NCEP, for all persons older than 2 years. The diet consists of 50% of calories in the form of carbohydrate (complex carbohydrate preferred), 20% as protein, and no more than 30% as fat. Saturated fat should constitute less than 10% of total calories, mono- and polyunsaturated fat up to 10% of total calories. Cholesterol intake should be limited to 250 mg/day or less. A more stringent restriction of saturated fat (<7% of calories) and cholesterol (200 mg/day) intake (Step 2 diet) is recommended for patients with established coronary artery disease. This diet is similar to the therapeutic lifestyle changes diet proposed by the NCEP. In patients with established CHD, drug therapy should be instituted concomitantly with dietary therapy. Changing from a typical Western diet to a Step 1 diet lowers plasma cholesterol levels by only 5% to 10%. The adoption of a Step 2 diet (25% of calories as fat) has produced mixed results in two noteworthy studies. One study, restricting fat intake to 25% of calories lowered cholesterol levels by only 5%; however, in this outpatient study, it was not clear that the diets were strictly adhered to, as evidenced by comparison of the expected and the actual weight loss in participants. In an inpatient (metabolic ward) study, reducing fat intake from 43% to 25% of calories lowered total cholesterol levels by 17% and LDL-C levels by 23%. Even more stringent limitation of fat intake (e.g., 10% of calories) can further lower plasma lipids. In conjunction with modifications of other lifestyle factors, this diet achieved a reduction of about 25% in total plasma cholesterol levels, an average weight loss of 10 kg, and angiographic regression of coronary artery disease.

TABLE 34-16 – National Cholesterol Education Program: Therapeutic Lifestyle Changes for Reducing Coronary Heart Disease Risk

1. Diet:
   - Saturated fat (and trans-esterified fatty acids) less than 7% of total calories
   - Polyunsaturated fat up to 10% of total calories
   - Monounsaturated fat up to 20% of total calories
   - Total fat 25%-35% of total calories
   - Carbohydrates (predominantly complex) 50%-60% of total calories
   - Fiber 20 g/d
   - Protein 15% of total calories
   - Cholesterol <5.2 mmol/L (200 mg/dL)
   - Consider plant stanols/sterols (2 g/d) to enhance LDL-C lowering

2. Weight reduction
3. Increased physical activity

LDL-C, low-density lipoprotein cholesterol.

latter studies suggest that dietary restriction of fat intake can lower plasma cholesterol levels provided the diet is followed. The typical saturated fat and cholesterol contents of common foods are indicated in Table 34.17.

The effects of various types of fat in the diet have been studied extensively. Current recommendations are that dietary fat intake be lowered, primarily by restricting saturated fat intake because saturated fats appear to have the greatest propensity to elevate plasma cholesterol levels. The mechanism of this effect appears to involve decreased receptor-mediated clearance of LDL from the plasma. Similarly, high levels of cholesterol intake raise plasma cholesterol by reducing receptor-mediated catabolism of LDL and by increasing LDL synthesis.

Polyunsaturated fats, such as linoleic acid, which are chiefly found in vegetable oils, have less deleterious effects on plasma cholesterol levels than saturated fats. However, because the long-term effects of consumption of large amounts of polyunsaturated fats are unknown, current recommendations are that polyunsaturated fat constitute no more than 10% of total calories. Polyunsaturated fats that have been hardened by hydrogenation (e.g., in margarines) result in the conversion of some double bonds in the fatty acid from the cis to the trans configuration; these trans fatty acids appear to exert effects on plasma cholesterol that are comparable to those of saturated fatty acids.

Fish oils are rich in a particular subset of long-chain polyunsaturated fats containing double bonds at the n-3 or omega (3) position, such as eicosapentaenoic acid (C-20) or docosahexaenoic acid (C-22). Because the incidence of CHD is decreased in populations that consume relatively large amounts of fish oils, these polyunsaturated fatty acids have been evaluated for the treatment of hyperlipidemia and the prevention of CHD. Although they lower VLDL levels and are effective for treating hypertriglyceridemia, fish oils appear to have little effect on total cholesterol levels and increase LDL levels in many patients with hypertriglyceridemia. Fish oils may have beneficial effects on cardiovascular disease by means other than their effects on lipoproteins, such as inhibition of platelet aggregation, but a prospective study of male health professionals found no protective effects of increased intake of dietary fish oil on the development of CHD. In addition, fish oil supplementation can worsen glycemic control in persons with type 2 diabetes.

Of all the types of fatty acids, monounsaturated fats may have the least deleterious effects on plasma lipoprotein metabolism. Monounsaturated fats, such as oleic acid, are found in high quantities in olive oil and canola oil. When substituted for saturated fats, monounsaturated fats lowered total plasma cholesterol levels without lowering plasma HDL-C levels.

Other dietary components may influence plasma lipid levels. For example, soluble fibers such as pectin or oat bran, which may bind bile acids in the gut and promote net cholesterol excretion, can result in modest (~10%) decreases in LDL-C levels. Margarine containing sitostanol, a nonabsorbed plant stanol that inhibits cholesterol absorption, reduces serum cholesterol by about 10%. Garlic and walnuts are reported to result in modest decreases in plasma cholesterol levels.

### Drug Treatment

Categories of drugs for treatment of lipid abnormalities are listed in Table 34.18. These include drugs that interfere with bile acid absorption from the gut, such as bile acid sequestrants, or with cholesterol biosynthesis in cells, such as HMG-CoA reductase inhibitors. These agents reduce cholesterol levels and increase LDL receptor expression in cells, thereby lowering plasma LDL concentrations. Other agents, including niacin and gemfibrozil, either inhibit VLDL synthesis and secretion or enhance the clearance of triglyceride-rich particles by enhancing VLDL-mediated catabolism. Finally, drugs that work primarily as antioxidants are being evaluated for treating hypertriglyceridemia, fish oils appear to have little effect on total cholesterol levels and increase LDL levels in many patients with hypertriglyceridemia. Fish oils may have beneficial effects on cardiovascular disease by means other than their effects on lipoproteins, such as inhibition of platelet aggregation, but a prospective study of male health professionals found no protective effects of increased intake of dietary fish oil on the development of CHD. In addition, fish oil supplementation can worsen glycemic control in persons with type 2 diabetes.

Of all the types of fatty acids, monounsaturated fats may have the least deleterious effects on plasma lipoprotein metabolism. Monounsaturated fats, such as oleic acid, are found in high quantities in olive oil and canola oil. When substituted for saturated fats, monounsaturated fats lowered total plasma cholesterol levels without lowering plasma HDL-C levels.

### HMG-CoA Reductase Inhibitors

Several potent inhibitors of HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol biosynthesis, are available. Inhibition of cholesterol biosynthesis up-regulates cellular LDL receptors and enhances clearance of LDL from the plasma into cells. The inhibitors differ in their side chains, which can affect their relative hydrophobicity. For example, lovastatin and simvastatin are relatively hydrophobic and lipophilic compared with others.

Niacin, which is more hydrophilic, these properties appear to have little effect on the ability to lower LDL levels. Therapeutic doses of these agents reduce total cholesterol and LDL-C levels by 20% to 55%. Plasma triglyceride levels greater than 250 mg/dL are reduced by amounts that are comparable to the reductions in LDL-C. High doses of the most potent statins reduce triglyceride levels by 35% to 40%. In patients with triglyceride levels less than 250 mg/dL, statins reduce triglyceride levels by less than 25%. Statins increase plasma HDL-C levels by 5% to 10%. In addition to lipid-lowering effects, a multitude of potentially cardioprotective effects are being ascribed to statins, including improved endothelial function, increased plaque stability, decreased inflammation, decreased lipidoprotein oxidation, and improved circulation. The reductase inhibitors are well tolerated and cause few side effects. The most serious potential side effect is myopathy, which occurs in less than 1% of persons taking lovastatin and can cause myoglobinuria and renal failure. Patients taking HMG-CoA reductase inhibitors in whom myalgias develop should have serum creatine phosphokinase measurements, and the drug should be stopped immediately if evidence of myositis is found. The risk of myopathy is increased if an HMG-CoA reductase inhibitor is used in combination with niacin or gemfibrozil which can cause myopathy by themselves, or with drugs that are metabolized by the 3A4 isozyme of cytochrome P450 (CYP3A4), such as erythromycin, cyclosporine, nefazodone, or protease inhibitors.

Bile acid sequestrants are anion-exchange resins that exchange chloride for negatively charged molecules in the intestine, these agents can interfere with the absorption of other medications, including levothyroxine, digoxin, warfarin, and thiazide diuretics. Therefore, resins are given at least 4 hours before or 1 hour after other medications.

The most inexpensive drug for treating hyperlipidemia is the B vitamin niacin. Therapeutic doses of niacin (typically 2.0 to 4.5 g/day) lower both total and LDL cholesterol by 15% to 30%, lower triglyceride levels by 30% to 40%, and raise HDL-C levels by 15% to 25%. Maximal HDL increases usually occur with therapeutic doses of 1.5 to 2.0 g/day. Niacin

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

Statins, only pravastatin and fluvastatin are not extensively metabolized by CYP3A4. Although these drugs may be less likely to cause myopathy when used with other CYP3A4-metabolized drugs, myopathy has been reported with their use.

To minimize the risk of myopathy, drug combinations should be avoided. However, statins may be used with a predisposing drug without increasing myopathy risk if the statin is administered at no more than 25% of its maximal dose. The plasma creatine kinase level should probably be monitored if the combinations are used. Serum transaminase elevations (greater than three times normal) occur in 2% to 3% of patients. The long-term side effects of HMG-CoA reductase inhibitor therapy are not known, but no significant long-term toxicities have been observed with lovastatin, which has now been in use for more than 15 years.

**Bile Acid Sequestrants**

Bile acid sequestrants are anion-exchange resins that exchange chloride for negatively charged bile acids. The bound bile acids are then excreted in the feces. The increased excretion of bile acids causes increased oxidation of cholesterol to form bile acids in hepatocytes, and the resultant up-regulation of hepatic LDL receptors in turn lowers plasma LDL concentrations. Because bile acid sequestrants act in the intestine, the side effects are limited to local effects in the gastrointestinal system (e.g., bloating, gas, constipation). At therapeutic doses, these agents can lower plasma cholesterol levels by 15% to 25%. However, they can increase plasma triglyceride levels and must be used with caution in patients predisposed to hypertriglyceridemia. In addition, because they bind negatively charged molecules in the intestine, these agents can interfere with the absorption of other medications, including levothyroxine, digoxin, warfarin, and thiazide diuretics. Therefore, resins are given at least 4 hours before or 1 hour after other medications.

**Niacin**

The most inexpensive drug for treating hyperlipidemia is the B vitamin niacin. Therapeutic doses of niacin (typically 2.0 to 4.5 g/day) lower both total and LDL cholesterol by 15% to 30%, lower triglyceride levels by 30% to 40%, and raise HDL-C levels by 15% to 25%. Maximal HDL increases usually occur with therapeutic doses of 1.5 to 2.0 g/day. Niacin

also lowers plasma Lp(a) concentrations by up to 40%. The preparation must be niacin and not niacinamide, which has no efficacy. The mechanism whereby niacin affects plasma lipids is unclear but seems to be associated with decreased hepatic VLDL production.

The most troublesome side effect of niacin therapy is a flushing syndrome that occurs shortly after taking the medicine. Flushing can be minimized by initiating therapy with small doses (e.g., 100 mg) and gradually increasing the dosage to the therapeutic range over weeks to months. Repeated dosing is associated with a gradual tolerance to the flushing syndrome. In addition, taking an aspirin about 1 hour before the niacin can diminish the flushing, possibly by inhibiting prostaglandin-mediated side effects.

The most serious complication of niacin therapy is hepatotoxicity, and therapy should be accompanied by monitoring of serum liver function tests. Mild increases in serum transaminases are common when doses are increased rapidly; however, therapy should be discontinued if transaminases reach highly elevated levels (e.g., <10 times normal). Because hepatotoxicity appears to be more common with sustained-release preparations of niacin, the immediate-release crystalline form is preferred. Other side effects of niacin therapy include impairment or worsening of glucose tolerance and hyperuricemia. Data suggest that niacin can be used safely in patients with glucose intolerance or diabetes mellitus, but the drug should be used with great caution in patients with a history of gout and is contraindicated in patients with active peptic ulcer disease.

Fibric Acid Derivatives

The fibric acid derivatives, clofibrate and gemfibrozil, lower plasma triglycerides by about 40% and increase HDL-C levels by about 10% but have only minor effects on LDL-C. These agents act by activating the peroxisome proliferator-activated receptor, a nuclear hormone receptor that is expressed in the liver and other tissues. This results in increased fatty acid oxidation, increased LPL synthesis, and reduced expression of apo-CIII, all of which contribute to lowering plasma triglycerides. The physiologic results are a decrease in VLDL triglyceride production and an increase in LPL-mediated catabolism of triglyceride-rich lipoproteins. This receptor also stimulates the expression of apo-AI and apo-AII, leading to increased HDL levels. These agents are given twice a day and are well tolerated. Side effects include gastrointestinal discomfort and possibly an increased incidence of cholesterol gallstones. Fibric acid derivatives should be used with great caution in the setting of renal insufficiency because patients with this condition have an increased risk of myopathy.

Clofibrate received adverse publicity because of a large clinical trial in which slightly more cancer deaths were noted in the clofibrate-treated group. However, a later analysis did not substantiate this finding, and there is no firm evidence that the drug is carcinogenic in humans. In two subsequent trials, the Helsinki Heart Study (primary prevention) and the Veterans Affairs High Density Lipoprotein Intervention Trial (secondary prevention), gemfibrozil treatment reduced fatal and nonfatal CHD events without changes in mortality rates.

Combination Therapy

For patients with severe elevations of plasma cholesterol (e.g., >7.8 mmol/L [300 mg/dL]), in whom treatment goals are to reduce the plasma and LDL cholesterol levels by 50% or more, combination drug therapy is usually required. Often this can be achieved with combinations that employ lower doses than needed when these agents are used as single agents. For example, combined therapy with an HMG-CoA reductase inhibitor and either niacin or a bile acid sequestrant can lower plasma cholesterol levels by more than 50%. Occasionally, in patients with severe hypercholesterolemia, combinations that include an HMG-CoA reductase inhibitor, niacin, and a bile acid sequestrant can achieve the desired lipid-lowering effect. Patients with diabetes mellitus who have high plasma levels of triglyceride and VLDL cholesterol may benefit from combination therapy with a low dose of an HMG-CoA reductase inhibitor and gemfibrozil. Because the use of HMG-CoA reductase inhibitors with niacin or gemfibrozil is associated with a higher risk of myopathy, such combinations must be used with caution. Monitoring of the serum creatine kinase level may be helpful, and only low doses of the reductase inhibitors (20 mg/day of lovastatin or the equivalent) should be used in most patients.

Drugs on the Horizon

A number of strategies to improve the treatment of dyslipidemia are under development. For example, more potent statins capable of lowering LDL-C levels by more than 65% are being developed. Inhibitors of MTP represent another strategy. These agents have the potential to lower both plasma triglycerides and cholesterol levels by inhibiting hepatic VLDL production. Agents that impair cholesterol absorption, such as ezetimibe or an ACAT2 inhibitor, may offer alternative strategies for lowering plasma cholesterol levels. Inhibitors of CETP have the potential to raise HDL levels and inhibit atherosclerosis.

There has been intense interest in the use of antioxidants to treat or prevent atherosclerosis. Probucol, a potent antioxidant transported on lipoproteins, protected against the development of atherosclerotic lesions in animals. However, in a trial in humans, probucol failed to benefit patients with established peripheral vascular disease. A number of new antioxidants are under development. The antioxidant vitamins (the fat-soluble vitamins E and A and the water-soluble vitamin C) may also be antiatherogenic. Evidence to support this comes from population studies in which high intake of antioxidants was associated with decreased coronary events. However, a prospective trial examining carotene supplementation failed to show a benefit. In a prospective trial of vitamin E supplementation, 400 IU/day reduced the risk of nonfatal infarction in patients with established CHD. More prospective data demonstrating that supplemental antioxidant vitamin therapy can prevent atherosclerosis or CHD events in humans are needed before a recommendation can be made.

Estrogen Replacement Therapy and Coronary Heart Disease

Because estrogen replacement therapy in postmenopausal women reduces LDL-C and Lp(a) levels and raises HDL-C levels and because CHD risk increases substantially in postmenopausal women, there has been intense interest in using estrogens to prevent CHD. However, two clinical trials have shown no benefit of estrogen replacement therapy in women with established CHD. It remains to be determined whether estrogen replacement will be effective in the primary prevention of CHD. Estrogen replacement has been shown to have multiple noncardiovascular benefits.

Surgical Treatment

Partial ileal bypass surgery has been used to reduce lipid levels in patients with severe hypercholesterolemia who cannot tolerate lipid-lowering drugs. This surgical therapy can reduce total cholesterol levels by 20% to 25% and cause regression of angiographically measured atherosclerotic lesions. In addition, liver transplantation and portacaval shunting have been used as experimental therapies for homozygous FH (see previous discussion).
Treatment to Raise High-Density Lipoprotein Cholesterol

Patients with familial hypoproteinemia may have normal or modestly increased plasma cholesterol levels but have very low HDL-C levels, resulting in a predisposition to CHD. Such patients may have high ratios of total cholesterol to HDL-C (e.g., >10) despite having a normal plasma cholesterol level. At present, there are no highly effective therapies to raise HDL-C levels. Estrogens can be given to postmenopausal women and exercise in sustained amounts may modestly increase HDL-C levels. HDL-C levels increased by approximately 2 mg/dL for every 10 miles run per week in one study of recreational runners. Alcohol, when consumed in modest quantities, can also increase HDL-C levels. Of the available drug therapies, niacin results in the largest increase in HDL-C levels (about 15% to 25%); gemfibrozil and HMG-CoA reductase inhibitors increase HDL-C by about 10%. However, the potent ability of HMG-CoA reductase inhibitors to lower total cholesterol can improve the ratio of total cholesterol to HDL-C.
Treatment of the Chylomicronemia Syndrome

Patients with the chylomicronemia syndrome often present with acute pancreatitis and severe hypertriglyceridemia (triglycerides >22.6 mmol/L [2000 mg/dL]). These patients should be treated with total fat restriction until the triglyceride level falls to a safe range (e.g., <11.3 mmol/L [1000 mg/dL]), at which time a fat-restricted diet (e.g., <10% of calories) can be instituted and the plasma triglyceride level further monitored. The goal is to maintain the triglyceride level at less than 11.3 mmol/L (1000 mg/dL) and preferably less than 4.5 mmol/L (400 mg/dL). Often this can be accomplished by modifying the diet and eliminating or modifying secondary causes of hyperlipidemia such as drugs, glucose intolerance, or alcohol consumption. However, such patients often require a triglyceride-lowering drug, such as gemfibrozil or niacin, to maintain the plasma triglyceride level in a range that should prevent subsequent episodes of pancreatitis. Recommendations for the management of the hypertriglyceridemia associated with pregnancy have been described.

A great deal is now known about the mechanisms underlying human tumorigenesis in general and about neoplasia of the endocrine glands in particular. The application of general principles of neoplasia to endocrine tumors has been a productive area of research and is now being translated into clinical applications. Endocrine tumorigenesis also involves some special, if not unique, features that must be considered in understanding the pathogenesis of endocrine tumors. The aim of this chapter is to present the general principles of neoplasia as a framework through which current knowledge about and future advances in endocrine tumorigenesis can be understood.
MOLECULAR TUMOR BIOLOGY

Both inherited tumor predisposition syndromes and the more common noninherited (sporadic) forms of neoplasia are genetic diseases in the sense that tumors develop when specific damage to a gene leads to deregulated cell growth. As a general rule, damage to one such gene controlling cell growth is not sufficient to confer a neoplastic phenotype on a cell; instead, multiple mutations accumulate over time. Inherited tumor syndromes constitute a special case in which mutation of one key gene is already present in each somatic cell at birth.

Clonality

Concepts of Clonality and Clonal Evolution

All cancers and many benign hypercellular expansions are monoclonal; that is, they are composed of cells that are the descendants of a single clonal progenitor cell in which the accumulation of a sufficient number of deoxyribonucleic acid (DNA) alterations (and, perhaps, other epigenetic damage that does not actually change the DNA) caused a selective advantage. Over time, this selective advantage, manifested as an increase in proliferative capacity, a decrease in the normal cell death rate, or both, leads to the development of a neoplasm.

The monoclonality of tumors implies that the necessary accumulation of mutations occurs only rarely in the large population of cells in a tissue. Viewed in another way, the identification of a specific monoclonal (also called clonal) change in DNA, found in all or most of the cells of a neoplasm but not in that individual’s constitutional DNA (e.g., obtained from adjacent normal tissue or leukocytes), indicates that this DNA alteration had been advantageous in the accelerated evolutionary process that is oncogenesis. Such a DNA lesion, especially if it recurs in other tumors of the same type, is therefore likely to contribute to tumor development. In fact, one of the strongest types of evidence to implicate a given gene as a driving force in tumorigenesis is the demonstration of clonal DNA changes within or near that gene.

This situation contrasts with the one in which an increase or a decrease in the expression (ribonucleic acid [RNA] or protein levels) of a particular gene occurs in a tumor; such changes can be secondary consequences of tumor-related processes and may or may not themselves drive or contribute to the neoplastic phenotype. This caveat is especially important to bear in mind, given that the Human Genome Project and modern microarray technology have made it possible to examine simultaneously expression changes in a huge number of genes in a tissue or tumor.

An original clonal progenitor or transformed cell does not necessarily contain all the genetic lesions that are ultimately present in the mature, clinically apparent tumor. A continuing process of clonal evolution may result in the development of additional DNA damage that provides an incremental selective advantage to the single tumor cell in which it occurs. Over time, the progeny of this cell may become the dominant clonal population. The percentage of neoplastic cells in the final tumor that contain such a later mutation may vary markedly and depends on factors such as the duration of the mutation’s existence and the relative rates of proliferation and death of the various cell populations.

Endocrine tumors are often sufficiently differentiated to express the hormonal activity characteristic of the corresponding normal cell type, but the hormonal function of the tumor is typically regulated in an abnormal fashion. It is important to understand that the genes that cause tumors of endocrine tissues do so only because of their effects on cell proliferation and accumulation. Such genes need not influence hormonal function. Furthermore, a mutant gene that alters hormonal function but confers no selective growth advantage is not tumorigenic. Nevertheless, the frequent coexistence of growth deregulation and hormonal hyperfunction in endocrine tumors does indicate that the tumor-causing genes may directly or indirectly alter hormone control pathways.

In certain instances, such as a mutation affecting the subunit of stimulatory G protein (Gαs) in growth hormoneproducing thyroid adenomas, a single mutant gene can directly contribute to both cell proliferation and hormonal hyperfunction. In general, however, the relationship between hypercellularity caused by clonally selected mutant genes and hormonal hyperfunction is poorly understood.

Hyperplasia versus Neoplasia

Not all hypercellular expansions are monoclonal. For instance, the generalized proliferative response of all cells of a tissue to an extrinsic stimulus yields a polyclonal expansion, examples of which include the hyperthyroidism of Graves’ disease and the early, reversible secondary hyperparathyroidism in states of chronic hypocalcemia. Such polyclonal expansions represent biologic hyperplasia, whereas any monoclonal growth (benign or malignant) is a true neoplasm. Analyses of tumor clonality have been used to distinguish between these types of tumorigenic mechanisms. Nevertheless, the genesis of some tumors may involve both types of processes. For example, a generalized stimulus to polyclonal hyperplasia can, by increasing the chances of mitosis-related DNA damage in one cell, foster the emergence of a monoclonal population capable of eventually overwhelming or replacing its hyperplastic neighbors.

The clinical and histopathologic use of the term hyperplasia does not necessarily correspond to the biologic meaning described earlier, a situation that has engendered much confusion. For example, the usual primary hyperparathyroidism has been clinicopathologically classified as adenomas when a single gland is abnormal and as hyperplasia when the individual patient has multiple hypercellular glands. No histopathologic criteria can reliably predict whether a single or multiple glands are involved on the basis of analysis of only one such gland. Not only are clinical adenomas monoclonal neoplasms, but many parathyroid glands from patients with multigland “hyperplasia” are also monoclonal. It is therefore important to ensure that the terms used in the description of endocrine tumorigenesis are clearly defined.

Insights into Tumor Pathogenesis

The clonal status of a cellular proliferation is of fundamental importance in deciphering its pathogenesis; thus, endocrine tumors have been studied to determine whether the expansion is monoclonal or polyclonal. One way of determining that a tumor is monoclonal is to identify a DNA or chromosomal lesion that, because of its tumor specificity and presence in all or most of the neoplastic cells, directly defines the expansion as monoclonal. Examples of cytogenetically defined clonal abnormalities are chromosome translocations such as the t(9;22) Philadelphia chromosome in chronic myelogenous leukemia and the t(14;18) translocation in follicular lymphoma.

The use of classical cytogenetics is technically more difficult in solid tumors than in hematopoietic tumors because hematopoietic cells divide in culture much more readily and yield excellent metaphase chromosomal spreads. Specimens of endocrine tumors are difficult to obtain for culture and to analyze cytogenetically. Fortunately, improved methods for the cytogenetic and molecular cytogenetic study of tumors, including fluorescence in situ hybridization, comparative genomic hybridization, and chromosome painting, promise to open up new avenues for the detection of clonal chromosomal lesions in endocrine tumors.

Examples of monoclonal abnormalities defined by molecular methods in endocrine neoplasia include (1) Gαs gene mutations in growth hormoneproducing pituitary tumors; (2) thyrotropin (TSH) receptor gene mutations in thyroid tumors, and (3) cyclin D1 or PRAD1 gene rearrangements in parathyroid adenomas.

Identification of tumor-specific changes, such as deletions of DNA markers in particular regions of the tumor genome, also serves as evidence of monoclonality, even though the specific genes affected by such deletions may not be known.

Indirect methods can determine the clonal status of tumors without the necessity of identifying the specific genes or chromosomal regions that are clonally mutated and involved in tumorigenesis. These methods have generally exploited the phenomenon of random X chromosome inactivation (the Lyon phenomenon) in women.

Random X chromosome inactivation occurs early in female embryonic development in all somatic cells. In any cell, the choice of which X chromosome is inactivated is random; once that choice is made, however, the decision is faithfully transmitted to all progeny of that cell (Fig. 35-1A). Usually, therefore, the maternally derived X chromosome is inactive in about 50% of the cells in a normal tissue, and the paternally derived X chromosome is inactive in about 50%.

Polychromatization, representing a generalized expansion of many or all original cells within a tissue, maintains the relatively even mix of active maternal and paternal X chromosomes characteristic of the normal tissues. In contrast, the neoplastic cells within a monoclonal tumor are derived from a single progenitor and all should reflect an identical X chromosome pattern, with either the maternal or the paternal X chromosome uniformly inactivated (see Fig. 35-1A).

A unifying feature of methods based on the analysis of X chromosome inactivation to determine the clonal status of a tumor is the use of a normally occurring variant, or polymorphism, at the genetic or protein level to distinguish between a woman’s two X chromosomes. The other step involves assaying some property that reflects the state of X chromosome inactivation imposed on the tumor cell chromosomes at the polymorphic site. Assays to reflect X chromosome inactivation status include assessment of gene expression (RNA or protein levels) or regional DNA methylation.

A polymorphism in glucose-6-phosphate dehydrogenase (G6PD) was the first to be used in X chromosome inactivational analyses of tumor clonality. Although only a small minority of women are heterozygous for electrophoretically distinguishable isoforms of this X chromosome-encoded enzyme, thus most tumors have been unsuitable for clonal analysis. Furthermore, the method fails to detect the monoclonality of certain tumors, perhaps because of differences in the level of G6PD expression in tumor cells compared with contaminating admixed normal cells within the analyzed samples.

DNA polymorphisms are now preferred for clonal analyses to distinguish between the two X chromosomes. High rates of heterozygosity make it possible to analyze most tumors. Some multiallelic polymorphisms, based on differences in the number of highly repeated sequence units in a genomic location, are heterozygous in more than 90% of women, and a large number of DNA polymorphisms have been described on the X chromosome (and on all chromosomes). Most, however, cannot be used in clonality studies because they have not been characterized for detectable changes that correlate with the state of activity of the X chromosome on which an allele resides. Some of the X-linked polymorphisms that have been valuable in clonal analyses of human tumors include restriction fragment length polymorphisms in the HPRT and PGK gene regions, a minisatellite repeat (>10 nucleotide core repeated unit) region called M27 or DXS255 and a microsatellite repeat (<10 nucleotide core repeated unit) locus within the androgen receptor gene. Changes in DNA methylation in the vicinity of certain polymorphic sites on the X chromosome correlate with the activity of that X chromosome and are useful in clonal analyses. Methylation of specific cytotoxic nucleotides is an epigenetic process.

that is faithfully replicated from a given cell to its progeny, and this process may have a role in maintaining the activity status of the particular X chromosome. Methylation at certain specific sites may be easily detected through the action of methylation-sensitive restriction endonucleases, which cleave when their target sites are unmethylated but cannot do so when a methyl group is present.

One cannot predict how or whether X chromosome inactivation will affect the methylation of a particular nucleotide in or near a gene; correlations must be established separately for individual genomic sites. For example, a useful restriction site in the HPRT region is consistently methylated when on the active X chromosome and unmethylated when on the inactive X chromosome; the opposite pattern is observed for an informative site in the PGK region. Despite the need for such empirical validation, the use of DNA methylation as a surrogate marker for the status of X chromosome activity has major advantages in clonality studies and eliminates the vulnerability of the assay to the vagaries of gene expression in tumor cells.

The analysis of clonality in endocrine tumors has yielded important insights. For example, the fact that most corticotropin-producing pituitary tumors are monoclonal has shown that Cushings’s disease is not explained solely by a generalized hypothalamic stimulation of corticocortrophs. Typical parathyroid adenomas are also monoclonal outgrowths and are not, as previously suggested, asymmetric forms of multiglandular hyperplasia. Most solitary thyroid nodules are monoclonal, which might have been expected, but some are nodules within multinodular goiters.

One often overlooked pitfall in the interpretation of any X inactivation analysis must be emphasized: Polyclonal patterns cannot be interpreted definitively. For example, admixed normal cells or tumor-specific aberrancies in DNA methylation may obscure the detection of a monoclonal cell population. Thus, the true extent of monoclonality in severe secondary or tertiary hyperparathyroidism might be even higher (but not lower) than demonstrated. These unexpected results indicate that monoclonal parathyroid neoplasms are common in uremic refractory hyperparathyroidism and suggest that autonomous parathyroid function in this disorder is due to the outgrowth of true neoplasms, presumably on a background of preexisting (and more reversible) polyclonal parathyroid hyperplasia.

Figure 35-1X chromosome inactivation analysis of tumor clonality with the use of the M27 polymorphism. A, Diagrammatic illustration of general principles. Left. Lightly shaded and dark rectangles represent the maternally and paternally inherited copies of the two X chromosomes of somatic cells early in the development of a female embryo. As embryogenesis proceeds, one of the X chromosomes in each somatic cell is randomly chosen for inactivation (lyonization); the inactivated chromosome is represented as a small oval with shading corresponding to its origin. Subsequently, daughter cells (third column) faithfully maintain the same selection of inactivated X chromosome as found in their parent cells. Accordingly, an adult tissue typically contains a mixture of approximately 50% cells with the maternally inherited X chromosome inactive and 50% with the paternally inherited X chromosome inactive. Right, A polyclonal tumor arising from a large number of cells in a tissue, maintains this relatively even mixture of cells with different X inactivation patterns. B, Partial restriction endonuclease map of the M27 locus (DXS255) and an example of two distinguishable M27 alleles. The variable number of tandem repeat (VNTR, minisatellite) region, which is highly variable in its length from person to person, is shown in stripes. A 2.5-kb DNA fragment used as the hybridization probe is shown as a solid rectangle. Cleavage sites for restriction enzyme Pst I flank the locus. The enzyme Msp I cleaves the sequence CCGG whether or not the internal cytosine is methylated. In contrast, the enzyme Hpa II cleaves this sequence only if the internal cytosine is unmethylated. The diagrammed Msp I-Hpa II site actually represents a 270-base-pair region containing three such sites, two of which vary in their methylation status in accord with location on the active versus the inactive X chromosome. In the example to the two distinguishable alleles, variation in size of the minisatellite repeat region (VNTR) causes a difference in the size of the Pst I fragment restriction detectable by hybridization to the labeled M27 probe. If an individual with these two alleles had a monoclonal tumor, in which the larger allele was uniformly associated with the active X chromosome, the resulting Southern blot pattern would correspond to monoclonal pattern 1 in C. C, Schematic diagram of prototypical Southern blot hybridization patterns for X inactivation analysis using M27. A monoclonal tumor can exhibit only one of the two monochromatic patterns shown. The Pat + Msp I control digestion is useful for marking the sizes of fully cleaved alleles. (A to C, From Arnold A, Brown MF, Urena P, et al. Monoclonality of parathyroid tumors in chronic renal failure and in primary hyperparathyroidism. J Clin Invest 1995; 95:20472053. Copyright, The American Society for Clinical Investigation.)

Figure 35-1B and C illustrates the methodology used in a study of X chromosome inactivation in the pathogenesis of refractory secondary (or tertiary) hyperparathyroidism in patients with uremia. Because of multigland involvement, it has been assumed that this disease predominantly involves polyclonal (non-neoplastic) cellular proliferations, but the clonality of these “hyperplastic” tumors had not been comprehensively assessed. Clonality was examined with the M27 (DXS255) DNA polymorphism; 64% of the informative patients with renal failure undergoing hemodialysis and with refractory hyperparathyroidism harbored at least one monoclonal parathyroid tumor, and 63% of all tumors examined had monoclonal X inactivation patterns.

One often overlooked pitfall in the interpretation of any X inactivation analysis must be emphasized: Polyclonal patterns cannot be interpreted definitively. For example, admixed normal cells or tumor-specific aberrancies in DNA methylation may obscure the detection of a monoclonal cell population. Thus, the true extent of monoclonality in severe secondary or tertiary hyperparathyroidism might be even higher (but not lower) than demonstrated. These unexpected results indicate that monoclonal parathyroid neoplasms are common in uremic refractory hyperparathyroidism and suggest that autonomous parathyroid function in this disorder is due to the outgrowth of true neoplasms, presumably on a background of preexisting (and more reversible) polyclonal parathyroid hyperplasia.
Predisposing Influences

Both environmental and genetic factors can contribute to the risk of a particular type of tumor development over a lifetime. In highly penetrant inherited syndromes, the genetic predisposition is overriding; in most instances, however, the intimate relation between environmental and genetic factors makes the traditional “nature versus nurture” question difficult to assess.

A commonly overlooked genetic component of tumor predisposition is sex; however, the specific mechanisms by which sex influences the risk of endocrine tumors such as thyroid cancer, parathyroid adenoma, and adrenal cancer are not well understood. Additional genetic variables, which may be common in the population, also influence the chance of tumor development. For example, some independent studies have shown that one allele of a common nucleotide polymorphism within the vitamin D receptor gene is overrepresented in women with primary hyperparathyroidism. It is possible that this hyperparathyroidism-associated allele may yield fewer vitamin D receptors than the other common allele and thereby confer less of an antiproliferative effect on parathyroid cells, subtly but significantly increasing the lifetime risk of parathyroid neoplasia.

An important environmental factor in endocrine tumorigenesis is ionizing radiation. Both thyroid and parathyroid tumors have been linked to prior head and neck irradiation in a dose-dependent fashion. Whereas the latency period for tumor development after radiation exposure in the United States is quite long, childhood thyroid cancer has been observed with markedly increased frequency in the aftermath of the 1986 Chernobyl nuclear accident. Whether such heightened susceptibility is solely a function of age and amount of exposure or is related in part to other factors, such as iodine deficiency in the region, has not been established but highlights the point that tumor predisposition and development can be influenced by complex interacting factors.
Oncogenes and Tumor Suppressor Genes

Two broad categories of genes are implicated in the excessive cell proliferation and other properties that result in the outgrowth and evolution of a neoplastic clone. An oncogene carries a gain-of-function mutation in its regulatory or coding region that results in dysregulation of its normal product or in the formation of an abnormal protein product. Typically, only one mutated allele need be present for an oncogene to exert its tumorigenic action. The normal, unmutated version of an oncogene is called a proto-oncogene. Proto-oncogenes may be converted to oncogenes by various molecular genetic mechanisms, such as fusion of part of its coding region with that of another gene, chromosomal translocations or inversions that alter its regulatory environment, and point mutations.

A tumor suppressor gene, in contrast, normally acts to restrain cell proliferation or other potential aspects of the malignant phenotype. This restraint can directly control proliferation, for example, by regulating the cell cycle, or affect proliferation indirectly, for example, by maintaining genomic stability. Thus, the definition of a tumor suppressor gene is not restrictive concerning its specific cellular function. Tumors are provoked by inactivating or loss-of-function mutations in such genes; the most common inactivating mechanisms are gene deletion and point mutations. Both alleles of a “classical” tumor suppressor gene must be inactivated to eliminate the functional protein product and to contribute to tumorigenesis.

The existence of a critical tumor suppressor gene is often inferred from the frequent finding that a particular subchromosomal stretch of DNA is clonally lost in a particular tumor type. The deletion typically involves only one of a gene's two alleles. Because such deletions are often large, the case that the correct tumor suppressor gene has been found can be made most convincingly when the nondeleted allele of the gene is shown to harbor another clonal inactivating lesion, such as a coding region mutation or microdeletion. It is also possible that certain “nonclassic” tumor suppressors may contribute to neoplasia through haploinsufficiency, in which inactivation of only one allele provides the relevant functional alteration.

Although there has been some evolution in, and even controversy about, the best definition of a tumor suppressor gene, “the simplest, most inclusive, and cleanest genetic definition” is that favored by Haber and Harlow, namely “genes that sustain loss-of-function mutations in the development of neoplasia.” This definition, although unrestricted concerning the function of the tumor suppressor, “does have an essential component—the unequivocal demonstration of inactivating mutations.” Thus, evidence for reduced or absent expression of a gene in a particular tumor, or even the ability of a gene to inhibit cell proliferation, should not be accepted as sufficient to award it designation as a tumor suppressor if not accompanied by clear evidence of clonal mutation.

Some oncogenes or tumor suppressor genes contribute to tumors of only one or a few cell types, whereas other genes are involved in many different types of tumors. It is rare for any one particular gene to be invariably involved in the development of a given type of tumor, and different combinations of mutated genes may have similar cellular and clinical consequences (genetic heterogeneity).

Finally, genetic “hits” affecting multiple oncogenes and tumor suppressor genes within a single cell appear to be required if that cell is to become neoplastic. Thus, in most instances, no single activated oncogene or inactivated tumor suppressor gene is necessary or sufficient for the development of tumors.
Tumors may acquire mutations that in themselves increase the rate at which new mutations develop at other sites in the genome. Many tumor biologists have commented on the apparently excessive number of genetic changes observed in individual cancers compared with measured rates of mutation in normal cells. Genetic changes are usually considered to occur or to be fixed during DNA replication or mitosis. However, some mutations may be time-dependent rather than replication-dependent, meaning that they can arise even in the absence of cell proliferation. One mechanism by which somatic mutations may occur would be a defect in postreplication mismatch repair, the pathway responsible for removing and correcting mismatched base pairs in DNA. At least one form of inherited genetic instability can result from inactivation of "mutator" genes in the mismatch repair system, hMSH2 or hMLH1, for example. Although such mutational mechanisms might in theory be quite important in benign or slow-growing endocrine tumors that derive from slowly proliferating normal tissues, to date little direct evidence supports this hypothesis. Furthermore, some investigators have drawn conclusions about the extent of genomic instability in endocrine tumors based on the number of observed chromosomal abnormalities. Such conclusions cloud the distinction between "state" and "rate." One must note that the presence of genetic alterations in a tumor, even at high prevalence, does not necessarily imply that the tumor is genetically unstable. True instability is defined as an abnormal rate, and the snapshot of a mature tumor's complement of mutations (state) does not provide information about their rate of occurrence.

As noted by Lengauer and colleagues, several factors in addition to true instability may explain the greater frequency of observed mutations in tumors than in non-neoplastic tissues. These include potentially crucial differences in the selective conditions of the tumor versus normal cell environment, involving humoral and intercellular interactions. Thus, a given mutation might confer an important selective advantage and lead to clonal expansion only when it occurs in a tumor cell environment, whereas the same mutation (occurring at the same rate) in a normal cell environment would not lead to clonal expansion, might even cause apoptosis, and would thus avoid detection. It is not necessary to invoke a raised mutation rate in explaining the evolutionary process of tumor outgrowth, and often an increased mutation rate might well confer a disadvantage on the cell.

In summary, selection is the driving force for tumor growth; this key principle is as applicable to slow-growing and benign endocrine tumors as it is to aggressive cancers.
SOMATIC GENETIC ALTERATIONS IN ENDOCRINE TUMORS: EXAMPLES

Neoplasia is, in large part, a genetic disease in which most of the critical DNA damage occurs somatically rather than through inheritance (germ line mutations). Somatic alterations of both oncogenes and tumor suppressor genes are implicated in endocrine tumorigenesis. A few illustrative examples are presented here.

Thyrotropin Receptor and $G_s$ in Toxic Thyroid Adenomas

The fact that solitary toxic thyroid adenomas often contain somatic mutations in different genes whose products are functionally interrelated highlights the point that heterogeneous genetic lesions can converge on common pathways to predispose to neoplasia. Solitary toxic thyroid adenomas are characterized by autonomous (TSH-independent) hyperfunction and growth. Because TSH is normally a stimulus to both functional activity and growth of thyroid cells, toxic adenomas behave as though they are stimulated by TSH chronically and inappropriately. Somatic mutations within the TSH receptor itself can lead to TSH-independent (constitutive) activation of the receptor and cause both clonal expansion and hyperthyroidism in a subset of toxic adenomas.\(^7\)\(^43\) Analysis of how these point mutations mimic the effects of TSH binding has provided insight into the mechanism of activation of $G$ protein-coupled receptors.

The TSH receptor is a member of the large family of $G$ protein-coupled receptors, and its major actions on thyrocyte proliferation and differentiated function are mediated through the cyclic adenosine monophosphate (cAMP) signaling pathway. The predominant $G$ protein involved in transducing the stimulatory effect of the receptor on adenylyl cyclase is $G_s$. $G_s$ is also a proto-oncogene and has undergone clonally selected, activating point mutation in a subset of toxic thyroid adenomas.\(^7\)\(^9\)\(^44\) $G_s$ genes bearing such gain-of-function mutations have been termed $gsp$ oncogenes and are also present in some growth hormone-secreting pituitary tumors. Not surprisingly, these pituitary tumors demonstrate constitutive activation of the cAMP pathway, a prime mediator of proliferation and hormonal function in the somatotroph.

In this context, it is instructive to raise the example of McCune-Albright syndrome (see Chapter 24 and see Chapter 27), in which activating $G_s$ mutations are present in multiple tissues of a given patient owing to mutation early in embryonic development and subsequent genetic mosaicism. Hyperthyroidism and acromegaly are among the characteristic components of this syndrome. Another gene encoding an element in the cAMP signaling pathway, the protein kinase A type I- regulatory subunit gene $PPKAR1A$, has been implicated in the familial syndrome termed Carney’s complex, which includes corticotropin-independent Cushing’s syndrome related to autonomously functioning adrenocortical nodules, growth hormone-secreting pituitary tumors, and male precocious puberty caused by hormonally active testicular tumors.\(^45\)
Cyclin D1 (PRAD1) in Hyperparathyroidism and General Oncology

Another illustrative example is that of the cyclin D1, or PRAD1, oncogene. Unlike many endocrine tumor-associated oncogenes, cyclin D1 is also commonly involved in nonendocrine tumors. Interestingly, this gene, now appreciated to be of central importance to molecular oncology and to normal cellular physiology, was discovered in the molecular dissection of an endocrine tumor.

Many human oncogenes were discovered because they are adjacent to nonrandom chromosome breakpoints in tumors. Chromosome breaks and rearrangements probably occur often in normal cells but are recognized only when they result in deregulation of the expression of a growth-related gene and confer a selective advantage on the cell. Cyclin D1 or PRAD1 was identified as the putative oncogene adjacent to one such breakpoint on chromosome 11 in a subset of parathyroid adenomas (Fig. 35-2). On the 11q13 side of the inversion breakpoint, the promoter and coding exons of the cyclin D1 gene remain in contiguity with each other. Across the breakpoint are regulatory sequences from the upstream region of the parathyroid hormone (PTH) gene on 11p15 that normally function to enhance PTH gene transcription in the presence of parathyroid tissuespecific signals (likely to be DNA binding proteins found in the nucleus). Such transcriptional enhancer sequences can act over distances of many kilobases to enhance transcription, and cyclin D1 transcription is increased in these tumors. Although the variability in potential breakpoint sites makes it difficult to determine the true incidence of such rearrangements, cyclin D1 protein levels are elevated in 20% to 40% of parathyroid adenomas.

In a broader context, the tissue-specific enhancer-driven expression of cyclin D1 in parathyroid tumors is analogous to the activation of oncogenes such as BCL2 or MYC in B-cell lymphomas. In these tumors, chromosomal rearrangements lead to a juxtaposition of immunoglobulin gene enhancer elements and the oncogene, which is thereby inappropriately activated.

One cautionary note: This functional assignment for cyclin D1 is overwhelmingly derived from cultured cell systems, which might not fully reflect the true in vivo roles of this key oncoprotein. Thus, the detailed mechanism of action of cyclin D1, both normally and when dysregulated in tumorigenesis, should be further explored.

Cyclins are regulatory subunits of holoenzymes whose catalytic subunits are cyclin-dependent kinases (CDKs). The major kinase partner for cyclin D1 appears to be CDK4 or, in some cell types, CDK6. The protein product of the retinoblastoma tumor suppressor gene, pRB, has been recognized as one substrate for cyclin DCDK4/6 complexes. Whether all such relevant phosphorylations occur in G1 phase progression or might in part push quiescent G0 cells into an active G1 cycling mode, for example, requires further study.

Natural inhibitors of CDK function also exist, and p16INK4a is recognized as a key inhibitor of cyclin DCDK4/6 complexes. Thus, inactivation of p16 might be expected to be as oncogenic as cyclin D1 overexpression, and p16 is, indeed, a tumor suppressor gene in familial melanoma and several types of sporadic human tumors. Interestingly, inactivating mutations of p16 are uncommon, if they occur at all, in parathyroid adenomas. Hence, the cellular consequences of p16 loss and cyclin D1 activation may not precisely overlap. Interestingly, some early evidence exists for possible noncdk-dependent actions of cyclin D1.

The significance of cyclin D1 in human neoplasia extends far beyond its involvement in endocrine tumors. It is the long-sought BCL1 oncogene that is deregulated by the characteristic t(11;14) translocation in mantle cell or centrocytic B-cell lymphomas. Thus, assessment of cyclin D1 gene rearrangement or expression is clinically useful in the molecular diagnosis of B-cell neoplasia. In addition, cyclin D1 is a key oncogene in breast cancer, squamous cell cancer of the head and neck, esophageal cancer, and a variety of other tumors. Cyclin D1 and other members of its oncogenic pathway or pathways may serve as targets for development of antineoplastic therapies.
RET Gene Rearrangements in Papillary Thyroid Cancer

Activating mutations of the RET proto-oncogene are responsible for multiple endocrine neoplasia type 2 (see Chapter 36), but this gene is also involved in human disease through another mechanism: Clonal somatic rearrangements of this gene are found in about 25% of papillary thyroid cancers but not in other types of thyroid (or nonthyroidal) cancer. Inactivating germ line mutations of RET are a cause of Hirschsprung's disease, in which parasympathetic ganglia fail to migrate properly in the gastrointestinal tract (see Chapter 36).

RET encodes a member of the receptor tyrosine kinase superfamily, and one endogenous ligand that binds to and activates RET is the glial cell line-derived neurotrophic factor (GDNF). Normally, RET acts mainly during embryogenesis.

The RET protein, like other receptor tyrosine kinases, has extracellular, transmembrane, and intracellular (tyrosine kinase) domains (Fig. 35-3). The papillary cancerspecific RET rearrangements described to date involve a chromosomal break that fuses the intracellular tyrosine kinase domainencoding portion of the RET gene to one of several alternative partners. The RET fusion partner gene segment provides a new promoter that is constitutively active in thyroid cells and encodes a new in-frame N-terminus for the oncoprotein (see Fig. 35-3).

Three major classes of RET fusion oncogenes are called RET-PTC1, RET-PTC2, and RET-PTC3; the corresponding fusion partner genes are H4, R1, and ELE1.

The N-termini of these fusion oncogenes allow dimerization and activation of the RET tyrosine kinase, bypassing the usual requirement for ligand binding. The specificity of these RET fusion oncogenes for papillary-type thyroid cancer is not well understood. It appears that only this thyroid cell type tends to produce such fusions or that only this cell has the molecular machinery that can respond to this form of RET kinase activation. Perhaps development of a papillary cancer may be an inevitable response to the occurrence of the RET rearrangement early in the life of a thyroidal neoplasm.

Finally, the RET proto-oncogene and its fusion partners, especially ELE1, may be highly susceptible to breakage and fusion as a consequence of ionizing radiation. More than 60% of papillary cancers that have developed in young people exposed to the nuclear fallout from the Chernobyl reactor contain RET-PTC fusion oncogenes. The spatial contiguity of RET and its rearrangement partners in the interphase thyroid cell nucleus may provide a structural basis for the occurrence of such rearrangements by enabling a single radiation particle track to cause a double-stranded DNA break that is misrepaired.
GERM LINE MUTATIONS PREDISPOSING TO ENDOCRINE NEOPLASIA: EXAMPLES

Patients in whom a particular tumor develops on the basis of a strong inherited predisposition typically constitute only a minority of patients with that tumor. Nonetheless, the lessons learned from identifying the molecular basis of inherited tumor predisposition are important, both clinically and from a fundamental biologic perspective. In addition, some genes in which germ line mutations cause rare genetic syndromes have subsequently been found to be somatically mutated in the more common, sporadic occurrences of the same tumors.

Germ line mutations that predispose to neoplasia can occur in either proto-oncogenes or tumor suppressor genes; in other words, mutations that cause inherited tumor syndromes can be of either the gain-of-function or the loss-of-function type. However, most germ line mutations identified to date are inactivating mutations, thus identifying the affected genes as tumor suppressors by definition. A few genes responsible for heritable endocrine neoplasia syndromes have been discovered, and others are still being sought.

RET Mutations in Multiple Endocrine Neoplasia Type 2

Multiple endocrine neoplasia type 2 (MEN 2) is a collection of three syndromes:

- MEN 2A
- Familial medullary thyroid cancer
- MEN 2B

These syndromes are detailed in Chapter 36.

All are autosomal dominant syndromes in which the most consistent feature is predisposition to medullary thyroid cancer. Genetic linkage analysis demonstrated that the MEN 2 gene or genes must lie near the centromere on chromosome 10, and an evaluation of candidate genes known to map to this region led to the identification of germ line RET point mutations that co-segregated with the disease. The existence of de novo RET mutations in patients with an MEN 2 phenotype, but a negative family history and the demonstration that the RET mutations activate RET as a transforming oncogene further helped establish that germ line RET mutations are the predominant cause of MEN 2.

Only a few codons (for cysteine residues in the extracellular domain) harbor the RET mutations in almost all patients with MEN 2A and most patients with familial medullary thyroid cancer, and only two codons (the predominant one encodes a conserved threonine within the tyrosine kinase domain's catalytic core) are mutated in virtually all patients with MEN 2B. This molecular specificity contrasts with the many ways in which tumor suppressor genes are typically found to be inactivated and provided the first clue that RET mutations in MEN 2 are activating mutations. In fact, MEN 2 was the first inherited human tumor syndrome found to be due to an activated oncogene in the germ line. The limited number of locations for RET mutations in MEN 2 makes it relatively easy to detect the mutations and make the molecular diagnosis. This methodology is available commercially.

At a time when the general concept of germ line DNA testing for cancer predisposition has been enveloped in controversy, MEN 2 has provided the best example in oncology of the efficacy of molecular diagnosis in mainstream clinical management. Specific features not often present in other cancer predispositions that have contributed to the impact of the molecular diagnosis of MEN 2 include:

1. The high penetrance of a life-threatening cancer (medullary thyroid carcinoma).
2. The ease and accuracy of DNA diagnosis (better than with previously available pentagastrin testing).
3. The availability of a lifesaving intervention (thyroidectomy) without major risk.

As alluded to earlier, somatic RET mutations (much more often of the MEN 2B type than the MEN 2A type) are also present in a minority of sporadic medullary thyroid carcinomas and pheochromocytomas, but not in primary hyperparathyroidism.

In MEN 2, although the germ line RET mutation is present in all somatic cells of the affected individual, the MEN 2-related tumors are not, strictly speaking, inherited but develop from a hyperplastic endocrine cell mass into clonal neoplasms over time. The monoclonality of the medullary thyroid carcinomas and pheochromocytomas in MEN 2 indicates that somatic molecular mutations, probably affecting several oncogenes or tumor suppressor genes, or both, must occur in a single cell and act in concert with the inherited germ line RET mutation for the neoplasms to emerge. In fact, several such clonal somatic molecular lesions, including allelic deletions on chromosomes 1, 3, 11, 17, and 22, have been found in MEN 2-associated tumors, pointing to the genomic locations of important but unidentified putative tumor suppressor genes.
MEN1 Tumor Suppressor Gene

Multiple endocrine neoplasia type 1 (MEN 1) is a familial predisposition to tumors of the parathyroid glands, anterior pituitary, pancreatic islets, and duodenum. Other tumors, including carcinoid tumors, adrenal adenomas, lipomas, and angiofibromas, also occur with increased frequency in this disorder (see Chapter 36).

MEN 1 is inherited in an autosomal dominant pattern, indicating that a single mutant gene is responsible for transmitting the tumor predisposition. Genetic linkage analysis implicated a region on the long arm of chromosome 11 (11q13) as the site of the MEN1 gene (i.e., the site of the normal gene whose mutant form causes MEN 1). However, this target region on 11q13 contains a large number of genes, resulting in a long and arduous positional cloning effort before the successful identification of MEN1.

Even before it was identified, considerable evidence indicated that MEN1 is a tumor suppressor gene. One of the two cellular copies of the MEN1-linked chromosomal region was frequently found to be somatically and clonally deleted in parathyroid and pancreatic tumor tissues from patients with MEN 1. When the parental origin of the deleted allele could be identified, it always derived from the unaffected parent. Thus, patients with MEN 1 were believed to have inherited one inactivated copy of the critical gene from the affected parent, with the remaining normal copy becoming somatically inactivated, often by a large regional deletion, in a clonal progenitor cell from which the tumor would emerge. Because the germ line aﬀected MEN1 chromosomal region appeared to be grossly intact in most instances, it seemed likely that most germ line mutations in the MEN1 gene would be small deletions or point mutations that would require sequencing of DNA for detection. Direct testing made possible by the cloning of the MEN1 gene has conﬁrmed these hypotheses.

MEN1 germ line mutations have been detected in most MEN 1 families and in so-called sporadic MEN 1, that is, where no positive family history exists. Many of these mutations would clearly be expected to truncate the translated product severely and can safely be categorized as inactivating mutations. It can be reasonably anticipated that when deﬁnitive functional testing is available, other reported mutations, especially in the missense category, will prove to be inactivating lesions as well. The identiﬁcation of MEN1 has also opened up the potential for direct and presymptomatic molecular diagnosis in established or suspected MEN 1 kindreds or individuals. However, the beneﬁts of such testing over existing methods with respect to prophylactic interventions and improvements in morbidity or mortality are not well established, in strong contrast to the situation for RET testing in MEN 2.

The MEN1 gene encodes a 610-amino-acid protein termed menin. The structure of menin has yielded few clues to menin’s normal function, except for its nuclear localization signals. That menin may play a role in regulation of gene transcription has been suggested by the finding that it can bind a member of the activator protein 1 (AP-1) transcription factor family, JunD, and inhibit the ability of JunD to activate transcription. The interaction of menin with JunD carries the potential to link its function with the regulation of cell senescence and apoptosis, given insights into the role of JunD in p53-dependent pathways. Tissue surveys have shown MEN1 expression to be nearly ubiquitous, and the reason for endocrine tissue speciﬁcity in the ultimate development of tumors remains to be deciphered.

As previously stated, the molecular pathology of MEN1 strongly suggests that it functions as a classical tumor suppressor gene, requiring biallelic inactivation in order to drive the emergence of a clinically signiﬁcant tumor. In a patient with MEN 1, after somatic deletion on 11q13 has occurred in a particular parathyroid or islet cell, for example, that cell would be devoid of the normal tumor suppressor function of the MEN1 gene product and would thereby acquire a selective advantage over its neighbors. The high incidence of endocrine tumors in MEN 1 (which demonstrates almost 100% penetrance) implies that somatic inactivation of the remaining normal gene copy is a common development in the context of the patient’s entire endocrine tissue complement. It does not mean, however, that loss of function in both MEN1 alleles is suﬃcient for tumorigenesis, and additional cooperating oncogenic lesions may be needed.

Allelic losses of DNA markers on 11q13, including the MEN1 region, are found in some of the more common, sporadically occurring versions of the tumors associated with familial MEN 1. They include a frequency of 25% to 40% for 11q13 allelic loss in sporadic parathyroid adenomas, for example. Interestingly,
Summary

Genetic paradigms that have originated in the study of malignant neoplasia are useful in the molecular dissection of endocrine tumors, including common benign endocrine tumors. Identification of clonally selected mutations in oncogenes and tumor suppressor genes has opened the door to understanding the control of growth in endocrine tissues. Furthermore, the fact that these genetic alterations can affect endocrine cell function as well as cell number may be exploited in devising medical therapies in the future.

The multiple endocrine neoplasia (MEN) syndromes were described early in this century\(^1\) and subsequently classified into two principal categories: MEN type 1 (MEN1) and MEN type 2 (MEN2). The MEN2 syndrome has been further subcategorized into two principal variants called MEN2A and MEN2B (formerly MEN3). Our understanding of the MEN syndromes has evolved through several phases. The first was the descriptive phase in which the fully developed clinical syndromes and their familial patterns were described.\(^2\)\(^3\)\(^4\)\(^5\)\(^6\)\(^7\)\(^8\)\(^9\)\(^10\)\(^11\)\(^12\)\(^13\)\(^14\)\(^15\)\(^16\)\(^17\) The second phase involved the development of tumor surveillance techniques to identify the syndromes before they became significant clinical problems.\(^9\)\(^10\)\(^11\)\(^12\)\(^13\)\(^14\)\(^15\)\(^16\)\(^17\) Early identification of the manifestations and improvements in management techniques have had a significant impact on the morbidity and mortality associated with these syndromes.\(^18\) We are now in the third phase, the elucidation of the genetic and molecular basis of these syndromes. This chapter summarizes the current understanding of these disorders and provides a framework for understanding future developments.

MEN1 and MEN2 share certain characteristics. First, the usual tumor is composed mainly of cells with the capability to secrete one or more peptide hormones or small amines. This defines the tumor as endocrine (secretory) in nature. Second, the tumors in MEN1 and MEN2 are often benign with major clinical effects caused by hormone hypersecretion. As a corollary, there are often excellent therapies based on medications or surgery. Third, malignant transformation of certain cell types is also a component of each syndrome. Fourth, as with many hereditary tumors, some tumors in MEN1 and MEN2 occur relatively early and some with multiplicity; multiplicity is seen here as multiple foci within a tissue and as tumors in multiple tissues. Last, both of these syndromes have an autosomal dominant pattern of inheritance.

The MEN syndromes provide clear-cut examples of two different genetic mechanisms for tumorigenesis. MEN1 tumors are caused by loss of function, inactivation of a tumor suppressor gene, MEN1. In contrast, MEN2 tumors are caused by gain of function, activation of a proto-oncogene, RET. There are also other important contrasts between MEN1 and MEN2. Most important is that the primary C-cell malignancy of MEN2, medullary thyroid carcinoma (MTC), can be recognized at the earliest stages and prevented or cured. This is an option, in part, because MTC arises within the thyroid gland, so that complete excision is possible. In contrast, malignancies associated with MEN1 are difficult to recognize, and they occur in organs (pancreas, duodenum, bronchi) whose ablation would carry unacceptable morbidity.
MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

The association of parathyroid, enteropancreatic endocrine, and pituitary neoplasia is called multiple endocrine neoplasia type 1. Although there were earlier descriptions, the syndrome was recognized as a clinical and familial syndrome by Moldawer and colleagues in 1964 (thus the eponym Wermer's syndrome). MEN2 was recognized and classified as distinct from it in 1968. In previous years, MEN1 patients presented with advanced manifestations of parathyroid, pancreatic islet, and/or pituitary neoplasia in the third and fourth decades of life. However, improved carrier ascertainment and improved tumor surveillance have now resulted in earlier identification of hormonal syndromes.

The most common mode of presentation for MEN1 is currently within the context of an identified kindred; less frequently, a newly ascertained individual with advanced disease may be the propositus of a new kindred, a previously unidentified member of a known kindred, or an example of a de novo mutation. Despite its earlier discovery, MEN1 remains the most challenging of the MEN syndromes. The many affected tissues cause complexity and expense in diagnosis and treatment. Each affected patient can be expected to undergo at least two surgical procedures. It is important for the clinician to recognize the high probability of recurrent or new neoplasms in all affected organ systems and to balance this likelihood against the potential effects of a deficiency syndrome associated with complete organ removal. Furthermore, even with satisfactory control of symptoms from hormone excess, cases have a high likelihood of eventual MEN1-related cancer.

ACTH, adrenocorticotropic hormone; VIP, vasoactive intestinal peptide.

*Italics indicate tumor type with substantial (>20%) of cases) malignant potential.

Many "nonfunctioning" MEN1 tumors synthesize a peptide hormone or other factors (such as small amine) but do not oversecrete enough to produce a hormonal expression. Omits nearly 100% prevalence of nonfunctioning and clinically silent tumors, some of which are detected incidental to enteropancreatic surgery in MEN1.

Hyperparathyroidism in Multiple Endocrine Neoplasia Type 1

MEN1 is uncommon with a population prevalence of about 1 in 30,000 and accounts for only about 1% to 3% of cases of primary hyperparathyroidism. Hyperparathyroidism is the most common hormonal manifestation of MEN1 (Table 36-1). Successful subtotal parathyroidectomy is also followed within 10 years by recurrent hyperparathyroidism in half of MEN1 cases. In fact, true recurrent hyperparathyroidism in sporadic hyperparathyroidism is unusual, and recurrence should suggest the possibility of MEN1. True recurrent hyperparathyroidism, as with other tumor recurrences in MEN1, could arise theoretically from a small remnant of tumor tissue or from new mutation (second hit) in residual normal tissue. Fourth, hyperparathyroidism in MEN1 almost never progresses to parathyroid cancer, despite the fact that hyperparathyroidism occurs earlier in MEN1 than in sporadic cases.

Expressions of Hyperparathyroidism

Hyperparathyroidism in MEN1 is most frequently asymptomatic; expressions include hypercalcemia, urolithiasis, parathyroid hormone (PTH)-induced bone abnormalities, musculoskeletal complaints, weakness, and alterations of mental status. These features are similar to those associated with other forms of hyperparathyroidism (see Chapter 26).

Hyperparathyroidism in MEN1 differs in some ways from that caused by a sporadic adenoma. The first way is a difference in epidemiology. Hyperparathyroidism in MEN1 has an earlier age of onset (typically 25 years versus 55 years) (see Chapter 26). By age 40 years, about 95% of MEN1 carriers have been hypercalcemic. The second is a different parathyroid pathology; enlargement, albeit highly asymmetric, of multiple parathyroid glands is usually present at the time of parathyroid exploration in MEN1 (Fig. 36-2). Third, the distributions of outcomes of parathyroid surgery differ. The presence of multiglandular disease and the need to examine each gland during a surgical procedure inevitably result in a higher postoperative rate of hyperparathyroidism and a lower rate of euthyroidism. Successful subtotal parathyroidectomy is also followed within 10 years by recurrent hyperparathyroidism in half of MEN1 cases. In fact, true recurrent hyperparathyroidism in sporadic hyperparathyroidism is unusual, and recurrence should suggest the possibility of MEN1. True recurrent hyperparathyroidism, as with other tumor recurrences in MEN1, could arise theoretically from a small remnant of tumor tissue or from new mutation (second hit) in residual normal tissue. Fourth, hyperparathyroidism in MEN1 almost never progresses to parathyroid cancer, despite the fact that hyperparathyroidism occurs earlier in MEN1 than in sporadic cases.

There are several characteristics of hyperfunctioning parathyroid cells in MEN1 that may have mechanistic implications. First, most or all parathyroid glands have been overgrown by one or a few neoplastic clones by the time of surgery in MEN1 (Fig. 36-3, top). Second, a circulating growth factor is specific to the plasma of MEN1 cases and mitogenic toward normal parathyroid cells in vitro (see later). Third, a phenomenon observed in sporadic parathyroid adenomas, a rightward shift in the set-point for calcium suppression of PTH secretion, occurs to a lesser extent in MEN1 parathyroid tumors (see Chapter 26). This set-point abnormality may

Larsen: Williams Textbook of Endocrinology, 10th ed., Copyright © 2003 Elsevier
be caused by secondary decrease in the amount of the calcium-sensing receptor on the parathyroid cell surface.

Hyperparathyroidism Management

Decision for Surgery

Surgery is the treatment of choice for hyperparathyroidism in MEN1, although the timing and the type of operation remain controversial. Parathyroid surgery is definitely indicated in a MEN1 patient with an elevated PTH and other moderately advanced features, such as an albumin-adjusted serum calcium level higher than 3.0 mmol/L (12.0 mg/dL), kidney stones, or PTH-induced bone disease.

An alternative pathogenesis could be stepwise evolution from one clone, that is, third hits to genes other than those encoding parathyroid hormone.

Minutes after inflation of a blood pressure cuff to occlude venous return from the graft, the graft is implicated as the main source of PTH.

Contralateral arm confirms graft function (this does not exclude other parathyroid tissue in the neck or chest). Similarly, if peripheral PTH falls by more than 50% within 45 minutes of the graft, graft function is expected to have multiple parathyroid tumors (as in MEN1). These tests are even more likely to be helpful during parathyroid reoperations in MEN1, as the number of parathyroid tumors is likely to be much greater in these patients.

Diagnosis of Parathyroid Gland Multiplicity

Sensitive ultrasound transducers routinely image parathyroid tumors intraoperatively in difficult locations, such as within the thyroid gland and within scar from prior surgery. Rapid "on-line" assay of PTH can be done at 5-minute intervals with a turnaround time of 10 minutes for each result.

Several intraoperative tools can increase the likelihood of successful parathyroid surgery. Rapid "on-line" assay of PTH can be done at 5-minute intervals with a turnaround time of 10 minutes for each result.

A PTH fall of 50% or more from baseline predicts that no hyperfunctioning parathyroid tissue remains. Sensitive ultrasonic transducers routinely image parathyroid tumors intraoperatively in difficult locations, such as within the thyroid gland and within scar from prior surgery.

Figure 36-2 Parathyroid gland sizes at initial parathyroidectomy for 18 cases with familial multiple endocrine neoplasia type 1. Volumes of all glands at one operation are connected by a vertical line. Dashed horizontal line is upper limit of normal gland volume (0.075 cm³, equivalent to 75 mg mass). (Modified from Marx SJ, Menzel J, Campbell G, et al. Heterogeneous size of the parathyroid glands in familial multiple endocrine neoplasia type 1. Clin Endocrinol (Oxf) 1991; 35:521-526.)

Figure 36-3 Tumor multiplicity within a tissue in multiple endocrine neoplasia type 1 (MEN1). Top, Hypercellular parathyroid gland from patient with MEN1. The gland is totally replaced by diffuse sheets and two discrete nodules of chief cells. This image could reflect three or more second hits to the normal copy of the MEN1 gene in three different clone precursor cells and thus growth of three or more independent clones. An alternative pathogenesis could be stepwise evolution from one clone, that is, third hits to genes other than MEN1. Bottom, Duodenal mucosa from a second MEN1 patient, showing two large, submucosal microgastrinomas. Each tumor was positive for gastrin immunostain and negative for other peptide hormones. Possible development of these tumors could be caused by secondary decrease in the amount of the calcium-sensing receptor on the parathyroid cell surface.
two adjacent tumors could have followed mechanisms suggested for the two parathyroid nodules at the top. (From I. Lubensky, National Institutes of Health, Bethesda, Md.)

peripheral PTH. Lastly, if curative, surgical removal of parathyroid tissue from the forearm graft bed during the inevitable second or third operation is technically easier than a neck reexploration. Cryopreservation of parathyroid tumor fragments is a useful option in MEN1, given the high rate of postoperative hypoparathyroidism in MEN1. Cryopreservation permits a late parathyroid autograft. [46]

At initial parathyroid operation in MEN1, partial thymectomy should be done through the cervical incision. This procedure not only results in removal of intrathymic parathyroid tissue but also can remove thymic carcinoid tissue, an issue discussed later in this chapter. It is important to do this during

![Figure 36-4](image)
**Figure 36-4** Effect of parathyroidectomy in patients with multiple endocrine neoplasia type 1 and Zollinger-Ellison syndrome. Basal acid output and fasting serum gastrin are shown. All patients became normocalcemic except for one (case 4), who remained hypercalcemic. Dashed line is upper limit of normal for serum gastrin. Upper limit of normal for basal acid output is 15 mEq/hour. (From Jensen RT. Management of the Zollinger-Ellison syndrome in patients with multiple endocrine neoplasia type 1. J Intern Med 1998; 243:477-488.)

![Figure 36-5](image)
**Figure 36-5** Intact parathyroid hormone (PTH) by rapid assay during parathyroid surgery. Normal range is indicated by dashed lines. The patient had multiple endocrine neoplasia type 1 and primary hyperparathyroidism without prior parathyroidectomy. Three and one half similarly enlarged parathyroid glands (0.8 to 1.6 g; normal less than 0.08 g) and the accessible portions of the thymus were removed at the times indicated; the thymus contained no parathyroid tumor. A rapid fall of PTH below a cutoff criterion (such as 50% drop within 5 minutes) indicates that little or no hyperfunctioning parathyroid tumor remains. Note that removal of the first two parathyroid tumors was not followed by a fall in PTH. The PTH assay result for each time point was available within several minutes to help establish the time at which no hyperfunctioning parathyroid tumor remained and thereby contribute to serial decisions about extending or ending the operation. (From S. K. Libutti, H. R. Alexander, and A. Remaley, National Institutes of Health, Bethesda, Md.)

![Figure 36-6](image)
**Figure 36-6** Serum ionized calcium and peripheral midregion parathyroid hormone (PTH) levels after total parathyroidectomy and graft of parathyroid tissue in a patient with multiple endocrine neoplasia type 1. After total parathyroidectomy (PTX) and grafting of parathyroid tissue to the nondominant forearm, the ionized calcium and PTH levels fell to subnormal values. Subsequent measurements demonstrated a continuous rise of the ionized calcium and peripheral PTH levels (taken from the arm not containing the transplant) over a 60-month period, which necessitated removal of some of the grafted parathyroid tissue. The numbers in parentheses represent selected PTH values for blood taken from the brachial vein immediately downstream from the grafted parathyroid tissue. These results demonstrate continued secretion of PTH by the graft in the presence of hypercalcemia. The upper, lighter shaded area shows the normal range for ionized calcium; the lower, darker shaded area shows the normal range for serum midregion PTH. (Data from L. E. Mallette, Baylor College of Medicine.)

the primary operation because scar tissue may prevent a simple transcervical thymectomy at parathyroid reoperation.

Parathyroid surgery in the patient with MEN1 requires judgment, familiarity with neck anatomy, and experience. The probability of an excellent outcome is improved substantially when primary or reoperative procedures are performed by an experienced endocrine surgery team.
Enteropancreatic Neuroendocrine Tumors

Neoplasia of the enteropancreatic neuroendocrine cells is the second most common endocrine manifestation of MEN1 and eventually occurs in about 60% or more of MEN1 patients (see Table 36-1). Also, multiple clinically silent enteropancreatic macroadenomas may be recognized at surgery or autopsy in nearly 100% of MEN1 cases older than 40 years. The tumors are multiple, can oversecrete various hormones, and can become malignant. Approximately one third of MEN1 patients die from MEN1-related cancer; among these fatal cases, the ratio of enteropancreatic neuroendocrine cancer to malignant carcinoid is 2:1. It is similarly notable that, in this era of excellent pharmacotherapy for gastric hyperacidity, about one sixth of MEN1 patients with gastrinoma may die from metastatic gastrinoma but rarely from hypergastrinemia-induced metabolic complications.

Although the MEN1 patient may show symptoms or signs caused by one enteropancreatic hormone, there are often several associated and asymptomatic tumors with production of the same or other hormones. The frequency of peptide immunostaining in MEN1 pancreatic islet tumors is glucagon 35%, insulin 25%, pancreatic polypeptide 25%, and no hormone 10%; limited data are available for immunostaining of commonly observed duodenal gastrinomas. Interpretation of pancreatic islet histology in MEN1 has changed over the decades. Early studies emphasized hyperplastic processes and budding of islet cells from ducts (nestsidioblastosis). Such features have now been reinterpreted as non-specific. The overriding and important islet lesion in MEN1, now termed multifocal microadenoma, is a mononuclear or oligonuclear process (see Fig. 36-3, legend). No earlier precursor stage is currently recognized. However, heterozygous knockout of the MEN1 gene in the mouse provides a good model of human MEN1; multiple giant hyperplastic islets are striking and precede insulinaemia in this model, suggesting that subtle islet hyperplasia is an undetected tumor precursor lesion in MEN1 of humans.

Rarely, enteropancreatic neuroendocrine tumors occur in several members of a family without other features of MEN1; these have been insulinomas. Nonfunctioning pancreatic islet tumors and pheochromocytoma can also appear uncommonly in a familial setting as expressions of von Hippel-Lindau (VHL) syndrome.

Gastrina

Gastrinomas are also seen in MEN1. The symptoms and signs reflect two processes, malignancy and gastrin induction of acid secretion by the stomach. Gastrinomas are found in about 40% of adults with MEN1 (see Table 36-1). ZES is defined here as symptoms or signs of gastric acid hypersecretion caused primarily by a gastrin-secreting enteropancreatic neuroendocrine tumor or tumors. Among patients with ZES, MEN1 is found commonly, on the order of 25% in large series. Most of these MEN1 cases are readily recognizable from personal and family history. In contrast, among carefully defined sporadic ZES cases without obvious MEN1, occult MEN1 is uncommon, a conclusion based on lack of family history, long-term follow-up, and mutational analysis of the MEN1 gene.

Symptoms of ZES include diarrhea, esophageal reflux, and those associated with peptic ulceration. Prospective tumor surveillance studies have more clearly defined the range of presenting features. Symptoms can antedate recognition of fasting hypergastrinemia. At the extreme, ulcer perforation can be caused infrequently by hypergastrinemia, even without prior symptoms. The laboratory diagnosis of gastrinoma is established by finding an elevated serum gastrin level. Other causes of elevated gastrin (false-positive results) that must be differentiated from gastrinoma include hypochlorhydria, including that resulting from pharmacologic agents that inhibit peptic acid secretion. Hyperparathyroidism in MEN1 can exacerbate hypergastrinemia (see earlier) (see Fig. 36-4).

Recognition of elevated gastrin should be followed by assessment of the gastric acid secretion rate without acid-blocking drugs; the normal rate is below 15 mEq/hour (or below 5 mEq/hour after acid-reducing surgery). The diagnosis of gastrinoma can also be confirmed by measuring the gastrin response to secretin (2 U/kg). A gastrin increase of more than 114 pmol/L (200 pg/mL) is diagnostic of gastrinoma. This test differentiates gastrinoma from other hypergastrinemic states, such as retained gastric antrum, massive small bowel resection, or gastric outlet obstruction. Secretin was unavailable for several years in the United States but was recently approved for diagnosis of gastrinoma. An alternative gastrin provocation method such as calcium infusion has not been standardized and would be unappealing with coexistent hyperparathyroidism. Gastric endoscopy is advisable at the initial evaluation for ZES and allows assessment of peptic ulcerations and duodenal gastrinomas; it should also be used to search for gastric carcinoids, which are frequent in MEN1 (see later).

Like hyperparathyroidism, gastrinomas have certain features that are relatively specific for MEN1. On the average, gastrinoma begins 10 years earlier with MEN1 than without it, a lesser age difference than 30 years for hyperparathyroidism. The gastrinomas in MEN1 are often small, multiple, and intraduodenal (see Fig. 36-3, bottom). The duodenal predominance differs only modestly from that in sporadic gastrinoma. Because the gastrin cell or D cell is not normally found in the duodenum or pancreas, gastrinoma in these locations may be judged as ectopic and malignant, independent of its histologic grade. Gastrinomas in MEN1 have a high propensity to metastasize to local nodes. High-grade aggressive behavior, including distant spread to the liver and occasionally other tissues, also occurs in about 20% of cases. Diffuse hepatic metastases are particularly ominous, predicting a 5-year survival of only 50%. The prognosis of gastrinoma in MEN1 is similar to that in sporadic cases. No early features have allowed reliable prediction of which gastrinomas behave aggressively.

Therapy of Gastrinoma

Most centers have reported virtually zero success rate for cure of gastrinoma in MEN1 by surgery, even though one third of gastrinoma cases without MEN1 are cured by surgery. Unique characteristics of gastrinoma in MEN1 that contribute to the low rate of curative resection are the multiplicity of small tumors and the frequency of local metastases. The largest tumor was not a gastrinoma in 40% of operations. Extreme approaches including total pancreatectomy have been suggested, but the associated surgical morbidity seems unacceptable. Only one group has reported frequent surgical cure of gastrinoma in MEN1, aided by duodenectomy and endoscopic transillumination of the mucosa. Other groups have not reported similar success rates despite the use of similar approaches. Differences in criteria for cure and in selection of patients, such as age, may contribute.

The development of H2 histamine receptor antagonists (cimetidine and ranitidine) and proton pump inhibitors (omeprazole and pantoprazole) makes it possible to perform a pharmacologic gastrectomy for ZES. The pump inhibitors are even more effective than the H2 receptor antagonists. If compliance is good, the need for total gastrectomy is eliminated. Side effects, including those from achlorhydria, are mild. Gastric carcinoids develop in rats given large doses of acid pump inhibitors. Gastric carcinoids are also seen in MEN1; however, the pump inhibitors do not seem to exacerbate them in MEN1. There remains disagreement about whether the pump inhibitors worsen enterochromaffin-like cell hyperplasia in sporadic ZES. The somatostatin analogue octreotide inhibits the secretion of both gastrin and gastric acid, and it is under evaluation for a role in malignant gastrinoma. In addition, the gastrin-lowering effect of somatostatin analogues may account for their effective suppression of gastric carcinoid mass in MEN1.

Although medical therapy for ZES in MEN1 is preferred and effective, the need for lifetime medical therapy, the recognition that small duodenal gastrinomas cause a high percentage of cases, and the poor outcome (50% 5-year survival) in patients with hepatic metastasis lead to frequent reexamination of treatment choices. The same issues have led to suggestions for earlier and more aggressive surgical intervention, although at present there is no objective evidence that such intervention is more successful.

Insulinoma

Insulinoma is the second most common hormone-secreting enteropancreatic neuroendocrine tumor in MEN1, with an overall frequency of 10% among adults with...
MEN1 (see Table 36-1). By coincidence, MEN1 also accounts for approximately 10% of all cases with insulinoma. The clinical features and diagnostic criteria are the same in MEN1 and sporadic cases gleaned from symptomatic fasting hypoglycemia with high insulin, C peptide, or proinsulin (see Chapter 32). Insulinoma syndrome in MEN1 is usually caused by a single dominant and benign pancreatic islet tumor, although ancillary non-hyposecreting islet tumors that stain for insulin or another gut hormone are common in MEN1. The main insulinoma is generally 2 to 3 cm in diameter and located anywhere in the pancreas. Removal of the main insulinoma is usually curative. Rarely, more than one tumor causes the insulinoma syndrome in MEN1. The postoperative recurrence rate of insulinomas may be higher in MEN1 than in sporadic cases (20% versus 5% at 5 years). As is the case with hyperparathyroidism, recurrent insulinoma in MEN1 may, in theory, have arisen from residual tumor or a new clone.

Preferred treatment is surgical removal of the insulinoma. Other incidental pancreatic islet macroadenomas should also be removed because of the possibility that one may be a hypersecreting insulinoma and also because it might become malignant. Somatostatin receptor scintigraphy (SRS) can give 30% to 60% true positive images. When surgery is done with guidance by intraoperative ultrasonography, the success rate should be satisfactory, although no large series has yet documented this in insulinoma in MEN1. Before intraoperative ultrasonography was available, routine distal pancreatectomy was sometimes recommended. This is now rarely needed but still should be contemplated for prevention of other tumors.

Several techniques, based on insulin radioimmunoassay, can be useful for localization of an insulinoma in patients with multiple islet cell tumors in MEN1. These include infusion of calcium into selectively catheterized pancreatic arteries with measurement of insulin in right or left hepatic venous effluent. Identification of an insulin peak after an intra-artrial calcium infusion localizes the insulinoma to the distribution of the artery. Other tests that have been useful include rapid intraoperative insulin and glucose levels in serum or intraoperative insulin levels in fine-needle aspirates of a pancreatic tumor (S. K. Libutti et al. National Institutes of Health, Bethesda, MD, unpublished).

Metastatic insulinomas causing hypoglycemia should be treated surgically, but operative strategies are less likely to be successful. Hypoglycemia caused by unlocalized or metastatic insulinoma can be controlled with diazoxide and somatostatin analogues are less effective.

**Tumors Secreting Glucagon, Vasoactive Intestinal Peptide, or Other Hormones**

**Glucagonoma Syndrome**

This syndrome consists of hyperglycemia, anorexia, glossitis, anemia, diarrhea, venous thrombosis, and a characteristic skin rash termed necrotic migratory erythema (see Chapter 30, Chapter 32, and Chapter 38). Glucagonoma syndrome is rare in MEN1, although one third of MEN1 enteropancreatic neuroendocrine tumors immunostain for glucagon. Glucagonoma is usually large and metastatic at presentation. Palliation is often possible with surgery or another ablative procedure (see later). Some patients have responded to the somatostatin analogue octreotide, although an initial response has not predicted a long-term response.

**Enteropancreatic neuroendocrine tumors in MEN1 frequently also oversecrete pancreatic polypeptide.**

**Other Endocrine and Enzymatic Hormones**

These are occasionally oversecreted by enteropancreatic neuroendocrine tumors in MEN1. They include adrenocorticotropic hormone (ACTH), PTH-related peptide, somatostatin, and calcitonin. The last can cause confusion with thyroidal C-cell cancer.

**Pancreatic Polypeptide/Secreting and Other "Nonfunctional" Tumors**

One third of enteropancreatic neuroendocrine tumors in MEN1 immunostain mainly for pancreatic polypeptide, similar to the fractions that immunostain mainly for insulin or for glucagon. Enteropancreatic neuroendocrine tumors in MEN1 frequently also oversecrete pancreatic polypeptide. This is not associated with any hormonal syndrome resulting from the peptide. Like other nonfunctional enteropancreatic neuroendocrine tumors in MEN1, these are often large, malignant, and metastatic at presentation.

Nonfunctional tumor is an abused but convenient term. In the context of MEN1, it is applied here to enteropancreatic neuroendocrine tumors, anterior pituitary tumors, or foregut carcinoids that do not immunostain for the common hormones of that tissue or that may immunostain for one or more hormones but do not hypersecrete the hormone and do not cause a hormonal syndrome. Most enteropancreatic tumors in MEN1 fit this definition, and most never become a clinical problem. However, if a nonfunctioning tumor becomes malignant, its lack of symmetric hormone hypersecretion can allow progression to an advanced stage before recognition.

**Staging of Enteropancreatic Neuroendocrine Tumors in Multiple Endocrine Neoplasia Type 1**

Appropriate management of enteropancreatic neuroendocrine tumor or tumors in MEN1 is challenging because of the multicentric nature of the tumors and the need to decide between surgical and other approaches. An enteropancreatic tumor causing a hormone excess state is likely to be accompanied by nonfunctional tumor(s). Management of these tumors is accomplished with imaging of sporadic tumors of the same types cannot be generalized to MEN1 tumors. Accurate localization of tumor and, in particular, identification of metastatic disease are critical for preoperative decision making. The multicentricity and variable size of these tumors stretch the limitations of radiologic techniques that have difficulty imaging tumors smaller than 1 cm in diameter. Their rarity has prevented organization of controlled trials. Despite these challenges, there has been considerable progress over the past decade.

Somatostatin receptor scintigraphy (SRS) is a generally useful method for imaging enteropancreatic neuroendocrine and foregut neuroendocrine tumor. It can image primary tumor and local or distant metastases. It is particularly useful for gastrinomas in MEN1, and it has led to the development of novel therapeutic procedures in MEN1-associated gastrinomas. Although it is the single most powerful imaging test, SRS still fails to image one third of lesions identified at surgery even in sporadic gastrinoma. The yield of SRS with sporadic insulinoma is somewhat lower than with other pancreatic islet tumors, with 30% to 60% true positives. Abdominal imaging by computed assisted tomography (CAT), particularly helical CAT, is a generally useful method for imaging enteropancreatic neuroendocrine and foregut neuroendocrine tumors. It is particularly useful for gastrinomas in MEN1 and it has led to the development of novel therapeutic procedures in MEN1-associated gastrinomas. Although it is the single most powerful imaging test, SRS still fails to image one third of lesions identified at surgery even in sporadic gastrinoma. The yield of SRS with sporadic insulinoma is somewhat lower than with other pancreatic islet tumors, with 30% to 60% true positives. Abdominal imaging by computed assisted tomography (CAT), particularly helical CAT, combined with early phase images after contrast injection or magnetic resonance imaging provides enhanced sensitivity for detection of small lesions and is complementary to SRS.

No imaging technique utilized for evaluation of MEN1 enteropancreatic tumors is completely satisfactory. Endoscopic ultrasonography with or without needle aspiration of a pancreatic mass may have selected applications but will probably be technically demanding, scarce, and expensive option for the foreseeable future.

With the exception of endoscopic ultrasonography, the current preoperative imaging methods are not able to image tumors confined to the pancreas and less than 1.5 cm in diameter. They also fail to identify metastases in 25% of cases and the extent of tumor multiplicity in MEN1 cases. In contrast, intraoperative ultrasonography is a useful tool for localizing small tumors not detectable by the eye or fingers of the surgeon. This technique has become the primary approach for diagnosis of small gastrinomas in most medical centers, although experience has been limited to sporadic tumors.
Functional (i.e., insulin-specific) testing can be useful to assess insulinoma because, unlike other enteropancreatic neuroendocrine tumors in MEN1, insulinoma may be symptomatic when small and solitary (see earlier).

Serum markers in MEN1, mainly chromogranin-A, provide useful diagnostic tools in creating suspicion of the presence of an enteropancreatic tumor. Chromogranin-A has not been helpful in insulinoma, perhaps because of the small tumor mass. An example of the usefulness of hormonal markers is the relationship between glucose and insulin, C peptide, and proinsulin in the diagnosis of quite small insulinomas. In contrast, chromogranin-A and gastrin as possible tumor markers have not been reliable indices of gastrinoma extent or progression.

Treatment of Enteropancreatic Neuroendocrine Tumors in Multiple Endocrine Neoplasia Type 1

Aspects of treatment specific to gastrinomas and insulinoma in MEN1 have already been described. Treatment of these and other enteropancreatic neuroendocrine tumors in MEN1 is controversial and guided in part by staging procedures and local preferences. The main controversies are highlighted.

Is Tumor Size Important?

Metastasis has been associated with gastrinomas more than 3 cm in diameter. This association has led some to recommend resection for all enteropancreatic tumors above a size cutoff of 2.5 to 3 cm. One analysis of this strategy suggested a failure to prevent later emergence of hepatic metastases. Some others have not found a relation of tumor size and metastasis and do not use a size criterion.

Should All Enteropancreatic Neuroendocrine Tumors Be Removed?

There is no consensus on this point. A reality confronted in MEN1 is that for every identifiable pancreatic tumor there are likely to be several smaller unidentified tumors (clones) that coexist or emerge at a later date. Improvements in pancreatic surgical technique, however, have made it possible to excise smaller lesions surgically, although the rationale for doing this is less clear. Certainly there is no compelling evidence to suggest that surgical removal of small tumors, unless they produce a hormonal syndrome, improves overall outcome. Some urge removal of all detectable macroadenomas if removal would not be dangerous. Others urge a large size cutoff (2.5 to 3 cm in diameter) for removal.

Should Metastatic Enteropancreatic Cancer Be "Debunked"?

Total pancreatectomy with a high rate of complications has been used for very large tumors. Many methods are under exploration for resecting or otherwise ablating enteropancreatic neuroendocrine cancer. Results are too preliminary to justify endorsing any of these.

Should Medications Be Used to Control Tumor Progression?

Enteropancreatic neuroendocrine tumors are generally differentiated and quite resistant to chemotherapy. Several regimens have been tried including streptozotocin, doxorubicin, or interferon, but there is no proof of long-term efficacy. Octreotide has been effective in inhibiting hormone secretion by benign and malignant enteropancreatic neuroendocrine tumors; however, it has not been effective by itself in blocking growth of these tumors except for malignant gastrinoma. Its use in multidrug regimens needs further evaluation.
Pituitary Adenoma

Anterior pituitary tumor occurs in about one third of MEN1 cases. The frequency of MEN1 in cases of apparently sporadic pituitary tumor is probably below 5%, although estimates vary widely to as high as 15% with prolactinoma. The overall frequency of hormones hypersecreted is similar to that in non-MEN1 pituitary tumors: oversecretion of prolactin 60%, oversecretion of growth hormone with or without prolactin 15%, nonsecreting 25%, and oversecretion of ACTH 5%. Excessive secretion of thyrotropin or gonadotropins is rare. Pituitary mass effects can be the principal problem. In fact, pituitary tumors in MEN1 have been larger and less responsive to treatment than those without MEN1. Pituitary tumor can occur early in MEN1 and is occasionally the first recognized feature. Rarely, two independent tumors have been suggested. However, the difficulty of recognizing multiple tumors in the anterior pituitary may lead to underestimation of their frequency. Inactivation of both copies of the MEN1 gene in one or a few pituitary cells leads to monoclonal or oligoclonal proliferation.

Prolactinoma

Prolactinoma is the most common pituitary tumor in MEN1 and the third most frequent endocrine tumor in MEN1 after parathyroid tumors and gastrinomas. The general properties are similar to those of sporadic prolactinoma. MEN1 prolactinoma may be large. Dopamine agonists (e.g., cabergoline, bromocriptine, pergolide, quinagolide) are the preferred treatment. A reduction in side effects and greater potency make cabergoline the current treatment of choice and have improved patients’ compliance. In patients who escape from the growth inhibitory effects of these dopamine agonists or who are noncompliant, transphenoidal surgery combined with radiation therapy is usually effective.

Tumors Producing Growth Hormone or Growth Hormone-Releasing Hormone

The clinical features of growth hormone excess are similar in cases with and without MEN1. There are two different etiologic mechanisms with different treatment implications. The majority of MEN1 pituitary adenomas arise clonally from inactivation of both alleles of the MEN1 gene in a tumor precursor cell. Additional genes such as Gsp (another term for the subunit of the stimulatory G protein) may be implicated, in this case by activating mutation of Gsp. The second mechanism of pituitary GH tumorigenesis is overproduction of GHRH by pancreatic islet or carcinoid tumor. The resulting secondary pituitary tumor is a polyclonal or hyperplastic process, which responds poorly to therapy directed only at the pituitary; removal of the primary GHRH-producing tumor is essential. Although acromegaly secondary to GHRH is rare in sporadic or MEN1 cases, a disproportional fraction of such cases have had MEN1. Thus, measurement of serum GHRH in MEN1 acromegalic cases seems worthwhile. GH-producing pituitary tumors also produce GHRH locally, but this has not interfered with the interpretation of serum GHRH levels.

Treatment for acromegaly with MEN1 is the same as without MEN1. Surgery is usually the first choice, but the development of other pharmacologic therapies including long-acting somatostatin receptor antagonists and growth hormone receptor antagonists can provide effective, albeit expensive, control. In patients with large tumors causing mass effects or those in whom GH effects are not controlled by surgery or pharmacologic therapy, radiation using an external beam, gamma knife, or proton beam is an alternative.

Corticotropin Hypersecretion or Primary Adrenocortical Hyperfunction

Cushing’s syndrome in MEN1 can be caused by a pituitary tumor producing corticotropin (ACTH) or uncommonly by ectopic production of ACTH from a carcinoid or an islet tumor, or by ectopic production of ACTH-releasing hormone (CRH). Therapy should be directed initially to treat the ACTH- or CRH-producing primary tumor. When therapy directed toward the primary source is not successful, corticosteroid production can be controlled by bilateral adrenalectomy or medical therapy. One or both adrenal glands are enlarged in up to 40% of MEN1 cases. This enlargement, most commonly discovered during panoramic imaging, is generally clinically silent and rarely requires treatment. The silent enlargement represents a presumably polyclonal or hyperplastic process of unknown etiology, and it rarely behaves as a neoplasm. Rare MEN1 cases have been identified with primary hypercortisolism, hyperaldosteronism, or adrenocortical cancer; these have not been proved to be intrinsic features of MEN1.
Foregut Carcinoid Tumors

Carcinoid tumor is recognized in 5% to 15% of MEN1 cases.\textsuperscript{21} \textsuperscript{154} Although sporadic carcinoid is derived mainly from midgut and hindgut, MEN1 carcinoid is primarily found in derivatives of the foregut (thymus, bronchus, stomach). Certain carcinoid tumors, unlike any other manifestation of MEN1, have a sex-specific distribution. Thymic carcinoid is found mainly in males, and bronchial carcinoid is identified mainly in females.\textsuperscript{1725} The average age of carcinoid recognition in MEN1 is 45 years,\textsuperscript{180} later than that of other MEN1 tumors. This later age may reflect their lack of compression-induced symptoms and the lack of a hormone oversecretion syndrome with most MEN1 carcinoids.

Thymic carcinoid in MEN1 is usually found at an already advanced stage as a large invasive mass. Less commonly it is recognized during chest imaging or during thymectomy adjunctive to parathyroidectomy. Thymic carcinoid is more frequently malignant (about 70%) than bronchial carcinoid (about 20%) in MEN1.\textsuperscript{180} \textsuperscript{181} \textsuperscript{182} \textsuperscript{183} \textsuperscript{184} MEN1 thymic or bronchial carcinoids rarely oversecrete ACTH, calcitonin, or GHRH; similarly, they rarely oversecrete serotonin or histamine and rarely cause the carcinoid syndrome. They may thus be considered as clinically nonfunctioning. Mediastinal or bronchial carcinoids are best imaged by computed tomography; however, SRS is often positive and therefore useful.\textsuperscript{187}

Gastric carcinoid has been recognized more recently and is less well characterized in MEN1. It is a tumor of histamine-secreting enterochromaffin-like cells. Gastric carcinoids do not cause a hormonal syndrome in MEN1. In up to 15% of MEN1 cases, they have been recognized incidentally during endoscopy.\textsuperscript{68} The overall malignancy rate seems low, but there are exceptions.\textsuperscript{188} At early stages they can regress after treatment with somatostatin analogues.\textsuperscript{85}

Carcinoid occurs occasionally in several members of a small family without other manifestations of MEN1; the etiology of these associations is not known.\textsuperscript{189} \textsuperscript{190} \textsuperscript{191}
Miscellaneous Features of Multiple Endocrine Neoplasia Type 1

Miscellaneous Endocrine Tumors in Multiple Endocrine Neoplasia Type 1

Pheochromocytoma

This is a rare feature in MEN1. There have been fewer than 10 reported cases. Most have been unilateral and chemically silent; one was malignant. In two tumors, 11q13 loss of heterozygosity (LOH) was documented, making it likely that all or most of these rare pheochromocytomas are true clonal expressions from biallelic MEN1 gene inactivation. This is supported by more frequent pheochromocytoma in a mouse model of MEN1.

Thyroid Follicular Neoplasms

This has been associated with MEN1 since the earliest reviews. Although the association is probably correct, it is more likely related to the high incidence of thyroid follicular neoplasms in the general population (unrelated to MEN1) that are uncovered during the inevitable neck exploration for parathyroid disease in MEN1 than any causal association. Further support for a coincidental association is the failure to identify MEN1 gene mutations in sporadic thyroid follicular tumors.

Miscellaneous Nonendocrine Tumors

MEN1 has nonendocrine features that vary from rare to common, with some offering possible use in the diagnosis of MEN1.

Lipoma

This has been associated with MEN1 for over 30 years. MEN1 lipomas are generally dermal, small, and sometimes multiple. Their frequency in MEN1 is about 30% versus 5% in control subjects without MEN1. The frequency of lipomas in normal subjects has limited their use for MEN1 carrier ascertainment.

Multiple Facial Angiofibromas

These have been found in 88% of MEN1 cases but not in control subjects. Half of MEN1 cases have five or more. They are acniform papules that do not regress and that may extend across the vermilion border of the lips.

Collagenoma

This was also observed in 72% of MEN1 cases but not in control subjects. Collagenomas are whitish macular lesions about the trunk, sparing the face and neck. The MEN1 lipomas, angiofibromas, and collagenomas show loss of one copy of 11q13. Thus, it is likely that these are clonal neoplasms and caused by inactivation of the (first and then) second copy of the MEN1 gene.

Spinal Cerebellar Ependymoma

This has been seen in four MEN1 cases. There are no studies to determine whether 11q13 LOH or other MEN1 gene abnormalities are causative.

Malignant Melanomas

This has occurred in at least seven MEN1 cases, but direct involvement of the MEN1 gene has not been tested.

Leiomyoma (of Esophagus, Lung, Rectum, or Uterus)

This has been reported in several MEN1 cases. Analyses of 11q13 LOH established that esophageal and uterine leiomyoma are specific to MEN1 cases. Similar MEN1 inactivation was not implicated in sporadic uterine leiomyoma.

Varying Penetrance of Tumors by Tissue or by Age

MEN1 is perhaps the most heterogeneous of all multiple neoplasia syndromes. The many tumors of MEN1 have a wide range of penetrance (see Table 36-1). If the organ is paired and the penetrance is high, the tumors are generally bilateral (i.e., parathyroid); if the tumor is rare in MEN1, its random occurrence is generally unilateral even in a paired organ (i.e., pheochromocytoma). Naturally, the apparent penetrance of any tumor type is heavily dependent upon the scrutiny that the organ is given. Thus, the frequent facial angiofibromas of MEN1 were not recognized until 1997. When symptoms alone are the main basis for disease recognition, the first feature of MEN1 in adolescents is not hyperparathyroidism but rather prolactinoma or insulinoma. For each tumor type, penetrance necessarily increases with age (see Fig. 36-1). Overall, the penetrance for MEN1 (usually parathyroid) reaches nearly 100% by age 50, but occasional obligate MEN1 mutation carriers have not shown any tumor beyond age 70. Earliest penetrance and earliest preventable morbidity must be evaluated in decisions about when to begin carrier ascertainment for tumors in a likely carrier. The earliest ages for identification of specific tumor expression in MEN1 have been as follows: prolactinoma at age 5, insulinoma at age 6, hyperparathyroidism at age 8, and gastrinoma at age 12 (R. Jensen, personal communication). The information about morbidity for most of these cases is incomplete; thus, more information is needed before it is possible to make consensus recommendations regarding the correct age at which to begin tumor surveillance and possibly intervention.

Phenotypes or Varying Tumor Penetrance by Family

Clustering of clinical subvariants of MEN1, similar to that seen for MEN2 (see later in chapter), has been evaluated. Preliminary analyses in small MEN1 families suggested clusters of ACTH-producing pituitary tumors, insulinomas, carcinoid, and aggressive gastrinomas. Identification of a specific mutation that correlates with a specific clinical variant in multiple kindreds would be most meaningful. Although subsequent analysis has failed to identify such a relationship (see
Hyperparathyroidism

Hyperparathyroidism is the most common clinical feature of MEN1 and occurs at a relatively young age. It would therefore not be surprising to identify isolated hyperparathyroidism in small families with early or occult MEN1, particularly those with a disproportionate number of young members. Larger families (four, five, or more affected members) have been identified with familial isolated hyperparathyroidism (FIH) and an identifiable MEN1 mutation but still could represent a random part of the normal spectrum of MEN1 expression. Eventually, most would probably develop other clinical features of MEN1. Two FIH families with MEN1 mutation have been particularly large, with 8 and 13 hyperparathyroid members, raising the likelihood that, in some families, isolated hyperparathyroidism may exist and continue as the only manifestation of MEN1 mutation. MEN1 mutation is rare in families with FIH.

When MEN1 occurs in its typical forms, it is easily diagnosed. Presentation as a single sporadic tumor, as FIH, or as familial isolated pituitary tumor (see earlier) not only is rare but also presents the clinician with a difficult diagnostic challenge.

Sporadic Tumor or Tumors

MEN1 can occur without a recognized or even recognizable family history of MEN1. When sporadic cases present with two or more typical tumors, some cases meet the definition criteria for MEN1 (see later), for others the suspicion of MEN1 is high. The prevalence of MEN1 mutation is 10% to 90%, depending on the specific tumors (see later). When the sporadic case presents in only one tissue, the suspicion and the true frequency of MEN1 mutation are low. The frequency of occult MEN1 with sporadic tumor can be estimated as follows: hyperparathyroidism (2%), gastrinoma (5%), pheochromocytoma (5%), progressing adrenal adenomas (5%). Factors that increase the likelihood of MEN1 in these settings are earlier onset and tumor multiplicity in the same organ.

Familial Isolated Hyperparathyroidism

When hyperparathyroidism is familial and isolated, the main possibilities include occult MEN1 (see earlier), familial hypocalciuric hypercalcemia (FHH), hyperparathyroidism with jaw tumor syndrome (HPT-JT), MEN2A, and so-called true FIH (see Chapter 28). FHH, with a frequency similar to that of MEN1, is an autosomal dominant disorder characterized by lifelong hypercalcemia with normal urine calcium excretion. PTH levels and parathyroid gland mass are normal or minimally increased. After subtotal parathyroidectomy, the residual parathyroid tissue directs persistent hypercalcemia after subtotal parathyroidectomy. The parathyroid dysfunction is not neoplastic but polyclonal. A remarkably high rate of persistence after subtotal parathyroidectomy and a low morbidity without surgery justify efforts to avoid parathyroid surgery in FHH. Useful diagnostic features of FHH are the low ratio of renal calcium clearance to creatinine clearance (in the presence of hypercalcemia) and the onset of hypercalcemia in relatives typically before age 1 year. Two thirds of FHH index cases have an activating mutation of the calcium-sensing receptor gene (CASR). Most of the rest are believed to have an undetected mutation of CASR, suggested by genetic linkage to chromosome 3q; occasional families have the FHH syndrome with mutation in unknown genes at 19p or 19q. One family with a missense mutation of CASR had features intermediate between FHH and typical hyperparathyroidism.

HPT-JT is a syndrome of hyperparathyroidism, jaw tumors, and renal lesions. Transmission is autosomal dominant, and it is caused only by the yet unidentified HRTF2 gene at 1q24–1q32. The commonest and sometimes the only feature is hyperparathyroidism. The hyperparathyroidism typically involves one parathyroid gland at a time and there is a uniquely high malignant potential in the parathyroid tumor; 15% of reported cases have had parathyroid cancer. The associated jaw tumors are osseous or cementifying fibromas. Unlike the jaw tumors of hyperparathyroidism, they are not influenced by the hyperparathyroid status. The associated renal lesions are multiple renal cysts, hamartomas, or Wilms’ tumor. An international consortium is working to identify this gene. Occult MEN2A, theoretically another cause of FIH, has not been identified in the form of FIH.

Many small kindreds with two or three affected members receive a diagnosis of FIH. For years FIH was not pursued as a syndrome because of bland features and the belief that most kindreds had occult MEN1. A detailed analysis of many kindreds with FIH found occult MEN1, FHH, or HPT-JT in the minority. Whether the remaining individuals have true FIH or some other genetic form of hyperparathyroidism will become clear only with long-term follow-up or when robust deoxyribonucleic acid (DNA) tests become available for all of the genes for FHH (at least three genes), HPT-JT, and other hereditary forms of hyperparathyroidism.

Familial Isolated Pituitary Tumor

Familial isolated tumor of the anterior pituitary has been recognized in several small and few large families. The tumors are usually somatotropinomas, occasionally prolactinomas. In theory, familial isolated tumor of the anterior pituitary could be an expression of occult MEN1. To date, however, no family with familial isolated somatotropinoma has had a MEN1 mutation (see later). It is more likely that most of these families harbor mutations of another unknown gene or genes.
The MEN1 Gene: Normal or Mutated

The Normal MEN1 Gene and Normal Menin

Larsson and colleagues showed in 1988 that the MEN1 gene mapped to chromosome 11q13 and that it was probably a tumor suppressor gene (see the following). However, almost a full decade passed before the MEN1 gene was identified by positional cloning. This strategy involved a progressive narrowing of the candidate gene interval, cloning all the DNA in the narrowed interval, and identifying all or most genes therein. The final step required sequence analysis of each of these genes in a panel of DNA from familial MEN1 index cases, a systematic process that led to the identification of the one gene that carried the defining mutations.

The MEN1 gene is 10 kilobases (kb) in size and encodes transcripts of 2.7 and 3.1 kb. The transcripts are expressed in all or most tissues and with little cell cycle dependence. They encode a 610-amino-acid protein termed menin. Rat, mouse, zebra fish, snail, Drosophila, and human menins are highly homologous.

Menin has two nuclear localization signals near the carboxyl terminus that are likely to be responsible for its predominantly nuclear compartmentalization. The first interacting protein partner identified for menin was selectively junD but not other members of the activator protein-1 (AP1) transcription factor family including fos, fra, or other jun proteins. The menin-junD interaction may confer upon junD unique effects by which junD differs from other members of the AP1 transcription family. For example, junD has several actions opposite to those of C-jun, and in the absence of menin binding to it, junD behaves more like C-jun. The importance of the menin-junD interaction for the development of MEN1 is unclear. Homozygous knockout of junD in the mouse resulted in no identifiable abnormality of tissues involved in MEN1. Other studies have identified SMAD3, PEM, NM23, nuclear factor B, and several other proteins that potentially interact with menin. Each interaction has unknown importance.

Tumorigenesis: Sequential Two-Step Inactivation of the MEN1 Gene

The first DNA-based discoveries in MEN1 suggested that the MEN1 gene was a tumor suppressor (see Chapter 35), observations supported by subsequent studies (see later). Complete inactivation of a gene's function, required in addition to the inherited or somatically acquired first hit (inactivating mutation), a second hit at the same genetic loci that finishes the inactivation of both copies of the MEN1 gene. Inactivation of the second allele can be by mutation or another (epigenetic) means such as promoter methylation, though the latter has not been found for MEN1. A two-hit model for tumorigenesis was developed by Alfred Knudson to account for epidemiologic observations in retinoblastoma: that, in comparison with sporadic cases, some hereditary tumors occurred earlier and in multiple sites. This can now be generalized to say that, in a hereditary tumor, the germ line mutation is obligatorily present in every cell. Thus, the earliest step seen in sporadic tumorigenesis is the presence of the second hit, by which the MEN1 gene is bypassed. Multiple independent cells in susceptible organs are thus primed for somatic mutations at the second and still normal copy to cause early and multiple tumors. This model can be extended to stepwise tumorigenesis by an oncogene such as RET (see later).

Somatic Point Mutations (First Hit) of the MEN1 Gene in Sporadic Tumors

MEN1 is one of the most frequently mutated genes in sporadic endocrine tumors. The frequency of MEN1 mutation is 10% to 20% in parathyroid adenomas, 50% to 58% in non-adenomatous parathyroid gland tumors, 10% to 20% in insulinomas, 50% in VIPomas, and 25% to 35% in bronchial carcinoids. Other sporadic endocrine tumors show a lower frequency of MEN1 somatic mutation: 0% to 5% in anterior pituitary tumors, 0% to 1% in thyroid tumors, 0% in benign or malignant adrenocortical neoplasms, 0% in uremic secondary hyperparathyroidism, and 0% in parathyroid cancer. Sporadic nonendocrine tumors have undergone little evaluation; the MEN1 mutation frequency was 2/19 in angiomatoses, 1/6 in lipomas, 0% in lung cancer other than carcinoid, 1% in malignant melanoma, and 0% in leukemia.

The First Step (First Hit) Can Be in Germ Line or in Somatic Tissue

Virtually all germ line or somatic first hits at the MEN1 gene have been small mutations, involving one or several bases. The mutations are broadly distributed across the MEN1 open reading frame, so much so that half of newly ascertained index cases are found to have a "novel" mutation. At the same time, the other half show a recurring mutation. These are equally distributed between cause by common ancestry (founder effect) and cause by a hot spot for new mutation.

Accumulated patterns of germ line and somatic first-hit MEN1 mutations have further supported the two-hit gene inactivation hypothesis for the MEN1 gene. Three fourths of MEN1 first-hit mutations predict premature truncation of the menin protein. Although the biologic functions of menin are not established, such truncation mutations would probably cause menin inactivation or even absence. For example, all truncation-type MEN1 mutations cause loss of the most carboxyl-terminal nuclear localization signal and could thus compromise the nuclear localization of menin. The remainder predict missense or replacement of one to three amino acids. The functional consequences of any one missense mutation are uncertain and even hard to distinguish from a rare benign polymorphism; however, their frequent occurrence specifically in MEN1 establishes that all or most are deleterious mutations. Loss of menin function in the junD-mediated transcription assay occurs even with many missense (amino acid-changing) MEN1 mutations; this result also predicts menin inactivation.

The Second Hit in MEN1 Tumorigenesis

The second hit is usually a large chromosomal or subchromosomal rearrangement (i.e., mutation), causing deletion that includes the remaining normal MEN1 gene. Another mechanism for creating a mutant second copy is deletion of the normal copy and then duplication of the DNA from the mutant chromosome 11, so called gene conversion. In either case, the result is that neither copy of the MEN1 gene remains normal. LOH or loss of alleles at the affected locus is usually inherent in this process and can provide evidence that gene inactivation has occurred in that chromosomal segment. Less common mechanisms for the second hit include small mutations (one to three bases) or promoter methylation. The second hit is delayed after the first hit. It is always in somatic tissue and usually occurs postnatally.

Loss of Heterozygosity about Chromosome 11q13 as a Research Tool

LOH about 11q13 has been used mainly to deduce loss of the normal copy of the MEN1 gene. In MEN1, 11q13 LOH was found for almost 100% of the following tumor types: parathyroid tumor, gastrinoma and other pancreatic islet tumor, gastric carcinoid, anterior pituitary tumor, and mesenchymal tumors (lipoma, angiofibroma, collagenoma, and...
Among sporadic endocrine tumors of the type found in MEN1, some but not all have frequent 11q13 LOH. The frequencies of 11q13 LOH in these tumors have been as follows: sporadic parathyroid 30% to 40%, gastrinoma 3% to 4%, uremic parathyroid 0% to 5%, parathyroid cancer 0%, gastrinoma 25% to 70%, insulinoma 30%, bronchial and other carcinoid 40% to 70%, anterior pituitary 5% to 10%. The subsequent finding of nearly universal 11q13 LOH in MEN1 parathyroids established that clonal growth was predominant, that tumorigenesis was by gene inactivation, and that a MEN1 growth factor for parathyroid glands in MEN1 could not represent the immediate product of the MEN1 gene.

**Germ Line MEN1 Mutations: Multiple Endocrine Neoplasia Type 1 Phenotypes and Phenocopies**

There have been no clear relations of MEN1 genotype with phenotype, unlike the situation in MEN2 (see later). The truncating MEN1 mutations have the same diverse types of tumor expression as the missense mutations, and phenotypic expression does not differ between amino-terminal and carboxyl-terminal mutations. The distribution of somatic mutations about the open reading frame is similar to that of germ line mutations and seems not entirely random. In particular, there appears to be a deficiency of missense mutations near the carboxyl terminus and a cluster of missense mutations between amino acids 100 and 200. Otherwise, there is no clear clustering of missense mutations that could point to a zone of menin protein susceptible to change of function.

The p16INK4a and p27KIP1 genes encode members of the two cyclin-dependent kinase inhibitor families that participate in the cell cycling pathway, which also includes retinoblastoma and cyclin D1. This syndrome resembles to MEN1 and MEN2 raises the possibility that the tumorigenic pathways of MEN1 or MEN2, or both, overlap and interact with the cell cycling pathway.

Among sporadic parathyroid tumors of varying aggressiveness.

**Conclusion**

Inactivation of certain other tumor suppressor genes, alone or in combination, can cause specific endocrine tumors in mice. In particular, mice with homozygous inactivation of both p16INK4a and p27KIP1 develop at least eight types of proliferative tissue, including tumors of parathyroid, pituitary, pancreas islet, and duodenum (as in MEN1); in addition, they develop C-cell cancers and pheochromocytoma (as in MEN2). The knocked out genes encode members of the two cyclin-dependent kinase inhibitor families that participate in the cell cycling pathway, which also includes retinoblastoma and cyclin D1. This syndrome resembles to MEN1 and MEN2 raises the possibility that the tumorigenic pathways of MEN1 or MEN2, or both, overlap and interact with the cell cycling pathway.

**Tumorigenesis: Steps Toward MEN1 Inactivation**

Other unknown genes can be implicated in MEN1 tumor evolution through gene loss of function (tumor suppressor gene) or gene gain of function (oncogene). Inactivation of certain other tumor suppressor genes, alone or in combination, can cause specific endocrine tumors in mice. In particular, mice with homozygous knockout of both p16INK4a and p27KIP1 develop at least eight types of proliferative tissue, including tumors of parathyroid, pituitary, pancreas islet, and duodenum (as in MEN1); in addition, they develop C-cell cancers and pheochromocytoma (as in MEN2). The knocked out genes encode members of the two cyclin-dependent kinase inhibitor families that participate in the cell cycling pathway, which also includes retinoblastoma and cyclin D1. This syndrome resembles to MEN1 and MEN2 raises the possibility that the tumorigenic pathways of MEN1 or MEN2, or both, overlap and interact with the cell cycling pathway.

The earliest tissue-level effects toward tumorigenesis in MEN1 are not well defined. Although a widespread role for hyperplasia prior to neoplasia has been seen in MEN2, hyperplasia has been subtle or absent in MEN1 tissues. However, the mouse Men1 knockout model for MEN1 has striking giant hyperplastic islets as a precursor for insulinoma, suggesting that more subtle hyperplasia may have gone unrecognized in human MEN1. If there is a role for hyperplasia, it would still be uncertain whether this is an expression of inactivation of one MEN1 allele or further processes.

Genome instability has been suggested in studies of MEN1 lymphocytes and fibroblasts. MEN1 leukocytes show a subtle deficiency in repair of DNA damage. Clonal cell proliferation has been identified in mesenchymal perivascular tissues about MEN1 angiofibromas; this could represent a precursor stage of that tumor. The MEN1 plasma contains a growth factor that promotes mitogenesis in normal parathyroid cells. Considering the overriding roles of MEN1 gene inactivation and of clonal growth, it is not certain whether the growth factor is a contributor to or a consequence of oncogenesis in MEN1.
Testing for Carrier State and for Tumor Emergence in Multiple Endocrine Neoplasia Type 1

Screening and Counseling for Multiple Endocrine Neoplasia Type 1

A screening-program for MEN1 patients should routinely meet three main objectives: identify MEN1 carriers, identify MEN1 tumors particularly at a treatable stage, and be cost-effective (Fig. 36-9). Screening tests can be classified in two categories: ascertainment of carriers of MEN1 predisposition and periodic surveillance for MEN1 tumors (see Fig. 36-9). *

*The term screening has been applied to several processes in the setting of MEN. Herein, a distinction is made between testing for carrier ascertainment and testing for periodic surveillance of tumors. Note that when carrier testing with DNA (mutation or haplotype test) is not possible, streamlined and periodic tumor surveillance becomes the preferred method for carrier ascertainment.

Encounters for carrier ascertainment often involve counseling patients. In addition to standard genetics topics, counseling in MEN1 addresses two different faces of MEN1: an endocrinopathy with good but complex management options and a cancer syndrome with limited management options. A MEN1 information Web page can help in orientation: (http://www.niddk.nih.gov/health/endocr/pubs/men1/men1.htm). Experience with tumor surveillance in MEN1 families has shown that compliance with a simple and regular surveillance protocol is high (Table 36-2); complicated, expensive, and erratic efforts are associated with lower compliance.

Benefits and Limitations of Carrier Ascertainment

The benefits of this type of analysis are several. First is the secure proof of the MEN1 carrier state in an individual with a mutation and, equally important, the potential to exclude the

MEN1 carrier state by a normal sequence analysis when an affected member of the kindred has an identified mutant MEN1 gene sequence. This type of information can assist in decisions about family planning, future medical needs, and so forth. Second, the information from an index case, if shared, can be helpful to relatives unaware of their status. In particular, after a germ line MEN1 mutation is first identified, the information may be shared with a laboratory and with relatives, and DNA-based information may be used to develop an accurate shortcut test for that mutation in relatives (see later). Third, the information is useful to the physician. It assists in further plans about counseling and tumor surveillance. Occasionally, it is important in a decision about surgery, as in a case of apparently sporadic gastrinoma.

What the MEN1 carrier ascertainment test does not do is also important. MEN1 carrier ascertainment, unlike similar testing for MEN2, does not routinely lead to a recommendation for medical or surgical intervention. MEN1 cancers, in contrast to MTC in the thyroid, arise in tissues that cannot easily be ablated. This lack of mutation-guided intervention makes mutation testing at early ages in MEN1 less urgent than in MEN2. One approach is to recommend DNA testing in children of gene carriers at age 5 years, the youngest age at which a morbid and possibly treatable MEN1 treated tumor (prolactinoma) has been identified. An alternative, based on the fact that MEN1 morbidity is rare before the age of 20 years, is to delay carrier ascertainment until the child can make a mature decision about a test that could affect availability of insurance or job opportunities.

No identifiable MEN1 mutation is found in up to 40% of typical MEN1 kindreds, although most are believed to harbor mutations not detected by the most common DNA sequencing strategies. Carrier ascertainment in such kindreds can be established by 11q13 haplotype analysis or by streamlined tumor surveillance (see later) (Fig. 36-9). The potential for benefit from the MEN1 mutation test is generally proportional to the likelihood of finding a MEN1 mutation. Thus, obvious benefit is possible for an index case with familial or sporadic MEN1 or with a state that resembles MEN1 but does not quite meet the usual definitions. For example, a MEN1 germ line mutation was found in each of four cases with sporadic hyperparathyroidism and carcinoid tumor. The value is less clear in an apparently unaffected adult relative of a MEN1.
Germ line DNA mutation analysis can identify or rule out most MEN1 mutation carriers by a test applied only one time during the life span. This test is available through several commercial and academic laboratories (a listing can be found at [http://www.genetests.org](http://www.genetests.org)). The usual tissue surrogate for germ line DNA is blood leukocytes; MEN1-associated tumor is less satisfactory because any identified mutation could have occurred somatically. The MEN1 mutation test is based on polymerase chain reaction amplification of the nine translated exons (the open reading frame) and the intron-exon boundaries. Laboratories use modestly differing protocols.

MEN1 germ line mutations have been detected in 60% to 100% of well-defined MEN1 families. The wide variability in mutation detection is explained partly by family selection but more likely by differences in laboratory detection methods. Genetic linkage analysis previously mapped all well-characterized MEN1 kindreds to 11q13, making it likely that mutation of the MEN1 gene causes almost all familial MEN1. Only two atypical MEN1 families have not been linked to 11q13. Failure to identify a MEN1 mutation could be explained by the presence of mutations involving 3' or 3' untranslated or central intronic sequences, regions that are not normally examined, or by a large MEN1 deletion that results in no abnormal polymerase chain reaction product.

The MEN1 mutation detection rate has been lower (10% to 80%) in sporadic than in familial MEN1, probably because of differences in selection of patients. The MEN1 germ line mutation rate has been high (about 75%) in sporadic cases with hyperparathyroidism and ZES but far lower (about 10%) in sporadic cases with hyperparathyroidism and acromegaly. For the same reason, the MEN1 mutation detection rate has also been lower (0% to 30%) in sporadic cases with atypical MEN1, a truly broad category without a consensus definition. Most MEN1 mutations are familial, but about 10% arise de novo. This cannot be deduced reliably by history; rather, it requires analysis of DNA from both parents, including haplotyping (i.e., genetic "fingerprinting") to verify parental assignment. This is rarely pursued for ethical or legal objections.

When MEN1 mutation cannot be detected in the germ line DNA of a MEN1 index case, ascertainment of the carrier state in relatives is more difficult. Carrier ascertainment can still be based on streamlined periodic tumor surveillance in a relative (see later) or on haplotype analysis (similar to genetic linkage analysis) in a kindred (see Fig. 36-9). Haplotype or linkage analysis for the MEN1 trait can be done with high degrees of confidence; however, few laboratories are doing these analyses, and a substantial number (two or more depending on the informativeness of the probes used and on the family structure) of additional definitely affected relatives must participate.

Multiple Endocrine Neoplasia Type 1 Carrier Ascertainment by Streamlined Surveillance for Tumors: An Alternative to DNA Testing

In kindreds with no identifiable MEN1 mutation or possibility of 11q13 haplotype analysis, it is necessary to base assignment of carrier status on the clinical identification of one of the major tumors of MEN1. Streamlined periodic surveillance for tumors by biochemical tests should be offered every 3 to 5 years. Hyperparathyroidism is the most frequent and usually the earliest manifestation of MEN1, and therefore its recognition is central to this carrier ascertainment strategy. The preferred parathyroid tumor surveillance test is the ionized calcium test, beginning at the age of 8 or later; if it is unavailable, an albumin-adjusted calcium test is suitable and is preferable to the measurement of total serum calcium. A PTH assay should be performed at the same time.

Five years is a suggested starting age for prolactinoma surveillance, based on the occurrence of a macroadenoma in a child of that age with MEN1. Because serum prolactin rises with stress, avoidance of phlebotomy stress in a child may require an indwelling venous catheter and three blood samples at 20-minute intervals. Gastrinoma surveillance can be introduced during adulthood because of the generally later age of onset of ZES in MEN1. Only rarely is gastrinoma the first clinical tumor to occur in MEN1. Surveillance for cutaneous manifestations of MEN1, collagenomas or facial angiofibromas, may be promising but has not yet been explored in children.

False-positive test results are commonly found in MEN1 tumor surveillance through the assays of prolactin (stress, pregnancy, or psychotropic medications) or gastrin (mainly hypochlorhydria including that resulting from inhibitors of gastric acid secretion). Occasionally, a sporadic but common endocrine tumor (such as parathyroid adenoma or pituitary tumor) occurs in a family member who is not an MEN1 carrier.

Periodic Surveillance for Tumors after Proving the Multiple Endocrine Neoplasia Type 1 Carrier State

When the MEN1 carrier status has been identified by any method, it is appropriate to focus continued and increased attention on the patient with the goal of identifying and treating neoplastic manifestations at an appropriate stage. Surveillance for parathyroid tumor, prolactinoma, and insulinoma can begin at age 5 to 8 years; surveillance for gastrinoma, other islet tumors, and foregut carcinoids should be delayed until after the age of 20 years. Cost-effective surveillance combines a carefully obtained history focused on clinical symptoms associated with these tumors, limited hormonal and serum chemistry analysis, and carefully defined (i.e., selective and less frequent) use of imaging.

Some have recommended more extensive surveillance measures that include measurement of pancreatic polypeptide, insulin, proinsulin, or cortisol. Furthermore, a mealstimulated test was developed in the hope of increasing the MEN1-related diagnostic information from pancreatic polypeptide and other markers. Although a case can be made that these tests may result in earlier tumor recognition, it is unclear whether such detection results in benefit to the patient. Any abnormal tumor surveillance test should initiate as appropriate, a sequence of confirmation, exclusion of falsepositives, a decision whether to proceed with staging or surgery or both, and finally preoperative and intraoperative tumor imaging tests. The specific details differ for each tumor type.

Figure 36-10 Bilateral medullary thyroid carcinoma in multiple endocrine neoplasia type 2A. Large bilateral foci of medullary thyroid carcinoma are located in each lobe of the thyroid gland.
MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Multiple Endocrine Neoplasia Type 2A

In 1959, John Sipple was asked to see a hypertensive patient who subsequently died. At autopsy Sipple "was amazed when [he] saw large, bilateral pheochromocytomas and a 2-cm pale tan mass in each lobe of the thyroid gland and nodular enlargement of the only parathyroid gland [they] could find." He reported this case and reviewed five others from the literature. Subsequently, the familial nature of the syndrome and the recognition of the thyroid tumor as medullary thyroid carcinoma were clarified by others. Williams reasoned that because MTC was a malignancy of the C cells it might produce calcitonin, a concept that led to the use of serum calcitonin measurements for early diagnosis of MTC and of MEN2.

The clinical syndrome of MEN2A, as described by Sipple and others, consists of bilateral and multicentric MTC, unilateral or bilateral pheochromocytoma, and, less commonly, parathyroid hyperplasia or adenoma. In the decade after Sipple’s description, patients with this syndrome frequently presented with manifestations of a pheochromocytoma, a thyroid nodule, hypercalcemia, or some combination of the three. Such clinical presentations are still observed, but MEN2 syndrome identification and routine carrier ascertainment in affected families now make early thyroid C-cell hyperplasia or microscopic MTC without metastasis the most common initial presentation.}

A feature of MEN2 that differs from MEN1 is clear progression of histologic changes from normal to hyperplasia to adenoma (pheochromocytoma or parathyroid adenoma) or carcinoma (MTC). The development of hyperplasia is probably a multicentric process, with each focus of tumor derived from a single clone. This point has been proved for only one manifestation of the syndrome (MTC) but is likely to be true for other tumors as well. The heterozygous activating mutations of the RET proto-oncogene may be the stimulus for hyperplasia, whereas additional mutational events appear to be required for progression of this process (to be discussed later).

Medullary Thyroid Carcinoma in Multiple Endocrine Neoplasia Type 2

Evolution of C-Cell Abnormalities

MTC in all variants of MEN2 is a multicentric neoplasm of the parafollicular or C cell of the thyroid gland. The earliest demonstrable abnormality in the thyroid gland of individuals with this syndrome is hyperplasia of C cells, followed by progression to nodular hyperplasia, microscopic MTC, and finally frank MTC. These changes are multicentric, with the frequent occurrence of more than one type of histologic lesion in one or both lobes of the thyroid. The time required for progression through these several histologic stages is not known, but such changes have been noted as early as 3 years of age in MEN2A and during the first month of life in MEN2B. It is also not known at which earliest histologic stage metastasis occurs, but local lymph node metastasis is common when the tumor diameter is larger than 1 cm, whereas lymph node metastasis is rare in a case with only C-cell hyperplasia. Occasionally, foci of MTC occur in extrathyroidal locations such as the thymus gland. Whether these lesions are primary or metastatic has not been determined with certainty.

Tumor Markers Associated with Medullary Thyroid Carcinoma

Proteins expressed by the normal C cell and by MTC include calcitonin, calcitonin generelated peptide, somatostatin, dihydroxyphenylalanine decarboxylase, and chromogranin-A. Proteins that are not normally expressed in the C cell but that are expressed by MTC include pro-opiomelanocortin, thyrotropin-releasing hormone, gastrin-releasing peptide, VIP, neurotensin, substance P, carcinoembryonic antigen, histaminase, and others. The only reported clinical syndrome associated with ectopic hormone production is the ectopic ACTH syndrome in fewer than 5% of patients with extensive MTC. Studies to exclude hyperparathyroidism and pheochromocytoma are mandatory; pheochromocytomas should be removed before thyroid surgery.

Younger individuals diagnosed by RET mutation analysis as described subsequently should have a total thyroidectomy, C-cell hyperplasia and microscopic MTC are the most common histologic findings in these patients, although minimal or no abnormalities of C cells have been identified in some younger gene carriers. A case can be made for a central node dissection even in early disease because of the finding of metastasis in young children, although a more extensive lymph node dissection is generally not recommended. Children with MEN2B may have earlier metastasis, and consideration should be given to more extensive lymph node dissection. Surgical management for children identified by DNA testing is discussed in a subsequent section.

Monitoring after Surgery for Medullary Thyroid Carcinoma

At 3 to 6 months following thyroidectomy, patients should be reevaluated by measurement of serum calcitonin and an ultrasound examination of the neck. Earlier measurement of serum calcitonin is discouraged because serum calcitonin values may remain elevated for 3 to 6 months after thyroid surgery and become normal at a later time. The elevated calcitonin values are presumed to be related to the generalized rise in serum calcitonin that occurs during inflammation or sepsis. Equally important, the fact that calcitonin gene expression can be activated in inflamed or infected tissue unrelated to the C cell suggests that one should be careful about overinterpreting the significance of a minimal or transient rise in the serum calcitonin value. Stimuli as nonspecific as exercise can cause a serum calcitonin rise.
It may be useful to measure calcitonin after calcium or pentagastrin stimulation at 6 to 12 months if basal serum calcitonin values are undetectable. In general, it is useful to perform this procedure only if it would direct a specific clinical action (discussed in the next paragraph). Serial measurement of the serum calcitonin or carciinoembryonic antigen is a useful indicator of long-term disease progression and helps define the aggressiveness of MTC in a patient with metastatic disease. This type of information may be useful in making decisions regarding intervention with chemotherapy or reoperation. Calcitonin is a secretary peptide, and there is considerable variability of the serum concentration. Serum calcitonin values may vary by as much as 50% or more from measurement to measurement without evidence of progression of disease. However, a plot of values over months or years is useful to establish a trend of disease activity.

Management of Locally Metastatic Medullary Thyroid Carcinoma

Reoperation for persistent MTC was attempted with initially poor results. However, improvement of surgical techniques led to the normalization of serum calcitonin values in approximately one third of reoperated patients. This experience has led others to examine the usefulness of reoperation, and a larger experience suggests that approximately 15% to 20% of carefully selected patients (patients with no evidence of pulmonary, hepatic, or bone metastasis) have normal or nondetectable calcitonin values after reoperation.

A major question confronting the physician contemplating reoperation is whether the tumor is located in the neck or whether distant metastases are present. Techniques that have been used with variable success for localizing the tumor include scanning with thallium 201 and metaiodobenzylguanidine, octreotide scanning, and venous catheterization for measurement of calcitonin in blood from selectively catheterized veins. Several lines of evidence suggest that nondetectable basal and calcium- or pentagastrin-stimulated calcitonin after surgery is likely to be indicative of a cure. These include promising results after the short-term follow-up (5 to 10 years) of reoperated patients and the generally favorable long-term outcome in patients with MTC and local nodal metastasis who had nondetectable calcitonin values after primary surgery. Whether a 20% cure rate justifies the extensive repeat operative procedure is unclear, but the generally poor outcomes of reoperative strategies suggested by earlier reports should be reconsidered in light of this newer experience. One concern related to reoperation is a higher incidence of hypoparathyroidism.

Pheochromocytoma in Multiple Endocrine Neoplasia Type 2

Evolution of Pheochromocytoma

Adrenal chromaffin tissue in patients with MEN2A undergoes the same type of histologic progression as observed for the C cell, including hyperplasia, diffuse expansion of the adrenal medulla, and pheochromocytoma. The usual finding is single or multiple pheochromocytomas, with a background of hyperplastic chromaffin tissue (Fig. 36-12). The pheochromocytomas may be unilateral or bilateral. If a tumor is present in one adrenal gland, hyperplastic changes are likely in the contralateral gland. Invasion of the adrenal capsule by chromaffin cells is observed, but it is rare for these tumors to metastasize. Pheochromocytomas in MEN2B do not differ substantially from those identified in MEN2A.

Most of the pheochromocytomas in MEN2 are intra-adrenal. There are rare examples of pheochromocytomas that develop in adrenal rest tissue, including one with multiple adrenal rests. Other series have described extra-adrenal pheochromocytomas, although it is difficult to determine whether these pheochromocytomas occurred in adrenal rest tissue or along the sympathetic chain. Recurrences are observed in a small percentage of patients, predominantly in the surgical bed. It is unclear whether these recurrences represent additional pheochromocytomas that have developed in adrenal rest tissue or result from residual tissue or seeding. In most cases, they can be easily resected during a second procedure.

Malignant pheochromocytoma occurs rarely in MEN2, and most of the described cases occurred in older series and were associated with larger pheochromocytomas. Reports of malignant pheochromocytoma in MEN2A have become uncommon, suggesting that resection of smaller pheochromocytomas may eliminate not only cardiovascular risk but also the potential for malignant transformation. Malignant pheochromocytoma has been observed in the context of MEN2B. The identification of malignant pheochromocytoma in some families has led to the performance of bilateral prophylactic adrenalectomy in some kindreds, although this approach should be considered only if there is a proven pattern of adrenal medullary malignancy within a family.

The clinical syndrome caused by adrenomedullary disease has changed over the past two decades. Before prospective tumor surveillance, patients frequently presented with hypertension, headaches, cardiac arrhythmias, and large pheochromocytomas. Death caused by a cardiac arrest or stroke was as likely as death from metastatic MTC. Routine surveillance and detection of pheochromocytomas coupled with -adrenergic and -adrenergic antagonist use and improved surgical management have resulted in improved outcomes. Early adrenomedullary abnormalities may cause intermittent headaches, palpitations, and nervousness; hypertension is uncommon. Death caused by pheochromocytoma is uncommon and the reported deaths over the past decade have occurred largely in patients in whom prospective surveillance was not performed because of either an unrecognized gene carrier or noncompliance with routine surveillance. Presumably, some combination of earlier detection and routine use of - and -adrenergic antagonists has affected this change.

Clinicians should be particularly vigilant with women of childbearing age or during pregnancy because of deaths during labor and delivery. If a pheochromocytoma is identified during pregnancy, the conventional practice is to resect the tumor during pregnancy (under the coverage of adrenergic blockade). However, through an unusual set of circumstances, one of the authors (RFG) has managed a patient through a successful pregnancy and delivery. She received adrenergic antagonists throughout her pregnancy and underwent postpartum surgery for the pheochromocytoma.

Adrenomedullary abnormalities associated with MEN2A produce distinctive biochemical features. Increased urinary excretion of epinephrine and elevations of serum metanephrine are the most sensitive indicators of abnormality. Later in the course of the disease or with larger pheochromocytomas, the 24-hour excretion of epinephrine, norepinephrine, metanephrine, and normetanephrine metabolites is usually increased. Urinary vanillylmandelic acid excretion is usually normal early in the course of disease and is not useful for prospective tumor surveillance. Provocative testing (with glucagon or histamine) is rarely required and carries some risk. The diagnosis of pheochromocytoma is confirmed by CT or magnetic resonance scanning of the abdomen in the context of abnormal catecholamines. In most cases, computed tomography scanning provides greater anatomic resolution, is less expensive, and is adequate for cases in which catecholamines are abnormal. Magnetic resonance scanning provides greater specificity (bright image on T2-weighted images) and may be useful for differentiating between a small pheochromocytoma and an adrenal cortical adenoma. Scanning with metaiodobenzylguanidine, a catecholamine analogue that is selectively concentrated in adrenal chromaffin tissue, is useful for confirming the presence of functioning intra-adrenal chromaffin.
tissue and excluding the rare extra-adrenal pheochromocytoma. It is generally not useful for distinguishing between adrenal medullary hyperplasia and pheochromocytoma because it can be positive in either. Octreotide scanning, although useful for identification of extra-adrenal sporadic pheochromocytomas, has little usefulness in the management of pheochromocytomas associated with MEN2. It is rarely necessary to perform adrenal angiography; if it is performed, the patient should receive - and -adrenergic antagonists during and preferably before the procedure. (see Chapter 15).

Therapy of Pheochromocytoma

There has been an evolution of thought regarding management of pheochromocytoma in MEN2A or MEN2B, influenced by several factors. The first is the recognition that death from pheochromocytoma in this syndrome is now rare. Combined early detection and early therapy with - and -adrenergic antagonists have lessened the risk of cardiovascular death. Second, death caused by adrenal insufficiency in patients who have undergone bilateral adrenalectomy may in fact now be more common in MEN2 than death from pheochromocytoma. Third, there have been dramatic improvements in imaging and laparoscopic surgical technology over the past decade that have rendered many of earlier management discussions regarding unilateral versus bilateral adrenalectomy moot, as discussed in subsequent sections.

Radiographic evaluation is generally considered equivalent or superior to direct visualization of the adrenal gland by the surgeon. Laparoscopic adrenalectomy, particularly for small pheochromocytomas, has largely replaced other operative techniques. Current management approaches focus on the identification and treatment of adrenal medullary abnormalities before they become life-threatening. The following discussion focuses on the range of approaches for specific clinical presentations.

Multiple Endocrine Neoplasia Type 2A Family Member with Symptoms of a Pheochromocytoma but No Catecholamine Abnormality

Occasionally, a patient with known MEN2A or 2B presents with symptoms suggestive of a pheochromocytoma and no identifiable catecholamine or radiographic abnormality. In these cases clinical judgment is required to separate anxiety from intermittent, abnormal secretion of catecholamines by a hyperplastic adrenal gland. If the symptoms are persistent, not improved by antianxiety agents, and become disabling or alarming to the patient, pressure to take some action builds. In this situation, a trial of -adrenergic antagonists may, over time, make it possible to separate anxiety from symptoms caused by intermittent catecholamine production. Such an approach, if effective, may also provide a therapeutic option, thereby delaying a surgical procedure until there is a clearly defined radiographic abnormality.

Although there is no literature regarding the usefulness of metaiodobenzylguanidine or octreotide scanning in this situation, if a unilateral abnormality were defined, such information might be helpful. A decision to proceed with a blind exploration (with no imageable abnormality) should be made on a case-by-case basis and is generally discouraged. Direct visualization of the adrenal glands through an abdominal approach rarely provides greater information than imaging studies, and it is preferable to wait until a radiographic abnormality is detected.

Unilateral Pheochromocytoma

Unilateral pheochromocytomas may be identified by the development of adrenergic symptoms, abnormal urine or plasma catecholamines, or by an imaging procedure. The unilateral adrenal nodule in MEN2A or 2B is most commonly a pheochromocytoma, although metastatic MTC or benign adrenal cortical nodules have occasionally been identified. It is difficult and time consuming to differentiate between pheochromocytoma, metastatic MTC, or a benign cortical nodule in this situation. If catecholamines or metanephrines measurements are abnormal, it is appropriate to perform adrenal surgery. Computed tomography-guided fine-needle aspiration or selective adrenal vein sampling is generally discouraged.

Two different approaches have been employed to treat unilateral pheochromocytomas. The first is unilateral laparoscopic adrenalectomy. Reports of several deaths caused by adrenocortical insufficiency over the past decade raise the distinct possibility that, at present, cortisol deficiency is a greater threat to life in MEN2 than a pheochromocytoma and, therefore, the contralateral normal adrenal should remain untouched if radiographically normal. A second approach, developed to maintain adrenocortical function, is cortical sparing adrenalectomy. This is an old technique that has gained increasing favor as the risks of death from adrenocortical insufficiency associated with bilateral adrenalectomy have become apparent. This approach has been applied to small groups of patients with MEN2-related pheochromocytomas with retention of adrenal function in approximately 80% of treated patients.

Resection of an intra-adrenal pheochromocytoma with retention of cortical tissue raises the inevitable possibility of late recurrence of pheochromocytoma caused by adrenal chromaffin tissue at the corticoomedullary interface, which develops into a tumor at a later time in approximately 20% of cases. If retention of adrenocortical function is considered essential (e.g., for employment purposes), consideration should be given to performance of a cortical sparing adrenalectomy on the first identified pheochromocytoma, thereby providing an opportunity for a successful procedure on the contralateral adrenal gland if the first procedure fails. It is also difficult to know whether the first procedure is successful without detailed studies of corticoid secretory function that involve venous catheterization with selective sampling. Cortical sparing adrenalectomy is generally performed through a flank incision; although it is technically feasible to perform this procedure by a laparoscopic approach, a successful example after this approach has not been described.
Bilateral pheochromocytomas eventually develop in approximately one half of MEN2A or MEN2B gene carriers, although there has been a change in the clinical presentation. Twenty-five years ago, pheochromocytomas were generally detected at a much later stage in the clinical course of the disease and, therefore, a higher percentage of patients had bilateral pheochromocytomas at presentation. Measurement of catecholamines and metanephrines, now routinely employed, has led to routine identification of pheochromocytoma at an earlier stage, yielding a higher percentage of unilateral pheochromocytomas at initial presentation. Of those who initially present with a unilateral pheochromocytoma, 50% have a pheochromocytoma develop in the contralateral adrenal gland over a period of 8 to 10 years. Thus, the mode of clinical evolution has changed, but eventually approximately one half of MEN2A or 2B patients experience pheochromocytoma.

The management for patients with bilateral pheochromocytomas follows a paradigm similar to that described for a unilateral pheochromocytoma. Because bilateral tumors are more likely to produce catecholaminergic signs and symptoms, adrenergic antagonists and inhibition of catecholamine synthesis with -methyltyrosine become doubly important (see Chapter 15). Bilateral laparoscopic adrenalectomy or cortical sparing adrenalectomy should be performed. In patients with very large pheochromocytomas, laparoscopic adrenalectomy may not be possible, necessitating bilateral flank approaches or the less preferred anterior abdominal approach.

Hyperparathyroidism

Reports from the 1960s and early 1970s described hyperparathyroidism in 10% to 35% of individuals with MEN2A. These reports described the presence of either parathyroid hyperplasia or multiple parathyroid adenomas in association with hypercalcemia, urolithiasis, or osteitis fibrosa cystica. A careful review of the histology of these tumors has demonstrated occasional adenomatous formation with a background of parathyroid hyperplasia, a finding that is analogous to that observed for C-Cell hyperplasia in the thyroid gland and chromaffin cell hyperplasia in the adrenal medulla.

Simultaneous hyperparathyroidism is almost never seen in patients thyroidectomized for early C-cell abnormalities, although histologic findings consistent with parathyroid hyperplasia have been observed. Partly for this reason most surgeons attempt to preserve parathyroid tissue, particularly in children who have a prophylactic total thyroidectomy. Whether patients who have had a prophylactic thyroidectomy for MTC eventually experience hyperparathyroidism is unknown. Surgical management of hyperparathyroidism is similar to that described for MEN1, although recurrent hyperparathyroidism is a less common occurrence in MEN2.

One concern related to thyroid surgery is the potential for development of hypoparathyroidism after aggressive thyroidectomy. A careful review of most series documents an incidence of hypoparathyroidism that is comparable to or higher than that for other thyroid surgical indications. To address this issue, some surgeons routinely perform a total thyroidectomy and removal and reimplantation of parathyroid tissue into the nondominant arm.

A number of MEN2A variants have been described (Table 36-3). The most common is familial medullary thyroid carcinoma (FMTC) without pheochromocytoma or parathyroid disease. Kindreds with this syndrome account for approximately 10% to 15% of all those with hereditary MTC. Familial MTC is most likely to be confused with sporadic MTC because of the absence of dramatic symptomatology associated with pheochromocytomas that is found in MEN2A.

TABLE 36-3 – Multiple Endocrine Neoplasia Type 2

| Multiple endocrine neoplasia type 2A (MEN2A) | Medullary thyroid carcinoma (100%) |
| Parathormone neoplasia (10%) |
| Variants of MEN2A |
| MEN2A with cutaneous lichen amyloidosis (MEN2A/CLA) |
| MEN2A or FMTC with Hirschsprung’s disease |
| Familial medullary thyroid carcinoma (FMC) |
| Medullary thyroid carcinoma (100%) |
| Parathormone neoplasia (50%) |
| Absence of parathyroid disease |
| Marfanoid habitus (>95%) |
| Intestinal ganglioneuromatosis and mucosal neuromas (>98%) |

is most likely to be confused with sporadic MTC because of the absence of dramatic symptomatology associated with pheochromocytomas that is found in MEN2A. Because the penetrance of pheochromocytoma in MEN2A is much lower than that for MTC, it is possible to designate small kindreds with MEN2A incorrectly as having FMTC. The concern, of course, is that there will be a failure to screen for and diagnose pheochromocytomas in such kindreds.

At least 15 families have been identified with the MEN2A/cutaneous lichen amyloidosis variant. In these families, affected individuals had a pruritic skin lesion over the scapular region of the upper back consisting of multiple infiltrated papules overlying a well-demarcated plaque. The histology is that of cutaneous lichen amyloidosis (deposition of amyloid at the juncture of the epidermis and dermis) in patients with the fully formed skin lesion. Immunohistochemical staining of the amyloid for keratin but not calcitonin was observed, which indicates that the amyloid is probably of dermal origin and not the result of deposition of calcitonin gene products from the thyroid carcinoma. In most patients, intense pruriitus precedes the development of the skin lesion by 3 to 5 years, suggesting that the primary defect may be a sensory abnormality in the C6-T6 dermatomes leading to chronic irritation and friction amyloidosis. In support of this hypothesis is the fact that there is RET expression in the normal dorsal root ganglion, the site at which the sensory nerve cells for this region are located. Neurologic and electromyographic abnormalities have been observed in some of these patients.

A third variant is MEN2A associated with Hirschsprung disease, which can be differentiated by rectal biopsy from the ganglioneuromatosis identified in MEN2B. Although this variant was considered uncommon a decade ago, the increasing focus on the RET proto-oncogene in the development...
of the enteric nervous system has led to more frequent identification of this variant.
Multiple Endocrine Neoplasia Type 2B

The association of MTC and pheochromocytoma with multiple mucosal neuromas is termed MEN2B (formerly MEN3). The hallmark of this syndrome is the presence of characteristic mucosal neuromas on the distal portion of the tongue, on the lips and subconjunctival areas, and throughout the gastrointestinal tract. Thickened corneal nerves may be identified by slit lamp examination, and enlarged nerves are frequently noted during neck or abdominal surgery. Ganglioneuromatosis of the gastrointestinal tract can cause obstruction, dilation of the colon, or a colic-like childhood syndrome with associated diarrhea and may be the first clinical manifestation of MEN2B. Other features associated with this syndrome include a marfanoid habitus, pectus excavatum, slipped femoral epiphysis, and long, thin extremities.

The mucosal neuroma phenotype is associated, in all reported cases, with bilateral and multicentric C-cell hyperplasia or MTC, or both. The MTC in this syndrome is more aggressive than that in MEN2A. Metastatic C-cell disease can occur in children younger than 1 year of age and there is a shorter average survival time in patients with metastatic disease. However, the presence of multigenerational families and a more extensive compilation of outcomes suggest that long-term survival is more common than indicated by earlier reports. Unilateral or bilateral pheochromocytoma occurs in approximately half of the individuals with this disorder, and occurs at similar ages, and is histologically similar to that seen in MEN2A.

The identification of the mucosal neuroma phenotype in a child should alert the physician to the diagnosis of MTC. It is important to confirm the diagnosis of MEN2B by DNA testing (discussed later) because there are rare examples of mucosal neuromas without other features of MEN2B or a RET mutation. In most cases, a RET mutation is identified; in those who do not have a codon 918, 883, or 922 mutation, calcitonin testing would be appropriate. In children with MEN2B, total thyroidectomy should be performed during the first month of life. It is not known whether such treatment is curative because experience is limited. The expressivity of the mucosal neuroma phenotype may be less than 100%. A case report in which a mother and one child had mucosal neuromas and MTC and a second child had MTC but no evidence of the mucosal neuroma syndrome suggests this possibility.

Hyperparathyroidism is rare in MEN2B.
The net effect of these rearrangements is that the tyrosine kinase of RET is expressed in a cell type (the thyroid follicular cell) that does not normally express this gene. These rearrangements involve two different genes and differ substantially from the single nucleotide changes that are most frequently associated with MEN2, discussed later. These gene rearrangements lead to expression of a structurally normal RET kinase domain fused to one of several proteins expressed in thyroid follicular cells. Other than a few reports of rearrangement of RET and a second extracellular protein, GFR-1, together form a receptor for glial cell-derived neurotrophic factor (GDNF), a secretory peptide. A fascinating series of events led investigators to piece together the components of this signaling system. Investigators seeking to understand the roles of RET and GDNF created transgenic knockout mouse models for these two genes and independently discovered a nearly identical phenotype in both. In a parallel search for a GDNF receptor, a 468-amino-acid protein that bound GDNF was isolated from an embryonic rat midbrain complementary DNA library. This protein was designated GDNFR-1/GDNF receptor, now GFR-1. GFR-1 is a glycosyl-phosphatidylinositol-linked cell-surface protein that lacks cytoplasmic and transmembrane domains. It is expressed in GDNF-responsive cells and binds GDNF with high affinity. GFR-1

</table>
is required for GDNF to bind and activate the RET receptor, forming a multisubunit receptor system in which GFR-1 is a ligand-binding component and RET is the signaling component (Fig. 36-16). Subsequent experiments showed that targeted disruption of GFR-1 produced the same phenotype as disruption of RET or GDNF. During the past 5 years, a family of GFR proteins (GFR-2, GFR-3) and GDNF-related ligands (artermin, persephin, and neurturin) has been identified. Each of these is likely to have an important developmental role, but there is currently no evidence for their involvement in MEN2.

One important and well-defined function of the RET receptor complex is to direct normal migration of several cell types during embryologic development. The targeting occurs through an interaction of the RET receptor system (RET and GFR-1) with GDNF. RET is expressed in several tissues of neural crest derivation including the neural crest (Fig. 36-15), peripheral nerve (nerve and muscle), and several extramural mesenchymal tissues (e.g., gut). The neural crest is a major source of cell types that migrate to sites of somatic tissues, where they give rise to mesenchymal cell types. In this manner, RET is involved in the normal migration of a variety of cell types. The importance of RET in normal development is illustrated by the observation that most patients with MEN2 have mutations in the RET gene, and a small number of patients with MEN2 have mutations in the GFR-1 gene. The majority of patients with MEN2 have activating mutations of RET, and a minority of patients have inactivating mutations of RET. The activating mutations of RET are located in the TK domain, whereas the inactivating mutations are located in the extracellular domain.

In contrast to MEN1, in which there is no relationship between a specific mutation and clinical phenotype, in MEN2 there is a high degree of genotype-phenotype correlation. Mutations of these two codons have been reported in Hirschsprung disease. Reported cases of MEN2/Hirschsprung disease variants have these mutations.

There is a similar relationship in the gastrointestinal tract. RET/GFR-1-expressing neurons from the neural crest migrate into the developing gastrointestinal tract, presumably enticed by GDNF-expressing cells. Predictably, disruption of any component of this system leads to a disordered migration of neurons into the gastrointestinal tract and a Hirschsprung-like phenotype. These observations are clinically relevant to both the development of mucosal neuromas (derived from the enteric nervous system) in MEN2B and disordered neural ganglia found in Hirschsprung disease. The RET mutations found in MEN2B are activating, whereas about 50% of hereditary Hirschsprung disease is attributable to inactivating mutations of RET. There is an unresolved and interesting paradox of hereditary Hirschsprung disease arising from either activating or inactivating mutation of RET.

**Figure 36-15** Molecular abnormalities of the RET proto-oncogene in multiple endocrine neoplasia type 2 (MEN2). Mutations of the RET proto-oncogene have been identified in MEN2A, familial medullary thyroid carcinoma (FMTC), MEN2A associated with Hirschsprung disease, MEN2A associated with cutaneous lichen amyloidosis (CLA), and some somatic mutations in sporadic MTC. Two regions of the RET tyrosine kinase are affected. The first is a cysteine-rich extracellular domain (Cys-Rich) important for dimerization of the ret receptor (codons 609, 611, 618, 620, 634). Mutations of individual cysteines at these codons cause RET dimerization, activation, autophosphorylation, and transformation. Mutations of the second region, the intracellular tyrosine kinase (TK) domain involving codons 768, 790, 791, 804, 883, 891, 918, and 922, causes activation, autophosphorylation, and transformation. A role for the cadherin-like region (Cadherin) has not been defined.

The diagram shows the exon-intron structure of the RET gene and the location of the mutations identified in most germline carriers of MEN2. A more complete listing of rare mutations can be found in the Human Gene Mutation Database (http://archive.uwcm.ac.uk/uwcm/mg/ns/1/120346.html#ref35) and Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/htbin-post/Omim/dispmin?164761). In addition, there are rare mutations that have been identified in individual patients or in sporadic tumors. In some cases the physical location of these rare coding changes adjacent to a sequence known to be mutated gives credibility to the role of the mutant sequence; in others the relevance is unclear. Further clarification of their relevance awaits examination of their transforming abilities or additional genotype-phenotype correlation.

Mutations of these two codons have been reported in Hirschsprung disease. Reported cases of MEN2/Hirschsprung disease variants have these mutations.

There is an unresolved and interesting paradox of hereditary Hirschsprung disease arising from either activating or inactivating mutation of RET.

**Mutations of the RET Proto-Oncogene: Correlations with Multiple Endocrine Neoplasia Type 2 Variant or with Tumor Phenotype**

RET can undergo gain of function by two types of mutations. The first, discussed two sections earlier, is a rearrangement in which genomic DNA from the RET kinase region is fused to a promoter sequence of another gene, creating the RET-PIC oncogene. The mutations of RET found in MEN2 are missense (amino acid or codon change) mutations. RET missense mutations in MEN2 fall into two broad categories: those that affect a group of highly conserved extracellular cysteine residues and a second group of intracellular mutations.

### Germ Line RET Mutations

The most common mutations in MEN2 affect codons 609, 611, 618, 620, 630, and 634, all encoding extracellular cysteine residues (see Fig. 36-15). Mutations at codon 634 account for more than 80% of mutations in MEN2, and a single coding change, cysteine to arginine at codon 634, is found in approximately 50% of cases.

In contrast to MEN1, in which there is no relationship between a specific mutation and clinical phenotype, in MEN2 there is a high degree of correlation. Kindreds with any substitution at codon 634 invariably have MEN2A or one of its variants (Table 36-3), and all reported patients with the MEN2A/cutaneous lichen amyloidosis variant have a mutation at the same codon. Mutations of codons 609, 618, and 620 have been identified in the MEN2A/Hirschsprung variant of MEN2. Other less common extracellular mutations are listed in Table 36-4.

Mutations of the intracellular domain of RET predominantly affect codons 768, 790, 791, 804, 883, 891, 918, and 922. Most cases of MEN2B have a codon 918 mutation, although there are rare examples of codon 883 and 922 mutations. Codon 883, 918, and 922 mutations account for approximately 5% of all mutations in hereditary MTC. The other intracellular domain mutations (codons 768, 790, 791, 804, and 891) are uncommon and account for 2% to 3% of all mutations.

Familial MTC has been identified in kindreds with codon
609, 611, 618, 620, 768, V804M, and 891 mutations, making the genotype-phenotype correlation for this clinical syndrome the least specific of the MEN2 variants. Indeed, there is overlap between FMTMC and MEN2A for codons 609, 611, 618, and 620 mutations. In a large French series, 60% of 148 patients with FMTMC in 47 kindreds had intracranial non-cysteine mutations (codons 768, 790, 804, 891); the remaining 40% had extracranial cysteine mutations at codons 611, 618, and 620. 1\textsuperscript{5} One experimentally based hypothesis to explain this overlap is that mutations of codons 609, 611, 618, 768, 804, and 891, relative to codons 634 or 918, have a lower in vitro transforming efficiency. 1\textsuperscript{6} Because MTC is most commonly the earliest manifestation of MEN2A, it is possible that kindreds with these RET mutations would develop other manifestations of MEN2A if they lived long enough. Alternatively, other potential explanations such as small population-based polymorphisms of the RET gene or GFR-1 or GDNF causing differential activity of this receptor system could be invoked.

The RET genotype-phenotype correlation is remarkable. Not only is it possible to predict the clinical phenotype with reasonable certainty (see Fig. 36-15), it is also possible to predict, albeit with considerably less certainty, the aggressiveness of MTC associated with a particular germ line mutation. There is an evolving literature attempting to correlate the clinical aggressiveness of MTC with in vitro studies of transforming efficiency. 1\textsuperscript{23, 24} Although it is possible to make broad correlations, they are at present imperfect in most respects. However, within a given family specific mutations appear to behave in a more predictable manner. For example, in some kindreds with intracranial domain mutations with FMTMC, there has never been a death caused by MTC, although the same mutations in other kindreds can be associated with more aggressive disease. These findings suggest that genetic differences of the RET gene or other components of the RET signaling system (GDNF, GFR-1, or downstream effectors in the kinase signaling cascade) may modify the impact of a particular mutation. Clearly, there is more to learn.

Germ line mutations of the RET proto-oncogene have also been identified in Hirschsprung disease. Many of these are inactivating mutations, 1\textsuperscript{25} 1\textsuperscript{26} 1\textsuperscript{27} 1\textsuperscript{28} 1\textsuperscript{29} 1\textsuperscript{30} 1\textsuperscript{31} although the association of Hirschsprung disease alone, or the MEN2A/Hirschsprung disease variant, with apparent activating mutations at codons 609, 618, and 620 (see Table 36-4) suggests that disordered expression can also lead to this phenotype. 1\textsuperscript{32}

Somatic mutation of the MEN1 gene contributes to the causation of certain sporadic tumors, with a spectrum similar to that of the tumors seen in MEN1. A similar phenomenon is seen for somatic RET mutations in sporadic MTC and, to a much lesser extent, pheochromocytoma. Twenty-five percent of sporadic MTCs have a somatic RET mutation (60 of 236 cases). 1\textsuperscript{33} 1\textsuperscript{34} 1\textsuperscript{35} 1\textsuperscript{36} 1\textsuperscript{37} 1\textsuperscript{38} 1\textsuperscript{39} 1\textsuperscript{40} 1\textsuperscript{41} 1\textsuperscript{42} 1\textsuperscript{43} The most common is a somatic codon 918 mutation identical to that found in the germ line in MEN2B, but other codons (609, 611, 618, 620, 631, 634, 768, 804, 883, and 891) are also mutated somatically. The presence of a codon 918 somatic mutation in an MTC is associated with a greater frequency of distant metastasis 1\textsuperscript{44} and shorter survival. 1\textsuperscript{45} In this respect, the behavior of the sporadic tumor with a somatic mutation parallels the aggressive behavior of MTC in the context of MEN2B caused by a germ line codon 918 mutation. 1\textsuperscript{46}

Somatic RET mutations are considerably less common in sporadic pheochromocytomas than in sporadic MTC. Somatic RET mutations were identified in 2 of 35, 1\textsuperscript{53} 1\textsuperscript{54} 1\textsuperscript{55} 1\textsuperscript{56} 1\textsuperscript{57} to 4 of 48, 1\textsuperscript{58} and 0 of 17 sporadic pheochromocytomas, for a total of 4 to 100 (4% to 6%). These results indicate that somatic RET mutation is an infrequent cause of sporadic pheochromocytoma. Similarly, in the only study to examine for the presence of somatic RET mutations in sporadic parathyroid tumors, none of 35 tumors examined had codon 609, 611, 618, 620, 630, 634, or 918 mutations, making it unlikely that somatic RET mutations play any significant role in sporadic hyperparathyroidism. 1\textsuperscript{59}

RET-PTC mutations in papillary thyroid cancer and in a few other neoplasms have already been described. These too are somatic RET mutations, but they have no counterpart in the form of RET germ line mutations.

Tumorigenesis: Mechanism of RET-Induced Transformation

The RET gene is normally expressed in the several cell types involved in MEN2, including the C cell, the parathyroid cell, and the adrenal medullary cell. Studies demonstrating tumorigenic mechanisms were performed in an in vitro transformation assay (the NIH3T3 cell culture system), utilizing a cell type that does not usually express RET (the only mutant RET was expressed) and is readily transformed. These studies, from several different laboratories, 1\textsuperscript{60} 1\textsuperscript{61} 1\textsuperscript{62} provide evidence for two different mechanisms of transformation.

The first mechanism is applicable to extracranial cysteine mutations (protoype was mutant codon 634). The cysteine-rich region has been shown to be important for normal RET receptor dimerization. Homozygous expression of a mutant RET receptor in NIH3T3 cells resulted in dimerization in the absence of either ligand or GFR-1 and activation of downstream signaling pathways. 1\textsuperscript{63} 1\textsuperscript{64} There is evidence that GDNF is not required for activation of the dimerized ret and, indeed, does not further activate the tyrosine kinase. 1\textsuperscript{65} A second mechanism has been demonstrated for a mutation of the tyrosine kinase domain at codon 918. This mutation causes activation of JNK (c-Jun NH2-terminal terminal.) and phosphorylation of downstream substrates (in the absence of RET dimerization or interaction with either GFR-1 or GDNF). It has been shown experimentally that GDNF can further activate RET kinase in the presence of a codon 918 mutation. 1\textsuperscript{66}

Activation of RET by GDNF or by intrinsic activating mutations leads to autophosphorylation of the tyrosine at codons 1015 and 1062 (see Fig. 36-16). 1\textsuperscript{67} There is considerable evidence that autophosphorylation of tyrosine 1062 is required for activation of downstream effector pathways and transformation. 1\textsuperscript{68} 1\textsuperscript{69} 1\textsuperscript{70} 1\textsuperscript{71} A third mechanism results from the gene termed RET-PTC; this is RET fused to regulatory elements of one of a small number of other genes, most commonly in the thyroid follicular cell (see earlier). These rearrangements drive RET expression in a cell type that does not normally express this gene and promote dimerization.

Tumorigenesis: Steps Diestal to Ret

At least three different pathways, JNK, 1\textsuperscript{72} 1\textsuperscript{73} 1\textsuperscript{74} 1\textsuperscript{75} 1\textsuperscript{76} 1\textsuperscript{77} and phospholipase C gamma, 1\textsuperscript{78} 1\textsuperscript{79} are activated through shc-grb2-src proteins linked to ret. 1\textsuperscript{80} 1\textsuperscript{81} 1\textsuperscript{82} There is also evidence that nuclear factor B is activated by mutant RET and is dependent upon activation of raf and MEKK1. 1\textsuperscript{83} It appears that additional genetic events are involved in the development or progression of the transformed phenotype. Multiple studies have demonstrated a consistent LOH of chromosome 1p, 3p, and 22q in MEN2related MTC 1\textsuperscript{84} 1\textsuperscript{85} 1\textsuperscript{86} and pheochromocytoma. 1\textsuperscript{87}

Loss of the normal RET allele or amplification of the mutant RET allele is found in a significant number of MEN2 tumors. 1\textsuperscript{88} 1\textsuperscript{89} These studies demonstrate somatic amplification of the mutant RET allele by at least two different mechanisms: trisomy of chromosome 10 (Fig. 36-17) and duplication of the mutant RET allele. 1\textsuperscript{90} 1\textsuperscript{91} 1\textsuperscript{92} 1\textsuperscript{93} Alternatively, in a small percentage of tumors there is loss of the normal RET allele. These mutational rearrangements are formally analogous to the second hit at a tumor suppressor gene (see earlier). They help explain why germ line gain-of-function tumorigenesis as in MEN2 shares major properties with germ line loss-of-function tumorigenesis as in MEN1; specifically, both processes have early onset and tumor multiplicity.

It is hypothesized that the effect of amplification of the mutant RET allele or loss of the normal copy results in predominant expression of a mutant RET receptor, a model analogous to that demonstrated for KRAS\textsuperscript{2}\textsuperscript{19} and MET. 1\textsuperscript{94} In these examples, the normal gene moderates the impact of the mutant version. Several mechanisms could be envisioned to explain this mechanism for RET that are directly related to dimerization of the receptor, interaction of the receptor variants with GDNF or linker molecules, or differential activation of downstream mediators by the two different variants. None of these has been proved. This mechanism of unbalanced RET expression was not identified earlier, presumably because LOH of chromosome 10, in fact, occurs in only a small percentage of tumors.
Testing for Carrier State and for Tumor Emergence in Multiple Endocrine Neoplasia Type 2

The identification of RET proto-oncogene mutations causing MEN2 and FMTM has simplified carrier ascertainment and MTC surveillance in families with identifiable mutations (see Table 36-4). Several different analytic techniques have been applied to the identification of mutations, although direct DNA sequencing remains the most widely used. These analytic tests are readily available throughout North America and Europe at modest cost from several commercial sources. Almost 10 years have passed since the discovery of RET mutations in MEN2, and it is now clear that DNA-based diagnosis will replace measurement of calcitonin after pentagastrin or calcium stimulation for carrier ascertainment. During this period, additional mutations have been described with some regularity and there are now few kindreds with hereditary MTC that do not have an identifiable mutation. In the rare kindred in which a mutation is not identified, continued calcitonin stimulation testing with calcium or pentagastrin (pentagastrin is not currently available in the United States but is available in other countries) is required.

Calctonin Measurement for Carrier Ascertainment and for Tumor Surveillance

The pentagastrin test is performed by measuring the serum calcitonin level before and after 2, 5, and 10 minutes after the intravenous injection of pentagastrin (0.5 μg/kg body weight). Administration of calcium immediately before the pentagastrin injection enhances the sensitivity of the test. A short calcium infusion (15 minutes) can also be used to stimulate calcitonin release. Calcium is the only potent calcitonin secretagogue currently available in the United States.

A positive test is one in which either the basal serum calcitonin concentration is elevated and is further increased by the administration of pentagastrin or calcium or one in which the basal value is normal but increases into the abnormal range.

A listing of available commercial testing sources is available through a Web site: http://www.genetests.org.

After the administration of pentagastrin or calcium. It is important that the samples be analyzed with the most sensitive assay available and with proper control samples; it is now possible to measure normal serum calcitonin levels (0.15 to 3 pmol/L [0.5 to 10 pg/mL]) routinely, thereby making it possible to separate normal subjects from those with early C-cell hyperplasia. Criteria that are useful for separation of normal from abnormal kindred members include a patient known to be affected and a consistently abnormal test result (two or more nonconsecutive test results that are abnormal). It is important to point out, however, that there is considerable overlap between the normal range of serum calcitonin after a provocative test and that observed in patients with early abnormalities of the C cell, a finding that was not fully recognized until RET mutation testing became available in 1993. In nearly every large kindred in which calcitonin abnormalities were used to determine carrier status, there are examples of false-positive calcitonin tests that in some kindreds approached 15% of the total number of carriers. In retrospect, the use of calcitonin testing was less of a “gold standard” than thought at the time.

The clinician confronted with the necessity to continue calcitonin testing in a kindred with no identifiable RET mutation should keep this experience in mind when assessing minor calcitonin abnormalities in such kindreds. Despite this caveat, it has been the authors’ experience that when an abnormal calcitonin test result has been identified, pressure builds to consider total thyroidectomy. A discussion with the family of the risks (hypoparathyroidism, need for continued thyroid supplementation, and recurrent laryngeal nerve damage) and a firm plan of continued testing at 6- to 12-month intervals often allay parental concern or provide a more balanced viewpoint. It is clear from the 25-year experience with provocative calcitonin testing that there is progression of calcitonin abnormalities over a several year period in carriers, the diagnosis. Whether a deferral of decision to operate increases the risk of metastatic disease is unknown, although long-term experience with children with codon 634 mutations indicates that 85% to 90% remain disease-free 25 years after total thyroidectomy, performed at an average age of 13 years.

An elevation of the basal serum calcitonin level with no further increase after a provocative test can be difficult to interpret. Such a test result can be seen in association with C-cell abnormalities, but this type of result is most likely to be caused by a nonspecific or false-positive increase of the serum calcitonin concentration or by production of calcitonin by a tumor other than MTC (lung carcinoma, hepatoma, pheochromocytoma, pancreatic islet cell tumor, or benign liver disease). Separation of a false-positive test result from a true elevation of the serum calcitonin concentration can be achieved by a radioimmunoassay using a different polyclonal antiserum or a two-site immunoradiometric assay. Establishment of ectopic production of calcitonin by a tumor other than MTC can be more difficult because calcitonin release is frequently enhanced by calcium or pentagastrin; however, such tumors frequently produce a high-molecular-weight form of unprocessed procalcitonin, a finding that may be helpful in selected cases.

Method of RET Sequence Testing in DNA

DNA diagnostic techniques currently in use to identify MEN2 gene carriers are based on the use of polymerase chain reaction techniques to amplify selected portions of the RET proto-oncogene known to be mutated in MEN2. All laboratories analyze for mutations in exons 10, 11, and 16 (codons 609, 611, 616, 620, 630, 634, and 918), those most commonly found in MEN2. If a mutation is not identified in one of these codons, some but not all laboratories analyze for mutations in exons 13, 14, and 15 (codons 768, 790, 791, 804, 883, and 891). If a mutation is not identified in exon 10, 11, or 16, it is important to identify a laboratory that will examine the other exons before concluding that no mutation is present. This is particularly true for kindreds with FMTM, a disproportionate number of which have an exon 13, 14, or 15 mutation. Although there is a potential for several types of errors in mutational analysis, a repeated analysis of each positive or negative test result in a separate testing facility with an independently obtained DNA sample provides nearly 100% certainty that an individual test result is accurate. About 10 years of experience with this type of testing has provided insight into its usefulness in various clinical settings.
There is now consensus that all patients with a RET mutation should be offered a total thyroidectomy. In the almost 10 years since the identification of these mutations, greater awareness of the relationship between mutation at a specific RET codon and the clinical aggressiveness of the MTC has developed. Although imperfect in many respects, a consensus has developed within the field that these difference should be considered in the decision-making process regarding early thyroidectomy. The consensus guidelines have divided hereditary MTC into three different risk categories.

Category 1. Highest risk: In the highest risk category are those with MEN2B and a codon 883, 918, or 922 RET mutation. In these children MTC with metastasis may occur during the first year of life. The presence of a pheochromocytoma is a strong indication for early thyroidectomy. The consensus guidelines recommend that these patients undergo total thyroidectomy by the age of 6 months and preferably during the first month of life. Only in exceptional circumstances, when the parents are convinced that the child may be at risk for an early thyroidectomy, is it reasonable to delay total thyroidectomy until the age of 1 year. 

Category 2. High risk: Cases with RET mutations of codons 609, 611, 618, 620, or 634 are classified as having high risk. They should have a total thyroidectomy, including removal of the posterior capsule, before the age of 5 years. This recommendation is based on the finding of microscopic MTC in two children with a codon 634 mutation at age 2 years and of nodal metastasis in one at age 5 and 6 years. There is less consensus regarding the need for central node dissection in children during the first 6 months of life and preferably during the first month. During this procedure, other level II to V lymph nodes should be sampled with performance of more extensive lymph node dissection if metastatic disease is identified.

Category 3. Intermediate risk: Cases with codons 768, 790, 791, 804, or 891 mutations are classified as having intermediate risk. The biologic behavior and clinical aggressiveness of MTC in patients with such mutations vary, but the MTC tends to be less aggressive. Lymph node metastasis and death have been identified in all of these mutations except mutation codon 791. There is no consensus regarding the age of total thyroidectomy in such patients. Two approaches are used. Some classify these patients with the high-risk category and perform a total thyroidectomy by the age of 5 years. Some recommend thyroidectomy by the age of 10 years. Others observe cases with these mutations with periodic provocative tests for calcitonin and perform a total thyroideectomy when calcitonin levels become clearly abnormal. There is consensus, however, that these patients should be followed up especially carefully if an early thyroideectomy is not performed. There are large kindreds with some of these mutations in which there has never been a death caused by MTC, making it difficult to convince family members that early thyroideectomy is indicated.

Multiple Endocrine Neoplasia Type 2 Kindred with Known RET Mutation

A normal RET analysis in a kindred with a known RET mutation excludes the carrier state with nearly 100% certainty. An individual with two independently obtained negative DNA test results in the context of a family with an identified missense mutation can be excluded from further carrier ascertainment. Pentagastrin testing in this situation adds nothing to the diagnostic accuracy and may actually confuse the clinical assessment because of a high incidence of false-positive results.

Occult Phenotypes. Should RET Germ Line Be Tested in a Case with an Apparently Sporadic Tumor in the Spectrum of Multiple Endocrine Neoplasia Type 2?

Germ Line Mutations in Sporadic Medullary Thyroid Carcinoma

A compilation of over 200 patients with apparent sporadic MTC who were examined for germ line RET mutations (codons 609, 611, 618, 620, 630, and in some cases 768) has identified mutations in approximately 6% of the total (this contrasts with data to be presented subsequently showing that approximately 25% of sporadic MTCs have a somatic RET mutation without a corresponding germ line abnormality). Subsequent investigation of the individuals in these studies with germ line RET mutations has demonstrated that the majority were members of previously unidentified kindreds or descendants of gene carriers who were separated from their kindred by many generations. Therefore, the proportion of sporadic MTCs in which a germ line mutation is identified is lower than 6%. There has been considerable disagreement among experts as to the clinical significance of finding a RET proto-oncogene mutation in an otherwise apparently sporadic tumor. The finding that 6% of patients with apparent sporadic MTC carry germ line RET mutations suggests that all patients with MTC should have a RET germ line analysis performed. This is especially important because identification of one hereditary case may have a multiplier effect, leading to the diagnosis of unsuspected cases in the family and effective early treatment. Negative family history, although useful, clearly does not exclude hereditary disease. A second reason for performing a RET germ line analysis is to reassure the patient and family members that there is no hereditary component. If the RET analysis is negative, hereditary disease can be excluded with greater than 99% certainty.

Most families of patients with sporadic MTC are assured by a less than 1% probability of hereditary disease; for those who want hereditary MTC excluded with 100% certainty, continued provocative calcitonin testing in relatives is required.

Germ Line Mutations in Sporadic Pheochromocytoma

The situation is less clear for apparently sporadic pheochromocytoma. Three genetic syndromesMEN2, VHL, and hereditary pheochromocytoma or paraganglioma syndromes present as a sporadic pheochromocytoma. This presentation is unlikely for type 1 neurofibromatosis. Estimates of frequency of heredity for pheochromocytoma in the general population have ranged from 9% to as high as 23% in some series. It is important to recognize that these estimates came from tertiary care centers and in one, located in southwest Germany, there is a high incidence of VHL (84% of those with apparent sporadic pheochromocytomas have a VHL mutation). In four of these cases in which it was tested and in most new MEN2B probands, the newly mutated allele is derived from the unaffected father, suggesting acquisition of the mutation during spermatogenesis.

The low frequency is not surprising because pheochromocytomas in MEN2 are most commonly found with codon 634 RET mutations. The 50% penetrance of pheochromocytomas in these families makes it likely that the hereditary nature of these tumors can be identified by a careful family history. Germ line mutation of GDNF has been identified in 1 of 50 sporadic pheochromocytomas. The significance of this single mutation is unclear. Similarly, germ line VHL mutations in apparent sporadic pheochromocytoma are uncommon, being found in only 9 of 173 sporadic pheochromocytomas (5.2%) in four series. Finally, there are at least four different familial pheochromocytoma-paraganglioma syndromes that have been mapped (PGL1, PGL2, PGL3, and familial pheochromocytoma-paraganglioma syndrome). Mutations of components of the succinate dehydrogenase complex gene, putative tumor suppressor genes because each of the mutations appears to be inactivating, have been identified in three of the four variants.

There is currently no information regarding the frequency of these mutations.

Estimates based on genetic testing of RET in three other studies were that 2 of 230 patients (<1%) with apparently sporadic pheochromocytoma had a germ line mutation. The low frequency is not surprising because pheochromocytomas in MEN2 are most commonly found with codon 634 RET mutations. The 50% penetrance of pheochromocytomas in these families makes it likely that the hereditary nature of these tumors can be identified by a careful family history. Germ line mutation of GDNF has been identified in 1 of 50 sporadic pheochromocytomas. The significance of this single mutation is unclear. Similarly, germ line VHL mutations in apparent sporadic pheochromocytoma are uncommon, being found in only 9 of 173 sporadic pheochromocytomas (5.2%) in four series. Finally, there are at least four different familial pheochromocytoma-paraganglioma syndromes that have been mapped (PGL1, PGL2, PGL3, and familial pheochromocytoma-paraganglioma syndrome). Mutations of components of the succinate dehydrogenase complex gene, putative tumor suppressor genes because each of the mutations appears to be inactivating, have been identified in three of the four variants.

There is currently no information regarding the frequency of these mutations.

The decision to pursue RET and VHL germ line testing in patients with apparent sporadic pheochromocytoma is somewhat more complicated than testing for MTC. There are several arguments for testing. When the incidences of RET and VHL mutations are combined (6%), they approximate the incidence observed for germ line RET mutations in apparent sporadic MTC. In addition, the argument can be advanced that identification of hereditary pheochromocytoma prevents sudden death or significant morbidity related to pheochromocytoma. In the case of MEN2A, results in earlier identification of MTC in other affected family members. The arguments against testing include the low frequency of mutations (particularly for RET), the necessity to test for both MEN2A and VHL (and possibly familial pheochromocytoma-paraganglioma syndrome) leading to a substantial expenditure, and the fact that most hereditary pheochromocytoma comes to attention because of its distinctive clinical features before serious morbidity. A pragmatic approach is to apply criteria similar to those outlined for carrier ascertainment in MEN1. The information is useful, helps families to address health problems, provides reassurance if the test is negative, and leads to appropriate screening when a mutation is identified. It is, however, not absolutely necessary because no specific clinical action other than screening for pheochromocytoma or other neoplastic components of VHL or MEN2 is based on the test result.
Mutations at codons 768, 791, V804M, and 891 have been associated exclusively with FMTC; nonetheless, it would be prudent to consider a screening urine catecholamines or metanephrine test for pheochromocytoma at the time of diagnosis and perhaps at 5-year intervals. Codon 609, 611, 618, 620, or 630 mutations have been associated with either FMTC or MEN2A. Unless there is a several generation pattern of FMTC in more than 10 affected family members, it would be prudent to screen every 1 to 3 years for pheochromocytoma. The molecular basis for the phenotypic variability (FMTC or MEN2A) with codon 609, 611, 618, 620, or 630 mutations is unknown at present, although an answer may be found in the population-based polymorphisms discussed earlier in this chapter.

Management of an Established Multiple Endocrine Neoplasia Type 2 Kindred

Counseling

Family education is an important component in the management of MEN2. Although a physician’s legal responsibility may end after immediate family members have been notified of the genetic nature of the disease, it is prudent to encourage patients to make even family members at distant risk aware of the nature of the disease. The fact that the disease appears to be benign in one generation should not deter carrier ascertainment and tumor surveillance efforts because the disease may assume a more virulent expression in a subsequent generation. This notification can be done by giving pamphlets describing the syndrome to immediate family members for distribution to more distant relatives (available at www.endocrine.mdacc.tmc.edu).

Prospects for Surgical Cure of Medullary Thyroid Carcinoma in Multiple Endocrine Neoplasia Type 2

Widespread prospective carrier ascertainment and tumor surveillance have had an impact on the natural history of the syndrome. The age at carrier ascertainment has progressively fallen from a mean of 33 years when prospective carrier ascertainment through tumor surveillance first began in 1969 to a mean below 13 years in 1988. The current mean age with widespread DNA testing is likely to be below the age of 5 years. Testing for RET mutations now makes it possible to identify carrier status at birth or in utero.

Whether prospective DNA-based ascertainment and early thyroidectomy are curative for the thyroid neoplasm is less clear. Follow-up data from several groups indicate that approximately 85% to 90% but not 100% of kindred members who were thyroidectomized for early disease on the basis of pentagastrin testing have normal or nondetectable calcitonin values at mean follow-up periods ranging from 1 to 15 years. It can be anticipated that earlier DNA-based ascertainment and treatment are likely to improve the outcome in gene carriers. None of the cases of MEN2A or FMTC identified by DNA-based carrier ascertainment and operated before the age of 5 years have had identifiable metastasis, although there was considerable variability in these small series in the numbers of nodes sampled.

The identification of MTC (without nodal metastasis) in a significant number of children with MEN2A between the ages of 2 and 5 years suggests that a child younger than 5 years with metastatic disease may be identified. There are insufficient data regarding the impact of a specific mutation on the presence or absence of metastasis in younger children, although several groups are now combining information from national databases, making it possible that such data will be available in the next few years. In summary, early carrier ascertainment and treatment by total thyroidectomy at an early age appear to identify and treat patients before there is identifiable lymph node metastasis. Thus, it is possible that death from hereditary MTC will be largely eliminated by this early intervention, making it the first example of successful use of genetic ascertainment to eliminate death from malignancy. However, it will be many years before the impact of this earlier intervention on cure of MTC will be demonstrated.
Overlap Syndromes

Overlap syndromes in single patients include gastrinoma in a MEN2 patient, adenomatous polyposis coli with MEN1 or MEN2B, posterior pituitary tumor and MEN1, pheochromocytoma in a patient with MEN2A, and pheochromocytoma in MEN1 (see earlier). There is a single case report of an ovarian strumal carcinoid tumor, a variant of an ovarian teratoma, in a patient with MEN2A. The tumor was composed of neuroendocrine cells with thyroid-like follicles that stained positive for thyroglobulin.

Most cases of overlap of MEN1 and MEN2 were published before the era of discovery of syndrome-causing genes. Currently, most can be understood as follows:

1. Unusual expressions of a syndrome. Thus, VHL can cause pheochromocytoma and islet tumor (see later), neurofibromatosis type 1 (NF1) can cause pheochromocytoma and duodenal somatostatinoma (see later), and MEN1 can cause pheochromocytoma with any other feature of MEN1 (see before).
2. Coexistence of two rare disorders.
3. Rare syndromes that have not yet been characterized sufficiently.
4. Few cases of unexplained overlap. In this regard, a mouse model (see earlier) has many features of both MEN1 and MEN2, suggesting a single pathway to both syndromes or an overlap.
Familial Occurrence of Two or More Endocrine Neoplastic Disorders

MEN1 and MEN2 are the only multiple neoplasia syndromes in which the two most prominent features are hormone-secreting tumors. In other MEN syndromes, nonhormonal tumors are more urgent. For example, the McCune-Albright syndrome (which is not hereditary) features fibrous dysplasia of bone and cafe-au-lait spots of skin (Chapter 27) and VHL syndrome features papillary renal cancer and central nervous system hemangioblastomas.

Von Hippel-Lindau Syndrome

VHL syndrome is an autosomal dominant neoplastic syndrome characterized by hemangioblastomas of the central nervous system, retinal angiomas, renal cell carcinomas, visceral cysts, pheochromocytoma, and islet cell tumors. More than 90% of gene carriers express one or more of the manifestations of this disorder by the age of 60 years. Over 70% of gene carriers have one or more central nervous system tumors. Of particular relevance to endocrinologists is the observation that 25% to 35% of these patients have unilateral or bilateral pheochromocytomas and 15% to 20% have islet cell tumors. Although the islet cell tumors may immunostain weakly for insulin, they virtually never hypersecrete it.

The VHL gene was mapped to chromosome 3p25.3 and identified by positional cloning. This gene is a tumor suppressor gene, implying that loss of function or inactivating mutations of both alleles or copies of this gene are associated with tumor formation. Studies have described an inhibitory effect of the VHL-encoded protein on transcription elongation through its binding to an elongin B/C complex. Mutation of the VHL gene, particularly in the region of codons 150 to 170, interferes with this interaction, resulting in an accelerated rate of transcription elongation.

Another mechanism may explain many of the properties of the VHL protein and disease. The action of the VHL protein to facilitate the proteasome-mediated degradation of the hypoxia-inducible factor 1 (HIF-1) protein and other proteins may prove central to many manifestations of VHL gene alteration. Mutation of codon 238 was identified in over 40% of VHL families with pheochromocytoma, suggesting that families with a mutation in this codon should be surveyed routinely for pheochromocytoma. As with other recessive oncogenes such as MEN1, p53, BRCA1, or retinoblastoma gene, a large number of inactivating mutations have been described for VHL.

Clinical management for patients with VHL syndrome is often complicated by the presence of renal or central nervous system tumors. Pheochromocytomas or islet cell tumors associated with hypertension, cardiac arrhythmias, hypoglycemia, watery diarrhea, carcinoid, or a glucagonoma-like picture should be surgically excised.

Von Hippel-Lindau Syndrome

Although the islet cell tumors may not hypersecrete insulin, they virtually never hypersecrete it. The association of pheochromocytoma and islet cell tumors can occur in familial or nonfamilial patterns. There is little information about the molecular genetics of these rare disorders, although it is possible that abnormalities of the VHL gene may be involved.

Neurofibromatosis Type 1

The main features of NF1 are neurofibromas and dermal cafe-au-lait spots. NF1 has been associated with a variety of endocrine neoplasms including pheochromocytoma, hyperparathyroidism, somatostatin-producing carcinoid tumors of the duodenal wall, MTC, and hypothalamic or optic nerve tumors that cause precocious puberty. The causative gene for NF1 encodes a ras guanosine triphosphatase (GTPase)-activating protein (GAP) of 2815 amino acids, named neurofibromin, which accelerates GTP hydrolysis on p21 ras. Loss of the GTPase-activating function of neurofibromin (through mutation or allelic loss) leads to p21 ras activation.

More specific evidence for a role of this protein in endocrine tumors is shown by allelic loss of this gene in NF1-associated sporadic pheochromocytomas. Targeted disruption of the mouse NF1 gene resulted in sympathetic ganglia hyperplasia, providing additional evidence for a potential role of this gene in the genesis of endocrine tumors derived from neural crest tissue.

Carney's Complex

Carney's complex comprises myxomas of the heart, skin, and breast; spotty skin pigmentations; testicular, adrenal cortical, and growth hormone-secreting pituitary tumors; and peripheral nerve schwannomas. Linkage analysis has identified a locus at 2p in half of the families and another locus at 17q in most others. The gene at 17q has been identified as encoding the regulatory subunit (type IA) of protein kinase A (PRKA1A), and it has tumor suppressor properties.

The activating GNAS1 mutations in McCune-Albright syndrome and the inactivating PRKA1A mutations in Carney's complex are likely to cause tumors in selected tissues with a similar tissue spectrum by raising cyclic adenosine monophosphate.
Confusion and Contrasts between Multiple Endocrine Neoplasia Type 1 and Type 2

There is occasional confusion between MEN1 and MEN2, particularly among patients, paramedical personnel, and non-specialists. The main source of confusion is the similar syndrome names. Several other similarities are recognized (see the introduction). In fact, the differences are more important than the similarities. MEN2 includes a cancer that can be prevented or cured by timely surgery. MEN1 also causes cancers, but these mostly cannot be prevented or cured. The principal tumors differ between MEN1 and MEN2, as do surveillance protocols and treatments. Gene testing in MEN2 should be started extremely early and management should be dependent on the phenotype or genotype. Gene testing in MEN1 has debatable indications for early usage and no genotype-phenotype correlation. Mutations of RET cause tumors in MEN2 by gain of function, whereas MEN1 does this by loss of function. As a result, the oncogenic RET mutations are confined to selected loci of the gene and are thus easier to identify than those in the MEN1 gene.

Chapter 37 - The Immunoendocrinopathy Syndromes

George S. Eisenbarth
Peter A. Gottlieb

Geneticists, immunologists, and endocrinologists have generated a wealth of new information concerning the pathogenesis of the polyendocrine autoimmune syndromes and their component disorders. In particular, the genetic loci underlying disease susceptibility and organ-specific autoantigens targeted by the immune system are being defined. Multiple distinct molecules are often the targets of autoimmunity for a single organ-specific autoimmune disorder, and in polyendocrine autoimmunity multiple molecules of multiple organs are usually targeted.

Autoantibodies highly specific for a given disorder are present before disease onset, such as anti-islet antibodies (GAD, islet cell antibody [ICA] 512 [IA-2], and insulin) in type 1 diabetes and 21-hydroxylase autoantibodies in Addison’s disease. Each specific autoantibody reacts with only a single autoantigen, although autoantigens may be present in multiple tissues. For example, 17-hydroxylase is present in both adrenal gland and gonads, and the coincidence of Graves’ hyper-thyroidism and Graves’ ophthalmopathy implies a specific shared immune target. For the most part, however, the targets of autoantibodies appear to be unrelated except for their presence as differentiation antigens in specific cells and cellular sites.

In contrast, less is known concerning the specificity of pathogenic T cells. Given the observation that cross-reactive recognition by pathogenic T-cell clones may be determined by as few as four properly spaced amino acids of a nonapeptide and the estimate that each T-cell receptor may react with a million different peptides, there is considerable potential for patterns of autoimmunity to be determined by cross-reactive T cells. One development has been the discovery within the thymus and other lymphoid tissues of what are termed peripheral antigen-expressing cells that express autoantigens such as insulin or glutamic acid decarboxylase (GAD65). Minute quantities of such molecules within the thymus can contribute to tolerance. Insulin messenger ribonucleic acid within the thymus is regulated by genetic polymorphisms of the insulin gene associated with diabetes risk.

Two distinct autoimmune polyendocrine syndromes with characteristic groupings of manifestations are readily recognized (Table 37-1). Autoimmune polyendocrine syndrome type I (APS-I) is a rare disorder with autosomal recessive inheritance that has been shown to be caused by defects in the autoimmune regulator (AIRE) gene on chromosome 21. In contrast, the most common syndrome discussed in this chapter, autoimmune polyendocrine syndrome type II (APS-II), is less well defined, including overlapping groups of disorders. A unifying characteristic within APS-II is the strong association with polymorphic genes of the human leukocyte antigen (HLA) region located on the short arm of chromosome 6 (band 6p21.3). In addition to HLA, many other genetic loci are likely to contribute to susceptibility to APS-II.

APS-II has also been known by various other names: Schmidt’s syndrome, polyglandular autoimmune disease, polyglandular failure syndrome, organ-specific autoimmune disease, and polyendocrinopathy diabetes. Such diverse names reflect the large number of studies and case reports of this syndrome and its historical importance. Studies of patients with APS-II were instrumental in the identification of the autoimmune basis of several diseases and the development of autoantibody assays (e.g., type 1 diabetes and cytoplasmic ICAs). Each of the preceding names has some shortcomings, such as failure to include the fact that both hyperfunction and hypofunction of endocrine glands can occur or failure to recognize that nonendocrine disorders such as pernicious anemia and celiac disease are a part of the syndrome.

Some authors have even broken APS-II into a third grouping called APS-III on the basis of the presence (APS-II) or absence (APS-III), for example, of autoimmune thyroid disease and type 1 diabetes without Addison’s disease. Subdividing APS-II on the basis of specific groups of component diseases appears to add little information in terms of predicting future disorders likely to develop in affected individuals or disorders likely to be present among their relatives. Therefore, in this chapter we distinguish between APS-I and APS-II. The spectrum of disorders that may be present in these syndromes is listed in Table 37-1, and the major differences between the two syndromes are highlighted in Table 37-2.
AUTOIMMUNITY PRIMER

Major determinants of autoimmune endocrine disease are T lymphocytes and autoantibodies produced by B lymphocytes. These

Two arms of the immune system differ fundamentally in their recognition of target antigens. Autoantibodies react with intact molecules (including both soluble and cell-surface molecules) and usually interact with conformational determinants of the autoantigen.

In contrast, T lymphocytes recognize peptide fragments of autoantigens, often 8 to 12 amino acids in length. Furthermore, T cells can recognize peptides only if they are presented on the surface of another cell by major histocompatibility molecules, also known as HLAs. CD4⁺ (helper) T cells react with peptides that are derived from the extracellular fluid and bound by class II histocompatibility molecules (HLA-DP, HLA-DQ, or HLA-DR in humans). Effective presentation requires specialized antigen-presenting cells (APCs) such as macrophages.

dendritic cells, and B lymphocytes. Helper T cells secrete various lymphokines, leading to an immune response to the antigen. CD8⁺ (cytotoxic) T cells react with peptides bound by class I histocompatibility molecules (HLA-A, HLA-B, and HLA-C). Class I molecules are present on the surface of nearly all nucleated cells. The antigen peptide in this case is derived from within the presenting cell. Recognition of antigen by viral origin typically leads to the release of cytotoxic chemicals that kill the infected cell.

However, the simple expression of histocompatibility molecules and recognition of antigen by a T cell are not sufficient for T-cell activation. The interaction of major histocompatibility complex (MHC), peptide, and T-cell receptor (called signal one) is critical to the activation process, and other molecules help to define the nature of the immune response (signal two). Co-stimulatory molecules are required for T-cell activation. For example, the cell-surface molecule CD28 engages the CD80 receptor on the T cell and amplifies signal one, which leads to T-cell activation.

Cytotoxic T lymphocyte-associated antigen (CTLA)-4 is a similar receptor but one for which engagement appears to down-regulate T cells. Co-stimulatory signaling includes both cell surfacebound receptors on APCs and secreted substances called cytokines, such as interferon and interleukin-4 (IL-4), which can modify the type of immune response elicited to the same antigen. In the absence of co-stimulatory molecules, engagement of a T-cell receptor leads to inactivation rather than stimulation. Co-stimulatory molecules are expressed or secreted primarily by professional APCs. The hypothesis that expression by endocrine cells of class II molecules is the cause rather than the consequence of autoimmunity (cytokine-induced) has largely been abandoned as the preceding pathway for T-cell stimulation has been unraveled.

The crystal structure of histocompatibility molecules has been elucidated, and these molecules resemble a "hot dog bun" with the antigenic peptide (the hot dog) bound in the groove of the histocompatibility molecule (the bun). Histocompatibility molecules are extremely polymorphic, with different amino acids lining the peptide-binding groove. These variable amino acids determine which peptides are bound and presented to T lymphocytes.

Molecular HLA typing has revealed many subtypes of the older serologically defined alleles, and the unique genetic sequence encoding each polymorphic chain of the histocompatibility molecules is now given a unique identifying number. Thus, for the DQ molecule, which is the histocompatibility molecule most strongly associated with endocrine autoimmunity, a number is given for each alpha and beta chain. Examples are DQA1*0501 for the alpha chain and DQB1*0201 for the beta chain of the DQ molecule commonly encoded on DR3 (DRB1*0301) haplotypes. This DQ molecule (also termed DQ2) is strongly associated with type 1A diabetes, Addison's disease, Graves' disease, and celiac disease. Each allele with its amino acid sequence is inherited in mendelian fashion.

On activation, CD8⁺ T cells can directly lyse cells. CD4⁺ cells are also capable (without CD8⁺ T cells) of destroying target cells. CD4⁺ T cells apparently kill through indirect pathways that include the induction of macrophages to produce cytokines and free radicals. CD4⁺ T lymphocytes are also essential for activation and maturation of B lymphocytes, which produce autoantibodies.

As a simplification, there are two major pathways of CD4⁺ T-cell activation, with subsets of helper T cells, termed Th₁ and Th₂. Th₁ cells produce proinflammatory cytokines such as interferon-γ, IL-2, and tumor necrosis factor-α. Th₂ cells produce lymphokines that suppress Th₁ cells and favor antibody production (e.g., IL-4, IL-5, IL-10, transforming growth factor-β). Thus, depending on the context of T-cell stimulation, T-cell activation may actually down-regulate rather than promote autoimmunity. The Th₁/Th₂ pathway is probably important for the induction of mucosal tolerance from either the oral or nasal route and may be initiated by other forms of antigen vaccination such as the use of altered peptide ligands that can suppress autoimmunity. Such types of therapy are being studied for the prevention and reversal of several autoimmune disorders, including type 1A diabetes, multiple sclerosis, and uveitis.

The natural history of autoimmune disorders can be divided into a series of stages beginning with genetic susceptibility, followed by triggering of autoimmunity (e.g., dietary gliadin exposure in celiac disease), active autoimmunity preceding clinical manifestations (e.g., progressive glanular destruction), and finally overt disease. An etiologic classification of autoimmunity based on initiating factors can be developed, illustrating the many ways autoimmunity, even to a single organ, can be initiated (Table 37-3). For example, myasthenia gravis has a druginduced form (penicillamine), an oncogenic form (thymoma-associated), and the most common idiopathic form.
AUTOLUMINANE POLYENDOCRINE SYNDROME TYPE II

Clinical Definition

APS-II is the more common of the immune endocrinopathy syndromes. It occurs more often in females than in males, frequently has its onset in adulthood, and exhibits familial aggregation. APS-II is usually defined by the occurrence in the same individual of two or more of the following: primary adrenal insufficiency (Addison's disease) \(\text{Fig. 37-1}\), Graves' disease, autoimmune thyroiditis, type 1A diabetes mellitus, primary hypogonadism, myasthenia gravis, or celiac disease. Vitiligo, alopecia, serositis, and pemphigus anemia also occur with increased frequency in individuals with this syndrome and their family members.

The diagnosis of APS-II can be confirmed when one of the component disorders is present; an associated disorder occurs more commonly than in the general population. Furthermore, circulating organ-specific autoantibodies are often present even in the absence of overt clinical disease. In our assessment of APS-II families with Addison's disease, we have noted that up to 15% of relatives have 21-hydroxylase autoantibodies (Addison's disease), anti-islet autoantibodies, or transglutaminase (TG) autoantibodies (celiac disease). In a study of 10 families with APS-II, one in seven relatives had unsuspected illness, most commonly autoimmune thyroid disease. \(\text{11}\) The initial lesion and precipitating events that result in the syndrome are unknown, but immunogenetic and immunologic similarities are present with regard to both the time course and the pathogenesis of each of the component disorders.

The chronic development of organ-specific autoimmunity necessitates endocrinologic evaluation over time of patients with the syndrome and their families. In a family in which the syndrome has been documented, relatives should be advised of the early symptoms and signs of the principal component diseases. A list is available at www.barbaradaviscenter.org. Relatives of patients with multiple disorders should have a medical history, physical examination, and screening every 3 to 5 years with measurement of anti-islet autoantibodies, a sensitive thyrotropin assay, measurement of serum vitamin B \(_6\) levels, and, if there are any symptoms or signs or 21-hydroxylase autoantibodies \(\text{12}\) that suggest adrenal insufficiency are present, annual assay of basal corticotropin and corticotropin-stimulated cortisol levels.

Among 224 patients with Addison's disease and APS-II reported by Neufeld and colleagues, \(\text{12}\) type 1 diabetes (52%) and autoimmune thyroid disease (69%) were the most common coexisting conditions. Other components were less common, including vitiligo (5%) and gonadal failure (4%). CD8+ , CTLA4+ , intercellular adhesion molecule-positive (ICAM+) , and HLA-DR+ cells representing activated cytotoxic T cells have been found at the sites of disappearing melanocytes, suggesting their involvement in the process of destruction that leads to loss of pigmentation in vitiligo lesions. \(\text{11}\) One target antigen for the antibody response noted in this disorder is tyrosinase. \(\text{12}\) Other reports have questioned whether this is the correct or dominant antigen and suggested that a protein comigrating with tyrosinase is the antigen of interest. \(\text{12}\)

Among patients with type 1A diabetes, thyroid autoimmunity and celiac disease coexist with sufficient frequency to justify screening. Thyroid peroxidase autoantibodies are present in 10% of children with type 1 diabetes, \(\text{12}\) and this frequency increases with age. However, thyroid autoantibodies are common without progression to overt disease in the absence of subclinical elevations of thyrotropin. Thus, annual screening of patients with type 1 diabetes with determination of thyrotropin levels is recommended as a cost-effective approach.

Previous reports have suggested that 2% to 3% of patients with type 1 diabetes have celiac disease. \(\text{12}\) With the identification of tissue transglutaminase (TG) as the major endomysial autoantigen of celiac disease, radioimmunoassays were developed and demonstrated that 10% to 12% of patients with type 1 diabetes have TG autoantibodies. \(\text{12}\) The prevalence of TG autoantibodies was higher in diabetic patients with HLA-DQ2; one third of DQ2-homozygous subjects were found to express anti-TG antibody. Seventy percent of those with high-titer antibody who underwent biopsy were subsequently found to have disease. \(\text{12}\) Therefore, screening with anti-TG antibody can be carried out; if the results are positive, small bowel biopsy to document celiac disease is warranted, with institution of a gluten-free diet if the disease is present. Many individuals have asymptomatic celiac disease that may nevertheless be associated with osteopenia and impaired growth. \(\text{12}\) Untreated, symptomatic celiac disease is also associated with an increased risk of gastrointestinal malignancy, especially lymphoma.

Hypoparathyroidism frequently occurs in APS-I but is rare in APS-II. If hypocalcemia occurs in a patient with the type II syndrome, celiac disease may be a more likely diagnosis than primary hypoparathyroidism. Nevertheless, we have described several elderly patients with APS-II who had a distinct form of hypoparathyroidism that, on the basis of a small series of patients, may be termed \text{geriatric hypoparathyroidism}. \(\text{12}\) These patients form a distinct group because they have antibodies to the surface of parathyroid cells capable of suppressing parathyroid function and have a self-limited course of antibody presence and hypoparathyroidism.
Immunogenetics

Although there is familial aggregation of APS-II and its component disorders, there is no clearly discernible pattern of inheritance. Susceptibility is probably determined by multiple genetic loci (with HLA having the strongest effect) interacting with environmental factors. In the case of celiac disease, a dietary precipitating antigen (gliadin) has been identified. For type 1 diabetes, the concordance of identical twins is approximately 50%, suggesting a possible role for environmental or other nongenetic factors, such as somatic mutation or the random rearrangement of T-cell receptors that occurs during the development of the immune system. We found that diabetes developed in identical twins much more often if it arose in the proband before 25 years of age but that initially discordant twins can become diabetic even after a prolonged period of discordance. Furthermore, approximately 40% of long-term discordant twins (>7 years) have persistent autoantibodies or loss of first-phase insulin release, or both. Identical twins may also be discordant for Addison's disease as well as type 1 diabetes.

Many of the disorders of APS-II are associated with an HLA extended haplotype formed by HLA-A1, B8, DR3, DQA1*0501, DQB1*0201 and HLA-DRA. DQA1*0301, DQB1*0302. These include Graves' disease, atrophic thyroiditis, type 1A diabetes (also DR4-associated), Addison's disease (also DR4-associated), myasthenia gravis, and celiac disease. Figure 37-2 illustrates a family in which seven members have type 1 diabetes and three have Addison's disease. The HLA alleles help to explain the high frequency of autoimmunity in this family. The father is homozygous for the high-risk DR3 haplotype that was inherited by six of his eight children.

For some disorders, the complete HLA haplotype is associated with disease; for celiac disease, the most specific association is with the two chains of the DR molecule. Celiac disease occurs primarily in individuals expressing DQA1*0501, DQB1*0201, either in cis (with both of these alleles from the preceding extended DR3 haplotype on the same chromosome) or in trans (with DR5 with DQA1*0501, DQB1*0301 from a DR5 haplotype on one chromosome 6 and DQA1*0201, DQB1*0201 from DR7 on the other chromosome 6). There are more than 100 genes within the MHC on the short arm of chromosome 6, including genes that influence the processing and transport of antigenic peptides. For celiac disease, it appears that the HLA contribution to disease may be limited to the DR5 molecule (DQA1*0501, DQB1*0201). In contrast, for type 1A diabetes and several other component disorders of APS-II, HLA alleles of genes such as A2, A24, and DPB1 may contribute to susceptibility. The MHC class I chain related (MIC-A) gene encodes an unusual class I molecule in the MHC. A specific allele of the MIC-A gene, 5.1, is strongly associated with Addison's disease.

Whereas some HLA alleles increase disease risk, others are associated with protection from disease. For example, the DR alleles DQA1*0102, DQB1*0602 (usually associated with DR2) confer strong protection from type 1A diabetes in a dominant fashion but confer susceptibility to another autoimmune disorder, multiple sclerosis. Furthermore, this protection appears to be organ specific because no protection from Addison's disease is afforded by DQB1*0602.

For both type 1A diabetes and Addison's disease in APS-II, the highest risk is conferred by heterozygosity for the DR3 (DQA1*0501, DQB1*0201) and DR4 (DQA1*0301, DQB1*0302) haplotypes. The DRB1*0404 subtype is found more frequently in those with familial Addison's disease and so is consistent with APS-II. Approximately 2% to 3% of the United States population carries the high-risk DR3-DR4 haplotype, compared with about 35% of individuals who have type 1A diabetes and about 60% of patients in the United States with Addison's disease.

Given the hypothesis that HLA molecules may predominantly determine the tissue targeting of autoimmunity (although other genetic loci may predispose to autoimmunity in general), there has been an intensive effort to identify non-HLA loci. Unlike the situation in APS-I (see later), multiple genetic loci are probably involved in APS-II. For type 1A diabetes, polymorphisms of the insulin gene region contribute to disease susceptibility. There is some evidence of linkage to several loci, including insulin-dependent diabetes mellitus 17 (IDDM17), which was found on chromosome 10 and conferred a 40% risk for diabetes in combination with HLA genes in the Bedouin Arab family in which it was identified. Other loci have been described, including a locus on chromosome 6 (6q) termed IDDM15 that has been confirmed in several studies. Analysis of mutations in the IDDM15 (see later) indicates that it does not play a role in type 1A diabetes or sporadic Addison's disease, with 1 of 90 (1.1%) patients with Addison's disease (non-APS-I) and 1 of 576 (0.2%) control subjects having IDDM15 mutations. The G allele at the CTLA-4 A/G polymorphism was associated with Addison's disease, especially in patients with APS-II and in those with Graves' disease.

Several disorders of the polyendocrine autoimmune syndrome are not associated with DR3. These disorders include pemphigus anemia, goitrous thyroiditis, and vitiligo. Vitiligo is a classic component of the syndrome and was included in Addison's original description. These relatively common disorders may have more than one pathogenic mechanism, one of which is associated with polyendocrine autoimmunity. For example, a polymorphism106base pair (bp) allele: (AT)
Organ-Specific Autoantibodies

Improved assays for several organ-specific autoantibodies have been developed with the cloning of specific autoantigens and the development of assays that use recombinant antigens. These radioimmunoassays are superior to assays based on immunofluorescence with tissue sections, such as ICA testing. The most notable finding is the identification of a large number of different autoantigens that are targeted even in single autoimmune disorders. Most of the endocrine autoantigens are hormones (such as insulin) or enzymes associated with differentiated endocrine function: thyroid peroxidase in thyroiditis, glutamic acid decarboxylase, carboxypeptidase H, and ICA512/IA-2 in type 1 diabetes; 17-hydroxylase and 21-hydroxylase in Addison’s disease (Fig. 37-3) and the parietal cell enzyme H+/K+ -adenosine triphosphatase in pernicious anemia.

In type 1 diabetes, the four most informative assays currently available determine autoantibodies that react with insulin, GAD65 (glutamic acid decarboxylase), ICA512/IA-2, and ICA512/IA-2. In a similar manner, a radioassay format for the detection of autoantibodies that react with the enzyme 21-hydroxylase in Addison’s disease has been developed and provides excellent disease specificity and sensitivity. Adrenal autoantibodies reacting with recombinant 21-hydroxylase usually precede the development of Addison’s disease. However, as with thyroid autoantibodies, there may be individuals who present with antibodies but have normal production of cortisol in response to adrenocorticotropic hormone (ACTH). Continued rescreening every year initially and then biyearly is indicated in this situation.

In contrast to the autoimmune polyendocrine disorders with T cell-mediated glandular destruction, autoantibodies may also be pathogenic. A hallmark of pathogenic autoantibodies is the existence of a neonatal form of the disorder, secondary to transplacental passage of the autoantibody. Examples include neonatal Graves’ disease (antithyrotropin receptor autoantibodies) and neonatal myasthenia gravis (antiacetyl choline receptor autoantibodies).
Thyroxine therapy can precipitate a life-threatening Addisonian crisis in a patient with untreated adrenal insufficiency and hypothyroidism. Thus, it is necessary to evaluate adrenal function in all hypothyroid patients in whom the syndrome is suspected before the institution of such therapy.

Because of the autoimmune nature of these disorders, several studies have evaluated immunosuppressive drugs. Such studies have contributed to our understanding of autoimmunity, and drugs such as cyclosporine have preserved some residual insulin secretion. However, the nephrotoxicity and potential for oncogenicity of cyclosporine have precluded its more generalized use. Newer immunosuppressive agents (mycophenolate mofetil or sirolimus) and biologics such as anti-IL-2 receptor (daclizumab) or "nonmitogenic" CD3 antibodies, for example, hOKT3(ala-ala), may be more effective and have a better safety profile, and these are currently in clinical trials in patients with new-onset diabetes. With further research, immunomodulatory therapies have been developed that are remarkably effective in preventing type 1A diabetes of the BioBreeding (BB) rat and nonobese diabetic (NOD) mouse models of type 1 diabetes.

There are also relatively benign therapies, such as administration of high doses of the vitamin nicotinamide or administration of immune adjuvants that appear to interfere with selected effector pathogenic mechanisms. Small trials of bacille Calmette-Guérin (BCG) vaccine and nicotinamide treatment suggest that these agents have little if any effect in humans, but large randomized trials of nicotinamide are under way in Europe that should define its potential within the next 2 years.

Mucosal administration of antigens is frequently associated with bystander immunosuppression, in which T cells specific to the antigen are apparently induced to produce suppressive T_{H}2-like or T_{H}3-like cytokines (e.g., IL-4, IL-10, and transforming growth factor). In addition, subcutaneous administration of insulin prevents diabetes and insulits in animal models, and subcutaneous administration of insulin peptides in adjuvants can prevent diabetes but not insulits. When such animal trials were extended to humans, oral insulin at diabetes onset had no effect but a small pilot trial suggested that a combination of daily subcutaneous insulin and intermittent intravenous insulin may delay the development of type 1A diabetes in humans. A large National Institutes of Health trial, the Diabetes Prevention Trial-Type I (DPT-I), is under way in the United States to test this hypothesis directly. DPT-I has two arms: (1) intravenous-subcutaneous for those at high risk and (2) oral insulin for those at moderate risk. Subcutaneous insulin injection did not slow progression to diabetes, and results of the oral trial should be known by 2003.

Hashizume and co-workers reported a lower relapse rate in women with Graves' disease who were given thyroxine at 100 µg daily than in those who did not receive thyroxine. Takasu and colleagues reported that autoimmune thyroiditis may be reversible with the disappearance of autoantibodies and maintenance of a euthyroid state in a minority of patients after the cessation of thyroxine therapy. However, subsequent trials have not confirmed such protection, suggesting that other factors may influence the occurrence of disease (iodine intake, for example). In the BB rat model, the administration of thyroxine resulted in a reduced frequency of appearance of lymphocytic thyroiditis. In prediabetic Addison's disease, a short course of glucocorticoids appeared to suppress the expression of adrenal autoantibodies and prevent progressive adrenal destruction.

De Bellis and co-workers screened patients with organ-specific autoimmune disorders and found that 0.9% were positive for adrenal autoantibodies. Three patients with high-titer adrenal autoantibodies and an impaired cortisol response to ACTH experienced remission and had negative results on assay for adrenal autoantibodies when treated with corticosteroids for Grave's ophthalmopathy. In contrast, in 11 other patients with high-titer adrenal autoantibodies, the antibodies persisted and various abnormalities developed, including elevated plasma renin activity, impaired cortisol response to ACTH, elevated ACTH, and overt Addison's disease. Feedback inhibition of endocrine gland function may decrease the exposure of autoantigens to the immune system or decrease the susceptibility of the targeted tissue to immune attack. This preliminary observation requires direct testing in a larger population and in randomized fashion.

Thyroxine therapy can precipitate a life-threatening Addisonian crisis in a patient with untreated adrenal insufficiency and hypothyroidism. Thus, it is necessary to evaluate adrenal function in all hypothyroid patients in whom the syndrome is suspected before the institution of such therapy.

A decreasing insulin requirement in a patient with insulin-dependent diabetes mellitus can be one of the earliest indications of adrenal insufficiency, occurring before the development of hyperpigmentation or electrolyte abnormalities.

In patients with both adrenal insufficiency and primary hypothyroidism, thyroid function may improve after glucocorticoid replacement. Addisonian crisis that responds to mineralocorticoid therapy can occur in patients receiving high-dose glucocorticoids for inflammatory disease. Immuneologic therapies, especially in patients with an autoimmune disease, may induce autoimmunity. A remarkable example is the treatment of patients with multiple sclerosis with an anti-CD52 monoclonal antibody. One third of 27 patients given the monoclonal developed antithyrotropin receptor autoantibodies and hyperthyroidism. Interferon therapy for hepatitis has been associated with thyroid autoimmunity and potentially type 1 diabetes.

AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 1

Clinical Features

APS-I, also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is characterized by the classic triad of mucocutaneous candidiasis, autoimmune hypoparathyroidism, and Addison's disease, although the presence of all three is not needed to make the diagnosis and various other manifestations may be present (see Table 37-1). The association of mucocutaneous candidiasis with glandular failure was recognized by Thorpe and Handley in 1929. More than 140 patients have since been reported, including two large series from Finland and the United States.

APS-I is characteristically recognized in early childhood, whereas APS-II has its peak incidence in middle age. Chronic mucocutaneous candidiasis is often the first manifestation, followed by hypoparathyroidism and Addison's disease, but new components can develop at any age. Decades may elapse between the diagnosis of one disorder and the onset of another in the same individual. Consequently, lifelong follow-up is important to allow the early detection of additional components.

In a series of 68 Finnish patients described by Ahonen and co-workers, all had chronic candidiasis at some time, 79% had hypoparathyroidism, 72% had Addison's disease, and 51% had all three of these classical components. Gonadal failure (60% in women, 14% in men) and hypoplasia of the dental enamel (77%) were also frequent findings. Other manifestations that occurred less frequently included alopecia (29%), vitiligo (13%), intestinal malabsorption (18%), type 1 diabetes (18%), pernicious anemia (13%), chronic active hepatitis (12%), and hypothyroidism (4%). The onset of chronic active hepatitis suggested by hepatomegaly, jaundice, or elevated liver enzymes is a serious complication requiring therapy. The presence of chronic candidiasis suggests that a defect in T-cell function may underlie the development of multiple autoimmune disorders in three of these classical components. Gonadal failure (60% in women, 14% in men) and hypoplasia of the dental enamel (77%) were also frequent findings. Other manifestations that occurred less frequently included alopecia (29%), vitiligo (13%), intestinal malabsorption (18%), type 1 diabetes (18%), pernicious anemia (13%), chronic active hepatitis (12%), and hypothyroidism (4%).

Other infections do not occur with such increased frequency. Ectodermal dystrophy is another non-autoimmune part of the syndrome (manifested by pitted nails, keratopathy, and enamel hypoplasia) and cannot be attributed to hypoparathyroidism. Enamel hypoplasia may precede the onset of hypoparathyroidism and, despite adequate replacement therapy, may also affect teeth forming after the onset of hypoparathyroidism. Friedman and colleagues reported the frequent occurrence of asplenia and cholelithiasis as additional features of APS-II. Malabsorption with steatorrhea is of uncertain origin, is usually intermittent, and may be exacerbated by hypocalcemia. Bereket and associates reported a case with patchy intestinal lymphangiectasia discovered by endoscopically directed biopsy. Pancreatic insufficiency has been treated with cyclosporine.

Antiparathyroid and antiladrenal antibodies have been reported. Cross-reactive autoantibodies may play a role in the multigland involvement of these disorders, as noted in several case reports. A target antigen for the autoantibodies found in autoimmune hypoparathyroidism was described by Li and colleagues, who showed that 56% of 25 patients, 17 with APS-I, reacted to the extracellular domain of a membrane-associated antigen of 120 to 140 kd, which was identified as the calcium-sensing receptor. Whereas 21-hydroxylase appears to be the major autoantigen in isolated Addison's disease and in Addison's disease associated with APS-II, autoantibodies against 17-hydroxylase and P450 side-chain cleavage enzyme (CYP11A1) have also been reported in Addison's disease associated with APS-I. Other autoantibodies that may be involved in other components of this disorder have been reported. These include antibodies to tryptophan hydroxylase in intestinal disease, tyrosine hydroxylase in alpoeica areata, and L-amino acid decarboxylase in hepatitis and vitiligo, and phenylalanine hydroxylase and antibodies reacting with hair follicles.

As with APS-II, Tuomi and co-workers originally observed that many more patients (41%) express anti-GAD65 autoantibodies than become diabetic. Among patients with APS-I in this study in whom diabetes developed, GAD autoantibodies could be detected up to 8 years before the onset of overt diabetes. They subsequently noted that many of the antibody-negative patients can demonstrate T-cell responses to GAD65. Nearly 76% of all tested subjects showed either autoantibody or T-cell responses to GAD65 but only 18% had diabetes (8 of 44 subjects), again suggesting that reactivity to this single autoantigen has low predictive value.

APS-I autoimmune polyendocrine syndrome type I.
Genetics

APS-I is unique among autoimmune endocrine disorders, in that it is not associated with high-risk class II HLA alleles, although the protective allele DQB1*0602 may protect against type 1 diabetes but not Addison's disease.\(^1\)\(^3\) Addison's disease in APS-II is strongly associated with HLA-DR3 and HLA-DR4. APS-I shows an autosomal recessive pattern of inheritance, with a 25% recurrence risk for siblings of affected individuals.\(^8\) The disorder has a high prevalence in Finland and in consanguineous Iranian Jewish families.\(^8\)

The etiologic gene was localized to the short arm of chromosome 21 (near markers D21s49 and D21s171 on 21p22.3) by Aaltonen and co-workers\(^6\) and identified as AIRE. The gene encodes a putative deoxyribonucleic acid (DNA)-binding protein of unknown function expressed in the thymus and in lymphoid and other tissues.\(^7\)\(^8\)\(^9\) Multiple mutations are causative, and the frequency of specific mutations varies in different populations (Table 37-4). For example, in Sardinia, a deletion of amino acid 257 is present in 90% of mutated alleles. A 136-bp deletion in exon 8 is present in 71% of British alleles and 56% of alleles in the United States. Analysis of haplotypes indicates that this deletion has arisen on multiple occasions.
Therapy

Note the following principles:

1. The treatment of adrenal insufficiency and hypoparathyroidism is the same as that discussed in Chapter 14 and Chapter 26, respectively, with the caveat that malabsorption may complicate treatment.

2. The therapy for mucocutaneous candidiasis has been improved with orally active antifungal drugs such as fluconazole \[90\] and ketoconazole \[91\]. Infection often recurs when the drug is discontinued or when the dosage is decreased. Patients must be monitored carefully because ketoconazole may inhibit adrenal and gonadal steroid synthesis and may precipitate adrenal failure. It is also associated with transient elevation of liver enzyme levels and, occasionally, hepatitis. Fluconazole is associated with a lower frequency of hepatiis and does not inhibit steroidogenesis when given in the recommended doses. \[90\]

3. Screening to allow the early detection of new disorders before overt symptoms and signs develop is recommended, including autoantibody studies, electrolytes, calcium and phosphorus levels, thyroid and liver function tests, blood smear, and plasma vitamin B \(_12\) levels. Patients at risk for adrenal failure can be screened by measurement of basal ACTH and supine plasma renin activity (PRA) levels, \[92\] followed by dynamic testing as appropriate. Evaluation for asplenism \[73\] with abdominal ultrasonography and blood smear examination for Howell-Jolly bodies is warranted, with pneumococcal vaccination and appropriate antibiotic coverage for affected patients.

4. Hypocalcemia has been associated with the intermittent steatorrhea characteristic of APS-I, and therapies that restore calcium levels have been beneficial. Treatment includes magnesium replacement for hypomagnesemia. Nevertheless, in individual patients, specific etiologic factors have been implicated, including pancreatic insufficiency, *Giardia lamblia* infection, and lymphangiectasia, and individualized therapy is required for these potentially diverse causes.

5. There are case reports of severely affected patients who have benefited from immunosuppressive therapy. For example, Ward and colleagues \[93\] treated a 13-year-old patient who had keratoconjunctivitis, hepatitis, and severe pancreatic insufficiency. Treatment with cyclosporine was associated with normalization of stool fat (from 31.5 g/day to 2.5 g/day).
OTHER POLYENDOCRINE DEFICIENCY AUTOIMMUNE SYNDROMES

Anti-Insulin Receptor Antibodies

In this rarely reported disorder (25 patients), also known as type B insulin resistance and acanthosis nigricans, insulin resistance is due to the presence of anti-insulin receptor antibodies. Approximately one third of patients with these antibodies have an associated autoimmune illness such as systemic lupus erythematosus (SLE) or Sjögren's syndrome. Arthralgia, vitiligo, alopecia, and secondary amenorrhea have also been reported. One patient had a daughter with hyperthyroidism and a granddaughter with SLE. Autoimmune thyroid disease has been described in two such patients, one with hypothyroidism and the other with antithyroid antibodies. Anti-nuclear antibodies and an elevated erythrocyte sedimentation rate, hyperglobulinemia, leukopenia, and hypocomplementemia are common.

The major clinical manifestations are related to the anti-insulin receptor antibodies. Severe insulin resistance is profound, and up to 175,000 U of insulin given intravenously per day may be ineffective in lowering the elevated glucose level. Despite hyperglycemia and marked insulin resistance, ketoacidosis is uncommon. The course of the diabetes is variable, and several patients have had spontaneous remissions. Other patients have had severe hypoglycemia (perhaps related to the insulin-like effects of anti-insulin receptor antibodies demonstrable in vitro). The acanthosis nigricans, which is due to hypertrophy and folding of otherwise histologically normal skin, appears to be related to the insulin-resistant state. Other forms of marked insulin resistance in the absence of antireceptor antibodies are also associated with acanthosis nigricans.
POEMS Syndrome

The components of the multisystem disorder POEMS (plasma cell dyscrasia with polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes or Crow-Fukase syndrome) consist of diabetes mellitus (50% of patients), primary gonadal failure (70% of patients), plasma cell dyscrasia, sclerotic bone lesions, and neuropathy. Patients usually present with severe progressive sensorimotor polyneuropathy, hepatosplenomegaly, lymphadenopathy, and hyperpigmentation. On evaluation, they are found to have plasma cell dyscrasia and sclerotic bone lesions.

POEMS is assumed to be secondary to circulating immunoglobulins, but binding of antibody directly to involved tissues has not been demonstrated. There is evidence implicating cytokines such as IL-1, IL-6, and tumor necrosis factor in addition to the M protein in the pathogenesis of this disorder. Several studies have also demonstrated that elevated levels of vascular endothelial growth factor (VEGF) correlate with the disease state and that treatment with immunosuppressive agents reduced both symptoms of the disease and levels of VEGF, suggesting that this growth factor may play a role in the disease. A therapeutic trial of an anti-VEGF antibody would provide more definitive evidence for this hypothesis. The diabetes mellitus responds to small subcutaneous doses of insulin. The hypogonadism is associated with elevated plasma levels of follicle-stimulating hormone and luteinizing hormone. Temporary resolution of disease, including a return of the blood glucose level to normal, may occur after radiotherapy for localized plasma cell lesions of bone.
Kearns-Sayre Syndrome

The rare Kearns-Sayre syndrome, also known as oculocraniosomatic disease or oculocraniosomatic neuromuscular disease with ragged red fibers, is characterized by myopathic abnormalities leading to ophthalmoplegia and progressive weakness in association with several endocrine abnormalities, including hypoparathyroidism, primary gonadal failure, diabetes mellitus, and hypopituitarism. Crystalline mitochondrial inclusions are found in muscle biopsy specimens, and such inclusions have also been observed in the cerebellum. The relationship between the mitochondrial disorders and endocrinologic abnormalities is not known. Other abnormalities include retinitis pigmentosa and heart block.

Antiparathyroid antibodies have not been described; however, antibodies to the anterior pituitary gland and striated muscle have been found, and the disease may have autoimmune components.
Thymic Tumors

The thymus has a central role in the ontogeny of cell-mediated immunity. DiGeorge described congenital aplasia of the thymus and parathyroid glands, both of which are derived from the third and fourth pharyngeal pouches. Affected infants present with tetany secondary to hypocalcemia, severe infections with markedly suppressed T-cell immunity, and normal humoral immunity.

The thymus is a complex tissue with a specialized endocrine epithelium that synthesizes a variety of biologically active peptides involved in the control of T-cell maturation. This epithelium is derived from the neural crest and contains complex gangliosides that react with monoclonal antibody (A2B5) and tetanus toxin in a manner similar to that of pancreatic islets. The role of these biologically active peptides of the thymus has not been defined, but they may be trophic factors in T-cell activation and increase in situations of primary failure of T-cell activation, just as the levels of trophic hormones increase in primary endocrine failure.

The illnesses associated with thymomas are similar to those in APS-II,\[105\] although the frequency of specific disorders is different. In one review of patients with thymoma, myasthenia gravis occurred in 44% of the patients, red blood cell aplasia in approximately 20%, hypoglobulinemia in 6%, autoimmune thyroid disease in 2%, and adrenal insufficiency in 1 of 423 patients. The frequency of autoimmune thyroid disease reported in patients with thymoma is probably an underestimate, given the frequency of unsuspected thyroid disease in patients with myasthenia gravis. Mucocutaneous candidiasis in adults is also associated with thymomas. In most patients, the thymomas are malignant, although temporary remissions of the autoimmune disease can occur with resection of the tumor.
Trisomy 21

Down syndrome, or trisomy 21, is associated with the development of insulin-dependent diabetes mellitus and thyroiditis. We have observed one patient with a partial distal translocation "leading" to trisomy 21 and "associated" with adrenal insufficiency, celiac disease, hypothyroidism, and insulin-dependent diabetes. Patients with trisomy 21 also have T-cell abnormalities, including increased Ia-positive T cells and a premature increase in the 3G5 age-related T-cell subset. It is not known whether the observed chromosomal abnormality influences the development of autoimmunity or whether part of the susceptibility to autoimmunity is associated with chromosomal disorders. Organ-specific autoimmunity also occurs with gonadal dysgenesis.
Congenital Rubella

Patients with congenital rubella have an almost 20% risk of acquiring diabetes mellitus and a higher than normal risk of acquiring thyroiditis and hypothyroidism. Those at highest risk for diabetes express diabetes-associated HLA-DR3 and HLA-DR4 alleles. Rubella appears to be associated with diabetes primarily after fetal infection, and it is not known whether the virus increases the probability of subsequent autoimmunity because it has permanent effects on the developing immune system.

Organ-specific autoimmunity is readily induced in animal models by perturbations of neonatal immune function (neonatal thymectomy, neonatal cyclosporine administration). Congenital diabetes, although rare, may occur as illustrated by a case report describing lymphocytic infiltration of the pancreas with CD45RO+ memory phenotype cells and the presence of autoantibodies to GAD and insulin in a child born with congenital diabetes and without serologic evidence of viral infection.
Wolfram Syndrome

Wolfram syndrome is a rare autosomal recessive disease that is also called DIDMOAD, which stands for diabetes insipidus, diabetes mellitus, progressive bilateral optic atrophy, and sensorineural deafness. In addition, neurologic and psychiatric disturbances are prominent in most patients and may cause severe disability.

Linkage analysis of several families with this disorder has identified a locus of chromosome 4 that was highly associated with the disease. Segregation analysis of the mutations found in familial and sporadic cases of Wolfram syndrome led to the identification of wolframin, or WFS1, a 100-kd transmembrane protein encoded by a gene located at 4p16.1. The disease has been mapped to a locus on the short arm of chromosome 4.

Atrophic changes in the brain have been found with magnetic resonance imaging.

Wolfram syndrome appears to be a slowly progressive neurodegenerative process, and there is also (non-autoimmune) selective destruction of the pancreatic beta cells. This association may be related to the many molecules and metabolic pathways shared by islets and neurons. Diabetes mellitus with an onset in childhood is usually the first manifestation. Diabetes mellitus and optic atrophy are present in all reported cases, but expression of the other features is variable. Linkage to other loci in addition to WFS1 may explain the variability in phenotype seen in this disorder. In one case report, two related children with Wolfram syndrome had megaloblastic and sideroblastic anemia that responded to treatment with thiamine. Furthermore, thiamine treatment was associated with a marked decrease in insulin requirements.
X-Linked Syndrome of Polyendocrinopathy, Immune Dysfunction, and Diarrhea (XPID)

XPID was first described in 1982 and was noted to be an X-linked immunodeficiency syndrome characterized by autoimmune enteropathy, polyendocrinopathy, atopic dermatitis, and fatal infections. Activated T cells can be found in the circulation and in the infiltrates along affected gut tissue. Linkage analysis demonstrated that a 17-cM stretch of the X chromosome is associated with XPID; this site is distinct from the adjacent site, which is associated with the similar Wiskott-Aldrich syndrome. The syndrome consists of loss of pancreatic islets (diabetes mellitus), infection, severe enteropathy, thrombocytopenia and anemia, endocrinopathy and eczema, and growth retardation, and is often fatal in infancy. It differs from Wiskott-Aldrich syndrome in that activated CD4+ T cells are found. Characteristics of the scuffy mouse (gene sf) bear a number of similarities to this syndrome, and abnormalities in the sf gene lead to abnormalities in the amount and function of scurfin, a DNA-binding protein. Wildin and colleagues studied four individuals with XPID for abnormalities in the sf gene and found that each had either nonconservative substitutions or deletion or insertion mutations that could affect function of this protein. This study indicates that this disorder is tied to abnormalities in the sf gene.
Summary

The most basic pathogenic lesion of the polyendocrine autoimmune syndromes is an inherited tendency to target self-molecules immunologically. The disease associations and the inheritance pattern make it possible to detect additional components of these syndromes in patients before the appearance of serious manifestations and to make the diagnosis in some first-degree relatives with unrecognized disease. Detection and diagnosis can now be facilitated by autoantibody assays with excellent sensitivity and specificity.

---

Endocrine tumors originating from islet, or enteroendocrine, cells may present with unique clinical symptoms that reflect the biologic actions of secreted peptide hormones. In this chapter, we discuss how endocrine cell lineages develop during organogenesis in the endocrine pancreas and intestine and review the biologic actions of peptide hormones produced in pancreatic and intestinal endocrine cells and enteric nerves. Although numerous physiologic actions of these peptides are still poorly understood and under active investigation, excessive production of one or more of these peptides frequently accounts for the clinical symptoms attributable to endocrine tumors arising from the gastrointestinal tract and pancreas.
ENDOCRINE CELL DEVELOPMENT IN THE PANCREAS

The endocrine and exocrine pancreas develop from the primitive foregut endoderm. Pancreatic morphogenesis is a complex process that begins with the evagination of the embryonic foregut into ventral and dorsal buds at 28 days' gestation in humans and at embryonic day (ED) 8 in mice. Upon rotation of the stomach and duodenum during development results in simultaneous rotation of the ventral bud that undergoes fusion with the dorsal bud to give rise to the primitive pancreas. The ventral bud develops into the posterior portion of the pancreatic head, including the uncinate process, while the remaining pancreas derives from the dorsal bud. In mice, a complex tree-like, epithelial-lined ductal system develops within the pancreatic diverticula with glucagon immunoreactive cells detected as early as ED 9.5, followed by detection of cells containing insulin at ED 10.5. Stem cells that give rise to both terminally differentiated endocrine and exocrine acinar cells are thought to reside within the ductal epithelium.

In humans, islet formation begins at gestational week (GW) 12 with the aggregation of polyclonal endocrine cells. Between GWs 13 and 16, small aggregates of endocrine cells arise from the pancreatic duct and develop their own blood supply. At GWs 17 to 20, fewer islets are observed in contact with the ducts, and a mantle of non-beta endocrine cells forms around the beta cells. Between GWs 21 and 26, a continual increase in the proportion of islet tissue and in the average size of the islets is observed with occasional non-beta cells in the center of the islet, a morphologic appearance that is characteristic of the postnatal islet.

At birth, the endocrine pancreas accounts for 1% to 2% of the entire pancreatic cell mass. The neuroendocrine marker nestin appears to be expressed on islet and ductal cells that exhibit properties consistent with human islet stem cells in vitro. Although genetic studies in mice have yielded valuable insights into the ontology of islet development, the relative order of appearance of unique populations of hormone-producing islet endocrine cells differs in humans and mice. Somatostatin- and pancreatic polypeptide (PP)-positive cells are detected at GW 7 in the human pancreas scattered among ductal cells. One week later, glucagon cells appear, and by

GW 9 to 10, insulin-producing cells are detectable. In mice, both insulin- and glucagon-expressing cells are first detected between ED 9.5 and 10.5, whereas somatostatin and PP are expressed later, by ED 15.5. Although cells coexpressing insulin and glucagon are detected during early islet development, cell lineage studies employing specific transgenes that mark or ablate islet cell precursors suggest that the alpha and beta cell lineages arise independently during ontogeny in the mouse. Peptide YY (PYY) co-localizes with each of the four main islet hormones in the developing pancreas. However, genetic evidence for an essential role of a PYY-producing precursor cell in pancreatic endocrine development has not yet been forthcoming.

Delineation of the genetic determinants that regulate the developmental formation and organization of pancreatic endocrine cell populations has been facilitated by studies of mice with disruption of candidate regulatory genes, principally islet transcription factors (Table 38-1). The homeobox transcription factor Pdx-1 is required for insulin gene transcription in the adult beta cell and for developmental formation of the entire pancreas. Mice homozygous for a null mutation in Pdx-1 fail to develop a pancreas, whereas restricted inactivation of Pdx-1 in the murine beta cell produces insulin deficiency and diabetes mellitus. Similarly, pancreatic agenesis has also been reported in human subjects homozygous for a loss of function Pdx-1 mutation. Subjects heterozygous for Pdx-1 develop a form of maturity-onset diabetes mellitus of the young (MODY4).

Targeted disruption of the LIM domain Isl-1 gene in mice results in abnormal development of the dorsal pancreatic mesenchyme and abnormal differentiation of islet cells, whereas a heterozygous human ISL-1 mutation has been reported in a single patient with type 2 diabetes mellitus. Although mutations in the Pax4 and Pax6 genes produce profound abnormalities in developmental formation of murine pancreatic endocrine cells, islet function has not been extensively studied in human subjects with PAX mutations. Nevertheless, binding sites for the MODY genes Pdx-1, HNF1, and HNF4 have been identified in the Pax4 promoter, suggesting that MODY genes may be upstream regulators of genes critical for islet cell formation and islet function in the pancreas.

Genes encoding members of the notch receptor family, their ligands, and downstream targets are essential for developmental formation of the endocrine pancreas. Mice lacking neurogenin 3 (ngn3), a basic helix-loop-helix (bHLH) transcription factor, fail to develop pancreatic endocrine cells and die of diabetes mellitus postnatally, whereas overexpression of ngn3 produces accelerated differentiation of pancreatic endocrine cells. These findings, taken together with the loss of Isl-1, Pdx-1, Pdx-6, NeuroD expression in ngn3 / mice, implicate ngn3 as a key upstream regulator of pancreatic endocrine cell development.

Research into the identification of upstream control mechanisms and downstream targets that promote islet cell formation, growth, and differentiation is likely to proceed rapidly in the next few years, providing scientists and clinicians with an enhanced understanding of the genetic determinants regulating the growth of normal and neoplastic endocrine cells. A summary of genetic mutations associated with abnormal formation of pancreatic endocrine cells is provided.
ENDOCRINE CELL DEVELOPMENT IN THE INTESTINE

Stem cells associated with the intestinal epithelium differentiate into four different cell lineages: (1) enterocytes, (2) Paneth cells, (3) goblet cells, and (4) enteroendocrine cells.

The enteroendocrine cell population comprises less than 1% of all intestinal epithelial cells but represents the largest mass of endocrine cells in the body. Compared with studies of pancreatic enteroendocrine cell development, much less is known about the molecular control of enteroendocrine cell formation and differentiation.

Numerous enteroendocrine cell types have been identified that can be classified according to morphologic criteria and expression of one or more secretory products. In the stomach, gastrin cells first appear in the duodenum, followed by their localization to the antrum and pylorus in adult gastric mucosa. In the small bowel, a secretin precursor cell appears important for enteroendocrine cell lineage formation. In the murine colon, PYY is the first detectable hormone marking appearance of enteroendocrine cells and is coexpressed in most enteroendocrine cells in the large intestine as they first differentiate.

The notch signaling pathway is essential for developmental formation of enteroendocrine cells. Activation of notch results in increased expression of the bHLH transcriptional repressor Hes1 that functionally antagonizes bHLH genes that regulate cellular differentiation. Mice deficient in Hes1 demonstrate premature cellular differentiation and severe pancreatic hypoplasia due to depletion of pancreatic epithelial precursors. These mice also demonstrate excessive differentiation of multiple endocrine cell types in the developing stomach and gut, suggesting that Hes1 is a negative regulator of endodermal endocrine differentiation. Both Notch1 and ngn3 act upstream of BETA2/NeuroD, a bHLH protein important for differentiation of endocrine cells in both the pancreas and intestine (Table 38-2).

Mice homozygous for a null mutation in the Pdx-1 gene demonstrate poorly differentiated duodenal intestinal epithelium with absence of Brunner’s glands and a deficiency of gastrin cells in the stomach. Just distal to the abnormal epithelium, a reduction in the number of enteroendocrine cells is observed. In contrast, expression of Pdx-1 in gut epithelial cells redirects cell lineage toward an enteroendocrine phenotype. Inactivation of BETA2/NeuroD in mice results in absence of secretin-producing and cholecystokinin (CCK)-producing enteroendocrine cells. The complexity of lineage relationships between gut endocrine cell populations is further illustrated by studies in mice with targeted ablation of secretin-producing cells. These mice exhibit nearly complete elimination of enteroendocrine cell populations producing CCK and PYY/glucagon and a reduction in cells producing gastric inhibitory polypeptide (GIP), somatostatin, and serotonin.

Members of the Pax gene family are also essential for the formation of enteroendocrine cells (see Table 38-2). Targeted disruption of Pax4 markedly reduces the number of murine duodenal cells immunopositive for serotonin, secretin, GIP, PYY, and CCK and decreases the number of somatostatin- and serotonin-positive cells in the stomach. Complete disruption of the Pax6 locus more selectively reduces the number of duodenal cells expressing GIP and CCK and decreases the number of gastrin-immunopositive and somatostatin-immunopositive cells in the stomach, whereas SEV Pax6 mice that express a dominant negative mutant Pax6 allele demonstrate markedly reduced levels of proglucagon messenger RNA (mRNA) transcripts in both the small and large intestine, with almost complete depletion of enteroendocrine cells exhibiting glucagon-like peptide 1 (GLP-1) and GLP-2 immunoreactivity (Fig. 38-1; see also Color Plate).

At present, the classification of enteroendocrine cells is based principally on the phenotype ascribed to the production of one or more peptide hormones. Nevertheless, it seems likely that additional enteroendocrine cell subpopulations will be described in different regions of the gut that exhibit considerable biologic complexity beyond that which is currently appreciated.
AMYLIN

Amylin, also known as islet amyloid-associated peptide, is a 37-amino acid hormone produced in islet beta cells and in scattered endocrine cells in the stomach and in the proximal small intestine. Exogenous administration of amylin inhibits gastric emptying and glucagon secretion in rodents and humans. Excess amylin secretion and deposition in the endocrine pancreas have been implicated as a potential pathogenic feature in some subjects with type 2 diabetes mellitus. Amylin exerts its physiologic actions through interaction with the calcitonin receptor in the presence of a receptor activity-modifying protein (RAMP). Mice deficient in amylin display modest perturbations in islet function and enhanced glucose clearance following glucose challenge.

The role of gut-derived amylin in human physiology has not been clearly established. Although amylin expression has been detected in both pancreatic and gut endocrine tumors, a specific syndrome attributable to amylin overexpression has not been delineated.
Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide (CGRP) is a member of a larger family of peptides that includes calcitonin, amylin, and adrenomedullin. In humans, distinct genes CALC-A and CALC-B encode for both calcitonin and CGRP and give rise to two 37 amino acid C-terminal amidated neuropeptides, designated \(-\text{CGRP}\) and \(-\text{CGRP}\). These neuropeptides share considerable amino acid sequence homology differing by only three amino acids in humans. \(-\text{CGRP}\) is expressed predominantly in primary afferent sensory neurons arising from the spinal cord, whereas \(-\text{CGRP}\) is expressed in enteric neurons. Two calcitonin/CGRP seven-transmembrane domain G-protein coupled receptors both interact with a family of RAMPs; coexpression of calcitonin receptor-like receptor with RAMP1 results in ligand specificity for CGRP, whereas expression of the same receptor with RAMP2 results in specificity for adrenomedullin.

CGRP immunoreactivity has been localized to enteroendocrine cells of the human rectum and to endocrine cells and neurons in the small intestine. Intestinal CGRP is released in response to glucose and by gastric acid secretion. CGRP produces marked vasodilation in the stomach, splanchnic, and peripheral circulation through stimulating nitric oxide (NO) release. CGRP also inhibits gastric acid and pancreatic exocrine secretion likely through stimulating somatostatin release. Although focal CGRP positivity has been detected in some human carcinoid and pancreatic endocrine tumors (PETs), its usefulness as a tumor marker has not been firmly established.
Cholecystokinin

Cholecystokinin (CCK) was first characterized as a factor that stimulates gallbladder contraction. The CCK gene is expressed in "open-type" enteroendocrine I cells in the proximal

Somatostatin
- Central nervous system, pancreatic D cells, enteroendocrine D cells
- 1. Inhibits secretion of islet hormones, including insulin, glucagon, and PP
- 2. Inhibits the secretion of gut peptides, including gastrin, secretin, VIP, CCK, GLP-1, and GLP-2
- 3. Inhibits pancreatic exocrine secretion
- 4. Acts in a paracrine manner on G cells, enterochromaffin-like cells, and parietal cells to inhibit gastric acid secretion
- 5. Reduces splanchnic blood flow, intestinal motility, and carbohydrate absorption while increasing water and electrolyte absorption

Tachykinins
- Throughout the central and peripheral nervous systems, including the respiratory tract, skin, sensory organs, and the urogenital tract; in the gastrointestinal tract, neurons localized in the submucous and myenteric plexuses, extrinsic sensory fibers, and enterochromaffin cells in the gut epithelium
- Substance P, neurokinin A, and neurokinin B
- 1. Regulate vasomotor and gastrointestinal smooth muscle contractility
- 2. Chemotaxis and activation of immune cells, mucus secretion, water absorption and secretion
- 3. Role in visceral inflammation, hyperreflexia, and hyperalgesia

Thyrotropin-releasing hormone (TRH)
- Central and enteric nervous system, colon, G cells of the stomach, pancreatic islet beta cells
- 1. Suppresses pentagastrin-stimulated gastric acid secretion
- 2. Chronic administration induces pancreatic hyperplasia and inhibits amylase release
- 3. Attenuates CCK-induced gallbladder smooth muscle contraction
- 4. Inhibits cholesterol synthesis within the intestinal mucosa

Vasoactive intestinal peptide (VIP)
- Widely expressed in the central and peripheral nervous system (including the enteric nervous system)
- PACAP, PHI and PHM
- 1. Induces relaxation of vascular and nonvascular smooth muscle
- 2. Mediates relaxation of the lower esophageal sphincter, sphincter of Oddi, and anal sphincter
- 3. Regulates relaxation-associated gut contraction and may be involved with reflex vasodilation in the small intestine
- 4. Inhibits gastric acid secretion
- 5. Stimulates biliary water, bicarbonate, pancreatic enzyme, and intestinal chloride secretion
- 6. Some evidence suggesting a role in regulating pancreatic release of insulin and glucagon

Small intestine (Table 38-4) and in nerve fibers branching to the gastric and colonic myenteric plexus and submucosal plexus where CCK acts as a neurotransmitter. CCK-immunoreactive peptides are found in the cerebral cortex and limbic system and in pituitary corticotrophs, C cells of the thyroid, adrenal medulla, and the acrosome of the developing and mature spermatozoa. The CCK gene encodes a 94-amino acid prohormone that is post-translationally processed in a tissue-specific fashion into multiple molecular forms of CCK-83, -58, -39, -33, -22, -8, and -5, all sharing a common C-terminus. The major active form, CCK-8, is an octapeptide containing a sulfated tyrosine residue and an amidated C-terminal phenylalanine residue, whereas CCK-33 appears to be the predominant circular form in human plasma.\(^{[29]}\)

CCK binds with high affinity to the CCK-A receptor, a seven-transmembrane domain G-proteincoupled receptor expressed.

CCK, cholecystokinin; GIP, gastric inhibitory polypeptide; GLP-1, -2, glucagon-like peptide 1, 2; PYY, peptide YY; TRH, thyrotropin-releasing hormone.
in pancreatic acinar cells, gallbladder, smooth muscle, chief and D cells of the gastric mucosa, and the central and peripheral nervous systems. In the stomach, CCK inhibits proximal gastric motility while increasing the force of antral and pyloric contractions. CCK also regulates meal-stimulated pancreatic enzyme secretion and gallbladder contraction.

CCK exhibits trophic effects on pancreatic acini in rats. Experimental manipulations that increase levels of circulating CCK, such as treatment with soybean trypsin inhibitor, or long-term pancreatobiliary diversion result in pancreatic growth and premalignant changes. Elevated circulating levels of CCK also enhanced the development of preneoplastic acinar lesions induced by azaserine, a pancreatic carcinogen in rats. In contrast, the Otsuka Long-Evans Tokushima Fatty (OLETF) rat fails to express a functional CCK-A receptor and demonstrates reduced pancreatic size.

Exogenous administration of CCK decreases the size of spontaneously ingested meals, whereas CCK-A receptor antagonists increase appetite. A human subject with polyglandular syndrome type I exhibited severe diarrhea and malabsorption in association with reduced numbers of enteroendocrine cells and CCK deficiency. Thus, CCK secretion in response to oral nutrient ingestion likely regulates nutrient absorption and postprandial satiety. Nevertheless, CCK receptors do not appear essential for weight regulation in vivo because mice with targeted disruption of the CCK-A and CCK-B receptors exhibit normal food intake and weight gain well into adult life.
Galanin was initially isolated from porcine intestine as a 29-amino acid C-terminally amidated neuropeptide. In humans, two molecular forms of galanin exist that are 19 and 30 amino acids in length. Galanin is expressed in the central and peripheral nervous systems and pituitary gland and in neural structures of the gut, pancreas, thyroid, and adrenal gland. In the intestine, galanin immunoreactivity is detected predominantly within enteric neurons located in the myenteric and submucosal plexuses that innervate the mucosa and the circular and longitudinal smooth muscle layer. Galanin is released by enteric neurons in response to intestinal distention, chemical stimulation of the mucosa, electrical stimulation of periarterial nerves, and extrinsic sympathetic neurons.

At least three different galanin receptor subtypes have been identified: GalR1, GalR2, and GalR3. These subtypes are widely expressed in gastric and intestinal smooth muscle cells, pancreas, and the central nervous system. The actions of galanin include regulation of food intake, memory and cognition, antinociception, and modulation of multiple neuroendocrine systems in the pituitary, pancreas, and gut. The importance of galanin for pituitary lactotroph biology is exemplified by studies of galanin knockout mice that exhibit normal growth rates but reduced levels of prolactin and complete failure of lactation.

Although galanin can inhibit GIP-induced and GLP-1-induced proinsulin gene transcription and insulin secretion, infusion of galanin in humans has no effect on levels of plasma insulin. Galanin also inhibits both pancreatic exocrine secretion and intestinal ion transport and induces the contraction and relaxation of intestinal smooth muscle. In humans, intravenous administration of galanin delays gastric emptying and prolongs colonic transit times. Although galanin expression has been detected in hypothalamic, pituitary, and adrenal tumors, galanin immunopositivity in pancreatic or gut endocrine tumor cells is rare.
Gastric Inhibitory Polypeptide

Also known as glucose-dependent insulinotropic polypeptide, GIP is a 42-amino acid peptide secreted by enteroendocrine K cells located in the duodenum and proximal jejunum. GIP levels rise immediately following nutrient ingestion, leading to modest inhibitory effects on gastric acid secretion and gastrointestinal motility.

The precise role of GIP as an enterogastrone remains controversial because supraphysiologic concentrations of GIP are required to inhibit both gastric acid secretion and gastric emptying in humans. The actions of GIP on the pancreatic beta cell are primarily those of an incretin, a gut-derived peptide that stimulates insulin secretion in the setting of raised plasma glucose levels following oral nutrient ingestion. GIP receptor knockout mice are viable but exhibit impaired oral glucose tolerance and enhanced susceptibility to diabetes mellitus following high-fat feeding. Although GIP-secreting endocrine tumors are rare, gut-derived GIP may contribute to the development of food-induced Cushing’s syndrome in a subset of patients with adrenal adenomas that express the GIP receptor.
Gastrin

A single mRNA transcript encodes a pre-progastrin precursor of 101 amino acids that undergoes post-translational processing into multiple biologically active molecular forms of circulating gastrin, including G34, G17, and G14. Gastrin is produced predominantly in G cells located in the gastric antrum and duodenal bulb; however, gastrin immunoreactivity has also been detected in the central and peripheral nervous systems, pituitary, adrenal gland, genital tract, and respiratory tract and in tumors. The fetal endocrine pancreas produces large amounts of amidated gastrin, suggesting a possible role of gastrin in pancreatic development. However, gastrin-deficient mice do not demonstrate overt abnormalities in pancreatic islet morphology. A possible role for gastrin in human islet biology derives from studies of the CCK-2 receptor on pancreatic A cells, which secrete glucagon in response to gastrin in vitro.

G cells are open-type endocrine cells subject to regulation by luminal contents in addition to humoral and neural influences. The effects of gastrin on acid secretion are mediated by the fully processed amidated forms of gastrin (G17 and G34) at the CCK-2 receptor (formerly known as the CCK-B/gastrin receptor) located on the enterochromaffin-like (ECL) cells of the oxyntic mucosa. Gastrin stimulates histamine synthesis and release from ECL cells, which then induce acid secretion by binding to the histamine 2 (H₂) receptor located on the basolateral aspect of the parietal cell. Gastrin also stimulates acid secretion from parietal cells via the CCK-2 receptor.

The physiologic roles of progastrin and glycine-extended gastrin (G-Gly) are less completely defined but may involve regulation of the growth and differentiation of the gastrointestinal tract. Amidated gastrin is trophic to the oxyntic mucosa of the stomach, where it stimulates proliferation of gastric stem cells and ECL cells, resulting in increased parietal and ECL mass. G-Gly exerts trophic effects on the colonic mucosa and mucosal thickness and are more prone to formation of aberrant crypt foci following treatment with azoxymethane, whereas inactivation of the gastrin gene results in reduced basal rates of colonic proliferation.

Gastrin has been reported to induce proliferation of colon cancer cell lines expressing the CCK-2 receptor; however, most colon cancers and normal colonic epithelium do not normally express the CCK-2 receptor. A truncated gastrin-binding receptor has been described in some colon cancer cell lines, and a constitutively active CCK-2 receptor mutant that confers ligand-independent growth to transfected cells has been identified in human colorectal cancers. The trophic effects of gastrin have led to studies of gastrin-neutralizing antisera for the potential treatment of intestinal neoplasia.
Gastrin-Releasing Peptide and Related Peptides

The bombesin family of peptides was originally isolated from frog skin and includes bombesin, gastrin-releasing peptide (GRP, the mammalian homologue of bombesin), neuromedin B (NMB), and neuromedin C (NMC). Gastrin-releasing peptide is a 27-amino acid peptide, whereas both NMB and NMC are decapetides. These peptides share an identical C-terminal amidated heptapeptide sequence that is essential for biologic activity. GRP is expressed in the central, peripheral, and enteric nervous systems, reproductive tract, and lung, where it acts as a neurotransmitter. NMB is expressed predominantly in the brain and gastrointestinal tract. Within the intestine, GRP and NMB are localized to neurons in the submucosal and myenteric plexuses of the stomach, small intestine, and colon. GRP-containing neurons are also distributed throughout the human pancreas. Bombesin and GRP stimulate smooth muscle cell contraction in the stomach, intestine, and gallbladder. GRP stimulates the release of CCK, gastrin, GIP, glucagon, GLP-1 and GLP-2, motilin, PP, PYY, and somatostatin in some, but not all, species.

Three GRP receptor subtypes have been cloned that are seven-transmembrane domain G-protein-coupled receptors that bind bombesin-like peptides, including a GRP-preferring subtype (expressed throughout the intestine), NMB-preferring subtype (expressed in the esophageal and intestinal muscularis), and a third subtype, designated bombesin receptor subtype 3, which preferentially binds GRP over NMB and is expressed in testes and small cell lung cancer. GRP regulates appetite, memory, and thermoregulation and suppresses appetite following intracerebroventricular or systemic administration. GRP stimulates pancreatic growth in part via a CCK-dependent mechanism. The expression of GRP in human tumors with neuroendocrine properties such as small cell carcinoma and medullary thyroid carcinoma, taken together with its autocrine and endocrine effects on cell growth, suggests that GRP may contribute to regulation of tumor cell growth.
Ghrelin

Ghrelin, a motilin-related peptide, is a 28-amino acid growth hormone-releasing factor originally purified from rat stomach that stimulates growth hormone release via the growth hormone secretagogue receptor (GHS-R). Fasting increases gastric ghrelin gene expression, and ghrelin exhibits gastric prokinetic activity and orexigenic activity following both intracerebroventricular and peripheral administration via the ghrelin receptor expressed in hypothalamic nuclei. Ghrelin expression is also induced by stressors, and ghrelin may play a role in the anxiogenic stress response in a corticotropin-releasing hormone (CRH)-dependent manner in mice.

The majority of rat and human gut endocrine cells that express ghrelin are localized to the stomach, with a small number of ghrelin-positive cells identified in the small and large intestine. GHS-R is also expressed in the gut; however, the function of the intestinal ghrelin/GHS-R axis remains poorly understood. Circulating levels of ghrelin in human subjects increase and fall before and after food ingestion, consistent with a role for ghrelin in appetite regulation.
Glucagon, Glucagon-like Peptide 1, and Glucagon-like Peptide 2

The proglucagon gene is expressed in the pancreatic A cell, intestinal L cell, and specialized regions of the brain, primarily neurons in the brain stem and, to a lesser extent, hypothalamus. In mammals, a single proglucagon precursor is differentially processed to yield multiple proglucagon-derived peptides (PGDPs), including glucagon in the islet A cell, and glicentin, oxyntomodulin, glucagon-like peptide 1 (GLP-1), GLP-2, and several spacer or intervening peptides in the gut enteroendocrine L cell.

Pancreatic glucagon is a 29-amino acid peptide that regulates plasma glucose levels via effects on gluconeogenesis and glycogenolysis. Increased glucagon secretion functions as the primary counterregulatory mechanism to restore normal levels of plasma glucose in the setting of hypoglycemia. In contrast,

**Figure 38-2** Glucagon-like peptide II receptor (GLP-2R) expression in subsets of endocrine cells in the human stomach (ST) and large bowel (LB). Most cells exhibiting positivity with antisera against the human GLP-2R also exhibited immunopositivity for an endocrine marker such as chromogranin (CHROM). In contrast, most endocrine cells in the stomach and both small and large intestine did not express the GLP-2R. Arrows denote cells positive for both the GLP-2R and chromogranin, and arrowheads denote cells positive for the GLP-2R or chromogranin.

GLP-1 secreted from the gut endocrine cell enhances glucose disposal following nutrient ingestion by inhibition of gastric emptying, stimulation of insulin secretion, and inhibition of glucagon secretion. GLP-1 also inhibits food intake and stimulates pancreatic islet neogenesis and proliferation, biologic actions that facilitate long-term control of nutrient homeostasis.

GLP-2 is a 33-amino acid peptide that is co-secreted with GLP-1, oxyntomodulin, and glicentin from enteroendocrine cells in a nutrient-dependent manner. GLP-2 inhibits both centrally induced antral motility and meal-stimulated gastric acid secretion. GLP-2 exhibits trophic actions in the small intestine and colon via stimulation of crypt cell proliferation and reduction of apoptosis within the crypt and villus compartments. GLP-2 also exerts actions independent of intestinal growth, including enhancement of intestinal epithelial barrier function and stimulation of intestinal hexose transport. The beneficial therapeutic actions of GLP-2 in experimental models of intestinal injury and in human subjects with short bowel syndrome suggest that GLP-2 may be useful for preventing injury and enhancing repair and regeneration in the gastrointestinal epithelium.

Although the actions of GLP-1 and GLP-2 are transduced via distinct GLP-1 and GLP-2 receptors, both GLP-1 and GLP-2 are rapidly inactivated by the same enzyme, dipeptidyl peptidase IV (DPP-IV). The GLP-1 receptor is widely expressed in GLP-1 target tissues, and disruption of the GLP-1 receptor in mice produces mild glucose intolerance and betacell dysfunction. The GLP-2 receptor is expressed in subsets of enteroendocrine cells; hence, many of the gastrointestinal actions of GLP-2 are likely indirect and mediated via enteroendocrine-derived factors. The coexpression of the GLP-2 receptor in minor subsets of distinct enteroendocrine subpopulations in the stomach and small and large intestine further illustrates the phenotypic complexity in defining subsets of functionally unique enteroendocrine cells (Fig. 38-2) (see also Color Plate). The GLP-2 receptor is also expressed in the central nervous system, where both GLP-1 and GLP-2 regulate the short-term control of food intake.

In contrast with the biologic actions of GLP-1 and GLP-2, those of glicentin and oxyntomodulin are less well established. Glicentin appears trophic for the gut mucosal epithelium, whereas oxyntomodulin inhibits food intake and pentagastrin-stimulated gastric acid secretion both in vitro and in vivo. Although distinct G protein-coupled receptors (GPCRs) for glucagon, GLP-1, and GLP-2 have been characterized, separate receptors that mediate the actions of glicentin and oxyntomodulin have not yet been identified.
Motilin

Motilin is a 22-amino acid peptide originally isolated from porcine intestine. Motilin immunoreactivity has been detected in open-type enteroeendocrine epithelial M cells located predominantly in the duodenum and proximal jejunum. Secretion of motilin occurs in a cyclical manner during the interdigestive state between meals. The presence of nutrients in the duodenum suppresses the endogenous release of motilin in both dogs and humans. Duodenal alkalinization, sham feeding, gastric distention, and administration of opioid agonists promote motilin secretion. A putative motilin receptor has been cloned that exhibits 52% amino acid identity with the human receptor for growth hormone secretagogues. The motilin receptor is expressed in multiple regions of the gastrointestinal tract, predominantly in smooth muscle and enteric neurons, and also recognizes the macrolide antibiotic erythromycin.

Motilin induces phase 3 contractions in the stomach, an effect that can be abolished by food ingestion, duodenal acidification, somatostatin, pentagastrin, and CCK. Atropine and 5-hydroxytryptamine antagonists also abolish phase 3 contractions, emphasizing the importance of the cholinergic and serotoninergic neuronal pathways. Motilin stimulates gastric and pancreatic enzyme secretion and induces contraction of the gallbladder, sphincter of Oddi, and lower esophageal sphincter.
Neuropeptide Y

Neuropeptide Y (NPY) is primarily synthesized and secreted by neurons in the central and peripheral nervous systems. In the brain, NPY is expressed not only in the hypothalamus, where it exhibits extremely potent effects on nutrient intake, but also in the cortex, hippocampus, basal forebrain striation, limbic structures, amygdala, and brain stem. In the peripheral nervous system, expression occurs predominantly in sympathetic neurons and in the myenteric and submucous plexuses of the enteric nervous system.

NPY and vasoactive intestinal peptide (VIP) are often coexpressed in enteric neurons. NPY is synthesized in and released from pancreatic islet cells and inhibits glucose-stimulated insulin secretion via the Y1 receptor. Elevated circulating NPY levels are observed following sympathetic nervous system activation and in patients with pancreatic endocrine tumors, carcinoid tumors, and neurogenic tumors, including neuroblastomas and pheochromocytomas.

Elevated circulating NPY levels are observed following sympathetic nervous system activation and in patients with pancreatic endocrine tumors, carcinoid tumors, and neurogenic tumors, including neuroblastomas and pheochromocytomas. Intravascular administration of NPY is associated with marked vasoconstriction of the splanchnic circulation, an effect that is not altered by -adrenergic or -adrenergic blockade.

NPY exerts its actions via several receptor subtypes, including the Y1 and Y2 receptors that bind NPY and PYY with similar affinities and the Y3 receptor that exhibits a preference for NPY over PYY. NPY and PYY are targets for N-terminal degradation by the enzyme DP-IV, leading to the generation of NPY (336) and PYY (336), peptides that exhibit preferential binding to the Y2 receptor. In the gastrointestinal tract, NPY reduces fluid and electrolyte secretion and inhibits both gastric and small intestinal motility.
Neurotensin

Neurotensin (NT) is a 13-amino acid peptide originally detected in bovine hypothalamus. NT-related peptides include neuromedin N, a 6-amino acid NT-like peptide co-encoded in proneurotensin, as well as xenin, and xenopsin. In the gastrointestinal tract, NT processing favors the generation of NT in N cells of the ileum and in enteric neurons. NT is also produced in the central and peripheral nervous systems, heart, adrenal gland, pancreas, and respiratory tract. NT secretion is stimulated by luminal nutrients, especially lipids, but not amino acids or carbohydrates. GRP also stimulates NT release, whereas somatostatin exerts an inhibitory effect.

At least three different NT receptor/binding proteins (NTS-1 to NTS-3) have been identified. NTS-1 and NTS-2 belong to the GPCR family, whereas NTS-3 represents a structurally unrelated protein with NT-binding properties. NTS-1 is expressed in both the brain and intestine, whereas NTS-2 and NTS-3 are expressed exclusively in the brain.

NT administration to rats augments the adaptive response to small bowel resection in the intestinal remnant, and NT stimulates growth of the colonic epithelium in vivo. NT also inhibits postprandial gastric acid secretion and pancreatic exocrine secretion, stimulates colonic motility, and inhibits gastric and small intestinal motility. NT facilitates fatty acid uptake in the proximal small intestine and induces histamine release from mast cells. NT receptor expression has been detected in a subset of human colon and pancreatic ductal cancers, and NT is trophic for some pancreatic and colon cancer cells in vitro.
Pancreatic Polypeptide

Pancreatic polypeptide (PP) was isolated from chicken pancreatic extracts as a by-product of insulin purification. The majority of PP is expressed in pancreatic endocrine cells located predominantly in the periphery of islets in the pancreatic head and uncinate process. Elevated plasma levels of PP have been detected in patients with gastrointestinal endocrine tumors; hence, PP may be used as a tumor marker in appropriate clinical scenarios. Nutrients, hormones, neurotransmitters, gastric distention, insulin-induced hypoglycemia, and direct vagal nerve stimulation regulate PP secretion, whereas hyperglycemia, bombesin, and somatostatin inhibit PP secretion.

The actions of PP are mediated by the Y4 receptor, a GPCR coupled to the inhibition of cyclic adenosine monophosphate accumulation. The human Y4 receptor is expressed in the stomach, small intestine, colon, pancreas, prostate, and enteric nervous system and in select central nervous system neurons. Exogenous administration of PP reduces CCK-induced gastric acid secretion and increases intestinal transit times by reducing gastric emptying and upper intestinal motility. PP also inhibits postprandial exocrine pancreas secretion via a vagal-dependent pathway. Transgenic mice that overexpress PP exhibit reduced weight gain and rate of gastric emptying and decreased fat mass. The biologic actions of PP in the gastrointestinal tract and pancreas are in part centrally mediated, because intracisternal injections of PP cause an increase in gastric acid secretion and gastric motility and a reduction in pancreatic secretion.
Peptide YY

Peptide YY (PYY), together with NPY, and PP are members of the PP family. These peptides consist of 36 amino acids, contain several tyrosine residues, and share considerable amino acid identity with amidated C-terminal ends. Although these peptides likely share a common ancestry, they exhibit unique actions and patterns of tissue-specific expression, with PYY and PP acting as hormones, whereas NPY acts primarily as a neurotransmitter.

PYY is expressed in the fetal and adult gastrointestinal tract in enteroendocrine cells. Distinct enterodendocrine subpopulations have been identified that express PYY alone, or both PYY and GLP-1, in the ileum, colon, and rectum. Immunoreactive PYY has also been detected in the developing endocrine pancreas and in a subpopulation of glucagon-producing A cells in mature islets. PYY is secreted as a 36-amino acid peptide and circulates as two molecular forms: PYY (136) and an N-terminally truncated form, PYY (336). Luminal nutrients, CCK, GRP, and vagal tone regulate PYY secretion.

PYY exerts its actions in part through the NPY Y1 and Y2 receptors and a separate PYY receptor. Whereas PYY (136) binds both Y1 and Y2 receptors, PYY (336) is selective for the Y2 receptor. PYY demonstrates inhibitory effects on gastrointestinal secretion, motility, and blood flow. In the stomach, PYY functions as an enterogastrone, inhibiting both gastric acid secretion and gastric emptying. PYY also increases intestinal transit times by inhibiting small and large intestinal motility. The role of PYY as an intestinal epithelial growth factor remains unclear because some, but not all, studies demonstrate an intestinotrophic effect of PYY in rodents. In the pancreas, both PYY (136) and PYY (336) inhibit pancreatic exocrine secretion.
Pituitary Adenylate Cyclase-Activating Peptide

Pituitary adenylate cyclase-activating peptide (PACAP), VIP, and GRF are structurally related members of the glucagon-secretin superfamily. PACAP-immunoreactive nerve fibers are distributed along the gastrointestinal tract from the esophagus to the colon. Both PACAP-38 and PACAP-27 are detected in many tissues, with PACAP-38 generally the predominant peptide. PACAP stimulates histamine release from the stomach; increases the secretion of pancreatic fluid, protein, and bicarbonate; and stimulates insulin secretion and catecholamine release. PACAP signaling in gastric ECL cells may also constitute an important component of the neural regulation of gastric acid secretion.

Three PACAP receptors (PAC1, VPAC1, and VPAC2) have been cloned and bind PACAP and VIP with varying affinities. Consistent with the putative importance of PACAP for islet function, PAC1 receptor knockout mice exhibit defective glucose-stimulated insulin secretion.
Secretin

Secretin is a 27-amino acid peptide synthesized predominantly in the brain and gastrointestinal tract. In the gut, secretin is produced by the enteroendocrine S cell in the duodenum and proximal jejunum. Gastric acid, bile salts, and luminal nutrients stimulate, and somatostatin inhibits, the release of secretin. Secretin stimulates pancreatic and biliary bicarbonate and water secretion and may regulate pancreatic enzyme secretion. Secretin also stimulates the gastric secretion of pepsinogen and inhibits lower esophageal sphincter tone, postprandial gastric emptying, gastrin release, and gastric acid secretion.

Although secretin is expressed in the fetal endocrine pancreas, its function in islet biology remains uncertain. To date, only a single secretin receptor has been isolated and characterized. Secretin has been proposed as a treatment for autism; however, clinical trial results examining this issue have not been consistently positive.
Somatostatin

Somatostatin, originally isolated as a hypothalamic growth hormone release inhibiting factor, is also expressed in the intestine and pancreas. Post-translational processing of prosomatostatin results in the generation of SS-14 and SS-28, biologically active peptides corresponding to the C-terminal 14 and 28 amino acids of prosomatostatin. SS-28 is the predominant molecular form liberated by enteroeendocrine D cells, whereas SS-14 is the predominant species liberated by D cells in the stomach and pancreas.

Five somatostatin receptor subtypes (SST-1 to SST-5) have been identified that are expressed in a tissue-specific manner. Somatostatin’s actions are generally inhibitory; that is, somatostatin inhibits the secretion of growth hormone and thyrotropin in the pituitary, and insulin, glucagon, and PP in the endocrine pancreas. In the gastrointestinal tract, somatostatin inhibits the secretion of a broad range of gut peptides. Somatostatin inhibits pancreatic exocrine secretion and also acts in a paracrine manner on G cells, ECL cells, and parietal cells to inhibit gastric acid secretion.

The inhibitory properties of somatostatin make it suitable for the treatment of conditions characterized by excess hormone secretion. Although the circulating half-life of native somatostatin is short, longer-acting synthetic somatostatin analogues such as octreotide and lanreotide are useful in the treatment of neuroendocrine tumors, acromegaly, and portal hypertension. Both octreotide and lanreotide are octapeptides that bind the SST-2 and SST-5 somatostatin receptor subtypes, receptors commonly expressed in neuroendocrine tumors. Somatostatin analogues are also employed for the treatment of portal hypertension and gastrointestinal bleeding. Tumor-associated somatostatin receptor expression forms the basis for the radiolabeled octreotide scan, a test that appears useful for the detection of a broad spectrum of human neoplasms. Somatostatin-deficient mice exhibit normal growth but defects in sexually dimorphic hepatic gene expression.
Tachykinins

The family of tachykinins includes substance P (SP), neurokinin-A (NKA), and neurokinin-B (NKB), all of which share a common C-terminal pentapeptide sequence essential for biologic action. Two genes encode the tachykinins: a pre-protachykinin-A gene that encodes SP and NKA and a preprotachykinin-B gene that encodes NKB. Tachykinins are synthesized within neurons localized to the submucous and myenteric plexuses, extrinsic sensory fibers, and in enterochromaffin cells in the gut epithelium. Tachykinins are also widely distributed throughout the central and peripheral nervous systems, the respiratory tract, skin, sensory organs, and the urogenital tract.

Four different tachykinin receptors (NK1 to NK4) have been cloned and bind tachykinin peptides with different affinities. NK1 receptors preferentially bind SP, NK2 preferentially binds NKA, and both NK3 and NK4 preferentially bind NKB.

The tachykinins regulate vasomotor and gastrointestinal motor activity. The ability of tachykinins to induce vasodilatation or vasoconstriction appears to be specific to the species and to the vascular bed. Tachykinins exhibit both direct and indirect effects on intestinal smooth muscle contractile activity.

Activation of NK1 receptors on the interstitial cells of Cajal and NK2 receptors on intestinal smooth muscle cells directly promotes peristalsis, whereas activation of NK3 receptors on enteric neurons exerts a prokinetic effect that is indirectly mediated through cholinergic stimulation of enteric smooth muscle cells. The NK1 and NK3 receptors can exhibit inhibitory effects on intestinal motility by inducing the release of inhibitory molecules such as NO and VIP from inhibitory neurons. NK2 receptors can also inhibit intestinal motility by either stimulation of sympathetic ganglia or activation of nonadrenergic inhibitory mechanisms. NK2 receptor antagonists reduce or prevent trinitrobenzene sulfonic acid induced weight loss and intestinal injury, whereas an NK1 receptor antagonist exhibits protective effects in acetic acid induced colitis.

Tachykinins are commonly produced by gut carcinoids and may be responsible for mediating some of the clinical manifestations associated with these tumors.
Thyrotropin-Releasing Hormone

Originally isolated as a hypothalamic regulatory peptide, thyrotropin-releasing hormone (TRH) is expressed throughout the gastrointestinal tract, including the stomach, colon, and pancreas. In the pancreas, TRH is most abundantly expressed during perinatal development. Pre-pro-TRH is synthesized by islet beta cells, G cells in the stomach, and neurons comprising the myenteric plexus of the esophagus, stomach, and intestine. In the stomach, histamine and serotonin stimulate, and endogenous opioids inhibit, TRH release.

TRH acts via two related GPCRs: TRH receptor 1 (TRHR1) and TRH receptor 2 (TRHR2). TRH suppresses pentagastrin-stimulated gastric acid secretion, and chronic administration of TRH induces pancreatic hyperplasia and inhibits amylase release. TRH also attenuates CCK-induced gallbladder smooth muscle contraction and inhibits cholesterol synthesis within the intestinal mucosa.
Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) is a 28-amino acid member of a peptide superfamily that includes PACAP, peptide histidine isoleucine, and peptide histidine methionine, all neurotransmitters and neuromodulators of the enteric nervous system. The VIP gene is widely expressed in the central and peripheral nervous systems. Receptors for VIP and PACAP belong to the same family of GPCRs. The PAC1 receptor binds both PACAP (1-27) and PACAP (1-38) with the same affinity but is unable to bind VIP, whereas the VPAC1 and VPAC2 receptors recognize both VIP and PACAP.

In the digestive tract, VIP functions as an inhibitory neurotransmitter that induces relaxation of vascular and nonvascular smooth muscle. VIP mediates the relaxation of the lower esophageal sphincter, the sphincter of Oddi, and the anal sphincter. VIP also regulates relaxation associated with gut contraction and may be involved in reflex vasodilatation in the small intestine, in part through a NO-dependent mechanism. In humans, VIP and PACAP may be co-localized to some neuronal subpopulations and are co-released as neurotransmitters leading to NO regeneration. VIP inhibits gastric acid secretion but stimulates biliary water and bicarbonate, pancreatic enzyme, and intestinal chloride secretion. VIP may also regulate pancreatic release of both insulin and glucagon and exerts either trophic or growth inhibitory effects on both normal and neoplastic cells.
Miscellaneous Gut Endocrine Peptides

In addition to the several peptide hormones outlined earlier and summarized in Table 38-3, several other gut endocrine peptides exist. Chromogranins and secretogranins are a family of secretory proteins that are found in secretory vesicles of both endocrine cells and neurons. Chromogranin-A (CgA) is a protein belonging to this family of peptides and is secreted into the circulation by several neuroendocrine tumors, especially small gastrinomas and pheochromocytomas. A direct correlation exists between circulating levels of CgA and tumor burden, making this a well-suited marker for assessing treatment response. In addition, opioid peptides regulate intestinal motility and gastric acid secretion and inhibit secretion.

Neuromedin U is a neurotransmitter that is expressed in the enteric nervous system, where it regulates intestinal motility and ion secretion.

A number of hormones are secreted by the gastrointestinal tract directly into the lumen, where they modulate secretion and the release of other hormones. Guanylin and uroguanylin stimulate water, bicarbonate, and chloride secretion by the intestine while inhibiting sodium reabsorption.

Other luminally secreted peptides include sorbin (a 153amino acid peptide involved with monitoring fluid and sodium fluxes in the duodenum) and monitor peptide (a 61amino acid peptide that stimulates CCK release).
PANCREATIC AND GUT ENDOCRINE TUMORS

Understanding the ontogeny of pancreatic and gut endocrine cell development provides some insight into the molecular pathophysiology of pancreatic endocrine tumors. Although gastrin is not normally produced in human adult islets of Langerhans, the finding of gastrinomas arising from the adult endocrine pancreas may reflect the dedifferentiation of neoplastic endocrine tumor cells that recapitulates, in part, patterns of islet gene expression observed during embryonic development. Similarly, the observation that pancreatic and gut endocrine tumors are frequently plurihormonal is consistent with studies demonstrating co-localization of peptide hormones in both fetal and adult endocrine cells in the pancreas and gut.

Pancreatic endocrine tumors may present in isolation or as part of a genetic syndrome such as multiple endocrine neoplasia type 1 (MEN-1), or the phakomatoses such as von Hippel-Lindau disease, von Recklinghausen's disease (neurofibromatosis type 1), and tuberous sclerosis. Defects in distinct tumor suppressor genes account for the phenotypic manifestations and development of tumors in these syndromes (Table 38-5). Loss of heterozygosity at 10q has been detected in several sporadic pancreatic endocrine tumors, with cellular rather than nuclear localization of PTEN (phosphatase and tensin homologue deleted on chromosome 10) detected in a substantial proportion of malignant pancreatic endocrine tumors. Similarly, loss of heterozygosity at the 11q13 MEN1 locus has also been detected in a few sporadic pancreatic endocrine tumors.

Genetic mutations in the menin gene give rise to the MEN-1 syndrome associated with an increased incidence of endocrine tumors in many organs, including the pancreas and gut carcinoids in the stomach. The MEN1 gene encodes a 610 amino acid nuclear protein that interacts with the RUN domain transcription factor, presumably resulting in derepressed cell growth. About 10% of all MEN1 germline mutations arise de novo. The current usefulness of genetic testing for all patients with suspected MEN-1 syndrome remains unclear.

Figure 38-3 Clinically "nonfunctioning" tumors are often found to express one or more peptide hormones after immunocytochemical analyses. The photomicrographs represent histologic sections from the identical nonfunctioning human pancreatic endocrine tumor that exhibit immunopositivity for glucagon (A) and pancreatic polypeptide (B). (Courtesy of Dr. G. Rindt, Brescia, Italy.)

Owing to the large number of heterogeneous mutations identified in the menin gene, potentially affected family members may find utility in ruling out the diagnosis with genetic testing, thereby precluding years of biochemical testing and imaging studies.

A search for clinical manifestations of diseases associated with these genetic syndromes is an important component in the initial diagnosis and ongoing management of patients with pancreatic endocrine tumors. More careful clinical phenotypic analyses have ascertained that facial angiolipomas, collagenomas, lipomas, leiomomas, and adenocortical tumors all may be seen with increased frequency in patients with MEN-1. Moreover, somatic mutations of the menin gene have been described in isolated cases of gastrinomas, insulinomas, and gut endocrine tumors. The secretion of one or more peptide hormones resulting in the production of symptoms attributable to hormone excess, such as hypoglycemia, gastric ulceration, or profuse watery diarrhea in patients with insulinomas, or VIPomas, respectively, clearly facilitates the diagnosis of a hormone-secreting endocrine tumor. In some instances, pancreatic or gut endocrine tumors may not be associated with clinically or biochemically detectable hormone excess, and the development of a recognizable syndrome and analysis of the tumor may fail to reveal evidence for peptide hormone biosynthesis.

Nonfunctioning pancreatic endocrine tumors are more common, often larger, and more frequently malignant at the time of diagnosis. The term nonfunctioning may be a misnomer, because these tumors may produce peptide hormones (Fig. 38-3) (see also Color Plate) whose biologic actions are less clinically apparent. In some instances, tumor-associated defects in post-translational processing may preclude the efficient synthesis and secretion of peptide hormones. Factors affecting prognosis include the presence of liver metastases, incomplete resection of the primary tumor, and poorly differentiated tumor cells.

The use of somatostatin receptor scintigraphy (SRS) and measurement of gene products commonly expressed in endocrine cells such as chromogranin, PP, neuron-specific enolase, or glycoprotein hormone subunits may be useful as an adjunct for monitoring the tumor response to therapy. The widespread expression of receptors for somatostatin and multiple peptide hormone GPCRs has stimulated efforts directed at developing novel radiolabeled peptide ligands for the localization and treatment of both endocrine and nonendocrine neoplasms.

Despite the large number and complexity of endocrine cell populations in the human small bowel, gut endocrine tumors, including ileal carcinoids, are comparatively rare. Similarly, although human colon cancer remains a major cause of cancer-associated morbidity and mortality, peptide hormonesecreting carcinoid tumors arising from the colon are comparatively much less common compared with colonic adenocarcinomas. The molecular basis for the infrequent malignant transformation of human gut endocrine cells remains incompletely understood. Mutations in the regI gene have been identified in a subset of patients with ECL tumors and associated hypergastrinemia; however, the contribution of this genetic mutation to transformation of ECL cells remains unclear. The clinical presentation, diagnosis, and treatment of several more common pancreatic and gut endocrine tumors are reviewed later, and both medical and surgical perspectives to treatment have been reviewed.

Gastrinoma (Zollinger-Ellison Syndrome)

In 1955, Zollinger and Ellison described two patients with intractable peptic ulcer disease and pancreatic islet cell tumors. Subsequent studies demonstrated elevated levels of circulating gastrin associated with gastric acid hypersecretion in patients with Zollinger-Ellison syndrome (ZES).

Although the gastrin gene is not normally expressed in the adult pancreas, gastrinomas commonly arise from within the pancreas and present as endocrine carcinomas, solitary adenomas, microadenomas, or endocrine cell hyperplasia. Gastrinomas and insulinomas represent the two most common pancreatic endocrine tumors. A smaller proportion of gastrin-secreting tumors (20% to 40%) arise from the duodenum. Most (75%) gastrinomas occur sporadically, whereas approximately 25% are associated with MEN-1 syndrome. MEN-1-related patients tend to exhibit a younger age of onset at the time of diagnosis. MEN-1-associated tumors are usually multiple but may be more localized at the time of diagnosis. It is estimated that 50% to 60% of gastrinomas are malignant, based on the presence of metastases at the time of diagnosis, perhaps due in part to the long delay between the initial clinical presentation and the diagnosis of ZES. Nevertheless, gastrin-secreting tumors are often slow growing and associated with prolonged survival, despite complications.
Clinical manifestations of gastrinomas are usually related to excessive gastric acid secretion resulting in severe refractory peptic ulceration complicated by hemorrhage, perforation, and stricture. Many patients report symptoms for 5 to 6 years before the diagnosis of ZES is established. Abdominal pain, diarrhea, and heartburn are common presenting symptoms, with diarrhea and pain observed in more than 70% of patients with ZES. The diarrhea results in part from fat malabsorption due to pancreatic lipase degradation by excess gastric acid. Small-bowel inflammation and impaired nutrient absorption may also arise from excess gastric acid. Antisecretory therapy usually abolishes the diarrhea and diminishes many clinical features of ZES.

The diagnosis of gastrinoma is based on the detection of elevated fasting circulating gastrin levels (>200 pg/mL) and gastric acid hypersecretion (basal acid output >15 mEq/hour with an intact stomach or >5 mEq/hour after ulcer surgery) in patients off all acid antisecretory medication (14 days for H⁺,K⁺-ATPase inhibitors and 3 days for H₂-receptor antagonists). Although many patients with ZES have serum gastrin values that exceed 500 pg/mL, a secretin stimulation test may be performed when the serum gastrin levels are in the range of 200 to 500 pg/mL to confirm the diagnosis. Provocative testing requires overnight fasting and the intravenous administration of secretin (2-unit/kg bolus), followed by serial measurement of circulating gastrin levels at 2, 5, 10, 15, and 20 minutes. A rise in the serum gastrin level of more than 200 pg/mL within 15 minutes or a doubling of the fasting gastrin levels strongly suggests the presence of a gastrinoma.

Localization of small primary tumors or endocrine hyperplasia can be difficult. Conventional endoscopy or an upper gastrointestinal series can occasionally be used to directly visualize duodenal lesions; however, tumors are often confined to the submucosa, making detection and biopsy challenging. Radiolabeled octreotide scanning can be useful for detecting the primary tumor and metastases. Magnetic resonance imaging (MRI) or computed tomography (CT) scans can also be informative; however, the primary tumor may not be detected with these modalities alone. Endoscopic ultrasonography has been used for tumor localization with increasing success, and, less commonly, angiography with selective venous sampling may be helpful in localizing occult tumors. Primary tumors may also be localized to lymph nodes, and ectopic gastrinomas in sites such as the ovary have also been reported.

Initial treatment of patients with gastrinoma is directed at pharmacologic reduction of gastric acid secretion. Although H⁺ blockers have been used with some success, H⁺,K⁺-ATPase inhibitors such as omeprazole have become the drug of choice owing to their longer duration of action. Doses should be titrated to keep the H⁺ ion output to less than 10 mEq/hour (5 mEq/hour in patients with previous acid-reducing surgery) for the hour prior to receiving the next dose of the drug.

As outlined in Figure 38-4, in the absence of resectable disease all patients with sporadic gastrinoma should undergo surgical exploration with the intent of curative surgical resection. Exploration should include a combination of duodenal palpation, endoscopic transillumination, intraoperative ultrasonography, and duodenotomy. In as many as 20% of patients undergoing surgical exploration, the primary tumor remains undetected at laparotomy despite meticulous exploration of the abdominal cavity. Total gastrectomy should be performed only under rare circumstances in patients with severe ulcer disease refractory to medical therapy in which the primary tumor cannot be resected. Surgery is generally not indicated in patients with gastrinoma and MEN-1 syndrome because these individuals often have multiple, small pancreatic tumors that are not all amenable to surgical resection.
Glucagonoma

Most glucagomas are pancreatic in origin. Approximately 80% of tumors occur sporadically, with the remainder associated with MEN-1 syndrome. Most glucagomas (75%) are malignant and have metastasized by the time of diagnosis.

The clinical presentation reflects the various actions of the PGDPs and may vary depending on the profile of PGDPs liberated due to tumor-specific differences in the post-translational processing of proglucagon. A hallmark of this syndrome is necrolytic migratory erythema, a skin rash that usually begins in the groin and perineum as a raised, erythematous patch with occasional bullae that may also involve the lower extremities and perioral area. The exact etiology of the skin rash remains unknown, and elevated plasma glucagon levels, as well as deficiencies of zinc, amino acids, and fatty acids may represent contributing factors.

Patients with glucagomas may exhibit weight loss, abdominal pain, diabetes mellitus, stomatitis, glossitis, cheilitis, nail dystrophy, thromboembolic events, anemia, hypoaminoacidemia, and neuropsychiatric symptoms. The triad of hyperglucagonemia, necrolytic migratory erythema, and a pancreatic tumor is seen in a minority of cases. Intestinal obstructive symptoms and increased intestinal transit times have also been reported and may reflect tumor-specific liberation of GLP-1 and GLP-2, peptides with antimotility and intestinotrophic properties, respectively.

The diagnosis may be confirmed by the presence of significantly elevated levels of plasma glucagon in association with a pancreatic mass. Extremely high levels of glucagon are more often seen with the classic glucagonoma syndrome, whereas more modest elevations of glucagon are detected in the setting of plurihormonal tumors. In contrast with insulinomas, glucagomas are often large and more easily localized with imaging modalities. SRS is effective in detecting metastatic disease that most commonly involves the liver, lymph nodes, adrenal glands, or vertebrae.

Therapy with a somatostatin analogue may be useful in the setting of metastatic disease by reducing levels of circulating glucagon via the SST2 receptor, improving the skin rash, and promoting weight gain. The skin rash may also respond to selective nutrient supplementation. Although somatostatin analogues may reduce glucagon secretion and tumor-associated symptoms, effects on tumor growth are often modest. Patients with nonresectable or recurrent disease can be treated with chemotherapeutic agents such as streptozotocin and dacarbazine or interferon or with the selective use of arterial embolization.
Somatostatinoma

Somatostatinomas are extremely rare tumors that arise in the pancreas and the duodenum. Most clinical symptoms observed in the originally described somatostatinoma syndrome reflect the inhibitory properties of somatostatin on most digestive organs. A classic triad involving mild diabetes mellitus, steatorrhea, and cholelithiasis is observed in a few patients due to reduced insulin secretion, reduced biliary and pancreatic secretions, and inhibition of gallbladder motility. More prominent symptoms seen with duodenal tumors may include weight loss, postprandial fullness and abdominal pain, cholelithiasis, anemia, and hypochlorhydria. Many patients do not present with the classic triad and exhibit only nonspecific symptoms. As a result, somatostatinomas are frequently malignant with extensive metastasis to the liver by the time of diagnosis.

Duodenal tumors are more frequently seen in association with neurofibromatosis type 1 or, less commonly, von Hippel-Lindau disease, and therefore may be associated with pheochromocytomas. Most duodenal tumors are not associated with symptoms of classic somatostatinoma syndrome and may present with local obstruction and abdominal pain. Pancreatic tumors usually occur sporadically or as part of MEN-1 syndrome and are most commonly located in the head of the pancreas.

The diagnosis is confirmed by the presence of markedly elevated levels of plasma somatostatin. CT scan and both conventional and endoscopic ultrasonography may localize the duodenal tumors (Fig. 38-5) (see also Color Plate). In the small proportion of patients with localized disease, surgical resection can be curative. Patients with incurable or recurrent disease can be treated with the chemotherapeutic agents streptozotocin and dacarbazine.
Vasoactive Intestinal PeptideSecreting Tumors

The VIPoma syndrome is also known as pancreatic cholera, Verner-Morrison syndrome, or WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome. Approximately 90% of individuals present with a pancreatic endocrine tumor that secretes VIP and often prostaglandins. The remaining tumors are extrapancreatic, usually involving the sympathetic chain or adrenal medulla. VIPomas may present as sporadic tumors or as part of MEN-1 syndrome.

Clinical manifestations include intermittent, severe watery diarrhea that contains large quantities of potassium, bicarbonate, and chloride. As a result, patients may exhibit signs and symptoms of hypokalemia, metabolic acidosis, and dehydration. Hypotension can occur due to dehydration and the vasodilator effects of VIP. Diarrhea is secretory and does not respond to antidiarrheal medications. Gastric analysis usually reveals hypochlorhydria or achlorhydria, although an appropriate increase in acid secretion is observed in response to a pentagastrin challenge. Glucose intolerance may be present due to hypokalemia and altered insulin sensitivity. Cutaneous flushing of the head and trunk may be observed in 15% of patients, usually during a bout of diarrhea, and may be associated with a patchy erythematous rash.

The diagnosis of VIPoma may be challenging due to the intermittent nature of the symptoms. A history of severe recurrent, severe diarrhea, together with elevated fasting levels of plasma VIP (>200 pg/mL), should prompt a search for a pancreatic tumor. Increased circulating levels of peptide histidine methionine, PP, NT, and prostaglandins have also been detected in patients with VIP-producing tumors. VIPomas can be localized by ultrasonography, CT scan, and SRS imaging, and exploratory laparotomy with intraoperative ultrasonography may also be used to identify the tumor.

Initial treatment of patients with VIPoma syndrome involves aggressive fluid and electrolyte replacement. Somatostatin analogues may be used preoperatively to control the diarrhea by both lowering circulating VIP and directly inhibiting intestinal secretion. Definitive treatment requires surgical resection of the tumor, commonly located in the body or tail of the pancreas. Although tumors are usually solitary, 60% are malignant at the time of diagnosis, with 75% metastasizing to the liver and regional lymph nodes, and, less commonly, to the lungs, mediastinum, stomach, and kidney.

If a pancreatic tumor cannot be identified, exploration of the retroperitoneum that includes the adrenal glands and sympathetic chains is indicated. If no pancreatic tumor is identified, some patients may elect to be closely monitored, whereas others may opt for a 80% distal pancreatectomy. This latter strategy may be beneficial for the 10% to 20% of symptomatic patients with diffuse islet cell hyperplasia. In patients with inoperable or metastatic tumor, a combination of 5-fluorouracil and streptozotocin may be effective.
Miscellaneous Gut Hormone-Producing Tumors

Although rare, pancreatic endocrine tumors may secrete PTH, growth hormonereleasing hormone, and adrenocorticotropic hormone, leading to the development of hypercalcemia, acromegaly, and Cushing's syndrome, respectively. A large number of peptide hormones may be produced by pancreatic endocrine tumor cells, including PYY, calcitonin, NT, melanocyte-stimulating hormone, corticotropin-releasing hormone, NPY, NMB, CGRP, GRP, and motilin. In some cases, the hormone precursors may be produced, but the correctly processed intact hormone may not be secreted by the tumor. Accordingly, excessive production of many of these hormones may not always be associated with characteristic signs and symptoms. Similarly, carcinoid tumors of the gastrointestinal tract often exhibit immunopositivity for multiple peptide hormones in the absence of a recognizable clinical syndrome.
Summary

A large number of peptides are synthesized in and secreted by endocrine cells of the pancreas and gastrointestinal tract. Many of these peptides circulate as hormones, but they also function as paracrine modulators or neurotransmitters not only in the gut but in the central and peripheral nervous systems. Although some biologic actions for many of these peptides have been delineated, it seems likely that new peptides, receptors, and novel biologic functions will continue to be discovered, which may provide new opportunities for understanding the pathophysiology, diagnosis, and treatment of endocrine disease.

BREAST CANCER

Etiology

A variety of data suggest that estrogens directly cause or contribute to the development of breast cancer. Administration of exogenous estrogens to various animal species results in breast cancer. Spontaneous development of breast cancer in aging rats can be prevented by oophorectomy or administration of aromatase inhibitors to block estrogen production. Oophorectomy before age 35 years in women lowered the risk of breast cancer by 75% over a 25-year period. Administration of antiestrogens caused a 50% reduction in breast cancers diagnosed in women at high risk for development of breast cancer. These observations and other data have led to the classification of estrogen as a carcinogen.
Sources of Estrogen

The breast derives estradiol from three separate sources: the ovary, extraglandular tissues, and the breast itself. First, direct glandular secretion by the ovary results in delivery of estradiol to the breast through an endocrine mechanism in premenopausal women. Second, after the menopause, extraglandular production of estrogen from ovarian and adrenal androgens provides the second source of estradiol. Third, the breast itself can synthesize estradiol through aromatization of androgens to estrogens or cleavage of estrone sulfate to estrone by the enzyme sulfatase. Estradiol acts through paracrine, autocrine, and intracrine mechanisms on cells in the breast. Several factors regulate in situ estradiol synthesis but the most important is the degree of obesity, which increases the amount of aromatase in breast and, consequently, estradiol production.
Estrogen-Induced Carcinogenesis

Mutations of key genes involved in cell proliferation, deoxyribonucleic acid (DNA) repair, or apoptosis must accumulate to produce cancer. It is likely that mitogenic as well as mutagenic effects of estradiol act in concert to initiate and promote the development of breast cancer. As a rule, the frequency of mutations increases in parallel with the number of mitotic divisions in a proliferating tissue. Accordingly, estradiols may initiate mutations leading to neoplastic transformation by increasing the rate of cell proliferation. As cells divide more rapidly, less time is available for DNA repair. Estradiols also enhance tumor promotion by increasing the rate of cell division with propagation of the mutations already present.

Metabolites of estradiol may be directly mutagenic through a pathway involving the 1B1 cytochrome P450 enzyme. This catalyzes conversion of estradiol to the catechol-estrogen 4-hydroxyestradiol, which is then further metabolized to 3,4-estradiol-quinone. This highly reactive species binds covalently to guanine or adenine molecules in the DNA helix, which activates a glycosidase and results in depurination. Error-prone or replicative repair of the depurinated site leads to point mutations. Recent studies directly demonstrated estradiol-guanine conjugates in benign and malignant human breast tissue, establishing the activity of the genotoxic pathway in women.

Estradiol is not the sole factor mediating the development of breast cancer. A number of specific genetic mutations are associated with a high incidence of breast cancer. Studies in twins suggest that approximately 27% of breast cancers arise because of genetic factors. The most common mutations involve the BRCA1 and BRCA2 genes and cause approximately 5% of breast cancer cases. Rarer genetic syndromes include mutations of the p53 gene in the Li-Fraumeni syndrome, impaired cell cycle checkpoint surveillance in the ataxia-telangiectasia syndrome, mutations in the PTEN gene in the Cowden syndrome, the MLH1 and MSH2 genes in the Muir-Torre syndrome, and an STK11 mutation in the Peutz-Jeghers syndrome. Dietary and environmental factors play a key role in breast cancer etiology and contribute to the fourfold difference in incidence between Japan, with a rate of 23 women per 100,000 per year, and the United States, at 90 per 100,000 per year. Epidemiologic observations suggest a role for a high-fat diet and resultant obesity in the genesis of breast cancer. In Japan, the rate of breast cancer peaks at the age of menopause; in the United States, however, the incidence continues to increase until age 90 years.
Hormonal Risk Factors for Breast Cancer

Most risk factors for breast cancer are related to the duration or intensity of a woman's exposure to endogenous or exogenous estrogens. Early menarche or late menopause, or both increase breast cancer risk. Elevations in circulating estradiol levels predict the risk for development of breast cancer over the ensuing years in postmenopausal women. An estradiol level in the top quintile is associated with an increase in the relative risk of breast cancer by five-fold. Putative markers of long-term estrogen exposure such as bone density are also predictive. Women in the top quartile of bone density have a threefold increase in risk of breast cancer.

Late first births increase the risk 2.8-fold and is believed to be related to the lack of the differentiating effect of pregnancy on the type of breast lobule present. Gain of at least 20 kg as an adult increases breast cancer risk twofold, probably as a result of increasing aromatase activity and estrogen production by adipose tissue. Increased waist-hip ratio is associated with a similar increase in risk. Several but not all studies suggest that alcohol intake can increase the risk of breast cancer, perhaps by decreasing the clearance of estradiol. Increased exposure to estradiol in utero, as shown by twin studies, may increase the risk of breast cancer by as much as twofold. Early pregnancy and prolonged duration of breast-feeding diminish the risk. More dramatic is the 75% reduction in risk caused by bilateral oophorectomy before age 35 years.

Mammographic density represents the most powerful risk factor for breast cancer. Increased breast density probably reflects either an increase in exposure to estrogen or sensitivity to it. Exogenous estrogens increase and antiestrogens reduce breast density. Because of these effects, hormone replacement therapy (HRT) alters the sensitivity and specificity associated with interpreting mammograms. The increase in breast cancer risk from the lowest to the highest breast density category is on the order of sixfold, depending on the age of the patient, with a greater relative risk seen in older women.

Exogenous Estrogens and Breast Cancer Risk

In premenopausal women, use of oral contraceptives for 10 or more years increases the relative risk of breast cancer by approximately 10%, However, this increase in relative risk affects few women because the age-related incidence of breast cancer is quite low in women taking oral contraceptives. Controversy surrounds the concept that HRT in postmenopausal women increases the risk of breast cancer. More than 50 observational studies have examined this question but have reported conflicting results. However, a key study clarified the factors responsible for the different conclusions in the various reports. A meta-analysis from the Collaborative Group on Hormonal Factors in Breast Cancer examined data for 52,705 women with breast cancer and 108,411 without. Five objective factors that confounded the interpretation of prior studies were identified.

1. The relative risk of breast cancer associated with estrogen replacement therapy is small, and large studies are required to minimize type I and type II statistical errors.
2. The risk of breast cancer appears to increase linearly with duration of HRT use. Accordingly, comparisons of "ever users" with "never users" are invalid because the duration of estrogen use is not considered.
3. The increased risk of breast cancer associated with estrogens appears to dissipate within 4 years of cessation of therapy. Therefore, only women using estrogen within 4 years of the study might be found to be at increased risk.
4. Breast cancer risk diminishes over a 4-year period after the menopause, presumably reflecting decreased estrogen levels. As a result, analyses of observational studies need to match users and nonusers according to time after menopause.
5. The increased risk of breast cancer appears to be limited to nonobese women (i.e., body mass index [BMI] < 25 kg/m²). Inclusion of a large proportion of obese women in a single study might obscure an association between estrogen use and breast cancer risk.

Taking into account these five factors, the meta-analysis concluded that the relative risk of breast cancer increases linearly by 2.3% per year of HRT for up to 25 years. Both the slope of the risk-time analysis (P value) and the overall risk of breast cancer among estrogen users (P value) were highly statistically significant. This study detected no increased risk associated with HRT use in obese women (i.e., BMI > 25 kg/m²). A hypothetical explanation for the differences between obese and thin women involves the degree of in situ estrogen production. Obese women may have an increase in breast tissue estrogen as a result of increased aromatase activity, whereas lean women have lower levels. Exogenous estrogen might then produce a greater percentage increase in estrogen levels in thin than in obese women.

Data suggest that addition of a progestin to an estrogen replacement therapy regimen enhances the risk of breast cancer to a greater extent than estrogen alone. Although data from cell cultures or animal studies are not conclusive, the weight of evidence from patients suggests that progestins are mitogenic in breast tissue. The physiologic basis for this conclusion rests on data indicating that progestins are mitogenic to breast tissue in contrast to their antimitogenic effects on the uterus. Although data from cell cultures or animal studies are not conclusive, the weight of evidence from patients suggests that progestins are mitogenic in breast tissue. Mammographic studies demonstrate that breast density in women taking an estrogen-progestin combination is greater than breast density in those taking estrogen alone. Histologic examination demonstrated increased cell proliferation and percentage of the breast containing glandular tissue as a function of duration of progestin usage. Increased proliferation would be expected to increase both initiation and promotion of breast cancer in a manner similar to that for estrogens.

A number of observational studies have suggested an increase in breast cancer risk in women receiving an estrogen-progestin combination, but these were not considered conclusive. Recent results from a large, prospective, randomized, placebo-controlled trial in postmenopausal women now provide compelling evidence for this effect. Nearly 16,000 postmenopausal women with an average age of 63 enrolled in the
over time. Shaded area represents the 95% confidence limits of that risk. 8. Increase in relative risk of breast cancer in women taking estrogen plus a progestin as HRT. Solid line represents the mean increase in relative risk over time. Shaded area represents the 95% confidence limits of that risk. (From Santen RJ, Pinkerton J, McCartney C, et al. Risk of breast cancer with progestins in combination with estrogen as hormone replacement therapy. J Clin Endocrinol Metab 2001; 86:1623.)

Women’s Health Initiative study and received either placebo or conjugated estrogens plus medroxyprogesterone-acetate for 5 years on average. The study was terminated early because of an increased incidence of breast cancer in the HRT group with a relative risk of 1.26 and 95% confidence interval of 1.00 to 1.59. The absolute excess of cases was small, with only 8 more invasive breast cancers per 10,000 person-years in the HRT group. Nonetheless, these data confirm the prior observational studies and indicate a relative risk increase of 5.5% per year in those receiving HRT. This is similar to the 8% per year increase reported in the observational studies (Fig. 39-4). At the present time it is not known whether the type or dose of progestin can alter breast cancer risk. Various observational studies have examined differences between combined continuous and sequential regimens and various types of progestins but data are insufficient to make definitive conclusions. It has been suggested that certain types of progestin may exert no effects on breast cancer risk, but this requires further study. With respect to estrogen alone and breast cancer, another Women’s Health Initiative study is currently comparing placebo with estrogen alone in women who had previously undergone a total abdominal hysterectomy. This study continues and has not at this time shown a sufficient increase in breast cancer with estrogen alone to warrant terminating the study.

Review of the totality of basic and clinical data strongly supports an adverse effect of adding progestins to estrogens in women. Regarding the effects of estrogen alone on breast cancer risk, one must interpret the existing data cautiously because of the retrospective/observational nature of available studies. Definitive information will await prospective information from the Women’s Health Initiative study that is comparing estrogen alone to placebo. In the meantime, it is considered prudent to advise patients about the worst case conclusion, that estrogen alone may increase their risk of breast cancer. Additional risks may also be imparted for ovarian and uterine cancer.
Relative, Absolute, and Attributable Risks

Epidemiologists use relative risk analysis as a tool that provides substantial power to determine statistical significance. However, this term is misleading to patients because actual risk is quite small in magnitude. The lay press, patients, and many physicians confuse the terms relative, absolute, and attributable risk.

Relative risk is defined as the ratio of risk under one condition to risk under another condition and does not take into account the frequency of occurrence of that condition.

Absolute risk is determined by multiplying the underlying incidence rate in the group being considered by relative risk. For example, the absolute risk of breast cancer development for an average 50-year-old woman in the United States is 2.52 per 100 women over a 10-year period. A 10% increase in relative risk resulting from estrogens alone would increase a woman's absolute risk of breast cancer to 2.77 per 100 women.

Attributable risk is defined as the number of women who would develop breast cancer that would not have occurred unless they had used estrogen replacement. Using the preceding example, the difference between breast cancer risk of 2.52 per 100 and 2.77 per 100 represents the increased risk attributable to estrogen or 0.252 per 100 women.

Attributable risks can be translated into the numeric odds of one's being adversely affected by estrogen (Table 39-1). For example, the chance of an estrogen-induced breast cancer in a 50-year-old woman receiving estrogen replacement therapy over 2 years is 1 in 9925; over 10 years, it would be 1 in 397. For a woman taking estrogen plus a progestin, the comparable odds are 1 in 1241 for 2 years of use and 1 in 50 for 10 years.

Attributable risk is the difference between the two, or 0.252 per 100 women.
Benign Breast Disease and Risk of Breast Cancer

Benign breast lesions with an enhanced rate of proliferation or increased degree of atypical features predict an increased incidence of breast cancer over time. Some of these lesions contain genetic mutations, and many lesions are analogous to adenomas because of clonal populations of mutated cells. Hyperplastic ductal lesions are often multicentric, suggesting that some type of underlying abnormality or field defect is present that predisposes to such lesions. The multifocal nature of the associated benign hyperplastic lesions is most apparent in breast tissue from women with cancer. Examination of tissue adjacent to an invasive breast cancer or in the contralateral breast reveals one or more additional hyperplastic lesions in approximately 40% of patients.

The nature of the field defect has not been specifically identified, but hypothetically it may represent a single mutation of a gene controlling local estrogen production, cellular proliferation, DNA repair, metabolism of procarcinogens to carcinogens, or other cellular events. Preliminary data suggest progression from adenomas to frank neoplasms. Eighty to 90% of hyperplastic lesions contain DNA mutations similar to those in the contiguous tumors. Extensive molecular genetic studies have now shown progression of abnormalities in the spectrum of breast lesions.

A major consideration for women who present with breast problems is whether they have a higher than normal risk of breast cancer. Certain breast lesions, such as fibrocystic changes, are associated with no increased risk of subsequent breast cancer (see Fig. 39-5), whereas other lesions, such as atypical ductal hyperplasia, involve an increased risk. The relative risk of development of invasive cancer is increased 10-fold to 12-fold when ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) are present.
Estimating Breast Cancer Risk

To aid in assessment of breast cancer risk, a questionnaire developed by Gail and co-workers utilizes answers to seven questions to calculate the 5-year and lifetime risks of breast cancer. This model has recognized deficiencies, in that it does not consider breast density, plasma estradiol levels, bone density, BMI, weight gain in adulthood, second-degree relatives with breast cancer, proliferative lesions of breast other than atypical ductal hyperplasia, alcohol intake, or birth control pill and HRT use.

Nonetheless, two major prospective studies validated the Gail model in a high-risk (National Surgical Adjuvant Breast and Bowel Project [NSABP] prevention study) and in an average-risk population of women (the Nurses Health Study). The ratio of observed to expected cancers with this tool is 1.03 (95% confidence limits of 0.88 to 1.21) in the high-risk patients and 0.94 (95% confidence interval [CI] 0.89 to 0.99) in average-risk women, and both are highly statistically significant. This risk tool, called the RISK DISK, is available from the National Cancer Institute. When second-degree relatives with breast cancer represent the major risk factor, the Claus model is a more valid risk assessment tool.
Breast Cancer Risk and Clinical Decisions

Knowledge about underlying breast cancer risk influences advice given by health care providers and choices made by patients. Women known to be at high risk for breast cancer frequently choose a surrogate for estrogen (see later) to obtain its benefits while avoiding its risks. Those at low risk usually choose estrogen or an estrogen-progestin combination to relieve symptoms of estrogen deficiency or to prevent osteoporosis. Those at intermediate risk have several options, including use of a selective estrogen receptor modulator (SERM), other alternatives to estrogen, watchful waiting, or HRT.

As a working guide, we arbitrarily define risk categories on the basis of the Gail model:

- **High risk**, more than a 3% chance of breast cancer in 5 years
- **Intermediate risk**, 1.5% to 3% chance
- **Low risk**, less than 1.5%

Women classified as **high risk** include patients with a strong family history of breast cancer (particularly if associated with ovarian cancer), a prior history of atypical ductal hyperplasia or LCIS, and age older than 60 years when combined with early menarche, late menopause, or late first live birth. **Intermediate risk** patients have some risk factors but not others. **Low-risk** patients are younger than 60 years, have a late onset of menarche, early menopause, early age of first live birth, and no family history of breast cancer or prior predisposing breast lesions.

Because no formal risk tool incorporates breast density, bone density, or plasma estradiol levels in its assessment, a physician must take these factors into account in advising patients.
Prevention of Breast Cancer

Depending on their risk category, women may wish to take tamoxifen or raloxifene to prevent breast cancer. Only the antiestrogen tamoxifen is approved for this use in the United States. Although evidence supporting antiestrogens for prevention is substantial, results from individual studies are conflicting. Five clinical trials provided data regarding the efficacy of antiestrogens for prevention of breast cancer.\[72\]

The most definitive trial, the NSABP P-1 study, involved 13,388 women randomly assigned to receive either placebo or 20 mg of tamoxifen daily.\[72\] Eligibility for the study required an intermediate or high risk of breast cancer, defined in the study as a 1.67% or greater chance of development of a new breast cancer over a 5-year period. The rate of breast cancers was 9.4 per 1000 women-years in the placebo group versus 4.7 in the tamoxifen group, a relative risk reduction of 0.50.\[72\]

Two other published tamoxifen cancer prevention trials did not find a statistically significant reduction of breast cancer risk. Both studies were much smaller than the NSABP trial (2471 women in the United Kingdom study and 5408 women in the Italian study)\[72\] and are considered flawed because of concomitant estrogen use (the United Kingdom study) or frequency of oophorectomy (the Italian study).\[72\]

A fourth trial (Multiple Outcomes of Raloxifene [MORE]) involved more than 7705 women taking the antiestrogen raloxifene or a placebo.\[72\] Although breast cancer incidence was only a secondary study end point, a highly significant 70% reduction in new breast cancers (relative risk 0.30) was observed after 48 months of raloxifene use.\[72\] A fifth study examined the effect of tamoxifen on contralateral breast cancer in women with diagnosed DCIS and found a significant reduction.\[72\] Review of these prevention trials led a panel of experts commissioned by the American Society of Clinical Oncology (ASCO) to conclude that tamoxifen does reduce the incidence of newly diagnosed breast cancer in high-risk women.\[72\]

Tamoxifen in the breast cancer treatment setting is considered well tolerated and safe. However, for use in otherwise normal women, infrequent side effects and toxicity become more important. Up to 40% of women who start tamoxifen do not continue it because of perceived side effects, including depression and mood changes.\[72\] Tamoxifen belongs to the class of agents called SERMs. Agents in this class exert antiestrogenic effects on tissues such as breast but estrogenic effects on other tissues such as uterus and liver. These various actions of the SERMs must be factored in when estimating risks and benefits in the setting of breast cancer prevention.

To compare risks and benefits in a meaningful way, the NSABP data are expressed as the number of women per 100 with a specific benefit or adverse event after 5 years of study. With respect to benefits, new invasive breast cancers were prevented in 1.7 of 100 women, noninvasive cancers in 0.67, and bone fractures in 0.50, for a total of 2.87 in 100 benefitted after 5 years. Risks of tamoxifen are primarily related to its estrogenic effects on the uterus, a prothrombotic effect, and adverse effects on the lens of the eye. To estimate actual risks validly for a patient, one must correct for the underlying risks in the population under study. For that reason, analysis of adverse events includes determination of attributable risk and involves subtracting the underlying rate from the total observed with tamoxifen. This analysis indicates an excess of 1.5 of 100 women who experienced xerostomia, 0.69 with endometrial cancer (nearly exclusively in postmenopausal women), 0.27 with cerebrovascular accident (CVA), 0.25 with deep venous thrombosis (DVT), and 0.23 with pulmonary embolus, or a total of 2.94 per 100.\[73\] The new endometrial cancers were exclusively stage I and pulmonary emboli nonfatal. Neither risk nor benefit was observed regarding cardiovascular effects,\[73\] but the number of patients was not sufficient for statistical significance.

The increased incidence of uterine cancer in patients receiving tamoxifen presents a clinical management problem. Substantial study has been addressing how best to detect this cancer early.\[72\]\[73\]\[74\]\[75\]\[76\]\[77\]\[78\]\[79\]\[80\]

Transvaginal ultrasonography was initially proposed as a means of assessing both endometrial hyperplasia, as a precursor lesion, and early cancer. A prospective study demonstrated a mean increase in endometrial thickness from 3.5 ± 1.1 to 9.2 ± 5.1 mm in response to 5 years of tamoxifen. In 20% of women, endometrial thickness exceeded 10 mm or appeared suspicious for neoplasm. In this subset of women, biopsies revealed atrophy in 73%, polyps in 17%, and hyperplasia in 7.7%.\[81\] Endometrial thickness does not usually indicate hyperplasia but, rather, the presence of edema and dilated myometrial glands.\[81\] It should be noted that nonprospective studies reported a higher prevalence of benign polyps (5% to 55%) and hyperplasia (8% to 16%),\[81\]\[82\]\[83\]\[84\] but these are likely to overestimate resulting from selection bias.

On the basis of these studies, recommendations for screening include a yearly gynecologic examination with reservation of endometrial sampling and ultrasonography for patients with signs of abnormal vaginal bleeding.\[82\]\[84\]

Guidelines for Breast Cancer Prevention

Premenopausal women with a 5-year risk of breast cancer greater than 1.67% are candidates for tamoxifen unless they are at increased risk for DVT or pulmonary emboli. Postmenopausal women are candidates for this approach if they no longer have a uterus and lack a predisposing risk for DVT or pulmonary emboli. The decision to take tamoxifen should be made by the patient in partnership with her health care provider and based on a full discussion of individual risks and benefits expressed in absolute and not relative terms.\[84\]\[85\]

Critical Assessment of Breast Cancer Prevention Strategies

Estimates indicate that between 20 and 100 women (depending on underlying risk) must be treated to prevent one breast cancer. Clinical decisions depend on analysis of risk/benefit ratios and should be made after full discussion between health care provider and patient.\[86\] Regarding efficacy, available data demonstrate a reduction in newly diagnosed breast cancers. It is too early to assess overall survival. It is not known whether tamoxifen prevents breast cancer, cures some preexisting subclinical cancers, or delays the onset of small tumors. Mathematical modeling techniques suggest that the "preventive effects" are equally divided between blockade of growth of occult tumors and prevention of new ones.\[86\] Tumors whose growth was blocked by tamoxifen during 5 years of administration might
be expected to regrow later. For this reason, data on overall survival (to be available from ongoing European studies) are critically important.

Because reports indicate that both tamoxifen and raloxifene prevent breast cancer, it is expected that many women will ask their physicians about these two agents. The use of raloxifene exclusively for breast cancer prevention is not currently recommended. Although the MORE study demonstrated a reduction of breast cancers diagnosed in women taking raloxifene, breast cancer prevention was not a primary end point. The ongoing STAR (Study of Tamoxifen and Raloxifene) trial is currently testing the efficacy of tamoxifen versus raloxifene for breast cancer prevention.

Future studies are needed that utilize additional factors to select women at higher risk for development of breast cancer. A study of raloxifene examined women with factors suggesting high long-term exposure to estrogen (i.e., increased bone mineral density, high BMI, and high plasma estradiol levels). Results indicated that raloxifene was more effective in preventing breast cancer in women with high, long-term estrogen exposure than in those with low exposure (94% versus 56% for BMD; 82% versus 64% for BMI; and 77% versus 55% for estradiol levels, \(P < .005\)).
Treatment of Established Breast Cancers

In the year 2000, there were 184,000 new cases of breast cancer diagnosed in the United States and 41,000 deaths. The mechanisms whereby estradiol stimulates breast cancer growth are complex and involve direct regulation of genes involved in control of proliferation and apoptosis, induction of growth factors through secondary actions, and cross-talk between growth factor and estrogen pathways at both upstream and downstream levels. Nongenomic effects of estradiol on mitogenic pathways may also be involved. Treatment strategies utilize agents that abrogate the effects of estrogen on these pathways and thus inhibit growth and induce apoptosis.

Common approaches involve blockade of estrogen action with antiestrogens or estrogen synthesis with aromatase inhibitors or gonadotropin-releasing hormone (GnRH) superagonist analogues. Patients who initially respond to hormonal therapy eventually have relapses. The biologic mechanisms for this phenomenon are not fully understood. A standard situation is that responders to the first-line treatment benefit from second-ary and tertiary hormonal therapies upon relapse. The sequential responses to hormonal therapies suggest an adaptive process whereby tumors do not become totally resistant to hormonal therapy but develop a transitional state in which alternative means of blocking hormonal pathways cause tumor regression.

Patients who have relapses after oophorectomy or tamoxifen treatment commonly respond secondarily to inhibitors of estrogen production (aromatase inhibitors) or, rarely, to the withdrawal of tamoxifen. A hypothesis to explain this phenomenon is that these tumors become hypersensitive to lower amounts of circulating estrogen or to the estrogen agonist properties of tamoxifen. Experimental support for this concept comes from observations in xenograft models and in vitro studies. Breast tumor xenografts adapt to long-term exposure to tamoxifen by responding to it as an estrogen rather than as an antiestrogen. Under these circumstances, the pure antiestrogen ICI 182,780 (fluvestrant [Faslodex]) caused tumor regression. In an in vitro model system, long-term deprivation of estradiol rendered breast cancer cells hypersensitive to the proliferative effects of this sex steroid. This adaptive process is associated with increments in mitogen-activated protein (MAP) kinase, an enzyme that stimulates cell proliferation. The hypersensitivity concept may explain secondary responses to aromatase inhibitors in patients who have relapses after oophorectomy or tamoxifen and secondary responses to the pure antiestrogen Faslodex.
Development of Hormonal Resistance

Women respond to each hormonal therapy on average for 12 to 18 months and then experience relapse. At some time in their course, tumors become totally resistant to further hormonal therapy. Several explanations for development of resistance have been suggested, including:

2. Constitutive increase in growth factor production as a result of additional oncogene mutations.
3. Enhanced growth factor receptor functionality.
5. Outgrowth or selection of hormone-resistant clones of tumor cells.
6. Other adaptive mechanisms.
Prognostic Factors

Clinical decision making requires knowledge of the degree of aggressiveness and natural history of the diagnosed breast cancer. Numerous histologic types occur, and pathologic features provide information related to the prognosis. Much attention has been directed toward multivariate and neural network analysis to calculate the precise prognosis in individual women. In general, these methods have not been particularly useful in practical decision making and individual factors are used in treatment algorithms. \[158\] \[159\] \[160\] \[161\]

**Figure 39-7** illustrates the prognostic power of various biologic factors by comparing the effects of individual parameters on 5-year survival. \[141\] \[142\] \[144\] \[145\] The most powerful prognostic parameters are related to tumor size, invasiveness, nodal status, histologic grade and type, and hormone and human epidermal growth factor receptor 2 (HER2/neu receptor status) (see Fig. 39-7). Other less useful prognostic characteristics include DNA labeling index (LI), percent S phase, percent PCNA or Ki67 positivity (markers of proliferation), degree of aneuploidy, and overexpression of certain oncogenes or coactivators (e.g., D1 cyclin, A1B1, MAP kinase, Ras, HER3 and HER4, heregulin, c-Src, and ODC [ornithine decarboxylase] levels). \[149\] \[150\] \[152\] \[154\] \[156\] \[158\] \[160\] 

Finally, tumors diagnosed in postmenopausal women receiving HRT have a lower histologic grade and a 10% better prognosis than those in women not receiving HRT. \[160\] \[165\] \[166\]
Predictive Factors

Certain other biologic parameters allow assessment of the potential effectiveness of certain therapies. Older age, long disease-free survival, high degree of tumor differentiation, and prior response to endocrine therapy predict a higher likelihood of responses to hormonal therapy. The ability to measure receptors markedly improves the process of selection of patients for hormonal therapy. Absence of estrogen receptor (ER) in the tumor predicts that fewer than 5% to 10% of women will respond to hormonal therapy. If both ER and progesterone receptor (PR) are negative, an even lower percentage respond. Patients with both ER-positive and PR-positive tumors respond to hormonal therapy 50% to 75% of the time, whereas 30% to 50% of patients with ER-positive but PR-negative tumors are responsive. Preliminary but conflicting data suggest that patients with ER- and PR-positive tumors respond to hormonal therapy less frequently if HER2/neu is positive.

Receptor measurements are commonly performed by immunocytochemical analysis, which correlates well with ligand-binding assays. Immunocytochemical techniques measure only ER alpha and not ER beta, but 76% of ER alpha-positive tumors also contain ER beta (S. Fuqua, personal communication, 2001). Currently, it is not clear whether measurement of ER beta would provide important clinical information. Data suggest that certain tumors make ER beta variant proteins that can heterodimerize with full-length ER alpha or beta and exert dominant negative effects. This concept suggests that further refinement of receptor assays may improve their predictive value.

Predictive parameters for chemotherapy are more limited. Measurement of HER2/neu content predicts responses to trastuzumab (Herceptin), an antibody directed against HER2/neu. Preliminary data suggest that this also predicts which ER-positive patients will not respond to hormonal therapy. A concept proposed many years ago was that ER-negative tumors responded better to chemotherapy than ER-positive tumors because of the more rapid proliferation rate of ER-negative tumors. Although originally controversial, meta-analyses now demonstrate the positive predictive value of a negative ER for chemotherapy.
Hormonal Therapies for Breast Cancer: Mechanism of Action

Surgical Ablative Therapies

Historically, the initial approaches to hormonal therapy involved surgical removal of endocrine glands responsible for synthesis of estrogen or its precursors. In 1896, Beatson first demonstrated that oophorectomy caused regression of breast cancer in premenopausal women; comprehensive studies later documented responses in one third of patients. The availability of glucocorticoid replacement therapy in the 1940s enabled the use of adrenalectomy or hypophysectomy. These maneuvers produced similar rates of response as a result of a reduction in estradiol levels and perhaps also of pituitary factors in the case of hypophysectomy. The development of medical means to block hormone synthesis or action has largely replaced adrenalectomy and hypophysectomy but surgical oophorectomy persists.

Hormone Additive Therapies

Clinicians learned from empirical observations that high doses of estrogen, androgen, or progestins caused tumor regression. The mechanism whereby estrogens paradoxically inhibit tumor growth is unknown. This therapy is most effective in women who experienced menopause several years previously. A variety of observations suggest that an increased ratio of androgens to estrogens exerts an antagonistic effect on breast tissue. Progestins have glucoceptic actions that suppress circulating estrogen levels and can also act through progesterogen mechanisms.

Medical Ablative Therapies

Medical means of abating hormone secretion or action avoid the need for major surgery and can effectively replicate the hormonal and clinical effects of these procedures. High doses of GnRH agonist analogs act as agonists, with concomitant reduction in plasma estradiol. Physiologically, the pituitary requires pulsatile exposure to GnRH to maintain gonadotropin secretion. GnRH agonists suppress luteinizing hormone (LH) and follicle-stimulating hormone by exposing the pituitary to a continuous GnRH stimulus that causes a paradoxical gonadotropin inhibition. Preparations lasting 3 to 4 months can be given by intramuscular injection. For the first several days after initiation of therapy, an increase in LH, follicle-stimulating hormone, and estradiol occurs, but thereafter these hormones fall to suppressed levels.

Antiestrogens with Mixed Agonist-Antagonistic Actions

Blockade of estrogen action rather than synthesis provides an additional strategy. These agents, called antagonists, exert effects similar to those of surgical oophorectomy in premenopausal women and hypophysectomy or adrenalectomy in postmenopausal women. Tamoxifen, the initial antiestrogen of this type, was introduced for use in the United States in the mid-1970s. Early clinical observations indicated that this drug has an antiestrogen effect on breast tissue but an estrogen agonist effect on uterus, vagina, bone, pituitary gland, and liver.

Attempts to determine the divergent actions of tamoxifen led to an understanding of the complexity of ER-mediated transcriptional regulation and actions of the antiestrogens. Tamoxifen binds to both ER alpha and ER beta in the ligand binding domain (AF 2) of the receptor, which then facilitates the binding of the antiestrogen-ER complex to specific estrogen response elements on DNA. Conformational changes in the ER binding pocket at helix 12 induced by antiestrogens interfere with binding of coactivators to the ER but rather facilitate binding of corepressors to this area. The continued presence of corepressor in the complex is thought to explain the antiestrogenic properties of tamoxifen. The relative amounts of corepressor and coactivator in certain tissues and the presence of other unknown factors determine whether tamoxifen acts as an agonist or antagonist. Additional estrogenic effects are mediated by nongenomic actions at the cell membrane as well as by protein-protein interactions with c-Jun, specificity protein 1 (SP-1), insulin-like growth factor receptor, phosphatidylinositol-3-kinase (PI-3-kinase), HER2/neu, c-Src, and potentially other factors.

On the basis of the SERM concept, other agents have been introduced or are being developed to enhance breast antagonistic and bone agonistic properties. One of these, toremifene, is quite similar to tamoxifen although slightly less effective as an agonist to bone. On the basis of the SERM concept, other agents have been introduced or are being developed to enhance breast antagonistic and bone agonistic properties.

Pure Antagonist Antiestrogens

Clinical and experimental data suggested that long-term exposure to tamoxifen might induce tumors to undergo adaptive mechanisms to cause the agonistic properties of this SERM to predominate. On the basis of these observations, antiestrogens were developed that were devoid of agonist properties. Faslodex, the prototype drug, increases the rate of degradation of the ER and also inhibits estradiol-mediated transcription by favoring binding of corepressors to the Fastest-EOR complex.

Inhibitors of Estradiol Synthesis

Aromatase catalyzes the rate-limiting step in the conversion of androgens to estrogens. Aromatase has been a key target for development of inhibitors over the past 25 years. The first-generation inhibitor aminoglutethimide inhibited aromatase by 90% in postmenopausal women and was as effective as tamoxifen in causing breast tumor regressions. However, it blocked cortisol production and induced significant side effects. The efficacy of aminoglutethimide in postmenopausal women served as an impetus to develop second-generation and third-generation inhibitors.

Three third-generation agents (anastrozole, letrozole, and exemestane) are now approved drugs in the United States and Europe. These agents are 100-fold to 10,000-fold more potent than aminoglutethimide and are called selective aromatase inhibitors because they do not inhibit other enzymatic steps. The two major subclasses are nonsteroidal competitive inhibitors and steroidal enzyme inactivators. The competitive inhibitors bind to the active site of the enzyme with high affinity and compete with substrate. Aromatase inactivators bind covalently to the enzyme and permanently destroy its activity. Theoretically, the inactivators could have advantages over the competitive aromatase inhibitors because inhibition might continue if one missed one or more doses of medication and the degree of blockade could theoretically be superior.

Both classes of drugs reduce aromatase to 1% to 10% of baseline activity. Inhibitors substantially reduce plasma estradiol levels, and suppress tissue concentrations of this steroid in breast tumors. Because they lack estrogen agonistic properties, aromatase inhibitors do not increase the incidence of endometrial cancer, as occurs with tamoxifen. If they are used for long periods, one would expect acceleration of bone loss and perhaps cardiovascular disease as a result of total body aromatase inhibition. Studies evaluating these effects are ongoing. Preliminary data do not show adverse effects on lipid concentrations.
Chemotherapeutic agents destroy granulosa cells in the ovary and result in transient or permanent amenorrhea in premenopausal women. Complete ovarian destruction, as evidenced by the onset of amenorrhea, is more common in women older than 40 years as opposed to those younger (Fig. 39-9). Incomplete information is available regarding estradiol levels. The effect of chemical castration was not initially thought to be clinically important. However, there are data suggesting that adjuvant chemotherapy in premenopausal women exerts antitumor effects on receptor-positive tumors predominantly through an ovarian ablative effect.
Hormonal Therapies for Breast Cancer: Clinical Efficacy

Background

Nearly all patients with breast cancer undergo lumpectomy or mastectomy to remove the lesion and receive radiotherapy if it is warranted. High-risk patients then receive adjuvant therapy to destroy occult cancer cells at locoregional sites and distant micrometastases. Upon tumor recurrence, first-line, second-line, and third-line hormonal therapies or chemotherapies are then utilized for advanced disease.

Antiestrogens with Mixed Agonist-Antagonistic Actions

The overall benefit of tamoxifen is usually reported as the relative improvement in frequency of defined events such as tumor recurrence or survival. In both the adjuvant and advanced disease setting, tamoxifen results in a relative benefit of approximately 50%. However, a more useful parameter is the absolute benefit, defined as the number of women per hundred treated who benefit from taking tamoxifen. As illustrated in Figure 39-10, the more common the event, the more likely a woman is to benefit from tamoxifen.

When tamoxifen is used as adjuvant therapy, women with positive lymph nodes at the time of diagnosis experience approximately a 10% absolute reduction of tumor recurrence at 5 years and those with negative nodes experience a 5% reduction. Tamoxifen causes an absolute reduction of contralateral breast cancers of 2% at 5 years and prevents breast cancer in 1% to 5%, depending on the underlying risk (see Fig. 39-10). This antiestrogen is active in both premenopausal and postmenopausal women with breast cancer but only in those whose tumors are ER-positive or PR-positive, or both.

The optimal duration of use is 5 years. Direct comparative studies indicate superiority of 5 years versus 1 or 2 years of tamoxifen therapy, whereas 10 years of therapy provides no additional benefit over 5 years. Although tamoxifen is administered for only 5 years, benefit persists over the long term because disease-specific survival increases from approximately 6% at 5 years to 10% at 10 years in node-positive patients (Fig. 39-11).

Approximately 40% of women with advanced disease benefit from tamoxifen. Responses last 12 to 18 months on average before relapse. Efficacy is limited to those with tumors that are ER-positive or PR-positive, or both. Women with disease in soft tissue, bone, or viscera are the best candidates; chemotherapy is the more likely a woman is to benefit from tamoxifen. As illustrated in Figure 39-10, the more common the event, the more likely a woman is to benefit from tamoxifen.

Pure Antagonist Antiestrogens

Data regarding these agents are preliminary. A comparative study in 458 women with advanced disease demonstrated similar efficacy in patients treated with Faslodex and with anastrozole. Clinical benefit (i.e., complete objective response, partial objective response, and stable disease for 6 months) occurred in 44.5% receiving Faslodex and 45% receiving anastrozole. Further data are required to determine the relative place of Faslodex in the therapeutic armamentarium.

Aromatase Inhibitors

Previously, tamoxifen was considered the most effective hormonal agent for the treatment of breast cancer and progestins the next most effective. However, because of their potency and lack of side effects, the third-generation aromatase inhibitors (anastrozole, letrozole, and exemestane) are challenging these concepts for postmenopausal patients. Large and well-designed
trials have compared the relative efficacy of the third-generation inhibitors with that of other hormonal agents including tamoxifen.

Initial trials examined the efficacy of third-generation inhibitors in comparison with aminoglutethimide and demonstrated superior efficacy and side effect profiles with the newer agents. Next, head-to-head trials compared anastrozole and letrozole with megestrol acetate in the second-line setting. Anastrozole was associated with a greater duration of survival than megestrol acetate. Both anastrozole and letrozole were better tolerated than megestrol acetate. These findings moved the third-generation agents ahead of megestrol acetate into a role as second-line agents for advanced disease.

The next logical step involved a direct comparison with tamoxifen. Three large multicenter trials involving 1949 women compared anastrozole and letrozole with tamoxifen. All three followed a similar trial design and included postmenopausal patients with locally advanced or metastatic breast cancer. No women had received adjuvant tamoxifen within 12 months, and none were known to be ER-negative. In the North American trial, women experienced clinical benefit more frequently with anastrozole (59%) than with tamoxifen (45%) (P = .009). In the European trial, there were no differences in clinical benefit between therapies. The different results may be explained by the greater number of patients of unknown ER status in the European trial (95% versus 15%). When a post hoc, subset analysis of results for the ER-positive patients in the European trial was conducted, anastrozole again appeared superior to tamoxifen. The letrozole versus tamoxifen trial demonstrated superior effects in all.

parameters with objective response rates of 30% versus 20%, clinical benefit of 49% versus 38%, and median time to treatment failure of 9 versus 5.8 months (P < .0001 by log rank test). Pooled data indicate that tamoxifen was associated with DVT and pulmonary emboli (7.6% versus 4.5%) significantly more frequently than anastrozole. If one combines observations from all three trials, it appears that nausea, hot flashes, and gastrointestinal distress were comparable with either agent. A fourth but smaller study (238 patients) involving only ER-positive patients also demonstrated superiority of anastrozole over tamoxifen (P = .05).

Taken together, these trials provide evidence that the third-generation aromatase inhibitors are superior in efficacy and toxicity to tamoxifen in the advanced disease setting. Letrozole and anastrozole have now been approved in the United States as first-line therapy for breast cancer. These three large aromatase inhibitor trials showed for the first time in a head-to-head randomized trial that one endocrine therapy is superior to another. Before these studies, it was thought that the available endocrine therapies produced similar rates of response and could be distinguished only on the basis of side effects and cost. Direct comparisons of letrozole and anastrozole are now needed to determine whether one agent is superior to the other. This is particularly important because hormonal data suggest that letrozole may be more potent as an aromatase inhibitor than anastrozole.

At present, the choice of aromatase inhibitors over tamoxifen as first-line therapy for advanced disease is warranted but based on incomplete data. Comparisons of tamoxifen with the first-generation aromatase inhibitor aminoglutethimide demonstrated equal efficacy but a different pattern of cross-resistance. The aromatase inhibitors were efficacious if used after tamoxifen; in contrast, tamoxifen, when used after the aromatase inhibitors, appeared less effective. If this were true for the third-generation aromatase inhibitors, one might still wish to use tamoxifen as the first-line agent. However, preliminary data suggest that tamoxifen is effective after crossover from the aromatase inhibitor anastrozole. In a crossover comparison, 51% of 98 patients experienced clinical benefit from tamoxifen when used as a second-line agent after initial use of letrozole. By comparison, second-line letrozole after initial tamoxifen produced clinical benefit in 66% of 61 patients.

The aromatase inactivator exemestane is currently being tested as a first-line agent for treatment of advanced breast cancer. Preliminary data for 122 patients showed 44.6% objective responses (complete response and partial response) with exemestane and 14.3% with tamoxifen. Currently, exemestane is approved for clinical use in the United States as a second-line hormonal agent for treatment of breast cancer.

Androgens or estrogens are generally considered inferior to tamoxifen, aromatase inhibitors, and megestrol acetate. High-dose estrogen has been used sparingly since the advent of tamoxifen. However, a 20-year follow-up of a randomized comparison of tamoxifen with high-dose diethylstilbestrol (DES) reported a significant survival advantage in patients receiving the estrogen and lack of cross-resistance between these two therapeutic approaches. This surprising study suggests reconsideration of high-dose estrogen for selected patients.

Although still used in both the adjuvant and advanced disease settings, surgical oophorectomy may be replaced by use of GnRH agonists. Laparoscopic oophorectomy, however, may make this a more attractive approach. Prophylactic oophorectomy represented the first adjuvant endocrine therapy for breast cancer. Although it was initially thought to be ineffective, meta-analyses demonstrate a clear benefit with a 6% absolute survival advantage at 15 years for patients younger than 50 years of age. Because the receptor status of the patients in these trials was unknown, a large fraction of receptor-negative patients were probably included. One would expect better results if only hormone receptor-positive patients were so treated. In the advanced disease setting, surgical oophorectomy was clinically beneficial in approximately 50% of patients who were ER-positive or PR-positive, or both.

Emerging data support the use of medical oophorectomy in the adjuvant setting, and research emphasis focuses on this strategy. Demonstration of the effectiveness of prophylactic oophorectomy was surprising to the medical community and led to reconsideration of this approach, although with use of GnRH agonists rather than surgery. The goal of these studies has been to determine the efficacy of medical oophorectomy in patients who are exclusively ER-positive. Two studies in the advanced setting indicated that the GnRH analogues produce clinical effects similar to those induced by surgical oophorectomy. Accordingly, one would expect similar effects in the adjuvant setting. Preliminary results from a four-arm trial suggested that this may be the case. Benefit appeared to be greater in...
women younger than 45 years and with ER-positive tumors.

Further studies are required to determine whether the GnRH agonist approach is superior to the use of tamoxifen in this setting. Long-term studies have clearly shown the efficacy of tamoxifen as adjuvant therapy. Because four studies in the advanced disease setting suggested that tamoxifen is as effective as the GnRH agonists, these analogues may produce similar results in the adjuvant setting as well. Current studies are examining the use of GnRH agonists in comparison with chemotherapy in the adjuvant setting rather than with placebo (see "Chemical Castration"). Additional trials are needed to compare GnRH analogues with tamoxifen in this adjuvant setting.

Complete Estrogen Blockade

Medical oophorectomy alone has been compared with medical oophorectomy plus tamoxifen in the advanced disease setting. The rationale for the combined approach is to inhibit secretion of estradiol by the ovary and, at the same time, to block the action of residual estrogens of adrenal origin. This strategy, called complete estrogen blockade, appeared superior to tamoxifen alone in a single large trial and in a meta-analysis of four similar studies. The combined approach resulted in more frequent objective responses as well as improved progression-free and overall survival. This strategy has not yet been studied in the adjuvant setting and particularly in comparison with chemotherapy. Because premenopausal women in the United States are usually treated first with adjuvant chemotherapy, the approach of complete estrogen blockade needs to be explored in this setting.

Chemical Castration

Studies are ongoing to determine the mechanism of action of chemotherapy in premenopausal women. At least three possibilities exist: hormonal effects resulting from chemotherapeutic destruction of the ovary, direct cytotoxic effects on the tumor, or a combination of these two effects.

Eight trials have compared adjuvant chemotherapy with medical castration with and without tamoxifen in premenopausal women. The chemotherapy and hormonal therapies appeared to produce comparable antitumor effects. However, trends suggest that chemotherapy is more effective than medical castration in ER-negative patients and that medical castration is superior in ER-positive patients. These results suggest that at least part of the benefit of chemotherapy in premenopausal women results from chemical castration. These studies also provide further support for the benefit of medical oophorectomy in the adjuvant setting. The enhanced survival produced by chemotherapy compared with a placebo may be improved further by the effects of estriadiol deprivation.

Further support for the medical castration hypothesis comes from studies showing that chemotherapy is less effective in patients without complete cessation of menses. Although effects of varying chemotherapeutic regimens on ovarian function differ, nearly 100% of women older than 40 years experience permanent amenorrhea after adjuvant chemotherapy. From these data, it appears that comparisons of chemotherapy and endocrine therapy are not yet definitive. Further trials comparing medical oophorectomy alone with chemotherapy alone in receptor-positive, premenopausal patients are required. In the meantime, medical oophorectomy is a reasonable alternative to chemotherapy as adjuvant treatment for premenopausal women who are ER-positive or PR-positive, or both, and for various reasons are not candidates for chemotherapy.

Combination of Hormonal Therapy and Chemotherapy

On the basis of a meta-analysis, the combination of surgical or medical oophorectomy (GnRH agonists or tamoxifen) with chemotherapy provides additional benefit over chemotherapy alone in the adjuvant setting. The addition of the GnRH agonists might be particularly important for women younger than 40 years in whom estradiol remains in the premenopausal range after chemotherapy, as suggested by one trial.

New Approaches to Adjuvant Endocrine Therapy

Aromatase inhibitors may provide a means to block estrogen effectively without the emergence of estrogen agonistic effects in the adjuvant setting. Detrimental effects on vaginal mucosa, bone density, and cholesterol levels could result from deprivation of estriadiol.

A large ongoing trial is comparing tamoxifen alone, anastrozole alone, and the combination (Anastrozole and Tamoxifen Alone and in Combination [ATAC] trial). Preliminary data demonstrate statistically significant superiority of anastrozole with respect to recurrence-free survival and to number of new contralateral tumors. Subanalyses will compare potential detrimental effects on estrogen target organs such as bone, uterus, and liver. Other ongoing trials are examining sequential regimens with 2 to 5 years of tamoxifen and 2 to 5 years of an aromatase inhibitor with comparison of various inhibitors, dosages, and sequences. These results should be available in 3 to 5 years and should be helpful in suggesting optimal regimens.

Emerging Therapies

The concept of neoadjuvant chemotherapy has been adopted in clinical practice, and neoadjuvant hormonal therapy is now undergoing clinical trials. The rationale is to decrease tumor size before surgery to allow breast conservation. This type of therapy is selected for patients with tumors larger than 2 cm. A nonrandomized trial demonstrated an 81% reduction in tumor volume with letrozole versus 75% with anastrozole and 48% with tamoxifen. A randomized trial involving 324 patients compared letrozole at 2.5 mg daily with tamoxifen at 20 mg daily in women with ER-positive tumors larger than 2 cm. Letrozole resulted in a 55% rate of objective response (CR and PR) compared with 36% for tamoxifen (P < .001). Breast-conserving surgery was chosen by 45% of patients receiving letrozole and 35% receiving tamoxifen (P < .001). Approximately half of the patients experienced a sufficient reduction in size of the tumor to allow lumpectomy. Comparison of groups of patients treated conventionally and

with neoadjuvant endocrine therapy is required before recommendations regarding this approach are warranted.
Recommended Approaches to Hormonal Treatment of Breast Cancer

Adjuvant Therapy

Premenopausal Women

Current opinion recommends chemotherapy for premenopausal women with ER-positive tumors and the addition of tamoxifen for 5 years (Fig. 39-15) (Figure Not Available). A meta-analysis demonstrated statistically significant prolongation of survival with a combination of tamoxifen plus chemotherapy versus chemotherapy alone. Medical oophorectomy with or without tamoxifen could be considered as an alternative for women adverse to chemotherapy. 

Postmenopausal Women

Tamoxifen is the preferred adjuvant therapy for postmenopausal women with tumors larger than 1 cm that are ER-positive or PR-positive, or both. For some women, chemotherapy in combination with or followed by tamoxifen may be chosen. In younger postmenopausal women with more aggressive tumors, chemotherapy may be preferred but clinical trial data regarding this are incomplete. Information obtained from meta-analyses suggests that the combination of chemotherapy and tamoxifen may be preferable to use of tamoxifen alone, and this approach is often chosen. Early studies showed adverse drug-drug interactions between megalphan (L-Pam) and tamoxifen. However, this does not occur with CMF (cyclophosphamide [Cytoxan], methotrexate, fluorouracil) and CAF (Cytoxan, doxorubicin [Adriamycin], fluorouracil) regimens and chemotherapy and tamoxifen can thus be given concomitantly. The main consideration is whether the modest benefit accrued by adding chemotherapy is worth the additional toxicity encountered.

Small Tumors in Premenopausal and Postmenopausal Women

No randomized trial has examined the use of tamoxifen in women with tumors 1 cm or smaller in size. However, pooled data from four NSABP trials indicate a 4% absolute benefit in disease-free status and a 5% survival benefit for this group of women when given tamoxifen. Individual decisions are made on the basis of risk-benefit analysis, and not all women are offered this therapy.

Ductal Carcinoma in Situ

Adjuvant tamoxifen appears to provide benefit for women with noninvasive tumors (i.e., DCIS). In a large NSABP clinical trial, 13% of women treated with lumpectomy, irradiation, and placebo experienced a new tumor event over 5 years. One third of these new events involved appearance of a contralateral breast cancer, one third a new ipsilateral tumor, and one third local recurrence of the original tumors. Tamoxifen reduced these events in absolute terms by 5% with equal benefit in reducing new contralateral, ipsilateral, and original tumor events. Risk-benefit analysis is also required to advise patients appropriately; benefit is not judged to outweigh risks in all patients.

Decision Making

(See Fig. 39-15.) (Figure Not Available) An overview of these data suggests that all women with tumors that are ER-positive or PR-positive, or both, are potential candidates for tamoxifen as adjuvant therapy. In order to make a decision, one must determine whether the benefits of tamoxifen outweigh the risks in individual patients. From the NSABP prevention trial, the absolute risks of tamoxifen are known and include uterine cancer, cataracts, DVT, pulmonary emboli, and cerebrovascular accident. Presence of a uterus, a history of DVT or pulmonary embolus, or existing cataract would enhance these risks. Presence of larger or invasive tumors would enhance the absolute benefits of tamoxifen.

In general, most women with invasive tumors larger than 1 cm should be advised to take tamoxifen. Those with small or noninvasive tumors should be counseled on the basis of risk-benefit ratios. Those without a prior history of a thromboembolic event or cataract and with prior hysterectomy might be advised to take tamoxifen, particularly if they also have osteopenia. Raloxifene has not been used in the adjuvant setting and would not be advised for the patients discussed here.

Treatment of Advanced Disease

The majority of women who have advanced disease had previously received tamoxifen as adjuvant therapy. Those experiencing tumor recurrence while receiving tamoxifen or within 1 year of its cessation are considered resistant to this antiestrogen. For them, other hormonal therapies are chosen. In the other group of women, tumors recur more than 1 year after cessation of tamoxifen, and these patients are candidates for an additional course of tamoxifen. An algorithm can then be used to choose hormonal therapy for women considered candidates for tamoxifen (see Fig. 39-15) (Figure Not Available). For those resistant to tamoxifen, the next therapy in the sequential approach can be utilized.

Premenopausal Women

Aromatase inhibitors do not effectively inhibit ovarian estrogen production in premenopausal women, and tamoxifen (or toremifene) is usually considered first-line therapy for recurrent tumors. On the basis of current data, this might be combined with a GnRH analogue. If the initial therapy is tamoxifen alone, medical oophorectomy with use of a GnRH agonist analogue as second-line therapy would be recommended. Surgical oophorectomy can be substituted for the GnRH analogue. Aromatase inhibitors can be used if the GnRH analogue is continued. Megestrol acetate is then advised as additional therapy.

Postmenopausal Women

Data from trials comparing aromatase inhibitors with tamoxifen as first-line therapy for advanced disease suggest that aromatase inhibitors be considered the first choice of endocrine therapy. Responders would be treated with tamoxifen as second-line therapy upon relapse, but nonresponders would be treated with chemotherapy. Third-line therapy would utilize megestrol acetate and fourth-line therapy the aromatase inactivator exemestane. After this, high-dose estrogen or androgens might be chosen. If rapidly progressive disease develops at any time in this sequence, chemotherapy may be chosen instead of the next endocrine therapy.

Chemotherapy

The detailed management of breast diseases with chemotherapy has been addressed in the work of Ellis and colleagues.
Long-Term Quality of Life in Breast Cancer Survivors

With earlier diagnosis of breast cancer, an increasing percentage of women survive breast cancer in the long term. Two thirds of these women are menopausal at the time of diagnosis, and half of the premenopausal women undergo permanent ovarian failure as a result of chemotherapy. HRT is generally thought to be contraindicated in these women because estrogens may cause regrowth of residual tumor tissue after surgery or cause a second primary. Data from observational studies, however, do not provide evidence of a deleterious effect. Study of the safety of HRT in this setting is currently undergoing testing in a moderately large group of women in the Habits trial (a large, multi-institutional Scandinavian and European trial coordinated by Dr. Lars Hølmberg, Uppsala University, Sweden). Until the results are available, it is prudent to avoid estrogens in breast cancer survivors if alternatives to estrogen are effective.

As reviewed previously, effective agents are available to substitute for estrogen, including the following:

1. Bisphosphonates to prevent or treat osteoporosis.
2. Statins to prevent heart disease.
3. Selective serotonin reuptake inhibitors (SSRIs) to diminish the number and severity of hot flashes.
4. Low-dose vaginal estrogen for symptoms of urogenital atrophy.
5. SSRIs for depression thought to be related to estrogen deficiency.

Alternatives to HRT would not protect against Alzheimer’s disease or improve cognitive function; however, the benefits of estrogen to protect against Alzheimer’s disease have not been proven in randomized prospective studies and estrogens have not shown cognitive benefit in patients with Alzheimer’s disease. Yet, estradiol does provide cognitive benefit in non-Alzheimer’s patients. Some women, then, might wish to consider the use of HRT to prevent Alzheimer’s disease or improve cognitive function. If alternatives to estrogen are not satisfactory, women could receive HRT after a full discussion of the risks and benefits and with the informed consent of the patient.
Breast Cancer in Men

The incidence of breast cancer in men is 100-fold lower than in women with 1400 new cases in 2000 and 400 deaths. Risk factors include clinical disorders associated with reduced testosterone production or estrogen excess such as orchitis, undescended testes, testicular injury, Klinefelter's syndrome, chronic liver disease, and gynecomastia. The breast cancer susceptibility genes \textit{BRCA1} and \textit{BRCA2} are also believed to increase the risk in men. Breast cancer is suspected when a subareolar or upper outer quadrant, firm painless lesion is palpated. A diagnosis is then made by mammography and biopsy of the lesion. Most tumors are ER-positive, and patients are then treated by mastectomy and adjuvant tamoxifen. Later therapy may include aromatase inhibitors or progestins.
ENDOMETRIAL CANCER

Etiology

Approximately 36,000 new cases of endometrial cancer occur annually in the United States, and 6500 die of this disease. Relative risk factors are related to conditions causing overexposure to endogenous or exogenous estrogen. Enhanced tumor initiation and promotion mediated by the proliferative effects of estrogen occur as with breast cancer (see earlier). Progestins are antimitogenic to the endometrium, as opposed to breast tissue, and result in a decreased rate of cell proliferation. Thus, unopposed estrogen increases the risk of endometrial cancer and progestins reduce that risk.

Animal studies with raloxifene suggested that this SERM does not exert estrogen agonistic effects on the uterus, whereas tamoxifen does (see earlier). It is interesting that raloxifene, another SERM, did not cause an increase in endometrial cancer in a large study monitoring this as a safety parameter.

Use of tamoxifen as adjuvant therapy for breast cancer or prevention is associated with an increased risk of endometrial cancer as well as hyperplasia and polyps. Combination oral contraceptives containing both estrogen and a progestin decrease the risk. Multiple pregnancies also increase the duration of exposure to large amounts of estrogen, and use for less than 5 years, there was no increase in endometrial cancer risk. There is a trend, however, for an increase in endometrial cancer with longer term use of this continuous regimen. Beresford and co-workers reported a relative risk of 2.7 (95% CI 1.2 to 6.0) for current users of this regimen for more than 5 years, whereas Pike's group reported a relative risk of 1.09 (nonsignificant).

Caution should be advised concerning long-term use of such regimens. Sequential regimens in which a progestin is administered for less than 10 days are associated with an increase in risk of endometrial cancer. Pike and colleagues reported an increase in relative risk of 1.87 per 5 years of use (95% CI 1.33 to 2.65), and Beresford and co-workers reported a relative risk of 2.1 (0.9 to 4.7) for less than 5 years of use and 4.8 (95% CI 2.0 to 11.0) for more than 5 years of use. Taken together, these data suggest that progestins do not protect against estrogen-induced endometrial cancer unless taken continuously. In premenopausal women, oral contraceptives containing both estrogen and a progestin decrease the risk. Multiple pregnancies also increase the duration of exposure to large amounts of progesterone and decrease the risk of endometrial cancer.

Use of tamoxifen as adjuvant therapy for breast cancer or prevention is associated with an increased risk of endometrial cancer as well as hyperplasia and polyps (see earlier). It is interesting that raloxifene, another SERM, did not cause an increase in endometrial cancer in a large study monitoring this as a safety parameter. Animal studies with raloxifene suggested that this SERM does not exert estrogen agonistic effects on the uterus, whereas tamoxifen does.
Endocrinology of Endometrial Cancer

Most endometrial cancers contain appreciable levels of ER, whereas only differentiated ones generally have PRs. Tumors resulting from estrogen replacement therapy are generally well differentiated, have ERs and PRs, and are of low grade and stage. The diagnosis is suspected when unexplained vaginal bleeding is detected. Instillation of saline into the uterine cavity followed by ultrasonography can reveal an area of focal thickening that is shown by biopsy to be cancer. An associated finding is generalized thickening of the endometrial stripe to greater than 6 mm as a sign of concomitant endometrial hyperplasia. Any unexplained vaginal bleeding in a postmenopausal women requires such evaluation to rule out endometrial cancer.

Treatment

Treatment requires initial hysterectomy and bilateral oophorectomy in all patients. Patients at risk for vaginal spread are pretreated with brachytherapy implants in the vagina. Those with a poor prognosis (25% of patients) are treated postoperatively with brachytherapy implants or external beam radiotherapy. Upon recurrence, high doses of systemic progestagens may be used. Response to therapy is independent of age, site of metastasis, or previous or concurrent therapy. Two large gynecologic oncology studies reported that objective responses to a progestin occurred in 24% to 25% of patients.

The exact mechanism of tumor regression is unknown but may involve the following:

1. Direct effects on tumor cells.
2. Stimulation of the inactivating 17-hydroxysteroid dehydrogenase type I enzyme, which converts estradiol to estrone.
3. Inhibition of the production by the adrenal glands of androgenic estrogen precursors.
4. Down-regulation of estrogen receptors by progestagen.
5. Suppression of gonadotropin production in premenopausal women.

Experimental trials are ongoing to test the efficacy of aromatase inhibitors, antiestrogens, GnRH analogues, and combinations of these agents. Various chemotherapeutic regimens are also available for such patients.

Hormone Replacement Therapy in Endometrial Cancer Survivors

Patients with an excellent prognosis and disease-free survival for at least 1 year can be treated with HRT to relieve menopausal symptoms.
PROSTATE CANCER

Incidence

In the United States, 198,000 new cases of prostate cancer and 31,500 deaths were predicted in the year 2001. Black men have an age-adjusted relative risk of 1.73 (95% CI 1.23 to 2.45) compared with white men. The mortality of black men is nearly twice that of white men. Introduction of prostate-specific antigen (PSA) screening in the mid-1980s resulted in a tripling of prostate cancer detection rates between 1985 and 1997 from 96,000 per year to 334,500 per year. However, estimated case detection rates have gradually declined to 198,000 as the pool of previously undiagnosed patients has diminished. With the advent of PSA screening, 1 in 6.25 men will be diagnosed with prostate cancer during their lifetimes. As a result of PSA screening, 75% of patients present with organ-confined disease compared with only 25% before PSA screening.
Etiology

Environment, Diet

Environmental and dietary factors play a major role in prostate cancer etiology, as evidenced by epidemiologic data. Global incidence figures vary widely from 1.08 per 100,000 per year in China to 190 per 100,000 per year in the United States. Dietary or environmental explanations for this wide variance are likely. Japanese men who move to the United States have rates of prostate cancer that ultimately approach those of United States citizens. Differences in ingestion of high-fat diets, green tea, or soy products provide potential explanations for the divergent rates of prostate cancer among different populations. The incidence of premalignant prostate lesions and latent prostate cancer is the same in Japan and China as in the United States, whereas the rates of invasive cancer differ markedly. The additional mutations or promotional factors necessary to convert latent to invasive cancer apparently occur less commonly in Japanese and Chinese men living in Asia. In contrast, the initial mutation or mutations leading to latent cancer occur at the same rate. This observation suggests that environmental or dietary factors may influence the later additional mutations or tumor promotion more specifically.

Hormonal and Genetic Factors

Hormonal factors and particularly circulating androgens probably play a role in the initiation and promotion of prostate cancer. Prostate cancer rarely develops in men surgically orchiectomized before the age of 30 years, although this has been difficult to document in the published literature (P. Gann, Fang-Liu Gu, Peking University, personal communications). Genetic factors play an important role as well. Twin studies suggest a genetic component in 44% of patients with prostate cancer. Men with prostate cancer report a family history of this tumor 3.1 to 4.3 times more commonly than healthy men. The relative risk of prostate cancer is increased approximately twofold in men with one first-degree relative with prostate cancer. Specific genetic lesions resulting in prostate cancer are uncommon. The BRCA2 gene probably accounts for a small percentage of prostate cancer cases. An increase in the number of glutamine repeats in the variable region of the androgen receptor from germ line cells occurs in 10% of patients with prostate cancer. Data from a Utah pedigree identified another high-risk gene on chromosome 17p called ELAC2. Ross and associates suggested that the lower frequency of prostate cancer in Japanese and Chinese populations may be related to a lower level of 5-reductase activity than in their white counterparts, perhaps on a genetic basis. This may lead to lower levels of dihydrotestosterone (DHT) in prostatic tissue and less androgen-induced proliferation. However, direct isotopic kinetic measurements of 5-reductase activity in Chinese versus white men demonstrated no differences in the levels of this enzyme.
Early Case Detection

Until the introduction of PSA measurements, digital rectal examination (DRE), followed by biopsy, represented the standard screening procedure. Currently, PSA measurements detect cancers at a time when most are not palpable by DRE. The principle behind PSA screening is that tumors release more PSA into the bloodstream per gram of tissue than does tissue with benign prostatic hyperplasia or normal tissue. \[340\] PSA may be transiently increased by prostatitis, after endoscopic urethral manipulation, by prostatic biopsy, or to a lesser extent by ejaculation. Routine DRE has a minimal effect on PSA levels, but most physicians defer PSA testing until several days after this examination. \[341\]

The sensitivity of case detection with PSA is high but the specificity is low, and routine PSA screening has been controversial. In addition, there may be no advantage in detecting "latent" prostate cancers. \[347\] Attempts to increase specificity include use of age-related PSA normal ranges and PSA density (i.e., PSA divided by ultrasonographically determined prostate volume). Other methods to enhance specificity include PSA velocity (rate of increase in PSA over time), and percentage of free PSA. \[348\]

When free PSA was used in patients with borderline PSA values of 4.0 to 10.0 and a normal DRE, the rate of biopsy-proven prostate cancer increased from 8% to 20% to 56% with free PSA fractions of more than 25%, 15% to 20%, and 0% to 10%, respectively. \[351\]

Various professional societies have provided guidelines for PSA screening, but no general agreement exists. \[361\] Randomized trials to determine whether screening improves survival are not yet conclusive, \[363\] although one study demonstrated benefit. \[364\] A commonsense approach suggests screening only when test results would dictate diagnostic and therapeutic decisions. The patient should understand the consequences of a positive result and be willing to proceed with further diagnostic and therapeutic measures if the PSA findings are positive. \[364\] Accordingly, patients selected for screening should be those for whom definitive treatment or hormonal manipulations, and not watchful waiting, would be the likely choice if cancer were detected. \[364\] On the basis of this reasoning, informed consent of the patient is required before embarking on screening with PSA.
Evaluation of Abnormal Prostate-Specific Antigen or Digital Rectal Examination Findings

If the PSA is elevated to greater than 10 ng/mL or the DRE is abnormal, transrectal ultrasound-guided biopsy is indicated. An algorithm for those with PSA values between 4 and 10 has been described. Common practice involves obtaining biopsy specimens of ultrasound-detected hypoechoic lesions as well as "blind" biopsies.

Clinical staging of prostate cancer provides a means of determining the prognosis and is used for making treatment decisions. Two analogous systems have been used in the past, but the Tumor-Node-Metastasis (TNM) classification is now preferred.
Endocrinology of Prostatic Cancer Growth

DHT, the 5-reduced product of testosterone, binds to androgen receptors with 2.5-fold higher affinity than testosterone itself and serves as the major regulator of prostatic tumor growth. Direct effects of androgen, indirect effects induced by stimulation of growth factors, or a combination of these two mechanisms may mediate androgen-induced proliferation.\(^\text{[371]}\) Approximately 7000 µg of testosterone is secreted daily by the testes, of which 500 µg is converted into DHT in various peripheral tissues.\(^\text{[371]}\) The adrenal gland provides an additional 5% of the androgen produced in adult men.\(^\text{[372]}\) Testosterone as well as preandrogens such as androstenedione, dehydroepiandrosterone (DHEA or alternatively DHA), and DHEA sulfate (DHEAS) originate in the adrenal gland and are also converted in peripheral tissues into DHT. In addition to peripheral conversion, a large fraction of the DHT present in benign and malignant prostatic tissue is produced locally in the prostate gland from circulating precursors. Approximately 40% of prostatic DHT originates from steroids of adrenal origin.\(^\text{[373]}\)

Prostate cancer cells contain androgen receptors that bind DHT and transmit proliferative signals in androgen-dependent prostate cancer.\(^\text{[374]}\) As opposed to the use of receptor assays in breast cancer, measurement of the androgen receptor does not provide predictive information regarding hormone responsiveness. Mutations of the androgen receptor occur, but the frequency in primary prostate cancer is controversial.\(^\text{[375,380]}\) An early study found a 30% incidence of androgen receptor mutations in primary prostate cancers.\(^\text{[376]}\) Others have found a much lower frequency ranging from 0% to 5%. All investigators found mutations in metastatic disease ranging from 21% to 50%.\(^\text{[377]}\) The frequency and type of mutation appear to be influenced by the selective pressure exerted by antiandrogens. For example, 5 of 16 men receiving flutamide had mutations compared with 1 of 17 not receiving flutamide.\(^\text{[380A]}\) Most of these cases involved a mutation at amino acid 877, the site involved in LnCAP cells (a type of prostate cancer cell model named for Ln [lymph node] Ca [carcinoma] P [prostate]), which allows flutamide to become an androgen agonist. This finding may explain the occurrence of flutamide withdrawal responses in men with prostatic cancer (see later).\(^\text{[378,380]}\)

\[\text{Figure 39-17} \quad \text{Diagrammatic representation of the endocrinology of prostate cancer growth. Androgens are directly secreted by the testes into the circulation, are synthesized in peripheral tissues from steroidal precursors, and are formed directly in the prostate gland. AR, androgen receptor; DHA, dehydroepiandrosterone; DHT, dihydrotestosterone; HRE, hormone response element. (From Denis LJ, Griffiths K. Endocrine treatment in prostate cancer. Semin Surg Oncol 2000; 18:5254. Published with permission of Seminars in Surgical Oncology.)}\]
Decisions Regarding Treatment

One of three strategies can be chosen for treatment of prostate cancer: watchful waiting, hormonal manipulation, or definitive (curative) therapy. The first decision after a diagnosis of prostate cancer is whether to recommend therapy or to advise watchful waiting. The underlying principle in decision making is that some prostate cancers are latent. The term latent prostate cancer has been applied to small lesions, generally smaller than 0.5 cm in volume, that do not progress and do not result in cause-specific death.\(^3\)

In older men with other medical conditions, the risks of definitive therapy may outweigh the benefits, particularly if latent disease is present. Only a small percentage of men with limited disease die of prostate cancer each year after diagnosis (Fig. 39-18), and those with a limited expected life span because of other diseases may die with prostate cancer and not because of it. In general, watchful waiting is reserved for patients in older age groups (older than age 70 years) and those with a low stage and grade, localized disease, and a life expectancy of less than 10 years.\(^3\) A reasonable working construct is that the younger and more healthy the patient, the more likely the benefit from definitive therapy. Prognostic factors that can be used to assess aggressiveness include tumor stage and tumor grade, as assessed by the Gleason score, and PSA.

Several competing approaches have been developed for definitive therapy. Radical prostatectomy with nerve sparing is one option. A risk stratification tool developed to assess the likelihood of recurrence after this procedure includes the initial PSA level and Gleason score. Low-risk patients (initial PSA < 10 and Gleason score equal to or less than 6) had a 5-year relapse-free survival of 81% versus 40% for high-risk patients (PSA > 10 and Gleason score greater than or equal to 7). Conventional radiation, three-dimensional conformal radiation, or brachytherapy techniques provide other alternatives. Patients are informed of the various treatment modalities, and a participatory decision is made on the basis of the best expected outcome. The younger and healthier the patient, the more reasonable is the recommendation of radical prostatectomy. An experimental therapeutic option for locally advanced disease that avoids surgery and radiation involves monotherapy with an antiandrogen. The concept is that hormonal therapy shrinks the primary tumor and prevents metastatic spread. Preliminary reports of three exploratory studies of antiandrogens in the setting of previously untreated locally advanced disease have appeared. These studies compare antiandrogens not with prostatectomy or radiation but with castration. Pooled mature data suggested no survival difference between bicalutamide at 150 mg daily and surgical castration in this setting.\(^1\)

Another large study recruited 1453 men with confirmed metastatic disease or T3 to T4 disease with elevated PSA into two trials comparing castration with bicalutamide. Pooled data demonstrated decreased efficacy of bicalutamide with respect to survival (hazard ratio 1.3). Taken together, these data suggest that bicalutamide is not as effective as castration. Even though antiandrogen monotherapy is not as effective as castration, some men may choose this therapy in preference to watchful waiting.
Neoadjuvant Hormonal Therapy

Neoadjuvant therapy is defined as use of hormonal therapy before definitive treatment and involves (1) medical castration with GnRH analogues, (2) steroidal or nonsteroidal antiandrogens, or (3) a combination.

Radical Prostatectomy

Neoadjuvant strategies used for 3 to 6 months prior to radical prostatectomy resulted in an increase in organ-confined cancers and decrease in positive surgical margins. However, no differences in PSA-detectable relapse rates have been observed in several trials. Data are not yet sufficiently mature to assess overall survival rates. However, the efficacy of this maneuver is still undetermined because longer follow-up is needed before definitive conclusions regarding overall survival can be reached.

Radiation Therapy

Radiation Therapy Oncology Group (RTOG) trial 86-10 examined the role of neoadjuvant endocrine therapy prior to radiation. The incidence of local progression at 5 years was 46% for patients with T2 to T4 tumors receiving adjuvant hormonal therapy and 71% for those receiving radiation alone \((P = .001)\), but no difference in overall survival was noted.
Adjuvant Hormonal Therapy

Therapy given with the initial definitive treatment and before evidence of recurrence is termed adjuvant hormonal treatment. Two large multicenter trials provided evidence of the efficacy of this approach. An RTOG study involved patients with stage T3 and stage T4 disease given radiation therapy followed by medical castration with goserelin starting in the last week of radiation. Disease-free survival at 5 years was 60% for the goserelin arm and 44% for radiation alone (P < .0001). Only the subset of men with Gleason grade 8 to 10 tumors experienced a survival benefit from 55% to 66% (P = .03).

In a similar trial of the European Organization for Research and Treatment of Cancer (EORTC), the 5-year disease-free survival was 85% in the adjuvant hormone-treated group (goserelin) versus 48% in the group given radiation alone (P = .001). Overall survival was 79% for the adjuvant hormonal group versus 62% for the radiation-alone group, and this difference was statistically significant (P = .001).

The majority of data favor the use of adjuvant hormonal therapy in patients undergoing radiation therapy as definitive treatment for prostate cancer. An analysis of pooled data from the RTOG neoadjuvant and adjuvant trials concluded that the key consideration may be the necessity for long-term rather than short-term hormonal therapy in either the neoadjuvant or adjuvant therapy approach. In men receiving short-term hormonal therapy (goserelin and flutamide for 2 months before and 2 months after radiotherapy), statistically significant improvements were observed for two end points, distant metastasis-free and evaluable disease-free intervals, but not for overall survival. Only long-term adjuvant therapy improved overall survival and only in the subset of men with Gleason grade 7 to 10 tumors. These conclusions concerning long-term versus short-term adjuvant hormonal therapy were supported by a nonrandomized Canadian trial.

In a large ongoing study, men are randomly assigned to placebo or 150 mg of bicalutamide daily after radical prostatectomy or radiotherapy or during watchful waiting. A total of 8055 patients have been entered. Bicalutamide significantly reduced the incidence of disease progression by 42% (hazard ratio 0.58, 95% CI 0.51 to 0.66, P < .0001). This encouraging result needs to be confirmed with respect to overall survival.
**Immediate versus Delayed Hormonal Therapy**

Approximately 25% of men now present either with metastatic (M+ or stage D) disease or with local spread into lymph nodes (N+). Whether to initiate hormonal treatment immediately in these patients or to defer treatment until symptoms occur is a major question. Because cure with hormones is not possible, the two goals of treatment are to increase life expectancy and to relieve symptoms. If treatment is advocated for asymptomatic patients, it should improve their length of survival.

Rigorously controlled series from the Veterans Administration Cooperative Urological Research Group (VACURG) trials during the 1960s indicated no clear survival benefit from endocrine therapy in patients with stage C or D disease at the time of diagnosis. On the basis of these findings, standard practice usually involved withholding hormonal therapy until symptomatic metastatic (stage D) disease was present. However, two later studies provided evidence favoring therapy immediately upon detection of metastatic disease.

Messing and colleagues studied men with prostate cancer found to have positive pelvic lymph nodes at the time of radical prostatectomy. They randomly assigned these men to an immediate therapy group (medical or surgical orchiectomy) or to a group observed until an indication occurred. Death from prostate cancer occurred in 3 of 47 men in the immediate treatment group and 16 of 51 in the deferred group (P < .01).

In another study, 934 men with locally advanced prostate cancer or with asymptomatic metastatic disease were randomly assigned to immediate or deferred hormonal therapy. There were 203 deaths from prostate cancer in the immediate therapy arm and 257 in the deferred group (P = .02). There were fewer cases of spinal cord compression (9 versus 23) and pathologic fracture (11 versus 21) in the immediate treatment group.

Other evidence of efficacy comes from nonrandomized studies from the Mayo Clinic that demonstrate a statistically significant survival advantage for early endocrine therapy (castration) in men with stage D1 (T0 to T3, N1 and N2, M0) disease. Seventy-three patients underwent either radical retropubic prostatectomy or radical prostatectomy plus orchiectomy. An advantage of immediate adjuvant therapy was demonstrated in that 5-year survival rates were 93% in the immediate orchiectomy group and 80% in the deferred orchiectomy group. In another study, a benefit was seen only in patients with diploid and not in those with tetraploid or aneuploid tumors.

Finally, a subset analysis in the RTOG 85-31 study examined a group of 139 men with capsular penetration or seminal vesicle involvement. Seventy-one men received radiation therapy plus luteinizing hormone-releasing hormone (LHRH) agonist therapy and 68 received radiation therapy alone. A statistically significant improvement in progression-free survival and freedom from biochemical relapse (i.e., PSA) was observed in the LHRH group. Overall survival was not statistically significantly different in this relatively small subset of men with follow-up for only a median of 5 years.

Taken together, these data suggest, but do not prove, that immediate hormonal therapy may be efficacious for asymptomatic men presenting with lymph node spread. The data at present do not provide definitive evidence that early endocrine therapy is beneficial regarding survival of patients presenting with metastatic (M+) disease, but evidence from one study is suggestive.

Men who experience a rising PSA (biochemical failure) after an initial fall to undetectable levels following radical prostatectomy may also benefit from hormonal therapy. Data indicate that a rapid rise in PSA suggests the presence of metastatic disease, whereas a slow rise suggests local recurrence.

In a single small study, 68% of men progressed to detectable clinical disease upon observation for a median of 19 months. With adjuvant hormonal therapy or radiotherapy, the rate of progression to clinically detectable disease decreased to 21%. Use of the capromab pendetide (ProstaScint) radioisotopic scan has been advocated to identify patients with distant metastatic disease under these circumstances. Such patients would not be considered candidates for salvage radiotherapy to the pelvis.
Choice of Endocrine Treatment for Initial Disease

Which endocrine therapy to use initially is a major question. Surgical orchietomy produces a rapid decrease in serum androgen levels, does not require the patient's long-term compliance, and is effective in inducing tumor regression in nearly 90% of patients. The clinician can be assured that testicular androgens are completely suppressed. However, nearly 50% of men in the United States prefer medical castration \[434\] as a means to avoid surgery.

Highly potent agonist analogues of GnRH, called superagonist analogues, have been approved for use in prostate cancer and effectively produce a medical orchietomy. These compounds paradoxically inhibit LH secretion by the pituitary gland and thereby suppress testicular testosterone production. Clinically, the GnRH agonists stimulate LH threefold to fourfold and testosterone twofold for 1 to 2 weeks from initiation of therapy. Thereafter, LH is profoundly depressed and the plasma testosterone level falls from approximately 500 ng/dL to a castration level of 15 ng/dL. No escape from inhibition occurs for up to 2 years of continuous therapy.

The initial rise in testosterone causes a transient disease flare in 5% to 10% of patients. This flare produces an objective increase in tumor size in approximately 3% of patients and a subjective increase in bone pain in the remainder. Although tumor flare \[395\] \[397\] is usually transient, severe reactions with spinal cord compression or death have been observed in occasional patients. For this reason, it is necessary to administer an antiandrogen for the first month after starting GnRH agonist therapy. \[394\] GnRH agonist analogues are now in clinical trial as a means to abrogate this problem. \[435\]

The rationale for using GnRH agonists is to induce a medical castration selectively and without unwanted side effects. Testosterone and DHT levels in patients treated with GnRH agonists and with surgical orchietomy fall to a similar extent. \[429\] Hormonal effects with the GnRH agonists are selective with no alterations of adrenal, thyroid, parathyroid, or pancreatic function. Objective regressions occur as frequently as with orchietomy. The efficacy of medical castration is equal to that observed with surgical castration or use of DES. \[397\] \[430\]

Initially, a major problem with GnRH agonist therapy was the requirement for daily subcutaneous administration with the possibility of noncompliance with daily injections and incomplete androgen suppression. \[395\] Third-generation formulations are now available that allow injections at 3- or 4-month intervals. These biodegradable preparations appear highly effective and are well tolerated and acceptable to patients. The frequency of tumor regression or stabilization does not appear to differ in patients treated with orchietomy or long-acting GnRH agonists. \[398\] Because some androgen-responsive cells remain in prostate tumors after relapse with the GnRH agonists, continued GnRH agonist treatment is advocated when disease relapse occurs and preferably for the remainder of the patient's life.

Monotherapy with antiandrogens provides an alternative to surgical or medical castration. These agents can be subclassified as steroidal and nonsteroidal antiandrogens. The nonsteroidal agents, flutamide and bicalutamide, bind to androgen receptors and block the cellular effects of circulating testosterone and DHT on cell proliferation. Interruption of the androgen negative feedback system results in reflex increments in serum LH, testosterone, and DHT levels. Studies with antiandrogens suggested that these agents preserve erectile function. More recent data suggest that only 20% maintain morning erections and sexual activity, \[397\] but this is still higher than after castration (18% reduction with bicalutamide versus 37% with castration). \[395\] Side effects include hot flashes and diarrhea, particularly with flutamide. \[394\] Long-term effects on bone density require more detailed study.

Randomized trials have compared antiandrogens as monotherapy with medical or surgical castration. \[395\] \[397\] Initial studies showed that 50 mg of bicalutamide is not as effective as orchietomy. \[395\] \[397\] Later studies compared 150 mg of bicalutamide with medical or surgical castration in patients with locally advanced (T1 to T4, N+, M0) and metastatic (T1 to T4, N+, M0) disease. Bicalutamide was equivalent to medical or surgical castration for locally advanced \[399\] but not metastatic disease (hazard ratio for survival of 1.3). \[397\]

Another study examined whether 150 mg of bicalutamide was the equivalent of maximal androgen blockade (MAB) in the setting of locally advanced or M1 disease. In this study of Boccardo and colleagues, \[395\] bicalutamide was as effective as MAB for locally advanced (T1 to T4, N+, M0) disease but not for metastatic disease (M0). Taken together, these data suggest that antiandrogens as monotherapy may not block androgen effects as effectively as medical or surgical castration.

Administration of high-dose estrogen in the form of DES has been used as a treatment for prostate cancer since the 1940s. In the VACURG studies, 5 mg of DES decreased the rate of recurrence of prostate cancer but increased the cardiovascular death rate. \[395\] \[397\] After this observation, careful doseresponse studies indicated that 3 mg of DES daily minimizes the risk of cardiovascular disease acceleration and maximizes the beneficial effects on prostate cancer. Gynecomastia and impotence are the major side effects.

Comparison of these monotherapies was the subject of a meta-analysis involving 10 separate trials. It was concluded by the Technology Evaluation Center, an agency of the Agency for Health Care Policy and Research, \[394\] that orchietomy, GnRH agonist analogues, and DES produced equivalent survival in men and that no differences existed among the various GnRH analogues that are available.
Complete Androgen Blockade

A more comprehensive strategy for the endocrine treatment of prostate cancer has been proposed. The rationale for complete, or maximal, androgen blockade (CAB, complete androgen blockade; MAB, maximal androgen blockade) rests upon three considerations:

1. The adrenal glands contribute 5% of the total androgen pool.\(^{(372)}\)
2. The concentrations of DHT in prostate cancer tissue of patients fall by only 50% to 80% after surgical orchiectomy\(^{(373)}\) and DHT levels in that tissue after castration are still higher than in nonandrogen target tissues (Fig. 39-20).\(^{(427)}\)
3. In vitro systems demonstrate that some tumor cell clones are hypersensitive to the proliferative effects of androgen.\(^{(441)}\)

On the basis of these considerations, inhibition of both testicular and adrenal androgens (MAB) might be more effective than inhibition of testicular androgens alone (testicular androgen suppression).

Forty-six studies have examined the concept of MAB as initial endocrine therapy for advanced disease (stage D or Tx Nx M+ disease) in randomized trials, but the results and conclusions drawn from the studies are conflicting.\(^{(371)}\)\(^{(442)}\) However, a meta-analysis involving nearly 90% of men treated worldwide provided several definitive conclusions and reasons for discrepancies among prior results:\(^{(443)}\)

1. MAB regimens using nonsteroidal antiandrogens provide a 2.9% improvement in overall survival from 24.7% to 27.6% at 5 years (Fig. 39-21).\(^{(446)}\) This difference is statistically significant (\(P = .005\)) but of marginal significance clinically.
2. MAB regimens using the steroidal antiandrogen cyproterone acetate produce adverse survival effects compared with testicular androgen suppression.
3. Analyses of studies of MAB that pool patients treated with either cyproterone acetate or nonsteroidal antiandrogens demonstrate no survival benefit produced by MAB over testicular androgen suppression.
4. Men with disease limited to the axial skeleton did not gain more benefit from MAB than those with metastases to the appendicular skeleton. A large prior study had reported this to be the case.\(^{(444)}\)
5. Results were similar when subsets of men treated with surgical or medical castration or with flutamide or nilutamide were examined.

Past controversies about MAB can be explained by fact that some trials used cyproterone acetate, an antiandrogen that shortens survival in these patients.\(^{(443)}\) Other trials did not use a short-term antiandrogen in the medical castration group, and the disease flare may have compromised overall efficacy. Finally, early trials used daily GnRH injections, which may not have induced effective medical castration because of the need for compliance with daily injections for 5 years.

It should be noted that no properly designed study has compared MAB with sequential androgen blockade (defined as initial castration followed by antiandrogen upon relapse). In the largest study of MAB,\(^{(445)}\) the use of antiandrogen upon relapse in the placebo group was left to the investigator’s discretion and only 50% of men in the placebo arm later took an antiandrogen. For this reason, there is no information about whether antiandrogen therapy given at the time of relapse after medical or surgical orchiectomy (i.e., sequential androgen blockade) is as effective as MAB. This is an important issue because flutamide given upon relapse after castration (sequential androgen blockade) resulted in objective benefit in 23% of patients.\(^{(446)}\)

On the basis of the data presented and the additional considerations discussed, this author and others favor the sequential androgen blockade strategy and use of antiandrogens only after relapse from medical or surgical orchiectomy.\(^{(445)}\) However, if GnRH agonists are used to produce a medical orchiectomy, short-term use of an antiandrogen to prevent disease flare is necessary.\(^{(447)}\)\(^{(448)}\)

Secondary Hormonal Therapy

Men who experience cancer recurrence after medical or surgical orchiectomy are treated with secondary hormonal therapies. Before the use of PSA measurements, the clinician had to rely on bone radiographs and soft tissue changes to document responses and these were rarely observed. Consequently, the efficacy of secondary hormonal therapies was controversial. Clinicians have now accepted a 50% decline in PSA as reflecting an objective response to therapy. Studies have shown that this PSA end point predicts a significantly prolonged median overall survival, objective progression-free survival, and time to pain progression. Using PSA measurements, it is now possible to demonstrate the efficacy of a number of secondary hormonal therapies. Responses to antiandrogens, ketoconazole, flutamide, bicalutamide, aminoglutethimide, DES, and glucocorticoids alone range from 14% to 60% (Table 39-2). Head-to-head comparisons are unavailable for these agents, and relative efficacy cannot be compared.
Experimental studies with LnCAP cells in vitro detected a mutation in the androgen receptor in this cell line that caused it to respond to flutamide with increased proliferation. As a result of this observation, clinical studies examined whether tumors in some patients might adapt to flutamide by developing mutations, allowing flutamide to behave as an androgen agonist. In support of this possibility, approximately 40% of men receiving flutamide experienced tumor regression after withdrawal of flutamide (so-called withdrawal responses). These data suggest that a first step in patients receiving flutamide, either as part of a complete androgen blockade regimen or as secondary hormonal therapy, is to stop flutamide. These responses occur with bicalutamide as well but with lower frequency.

Other Secondary Hormonal Therapies

Prior to the PSA era, objective regression, stabilization, or symptomatic relief was reported with several agents. These included a high-dose formulation of DES called Stilphostrol and tamoxifen. A subsequent study using high-dose tamoxifen (160 mg/m² per day) observed only a 3.3% rate of objective response on the basis of PSA in heavily pretreated men with prostate cancer. Each of these agents could be considered for patients who have slow relapses after castration.
Experimental Hormonal Approaches

Experimental data for Shionogi tumors in mice suggest that intermittent androgen withdrawal might control tumor growth and delay development of hormonal resistance. Several pilot reports suggest the feasibility of this approach, and observations are ongoing. This approach cannot be recommended until sufficient data are available to support its efficacy. Another approach undergoing extensive testing of efficacy is PS SPES, an herbal supplement.
Development of Androgen-Independent Tumor Growth

At some point in the patient's course, the tumor becomes refractory to hormonally based therapies. Current theory holds that tumors escape androgenic regulation of growth and co-opt mechanisms utilizing ligand-independent activation of androgen receptors, up-regulation of growth factor pathways, or a combination of these mechanisms. Considerable experimental support for these concepts derives from the demonstration of increased activated MAP kinase activity (a protein that mediates mitogenesis) and enhanced phosphorylation of the androgen receptor, a marker of ligand-independent receptor activation.

A major decision at the time of prostate cancer relapse after medical or surgical castration is whether to use hormonal therapy or chemotherapy. No diagnostic test is available to make the distinction between hormone dependence and independence. Men with a rapid downhill course with widespread systemic metastases should probably receive chemotherapy. Others have already been treated with all available options of endocrine therapy. Chemotherapy or combination chemohormonal therapy is chosen at that point. The choice of agents is beyond the scope of this chapter, and the interested reader is referred to the comprehensive treatise of Carroll and colleagues.
Algorithm for Treatment of Prostate Cancer

To date, no standard approach to the treatment of prostate cancer has been universally accepted. To outline the options available, the algorithm in Figure 39-22 details decision branch points and currently accepted approaches with asterisks to indicate therapies that are controversial.

Initial Treatment of Nonmetastatic Prostate Cancer

No consensus exists regarding the selection of radical prostatectomy, radiation therapy, or watchful waiting. Patients with potentially curable, nonmetastatic (T1 to T3, N0, M0; stages A to C) prostate cancer are commonly treated by radical prostatectomy, radiation therapy, or watchful waiting. Individual considerations, including age, risk factors for recurrence, and overall health of the patient, influence these decisions, which are often based on personal choices. In general, the younger and healthier the patient, the more likely is a choice of radical prostatectomy. The older and more debilitated the patient, the more likely is the choice of watchful waiting. Radiotherapy is often selected for patients falling at neither extreme.

Patients with T1 to T3, N0, M0 (stages A to C) prostate cancer are commonly treated with radical prostatectomy. Neoadjuvant or adjuvant hormonal therapy is not usually recommended for these patients. Upon first recurrence, these men are then treated with either medical or surgical orchietomy.

In men undergoing radiation as definitive treatment, adjuvant hormonal therapy appears to be warranted. Neoadjuvant therapy has not been adequately tested in a trial in which this step is added to long-term adjuvant therapy. Nonetheless, neoadjuvant therapy would appear reasonable on the basis of the minimal additional toxicity and side effects associated with this therapy for an additional 3 to 6 months before radiation therapy.

Watchful waiting is selected for men whose other illnesses would be expected to result in demise before death related to prostatic cancer.

Initial Therapy for Men with Metastatic Disease at Time of Diagnosis

Men with metastatic disease (T1 to T4, N+, or M+) at presentation are not treated definitively with radical prostatectomy or irradiation but are frequently offered hormonal therapy before the development of symptomatic disease. This decision is based on incomplete data suggesting superior efficacy of early rather than late hormonal therapy for locally advanced disease. Randomized trials with a large number of patients are required before definitive advice can be given regarding management of PSA relapses.

Which hormonal therapy to use is a matter of choice. A meta-analysis of 10 trials suggested that medical castration, surgical castration, and DES all have equal efficacy, but individual trials indicated that antiandrogens are less effective. In this author's opinion, surgical orchietomy appears preferable for the initial treatment of these patients. The operation is relatively minor and can be performed under local anesthesia, if desired. Rapid and complete cessation of testicular androgen secretion ensues, and the patient's compliance after surgery is not a factor. Unwarranted cardiovascular or other toxic side effects, such as those occurring with DES, are unknown. The incidence of impotence and loss of libido is the same as with other available therapies with the exception of the antiandrogens.

In practice, nearly half of patients in the United States prefer a form of medical castration for psychological or other reasons. The greater safety of the GnRH agonists is an increasingly important consideration in prostate cancer therapy. Some patients may choose to continue the antiandrogens in the long term to gain the slight (2.9%) maximal benefit from MAB. An antiandrogen or DES, 3 mg/day, can be chosen as an alternative but is not preferred.

At present, medical castration with GnRH agonists can be achieved with a 3- or 4-monthly injection that is well tolerated and should not be associated with cardiovascular complications. Cost ($2700 for the 4-month injection) is the limiting factor. When concern about erectile dysfunction is a limiting factor, the persistence of libido and erectile function in a subset of patients treated with antiandrogens as primary therapy may be a decisive factor. Under these circumstances, some men may choose monotherapy with antiandrogens, even though this approach is not as effective as medical or surgical castration. This decision is related to quality of life, which is an increasingly important consideration in prostate cancer therapy.

Disease Recurrence

Antiandrogen therapy provides a reasonable next option unless it has previously been given as part of an MAB regimen. Patients receiving an antiandrogen as part of a complete androgen blockade regimen are observed for an antiandrogen withdrawal response. Regarding the choice of antiandrogen, bicalutamide is preferred to flutamide because of its better side effect profile and potentially superior efficacy. Upon relapse, men are observed for an antiandrogen withdrawal response and treated further only when progressive disease is documented.

A variety of therapies are available for men experiencing relapse after antiandrogen withdrawal. One group preferred ketoconazole and hydrocortisone because of their lack of toxicity and observed efficacy (i.e., 60% PSA response rate). The other agents listed in Table 39-2 can be used as alternatives or as third-line therapies. Further choices of chemotherapy alone or chemotherapy in combination with hormonal agents are a matter of individual preference.

Chapter 40 - Humoral Manifestations of Malignancy

Gordon J. Strewler

The syndrome of ectopic secretion of corticotropin (also known as ACTH) was first described by Brown in 1928 in a woman with bronchogenic carcinoma, 4 years before Cushing's description of the clinical syndrome of corticotropin excess and before the relationship between the hormone and the clinical syndrome was recognized. In 1941, Albright proposed the idea that tumors can cause endocrine syndromes by secreting hormones inappropriately; he suggested that hypercalcemia in a patient with renal carcinoma might be due to production of parathyroid hormone (PTH) by the tumor. Albright was led to this conclusion by the coexistence of hypercalcemia with hypophosphatemia (biochemical features of primary hyperparathyroidism) in a patient with a single bone metastasis.

In 1956, cases were reported in which hypercalcemia was cured by resection of the primary tumor, supporting Albright's hypothesis that the neoplasm produced humoral hypercalcemia. Subsequently, Schwartz and colleagues described the syndrome of inappropriate vasopressin (ADH) secretion in bronchogenic carcinoma. Meador and co-workers described the ectopic corticotropin syndrome in lung carcinoma, and Liddle and colleagues coined the term ectopic hormone syndrome to describe such situations.
INAPPROPRIATE HORMONE SECRETION IN MALIGNANCY

Common Features

Inappropriate secretion of peptide hormones is probably the most common cause of paraneoplastic syndromes. Although the manifestations vary widely, paraneoplastic hormonal syndromes have features that distinguish them from overproduction of hormones by endocrine glands (Table 40-1).

First, the secretion of hormones by extraglandular tumors is rarely suppressible. Tumor cells that secrete hormones typically do not possess the cellular machinery that allows regulation of hormone secretion. The most notable exception to this general rule is the secretion of corticotropin by carcinoid tumors of the lung or thymus. Corticotropin secretion by these tumors is often suppressible by glucocorticoids, with secretory dynamics that can be difficult to distinguish from those of corticotrope adenomas of the pituitary.

Second, because extraglandular tumors produce hormones relatively inefficiently, clinical syndromes of hormone excess become evident only in patients with advanced malignancies. It is probably for this reason that hormones are disappointing as tumor markers.

Third, tumors often lack the ability to process peptide hormones normally and secrete large, incompletely processed forms of hormones with reduced biologic activity.

Finally, some malignant tumors mimic syndromes of hormone excess not by secreting the expected hormone but by secreting related hormones that mimic the biologic actions of the expected hormone. For example, nonislet cell tumors can cause hypoglycemia not by secreting insulin but by secreting the related peptide insulin-like growth factor II (IGF-II). IGF-II does not ordinarily play a major role in glucose metabolism, but it has insulin-like activity and in large amounts causes hypoglycemia. Similarly, hypercalcemia in malignancy is a manifestation not of PTH excess but of an excess of parathyroid hormonereleated protein (PTHrP). PTHrP resembles PTH and in most circumstances is a local regulator but acts as a hormone when it is released into the circulation by malignant tumors.

| TABLE 40-1 -- General Characteristics of Paraneoplastic Hormonal Syndromes |
|-----------------|---------------------------------------------------------------|
| 1.              | Secretion of hormones is rarely suppressible.                |
| 2.              | Clinical syndromes are usually associated with advanced malignancies. |
| 3.              | Hormones are not useful as tumor markers for nonendocrine tumors. |
| 4.              | Tumors may mimic syndromes of hormone excess by secreting a related peptide (e.g., insulin-like growth factor II, causing hypoglycemia). |

become evident only in patients with advanced malignancies. It is probably for this reason that hormones are disappointing as tumor markers.

Finally, some malignant tumors mimic syndromes of hormone excess not by secreting the expected hormone but by secreting related hormones that mimic the biologic actions of the expected hormone. For example, nonislet cell tumors can cause hypoglycemia not by secreting insulin but by secreting the related peptide insulin-like growth factor II (IGF-II). IGF-II does not ordinarily play a major role in glucose metabolism, but it has insulin-like activity and in large amounts causes hypoglycemia. Similarly, hypercalcemia in malignancy is a manifestation not of PTH excess but of an excess of parathyroid hormonereleated protein (PTHrP). PTHrP resembles PTH and in most circumstances is a local regulator but acts as a hormone when it is released into the circulation by malignant tumors.
Ectopic versus Eutopic Secretion

The term ectopic hormone secretion is a misnomer. Ectopic means "out of place," implying secretion of a hormone by tissues that do not ordinarily do so, whereas hormones that are secreted by tumors are usually present in the nonmalignant precursor cells, albeit often in small amounts. For example, many of the hormones typically secreted by small cell lung carcinomas—vasopressin, calcitonin, and gastrin-releasing peptide (GRP)—are thought to be present in the neuroendocrine cells in the normal bronchial mucosa that are the probable precursors of the tumor. PTHrP is a normal product of the keratinocyte, the cell of origin of squamous carcinomas that cause humoral hypercalcemia by secreting PTHrP. Human chorionic gonadotropin (hCG), usually considered a placental hormone, is not under tight transcriptional control, and low levels of the hormone are detectable in a variety of other normal tissues, a finding that is in keeping with the occurrence of hCG secretion by many tumor types.

Thus, most endocrine manifestations of malignancy are caused by eutopic secretion of hormones by cells that were previously programmed to secrete them. This feature has implications for the pathogenesis of the humoral manifestations of malignancy that are discussed later. As for nosology, the term ectopic is firmly ingrained and will not soon be abandoned, even though true ectopic secretion of hormones is rare.
Peptide versus Nonpeptide Hormones

Most peptide hormones are secreted by nonendocrine malignant tumors (Table 40-2), with some exceptions. The glycoprotein hormones follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyrotropin (TSH) are rarely, if ever, produced by extrapituitary tumors, possibly because it is necessary to express the genes for two subunits, to glycosylate the subunits appropriately, and to assemble the complete dimer to produce a biologically active hormone. However, the glycoprotein hormone hCG is frequently secreted by nontrophoblastic tumors, illustrating that the requisite machinery can be present in nonpituitary cells.

Unlike the case of pituitary cells, synthesis of hCG by tumors is not tightly regulated. Pituitary glycoprotein hormone synthesis is tightly controlled by a series of pituitary-specific transcription factors, whereas hCG is normally expressed at low levels in a variety of nontrophoblastic cells. In the same vein, only one case of extrapancreatic secretion of insulin has been authenticated. Although a few copies per cell of insulin messenger ribonucleic acid (mRNA) can be detected in many cells by sensitive polymerase chain reaction (PCR) methods, physiologic expression of the insulin gene is driven by transcription factors that are specific to the pancreatic beta cell, and these factors are rarely, if ever, expressed in other cell types. Thus, the propensity of a peptide hormone for secretion by extraglandular tumors may be a function of the tightness of its transcriptional suppression in normal extraglandular tissues.

Steroid and thyroid hormones are not secreted by extraglandular tumors, although they are occasionally produced by teratomas that contain glandular elements. Their synthesis requires an extended series of enzymatic steps that are not present in nonsteroidogenic tissues. In contrast, 1,25-dihydroxycholecalciferol (1,25(OH)\(_2\)D, also called 1,25-dihydroxyvitamin D\(_3\)) is secreted by lymphomas as well as macrophages resident in granulomas of sarcoidosis and other granulomatous disorders. In these tissues, the synthesis of 1,25(OH)\(_2\)D requires a single enzymatic step, the 1-hydroxylation of the circulating precursor, 25-hydroxycholecalciferol.

Cellular Basis of Ectopic Hormone Secretion

Why is the secretion of hormones by malignant neoplasms so commonplace? The simplest idea is that random sets of genes are “derepressed” in the cancer cell, including genes that code for hormones. For example, epigenetic phenomena such as demethylation of deoxyribonucleic acid (DNA) may derepress hormone genes. However, the association of tumors and hormone secretion is nonrandom, with certain tumors (e.g., lung carcinoma) characteristically secreting certain hormones (e.g., corticotropin or vasopresin). Moreover, in a number of cases, the peptides that are secreted by tumors are the same peptides that are secreted by the normal cell of origin of the neoplasm. Derepression is again nonrandom and is a quantitative rather than a qualitative phenomenon.

The dedifferentiation hypothesis posits a retrograde movement of tumor cells along the pathway of differentiation, leading to the expression of fetal proteins (e.g., -fetoprotein and carcinoembryonic antigen) or hormones that are normally formed in immature cells. This hypothesis would account for both the nonrandom nature of ectopic hormone secretion and the propensity for secretion of hormones that play a critical role in development, for example, IGF-II, PTHrP, and possibly GRP and other peptides of neuroendocrine cells. In addition, tumors frequently secrete other fetal proteins (carcinoembryonic antigen, -fetoprotein). However, there is no compelling evidence for a generalized pattern of expression of primitive genes in tumor cells.

The dysdifferentiation hypothesis of Baylin and Mendelsohn holds that epithelial malignancy is the result of clonal expansion of a particular cell type that occurs along a complex pathway of epithelial differentiation. This process may give rise to overexpression of a hormone because of (1) clonal expansion of a normally rare population of committed cells or (2) clonal expansion of a primitive cell type not normally present in the mature epithelium.

Because the defining characteristic of neoplastic cells is uncontrolled growth, it is worth considering the possible relationship of disordered growth and the secretion of hormones. In some instances, an oncogenic event might directly activate transcription of a hormone gene. One example of direct gene activation is the secretion of PTHrP in adult T-cell leukemia, with associated severe hypercalcemia. The oncogenic event that gives rise to this form of leukemia involves integration of the human T-cell lymphotropic virus type I (HTLV-I), which can target the promoter of the PTHrP gene to induce its transcription using the trans-activating viral protein tax. Another clinical example is the association of the von HippelLindau suppressor gene VHL with the development of cerebellar hemangioblastoma and renal carcinoma. Evidence suggests that erythropoietin gene expression is directly up-regulated by this oncogenic event.

Secretion of a hormone might stimulate the growth of tumor cells by an autocrine or a paracrine mechanism, so that hormone secretion may provide a growth advantage, leading to selective outgrowth of cells that secreted high levels of the hormone. One of the characteristic products of small cell lung carcinoma (SCLC) is GRP, the mammalian counterpart of the amphibian hormone bombesin. GRP fulfills criteria for being an autocrine growth factor in SCLC: (1) it is secreted by tumor cells and can stimulate replication of the cells via specific receptors, and (2) blockade of its action by neutralizing antibodies to GRP or peptide antagonists inhibits cell replication in vitro and tumor formation in vivo. -Endorphin, one of the products of the pro-opiomelanocortin (POMC) gene, may also function as a growth factor in SCLC.

Endothelin receptors are often coexpressed on tumor cells with endothelin-1, and endothelin-1 is reported to have paracrine effects on tumor cell growth. Prolactin and its receptor are expressed by breast cancer cells, although rarely, if ever, at high enough levels to raise serum prolactin levels, and an autocrine pathway has been described in which prolactin induces constitutive phosphorylation of erbB-2 (Her/Neu), an oncogene that is important in growth of breast cancer. Another ectopic hormone with growth factor activity is IGF-II, the factor that is believed to cause hypoglycemia in nonislet cell tumors. However, there is no direct evidence for a role of IGF-II in the growth of these neoplasms.

Epigenetic events associated with tumorigenesis may activate the transcription of hormone genes. Altered methylation of CpG islands appears to play a role in the expression of PTHrP in renal carcinoma, with undermethylation of the PTHrP promoter in tumors that express the gene. Evidence suggests that demethylation of the POMC promoter may also be involved in expression of corticotropin in neuroendocrine tumor cells.

Thus, ectopic hormone production can be partly understood in the context of the determinants of tumor cell behavior generally. Nevertheless, why specific tumor types overexpress hormone genes and why overexpression occurs in some tumors of a given type (e.g., SCLC) and not others are questions that remain largely unanswered.
Neuroendocrine Cells and Hormone Secretion

Tumors that secrete corticotropin, vasopressin, calcitonin, gut peptides (GRP, somatostatin, vasoactive intestinal peptide [VIP]), and biogenic amines such as 5-hydroxytryptamine (5-HT) are characteristically of neuroendocrine cell origin. Neuroendocrine cells specialized for the production of peptide hormones and biogenic amines possess pathways for the rapid release of peptides or neurotransmitters in response to stimuli; such regulated pathways for protein secretion are distinct from the mechanism of constitutive secretion, which is ubiquitous in eukaryotic cells.

The most readily recognizable feature of the regulated pathway is the dense neurosecretory granule, which is designed for the secretion of peptides and amines. The neurosecretory granule, which is involved in both the storage of hormones in concentrated form and the rapid release of these stores in response to stimulation, is recognizable histologically because it is electron dense and intensely argyrophilic, reflecting the dense, nearly crystalline packing of its contents.

The neurosecretory granules bud from the trans-Golgi network after it is packed with its peptide or neurotransmitter contents. Proteins on the surface of the neurosecretory granule, in the vesicular compartments from which the granule buds, and on the plasma membrane of neurosecretory cells collectively determine the properties of the regulated pathway of hormone secretion. They are probably important in ectopic hormone secretion. In addition to stored hormones, the neuroendocrine granule contains one or more acidic proteins called chromogranins, which are released together with stored hormone and serve as additional neuroendocrine tumor markers, both in immunohistochemistry and in the circulation. The chromogranins are highly conserved in evolution and presumably play a role in the assembly, packing, or release of neurosecretory granules, but this role has yet to be fully clarified.

The neurosecretory granules contain serine proteases called prohormone convertases, which process precursor proteins to their mature forms. The prohormone convertase family is widely distributed in evolution, and several members of the family, such as furin, are localized in the trans-Golgi network and process a wide variety of proteins in the constitutive pathway. The two members of the family that occur mainly in neurosecretory granules, PC2 (SPC2) and PC1/PC3 (SPC3), have acidic pH optima and are dependent on calcium, suiting them for the environment of the neurosecretory granule. Both enzymes cleave their substrate peptides on the carboxyterminal side of polybasic residues, but they have slightly different specificities, and their different distribution in the pituitary accounts for the differences in processing of POMC in the anterior and intermediate pituitary lobes.

The prohormone convertases are important for our understanding of ectopic hormone secretion. Their levels in tumor cells account for the efficiency of precursor processing to mature and biologically active versions of peptide hormones, thus determining whether a given tumor produces a clinical syndrome of hormone excess. Further, they determine the pattern of peptides produced (e.g., from the polyhormone precursor POMC) and thus the nature of the clinical syndrome.

Neuroendocrine cells are scattered through the bronchial mucosa of the developing and mature lung. They occur singly and in distinct inervated corporcles referred to as neuroepithelial bodies. Subpopulations of the cells contain the peptides calcitonin, GRP, vasopressin, and leu-enkephalin, and some may also contain somatostatin, motilin, or pancreatic polypeptide. Neuroendocrine (enterochromaffin) cells are also scattered through the gastrointestinal mucosa and are found in other organs, such as the ovaries and the prostate gland. Some years ago, Pearce suggested that neuroendocrine cells, which he called APUD cells (amine precursor uptake and decarboxylation), although widely scattered in many tissues, have a common origin in the neural crest and represent a diffuse neuroendocrine system, a third branch of the nervous system. Not all APUD cells are of neural crest origin, however; some arise from primitive endoderm.

Neuroendocrine cells in the gut and lung are specified by a set of basic helix-loop-helix (bHLH) transcription factors that are involved in the determination of neuronal fate in mammals and Drosophila. Transient expression of the mouse achaete-scute homologue-1 (mASH1) is required for neurogenesis of autonomic and enteric neurons and adrenal chromaffin cells. Pulmonary neuroendocrine cells do not develop in mice deficient in mASH1 and forced expression of mASH1 induces metaplasia and cooperates with simian virus 40 (SV40) T antigen in tumorigenesis. Neuroendocrine tumor cells such as SCLC cells express the human orthologue hASH1.

Disruption of an inhibitory pathway may also lead to neuroendocrine cell expansion. Drosophila and vertebrate neurogenesis is characterized by lateral inhibition, a cell-cell interaction in which differentiating neuronal cells inhibit neuronal differentiation of their neighbors through actions of a transmembrane receptor, Notch, and the ligand Delta. One of the chief targets of the inhibitory pathway is hairy-enhancer-of-split-1 (Hes-1), which inhibits the proneural genes neurogenin, neuroD, and ASH. Ablation of Hes-1 leads to a marked increase in enteroendocrine cells, and SCLC cells are characteristically deficient in Hes-1. Collectively, these data delineate a pathway of origin of neuroendocrine tumor cells and identify transcription factors that may be directly involved in up-regulating expression in neuroendocrine cells. However, examples of direct regulation of hormonal expression by such genes have not yet been adduced.
Criteria for Diagnosis of Ectopic Hormone Secretion

Criteria for the diagnosis of ectopic hormone secretion, arranged in increasing order of stringency, are summarized in Table 40-3. The association of a clinical syndrome of hormone excess with a neoplasm provokes a search for inappropriate plasma or urinary hormone levels. In many cases, the clinician performs suppression tests because glandular hypersecretion of hormones is often suppressible whereas the secretion of hormones by neoplasms is typically autonomous and non-suppressible. In the usual clinical circumstance, the last step is to exclude other possible causal mechanisms for hormone excess.

The coincidental occurrence of an endocrine tumor and a cancer is not uncommon; for example, primary hyperparathyroidism can be present in a patient who also has cancer and can be detected with relative ease using modern assays for PTH. Occasionally, the presence of an ectopic hormone syndrome can be confirmed by showing that resection of the tumor reverses the clinical syndrome. Because such syndromes are typically late manifestations of widespread neoplasms, these opportunities are sadly rare.

The remaining criteria for ectopic hormone secretion are useful mainly for research purposes. The detection of a hormone in tumor tissue by immunoassay methods provides evidence that the tumor is a site of its production, although caution must be exercised because of the possibility of false-positive reactions in immunohistochemistry and radioimmunoassay. An additional theoretical concern is that the tumor may accumulate hormone from the circulation; no examples of this phenomenon have been reported, however. Detection of mRNA for the hormone confirms that the tumor is indeed a site of synthesis of the peptide. For this evidence to be compelling, hormone mRNA should be detectable in solution hybridization or RNA blotting assays. The technique of reverse transcription and PCR is so sensitive that a signal can be obtained from samples containing only a few molecules of hormone mRNA, a level that may be insignificant. In addition, identification of hormone mRNA without hormone protein leaves open the possibility that the mRNA is not translated for example, many normal tissues express a form of POMC mRNA that cannot be translated to protein.11

Demonstration of the presence of both hormone mRNA and protein provides strong evidence for synthesis in the tumor but does not directly establish that the hormone is secreted. The most rigorous criterion for ectopic hormone secretion is the demonstration of an arteriovenous gradient of the hormone across the tumor or of production and secretion of the hormone by tumor cells cultured in vitro. Unfortunately, selective catheterization to obtain a true arteriovenous gradient is often impossible, as many of the tumors are present in the pulmonary or splanchnic bed or are widely metastatic. Establishing tumor cells in culture provides an important research tool but requires an element of good fortune—many tumor cells, exuberant as their growth may be in the host, are difficult to propagate in cell culture.

MALIGNANCY-ASSOCIATED HYPERCALCEMIA

Clinical Features

Hypercalcemia is probably the most common endocrine complication of malignant tumors, occurring in as many as 5% of all cancers. The incidence of hypercalcemia in malignancy is 15 cases per 100,000 person-years, about one half the incidence of primary hyperparathyroidism, and malignant tumors are the most common cause of hypercalcemia in hospitalized patients (see Chapter 26).

Hypercalcemia in malignancy usually has a rapid onset and can cause confusion, stupor, nausea, vomiting, and dehydration. The offending neoplasm is almost always evident clinically, even when hypercalcemia is the initial manifestation. Thus, physical examination and a chest radiograph disclose the underlying tumor in about 98% of patients. Because hypercalcemia usually occurs in advanced malignancy, the prognosis is poor, with a median survival of only 4 to 8 weeks after the discovery of hypercalcemia. Exceptions are breast carcinoma and multiple myeloma, in which successful treatment of the underlying malignancy may allow long survival of the hypercalcemic patient.

The frequency of individual tumors in patients with hypercalcemia is shown in Table 40-4. Lung carcinoma, breast carcinoma, and multiple myeloma account for more than 50% of all cases of malignancy-associated hypercalcemia. Lung carcinomas that produce hypercalcemia have squamous or large cell histology, whereas small cell carcinoma almost never causes hypercalcemia. About two thirds of lung cancer patients have bone metastasis at the time when hypercalcemia develops. Among other solid tumors, the most common are squamous and renal carcinomas. Gastrointestinal tumors and prostate carcinoma are less common causes of hypercalcemia.

Hypercalcemia is uncommon in lymphomas and leukemia but occurs in two thirds of patients with adult T-cell leukemia syndrome, which is caused by the retrovirus HTLV-I. Another rare variety of leukemia in which hypercalcemia is common is the M7 variant of acute myelogenous leukemia.

Hypercalcemia is a common complication of multiple myeloma. Hypercalcemia in myeloma has been ascribed to a local osteolytic cause, but a substantial fraction of cases have increased PTHrP levels. Pheochromocytomas may produce hypercalcemia by secretion of PTHrP.

Data from references 63, 64, 65. Data on metastatic disease from references 64 and 65.

Laboratory Features

Overall, about 80% of cases, including most patients with solid tumors, have increased serum levels of PTHrP, which can be measured in two-site, amino-terminal or midregion assays (Fig. 40-1). Hypophosphatemia is common because of the phosphaturic effect of PTHrP. Although the combination of hypercalcemia and hypophosphatemia is consistent with the presence of primary hyperparathyroidism, the level of intact PTH is suppressed to less than 2 pmol/L (20 pg/mL) in patients with malignancy-associated hypercalcemia. The serum level of 1,25(OH)₂D is also suppressed in hypercalcemic patients, except in lymphoma, in which 1,25(OH)₂D levels are often high. Renal function may be impaired by hypercalcemia; the decreased glomerular filtration rate may lead to normalization of blood phosphate in patients with PTHrP-mediated hypercalcemia.
Pathogenesis

Hypercalcemia in malignancy is caused by excessive bone resorption. Multiple myeloma and some breast cancers induce hypercalcemia by local osteolytic mechanisms, but in most patients bone resorption is induced by humoral factors. The most common humoral factor is PTHrP, but 1,25(OH)2 D is a hypercalcemic factor in lymphomas and in some instances PTH is secreted ectopically by nonparathyroid tumors.

Parathyroid Hormone-Related Protein

PTHrP is related to PTH structurally (see Fig. 24-12) and shares a common receptor with PTH1R (see Chapter 26 for a discussion of the chemistry of PTHrP). Because PTH and PTHrP share a receptor, their biologic actions are similar. PTHrP produces hypercalcemia by increasing resorption of bone throughout the skeleton and by increasing the renal resorption of calcium and causes hypophosphatemia through a phosphaturic effect at the kidney. The hypercalcemic effect of PTHrP probably plays a significant role in the pathogenesis of hypercalcemia, albeit secondary to the role of bone resorption. In some studies, the effects of bisphosphonate treatment of hypercalcemia, the effect was not negatively correlated with the serum level of PTHrP, suggesting that increased renal calcium reabsorption may limit the response of some patients to treatment with inhibitors of bone resorption.

PTHrP functions in normal physiology as a tissue factor that regulates cellular proliferation and differentiation in fetal development and in tissues such as the breast, skin, and hair follicle in the adult (see Chapter 26). Remarkably, PTHrP locally regulates development, in part acting via the same receptor that PTH uses systemically to regulate its target tissues, bone and kidney. However, when PTHrP is produced by a tumor of sufficient mass, it enters the systemic circulation, where it activates PTH-PTHrP receptors in bone and kidney and produces hypercalcemia.

PTHrP can either produce humoral hypercalcemia or cause local osteolytic hypercalcemia by direct activation of osteoclasts in the vicinity of bone metastases. In lung and renal carcinoma, PTHrP often acts as a humoral factor because hypercalcemia can occur without evidence of bone metastasis (see Table 45-1). Even when bone metastases are present, hypercalcemia is predominantly humoral because the serum calcium level correlates better with the level of PTHrP than with the number or size of bone metastases.

There is experimental evidence that PTHrP, when expressed in bone metastasis, can also be a local osteolytic factor. In an experimental model, transfusion of PTHrP complementary DNA into breast carcinoma cells increased their propensity for bone metastasis, and bone metastasis induced local osteolysis without an increase in the circulating level of PTHrP. This result is in agreement with the biology of human breast carcinoma, in which about 50% of hypercalcemic patients have extensive bone metastases without increased serum levels of PTHrP and are presumed to have local osteolytic hypercalcemia (see Table 45-1).

In humans, metastases of breast cancer to bone are immunohistochemically positive for PTHrP in 92% of cases, compared with 17% for nonosseous metastases. Tumor cells that secrete PTHrP have a selective advantage in bone, probably because they induce local resorption. Moreover, transforming growth factor-β (TGF-β) released from bone matrix as a result of bone resorption induces the expression of PTHrP, setting up a positive feedback loop to perpetuate the process.

At least two aspects of the hypercalcemia syndrome associated with PTHrP are paradoxical. First, plasma levels of 1,25(OH)2 D tend to be low in malignancy, despite the acute effect of PTHrP to suppress renal synthesis of 1,25(OH)2 D. This finding contrasts with normal to high levels of 1,25(OH)2 D in primary hyperparathyroidism. This difference may be due to the capacity of hypercalcemia itself to suppress production of 1,25(OH)2 D, tending to counteract the acute stimulatory effect of PTH or PTHrP. Thus, a continuous chronic infusion of PTH or PTHrP, in contrast to the effects of primary hyperparathyroidism, suppresses 1,25(OH)2 D levels, but it does not suppress the serum calcium level. In some patients, normocalcemic with malignancy have a marked increase in 1,25(OH)2 D to supranormal levels when hypercalcemia is treated with bisphosphonates. It is possible that the parallel secretion of PTHrP (continuous?) or associated ancillary factors increases the susceptibility of 1,25(OH)2 D synthesis to suppression by hypercalcemia.

A second paradox concerns bone turnover in the setting of high PTHrP levels. Despite avid bone resorption, bone formation is reduced in postmortem bone biopsy specimens from patients with malignancy and hypercalcemia. This uncoupled state contrast with primary hyperparathyroidism and most other resorptive states, which are characterized by coupled increases in bone formation, and also contrasts with the results of a PTHrP infusion. It is possible that immobilization, anorexia, illness, or other cytokines secreted by neoplasms depress osteoblastic activity.

Mechanisms involved in the activation of PTHrP gene expression in malignant tumors may include trans-activation by tumor-specific factors and differential methylation. The best example of trans-activation is adult T-cell leukemia, which is commonly characterized by PTHrP-dependent hypercalcemia.

A specific trans-activating protein, called tax, in the genome of HTLV-I is capable of direct activation of PTHrP transcription, acting primarily at an Ets-1 site near the most downstream promoter. The keratinocyte is a prominent site of normal PTHrP expression; thus, secretion of PTHrP by squamous carcinomas can be regarded as ectopic. However, only a fraction of patients with squamous carcinomas have hypercalcemia. When PTHrP promoter constructs were fused to a reporter gene and transfected into squamous carcinoma cell lines, the relative level of expression of the reporter gene correlated with the intensity of endogenous PTHrP gene expression in the same cell lines, suggesting that in this circumstance also, the expression of PTHrP is regulated in trans by a factor or factors that are differentially expressed in different squamous carcinomas.

PTHrP expression in human squamous carcinoma cells is repressed by mutant forms of the tumor suppressor gene p53. Most squamous carcinomas express the PTHrP gene at some level, but renal carcinomas are more sharply divided between PTHrP expressors and nonexpressors. The PTHrP gene is undermethylated in renal carcinomas that express PTHrP compared with those that do not. This finding suggests that hypomethylation may be a mechanism by which the gene is expressed in some renal carcinomas.

About 50% of lymphoma patients who become hypercalcemic have inappropriately high serum 1,25(OH)2 D levels. In a few cases, lymph node tissue from...
such patients has been shown to produce 1,25(OH)\(_2\) D in vitro from 25-OHD. \[120\] Challenge of normocalcemic lymphoma patients with the precursor sterol 25-OHD resulted in increased serum 1,25(OH)\(_2\) D levels, increased serum calcium levels, and suppression of PTH. \[120\] This response is in marked contrast to that of normal individuals, who regulate the conversion of substrate to 1,25(OH)\(_2\) D tightly.

The enhanced responsiveness of normocalcemic lymphoma patients to vitamin D indicates that the fundamental abnormality in lymphoma, unregulated extrarenal production of 1,25(OH)\(_2\) D, is more common than hypercalcemia. As would be expected from this interpretation, hypercalcemia is also more common than hypercalcemia in lymphoma patients \[13\] and presumably compensates at least in part for the inappropriate synthesis of 1,25(OH)\(_2\) D. This syndrome resembles the hypercalcemia of sarcoidosis, which is also due to enhanced extrarenal production of 1,25(OH)\(_2\) D. \[89\] As in sarcoidosis, hypercalcemia in lymphoma is frequently responsive to administration of glucocorticoids. Hypercalcemia may not respond well to treatment with hydroxychloroquine. \[129\]

**Parathyroid Hormone**

Secretion of PTH from extraparathyroid tumors is extremely rare, \[71\] \[91\] \[92\] \[93\] although one case fulfilled the most rigorous criterion: demonstration of an arteriovenous gradient for PTH across the tumor. \[124\] Most nonparathyroid tumors that secrete PTH are neuroendocrine tumors, although one was an ovarian adenocarcinoma and one a hepatocellular carcinoma. The diagnosis should be considered in patients with malignant tumors (particularly small cell tumors), hypercalcemia, and elevated PTH levels. However, most patients with these findings have a malignant tumor with coincident primary hyperparathyroidism because this coincidence is more likely than the truly rare syndrome of ectopic PTH secretion. Consequently, exploration of the parathyroid glands may be indicated in patients who require treatment for hypercalcemia.

**Local Osteolytic Hypercalcemia**

Osteolytic lesions cause hypercalcemia by activation of osteoclasts and secretion of bone-resorbing cytokines. Cytokines with osteoclast-activating activity include interleukin-1, tumor necrosis factor (TNF-\(\alpha\)), interleukin-6, TGF-\(\beta\), and PTHrP. \[126\] \[127\] \[128\] \[129\] As discussed earlier, PTHrP appears to be the local osteolytic factor that causes osteolytic hypercalcemia in breast carcinoma. \[126\] \[127\] \[128\] \[129\] The other classic example of local osteolytic hypercalcemia is multiple myeloma. Although at least one third of myeloma patients have hypercalcemia at some time during their disease, the offending cytokine has not been identified with certainty. Cultured human myeloma cell lines produce bone-resorbing factors that can be neutralized with antisera to interleukin-1 \[126\] or TNF-\(\alpha\) (lymphotoxin), \[127\] but it is likely that other factors are responsible for the hypercalcemia.

A preliminary report suggested a strong association of hypercalcemia with secretion of the chemokine macrophage inflammatory protein 1. \[129\] It is clear that a fraction of hypercalcemic patients with multiple myeloma have high serum PTHrP levels and thus humoral rather than local osteolytic hypercalcemia. \[129\] \[130\] \[131\] \[132\] This finding raises the question of whether PTHrP, which may be expressed commonly in marrow myeloma cells, \[130\] is also a dominant local osteolytic factor in multiple myeloma and lymphoma.
Diagnosis

The diagnosis of malignancy-associated hypercalcemia is usually not difficult because the offending neoplasm is clinically evident. It is important to exclude intercurrent primary hyperparathyroidism by showing that the level of intact PTH is suppressed below 2 pmol/L (20 pg/mL). A low serum phosphorus level in conjunction with suppressed PTH levels suggests that the causative factor is PTHrP. Demonstration of elevated levels of PTHrP confirms the diagnosis in patients with solid tumors, but this is often unnecessary clinically. PTHrP is processed to amino-terminal, midregion, and carboxyl-terminal peptides, and similar assay performance has been achieved with assays of the amino terminus and mid-region and two-site immunoradiometric assays (see Fig. 40-1). Two-site assays for PTHrP have become the standard.
Treatment

The treatment of hypercalcemia is discussed in Chapter 26. The mainstays of therapy for tumor patients, in whom hypercalcemia is often acute and severe, are rehydration, institution of a saline diuresis, and institution of chronic treatment. In general, the treatment of choice is the second-generation bisphosphonate pamidronate, 60 to 90 mg by intravenous infusion. Patients with multiple myeloma or lymphoma often respond to glucocorticoid treatment.
SYNDROME OF INAPPROPRIATE VASOPRESSIN SECRETION (See Chapter 9)

Clinical Features

The syndrome of inappropriate vasopressin secretion (commonly termed the syndrome of inappropriate antidiuretic hormone [SIADH]) is probably the second most common endocrine complication in cancer patients. The secretion of vasopressin impairs the ability to dilute the urine, leading to a state of water intoxication with hypotonicity and hyponatremia. Patients with hyponatremia may be asymptomatic if the condition has developed gradually. Patients may experience weight gain because of water retention, but because the retained water is distributed among both extracellular and intracellular spaces, there is no edema. However, when the serum sodium level falls rapidly to below 120 mmol/L, somnolence, coma, and seizures can occur. Symptomatic hyponatremia carries a mortality rate of 10% to 15%, but this rate is higher when the serum sodium level is below 110 mmol/L.

By far, the most common tumor that causes SIADH is SCLC. SIADH occurs in 5% to 15% of patients with SCLC and in fewer than 1% of patients with non-small cell lung cancer (non-SCLC). Other neuroendocrine tumors, including carcinoids and small cell carcinomas of the prostate and cervix, can also cause SIADH. SIADH also occurs occasionally in a wide range of carcinomas, including as many as 2% of squamous carcinomas of the head and neck, adenocarcinoma of the colon, Hodgkin’s disease, non-Hodgkin’s lymphomas, and several varieties of brain tumors. The finding of hyponatremia in cancer is nonspecific, and central secretion of vasopressin from various nonosmotic stimuli may be at fault in some of these patients, for example, patients with thoracic or intracranial tumors. However, vasopressin and associated neurophysins have been found in non-neuroendocrine tumor cells, and some epithelial tumors have the ability to secrete vasopressin.
Laboratory Features

The cardinal features of SIADH are hyponatremia and an inappropriately concentrated urine. It is often unnecessary to measure serum osmolality directly in a hyponatremic patient because the effective serum osmolality (serum sodium (mmol/L) × 2 + glucose (mmol/L)) closely approximates direct measurements. A urine osmolality greater than 50 to 60 mmol/L water is inappropriate in the setting of serum hypotonicity, which should inhibit the release of vasopressin and permit the excretion of a maximally dilute urine. The urine osmolality in SIADH is often higher than the serum osmolality, but that is not a necessary feature of the syndrome. If measured directly, vasopressin levels are inappropriately elevated, as are the levels of the associated neurophysins. However, it is rarely necessary to measure vasopressin. As discussed later, other causes of hypotonicity can generally be excluded with reasonable certainty by reliance on clinical and biochemical criteria.

Several other laboratory features of SIADH are helpful in diagnosis. The urinary sodium concentration is typically high, reflecting the natriuresis induced by expansion of extracellular fluid volume. However, the ability to conserve sodium in SIADH is usually unimpaired, and the urinary sodium excretion can fall to low levels in the setting of reduced dietary sodium intakes. The blood urea nitrogen and serum uric acid levels are low, again reflecting expanded extracellular fluid volumes and decreased tubular resorption of these solutes. Other electrolytes are diluted in proportion to the serum sodium, except for serum bicarbonate, which is normal.
Pathogenesis

Vasopressin is synthesized as a prohormone of 166 amino acids that is processed to produce three peptides: the mature octapeptide hormone, a midregion peptide of molecular weight 10,000 with vasopressin-binding activity called neurophysin II, and a C-terminal glycopeptide. Vasopressin and its neurophysin are packaged together in neurosecretory granules, stored in nerve terminals in the posterior pituitary, and released in response to hypotonicity or nonosmotic stimuli (baroreceptor stimulation, pain, nausea). Vasopressin is similarly processed in neuroendocrine tumor cells, but these cells frequently secrete not only vasopressin and neurophysin II but also vasopressin’s sister peptide oxytocin together with its binding protein, neurophysin I.

The molecular basis for inappropriate secretion of vasopressin from tumor cells is poorly understood. Immunoreactive vasopressin is identifiable in a portion of bronchial neuroendocrine cells, the presumed precursors of SCLC. Thus, like other hormonal products of neuroendocrine neoplasms, vasopressin may be regarded as secreted ectopically from neuroendocrine tumors. The usual coordinate expression of vasopressin and oxytocin precursors in tumor cells may be related to the physical linkage of the two genes, which are found within 12 kb of each other in the human genome with an inverted arrangement of the coding strands. Either DNA rearrangements or trans-acting factors expressed in malignant tumors could simultaneously activate both promoters.

An E-box in the vasopressin promoter, a binding motif for bHLH transcription factors, is necessary for increased vasopressin gene expression in high-expressing SCLC cell lines. This motif appears to bind the transcription factor USF (upstream transcription factor); a nearby sequence appears to interact and is a candidate for binding other bHLH factors. A neuron-specific silencer element has also been identified in the arginine vasopressin promoter. Vasopressin receptors (V1α and V2 receptors) are present on SCLC cells, and vasopressin can have paracrine effects on the growth of SCLC cells to promote their growth, but increased proliferation in response to vasopressin has not been observed.

It is not known whether the secretion of neurohypophyseal peptides from tumor cells is under regulatory control. Four patterns of vasopressin release have been identified in SIADH. Most commonly (37%), vasopressin levels fluctuate widely and independently of the serum osmolality. In a second group (33%), vasopressin is released in response to changes in osmolality, but the osmotic threshold for vasopressin release is decreased (reset osmostat). Other patients with SIADH manifest a constant leak of vasopressin or have no demonstrable abnormality in vasopressin secretion and could conceivably produce a different antidiuretic substance.

Patients with cancer and SIADH fall into all four categories. It is conceivable that those with a reset osmostat express both the vasopressin gene and an osmoreceptor in their tumors; more likely, however, vasopressin is released centrally in these patients because of stimulation of baroreceptors in the pulmonary bed or periphery, invasion of the vagus nerve, or metastasis to regulatory centers, for example, the hypothalamus.

Expression and secretion of vasopressin are more common than hyponatremia in SCLC. More than 50% of SCLC patients have elevated plasma vasopressin levels, and plasma levels of the neurophysins are increased in 44% to 65% of untreated patients with SCLC. Some tumors also express the gene for oxytocin but no clinical syndrome of inappropriate oxytocin release has been reported in tumor patients.

In patients with elevated vasopressin levels who do not have hyponatremia, abnormalities in water metabolism can be elicited by water loading, which discloses an impaired diuretic response in 47% of patients with limited SCLC and 86% of patients with extensive disease. Patients with milder degrees of vasopressin excess may secrete for reduced free water excretion by reducing fluid intake; only if free water intake exceeds the maximal excretion of free water does hyponatremia result. Thus, the development of hyponatremia is a function not only of the level of vasopressin but also of fluid intake. Although some tumors may secrete abnormally processed forms of vasopressin with reduced biologic activity, it is likely that compensatory mechanisms of this type account for the disparity in the frequency of biochemical and clinical abnormalities in SIADH.

When water is retained, extracellular and intracellular volumes are expanded. The expansion of extracellular fluid volume, probably by causing suppression of aldosterone and an increase in atrial natriuretic peptide (ANP), induces the natriuresis that is characteristic of patients with SIADH who have an adequate intake of sodium. Plasma levels of ANP are normal or high in SIADH; it is not clear whether high ANP levels are a compensatory response to extracellular fluid volume expansion or a consequence of release of ANP from the tumor. Many tumors that express the vasopressin gene also express the gene for ANP. Restriction of sodium intake in patients with SIADH causes weight loss, however, and as the extracellular fluid volume returns to normal, natriuresis is reversed and sodium is conserved appropriately. This suggests that the secretion of ANP is compensatory and that an ANP-induced natriuresis does not contribute significantly to the genesis of hyponatremia.

Acute water retention causes neurologic symptoms by rapidly increasing the intracellular volumes of brain cells and thus inducing cerebral edema. Chronic hyponatremia is probably less symptomatic because there is time for activation of compensatory volume-regulatory mechanisms in the central nervous system. Brain cells compensate for volume gain by activating ion transport processes that pump out intracellular potassium chloride (KCl) and sodium chloride (NaCl). This compensation has therapeutic importance because rapid correction of hyponatremia by infusion of hypertonic saline produces a transient hypertonic encephalopathy as water is drawn out of the already contracted intracellular space. This can cause permanent neurologic damage (e.g., central pontine myelinolysis) and death.
Diagnosis

The diagnosis of SIADH is usually made on clinical grounds. The first step is to establish that the urine is inappropriately concentrated in the presence of hypotonicity. In a hyponatremic patient, a urine osmolality higher than 50 to 60 mmol/L water is inappropriate, and many patients with SIADH have urine osmolalities higher than the plasma osmolality. Next, other causes of hypotonicity must be excluded. The differential diagnosis of hyponatremia includes states of true volume contraction; edematous states such as congestive heart failure and hepatic failure, in which the effective central plasma volume is diminished; adrenal insufficiency; hypothyroidism; drug effects; and SIADH (see Chapter 9).

Measurements of vasopressin are of little value in the differential diagnosis because vasopressin levels are increased in most hyponatremic states. True volume contraction and edematous states can usually be excluded on clinical grounds. It is appropriate to exclude adrenal insufficiency with a corticotropin stimulation test in patients with malignant tumors and SIADH, particularly because patients with bilateral adrenal metastases are at risk for adrenal insufficiency. Thyrotropin should be measured to exclude hypothyroidism. Among the drugs that stimulate the nonosmotic release of vasopressin are the cancer chemotherapeutic agents vincristine, vinblastine, and cyclophosphamide. Normovolemic patients without hormonal disorders or drug causes are presumed to have SIADH.

SIADH is a common cause of hyponatremia in hospitalized patients, but only a small minority of these patients develop the syndrome as the result of inappropriate secretion of vasopressin by a tumor. Furthermore, not all patients with cancer who meet the criteria for SIADH have ectopic secretion of vasopressin from a tumor. Not only are benign forms of SIADH more common, but the response of vasopressin to osmotic stimuli in some patients with malignant tumors is consistent with eutopic secretion of the hormone from the pituitary.

The uncertainty regarding the etiology in an individual patient may be intellectually unsatisfying but is not of great practical importance. Patients with severe and symptomatic hyponatremia are more likely to have a true ectopic source of vasopressin. The treatment of hyponatremia in SIADH is similar regardless of the cause of the syndrome.
Treatment

Symptomatic hyponatremia in patients with a serum sodium level below 120 mmol/L requires immediate treatment (see Chapter 9). The therapeutic options include infusion or administration of hypertonic saline (3% or 5% saline) or of saline and furosemide. The latter regimen has the advantage of not rapidly expanding extracellular fluid volume in an already volume-expanded patient. The goal of acute treatment is to raise the serum sodium level above 125 mmol/L. Such an increase takes the patient out of immediate danger, and further correction can be accomplished in a more leisurely fashion.

How rapidly the initial phase of correction should be carried out is controversial; one school argues for rapid correction in view of the high mortality of the untreated syndrome, and the other suggests that too rapid correction of hyponatremia can predispose to central pontine myelinolysis and other neurologic sequelae. As discussed earlier, the risk of rapid correction probably has to do with brain shrinking in the presence of high concentrations of extracellular sodium and intracellular dehydration, which is exacerbated by prior loss of cell solute, the adaptive response of the central nervous system to hyponatremia (see Chapter 9). Under most circumstances, it seems best to correct hyponatremia at a rate of 0.5 mmol/L per hour until the serum sodium concentration reaches 120 to 125 mmol/L.

In asymptomatic patients or after acute correction of hyponatremia in symptomatic patients, the mainstay of chronic therapy is water restriction. Moderate fluid restriction may be reasonably well tolerated. The goal is to establish a fluid intake at which the intake of free water does not exceed the maximal free water clearance, which is determined by the circulating vasopressin level. If necessary, most patients can be maintained with severe restrictions to 800 to 1000 mL of fluid intake daily. At this level, the free water intake is actually negative because the patient is ingesting osmoles from food in excess of water. Therefore, even a patient who is obliged to excrete a concentrated urine and thus has negative free water excretion may be maintained in zero net water balance. However, severe fluid restrictions are onerous and difficult to maintain.

As an adjunct to water restriction, it can be beneficial to interfere with vasopressin action. The drug of choice for this purpose is demeclocycline, an antibiotic that blocks the action of vasopressin and produces nephrogenic diabetes insipidus. At a dose of 150 to 300 mg four times a day, demeclocycline has a reproducible effect on the urine-concentrating mechanism but up to 2 weeks may be necessary for the full effect. Side effects include photosensitive rashes and liver toxicity.

An alternative, fludrocortisone in doses of 0.1 to 0.3 mg/day, corrects hyponatremia partially but at the risk of causing edema and congestive heart failure. Lithium also produces nephrogenic diabetes insipidus, but its effects are less predictable than demeclocycline or fludrocortisone and the drug should be given only in refractory cases. SCLC is now treated with aggressive combination chemotherapy, and SIADH often remits in responders to chemotherapy.
ECTOPIC CORTICOTROPIN SYNDROME AND ECTOPIC SECRETION OF CORTICOTROPIN-RELEASING HORMONE

Clinical Features

The ectopic corticotropin syndrome accounts for 10% to 20% of cases of Cushing's syndrome. Unlike Cushing's disease, with an 8:1 female preponderance, this syndrome is more common in men than in women. The typical presentation also differs; the onset is sudden, and progression is rapid. Patients complain of proximal myopathy and peripheral edema. Hypertension, hypokalemia, and severe glucose intolerance are often present. Hyperpigmentation may occur, but hirsutism is unusual. Other manifestations of cancer, such as anorexia, weight loss, and anemia, are common.

The somatic features of Cushing's syndrome are notably absent in the typical patient, perhaps because of the rapid evolution of the clinical picture. Patients with slowly growing carcinoid tumors of the bronchus or thymus have a more indolent disease and often present with the classic habitus of Cushing's syndrome—moon facies, centripetal obesity, proximal myopathy, polydipsia, and polyuria. Hyperpigmentation is common in these patients, as is hirsutism in women.

The tumors that produce the ectopic corticotropin syndrome are primarily of neuroendocrine cell origin. In published series, approximately 45% are SCLC, 15% are thymic carcinoids, 10% are bronchial carcinoids, 10% are islet cell tumors, 5% are other carcinoid tumors, 2% are pheochromocytomas, and 1% are ovarian adenocarcinomas. However, adenocarcinoma and squamous carcinoma are also occasionally associated with the syndrome. It appears that SCLC is greatly underrepresented in these referral series; it probably accounts for well over 50% of unselected cases.
Laboratory Features

Both the level of cortisol secretion and the level of corticotropin tend to be higher in ectopic than in pituitary Cushing's syndrome, although there is some overlap. In most ectopic cases, both cortisol and corticotropin levels are elevated to two to four times the normal morning values and the normal diurnal variation in their levels is lost. Urinary excretion of adrenal steroid metabolites is increased correspondingly. Two-site immunoradiometric assays, which are coming into common use for detection of corticotropin, give lower values for corticotropin in ectopic cases than older radioimmunoassays, probably because they do not detect partially processed forms that are common in the ectopic syndrome.

Despite the abnormal processing of corticotropin by nonpituitary tumors, there is no other POMC peptide in serum whose presence is decisive in the diagnosis of the ectopic syndrome. More than one half of nonpituitary tumors that secrete corticotropin also secrete other peptides, including carcinoembryonic antigen, GRP, calcitonin, somatostatin, and corticotropin-releasing hormone (CRH), and the presence of these peptides is suggestive of the ectopic corticotropin syndrome.

Hypokalemia occurs in 80% to 100% of cases in various series, and potassium wasting is more severe than in pituitary Cushing's disease. The hypokalemia is probably explained by the mineralocorticoid effects of cortisol, which are more evident both because cortisol levels tend to be higher in ectopic than in pituitary Cushing's syndrome and because 11-hydroxysteroid dehydrogenase activity appears for unknown reasons to be decreased in patients with ectopic corticotropin secretion. A deficiency of 11-hydroxysteroid dehydrogenase activity impairs the inactivation of cortisol in the renal tubule, leading to increased exposure of mineralocorticoid receptors to cortisol. In disorders such as congenital deficiency of 11-hydroxysteroid dehydrogenase and licorice intoxication, in which the activity of the enzyme is inhibited, normal levels of cortisol produce a state of pseudohyperaldosteronism.
Pathogenesis

Although many nonpituitary tissues contain POMC mRNA, most are short transcripts (800 nucleotides) that are initiated by a downstream promoter at the third exon of the POMC gene and do not include coding sequences for the signal peptide that is necessary for direction of POMC into the secretory pathway. Thus, nonpituitary POMC transcripts probably do not generate bioactive POMC products that can be secreted. In contrast, nonpituitary tumors that secrete corticotropin contain a 1150-nucleotide mRNA similar to the predominant pituitary species, and many nonpituitary tumors also contain 1350-nucleotide transcripts initiated from an upstream promoter that is largely quiescent in pituitary cells.

Two regions of the POMC promoter contribute to activity in SCLC; the region that confers high POMC promoter activity on pituitary cells is not active. One region binds the transcription factor E2F in a methylation-sensitive fashion, and E2F is inactivated by the tumor suppressor gene Rb, which is inactive in 90% of cases of SCLC. Thus, both loss of Rb and differential methylation of the POMC promoter are potential mechanisms of POMC expression in SCLC.

Consistent with the nonsuppressibility of most nonpituitary tumors by glucocorticoids, the sensitivity of POMC gene expression to inhibition by glucocorticoids is reduced in SCLC cell lines. In some cell lines, glucocorticoid receptors are absent; in others, glucocorticoid receptor action appears to be defective. Negative glucocorticoid regulatory elements are typically composite elements that require binding of regulatory factors in addition to the glucocorticoid receptor, leading to the possibility that such accessory factors may be abnormal in transformed cell lines. However, glucocorticoids also fail to stimulate transcription from classic glucocorticoid regulatory elements in SCLC cell lines, and this defect is overcome by overexpression of the wild-type glucocorticoid receptor.

POMC processing in nonpituitary tumors is often incomplete, with the release into blood of POMC fragments with reduced biologic activity. These incompletely processed forms are larger than corticotropin by gel filtration and were first described in the serum of cancer patients with the ectopic corticotropin (ACTH) syndrome as big ACTH. As noted earlier, some incompletely processed POMC peptides can be detected by radioimmunassay techniques for corticotropin but not by two-site immunoradiometric assays. In one study using a precursor-specific assay, the ratio of corticotropin precursors to corticotropin in plasma was 58:1 in the ectopic corticotropin syndrome and 5:1 in pituitary Cushing's disease.

Unusual small peptides are also produced from POMC in nonpituitary tumors. In anterior pituitary corticocyte cells, four of the six dibasic sites in POMC are cleaved by the prohormone convertase PC1/PC3, and the predominant products are six peptides:

- An NH$_2$-terminal peptide
- A joining peptide
- Corticotropin
- Lipotropin (-LPH)
- Smaller amounts of -LPH and -endorphin

Additional products that are detected routinely in extracts of nonpituitary tumors include the corticotropin-like intermediate lobe polypeptide (CLIP) and melanocyste stimulating hormone (MSH) (522). Both peptides are present in the intermediate lobe in the rodent pituitary gland, and their presence in nonpituitary tumors indicates that nonpituitary tumors contain the PC2 convertase, which is normally present in intermediate but not anterior pituitary cells. These peptides are not secreted in large amounts and are not useful as tumor markers in blood, but the serum LPH/corticotropin ratio in the ectopic corticotropin syndrome is higher than in pituitary tumors, possibly reflecting the increased PC2 activity in nonpituitary tumors.

Corticotropin-like activity can be identified in extracts of many nonSCLCs and in virtually all SCLCs, and at least one third of all SCLCs show POMC mRNA by in situ hybridization. Yet only 1% to 3% of patients with SCLC have clinical evidence of corticotropin excess. Thus, the ectopic corticotropin syndrome is a good example of the principle that ectopic production of hormones is more common than clinical syndromes of hormone excess. Differences between tumors in trans-acting nuclear factors or epigenetic regulation of the POMC promoter by DNA methylation may account for differential expression of the POMC gene.

Patients with corticotropin-producing neoplasms are protected from the consequences of hormone excess by several mechanisms. Malignant tumors contain much smaller quantities of POMC mRNA and peptides than the pituitary and are thus inefficient in producing corticotropin. Tumor cells are much poorer in neurosecretory granules than pituitary corticotropes and are relatively deficient in the ability to process POMC efficiently and secrete the peptide products. Inefficient cleavage of POMC leads to incompletely processed forms of corticotropin with little biologic activity. Processing of POMC by tumors can also lead to production of biologically inactive products. For example, some tumors produce significant amounts of corticotropin but cleave it to the CLIP.
Laboratory Diagnosis

The diagnosis of the ectopic corticotropin syndrome is described in Chapter 8 and Chapter 14.

The first step consists of determining whether cortisol excess is present and whether it is corticotropin-dependent. Increased basal cortisol secretion can often be shown by measurement of serum cortisol or urinary free cortisol, both of which are increased in the ectopic corticotropin syndrome. When the basal levels are not markedly increased, the presence of cortisol excess can be established with a low-dose dexamethasone suppression test, for example, the 1-mg overnight dexamethasone suppression test. The corticotropin dependence of cortisol excess can be established by measurement of corticotropin in the same sample in which cortisol is measured.

Corticotropin-dependent Cushing's syndrome results from either pituitary or ectopic secretion of corticotropin. In the classic form of the syndrome (e.g., corticotropin-secreting SCLC), secretion is nonsuppressible and there is little or no response of serum or urinary cortisol to the administration of high-dose dexamethasone, whereas the secretion of corticotropin by pituitary adenomas is dexamethasone-responsive. In a patient with a recognized malignancy and clinical features suggestive of the ectopic syndrome, the finding of nonsuppressible hypercortisolism usually suffices to make the diagnosis.

In occasional lung cancers and in about 50% of bronchial or thymic carcinoid tumors, the secretion of corticotropin can be suppressed with high-dose dexamethasone. This circumstance has been called the occult ectopic corticotropin syndrome and presents a major diagnostic challenge because the clinical presentation and secretory dynamics may be identical to those of pituitary Cushing's syndrome and because neither these small tumors nor pituitary corticotroph adenomas may be evident on routine radiologic studies.

Although a number of noninvasive methods are used in this circumstance, none is definitive. Because nonpituitary tumors are not as well suppressed by glucocorticoids as corticotrope adenomas of the pituitary gland, it is useful to apply stringent criteria for glucocorticoid suppressibility, namely suppression of urinary free cortisol by more than 80% after administration of high-dose dexamethasone, which has a sensitivity of 81% and a specificity of 92% for pituitary Cushing's syndrome. Stimulation with the ovine CRH test is valuable because nonpituitary tumors do not respond well to CRH. An increase in plasma corticotropin of 35% after administration of ovine CRH (1 µg/kg body weight) was reported to have a sensitivity of 93% and a specificity of 100% for the diagnosis of pituitary Cushing's syndrome. Metyrapone testing in combination with high-dose dexamethasone may also improve diagnostic accuracy.

The definitive study for distinguishing pituitary from nonpituitary forms of hypercortisolism is inferior petrosal sinus sampling with administration of ovine CRH. The ratio of corticotropin in the inferior petrosal sinus to that in peripheral blood after administration of CRH is greater than 3 in patients with pituitary tumors and less than 2 in patients with corticotropin-secreting nonpituitary tumors. Cavernous sinus sampling has also been successful. Localization of bronchial and thymic carcinoids may also be difficult. Thin-section computed tomography of the chest and scanning with labeled octreotide have sometimes been of use but have a high failure rate.
Treatment

The management of Cushing's syndrome is discussed in Chapter 8 and Chapter 14.

When possible, the treatment of the ectopic corticotropin syndrome is surgical. With slow-growing carcinoid tumors of the bronchus, thymomas, or pheochromocytomas, surgical resection can be curative. If the tumor cannot be identified, it is necessary to block cortisol secretion with adrenolytic agents. Some patients ultimately require surgical adrenalectomy to control hypercortisolism.

Malignant nonpituitary neoplasms that secrete corticotropin are rarely amenable to resection because the tumor is usually advanced and inoperable by the time the clinical syndrome appears. With malignant neoplasms the aim is to palliate hypercortisolism by medical adrenalectomy using adrenolytic drugs, such as aminogluthethimide (250 mg three times a day) or metyrapone (250 to 500 mg three times a day). Ketoconazole (200 to 400 mg twice a day) has also been useful for the treatment of ectopic corticotropin syndrome. A replacement dose of hydrocortisone should be administered with these drugs to avoid adrenal insufficiency. Some patients respond to the long-acting somatostatin agonist octreotide, and the glucocorticoid antagonist mifepristone has also been used.
Ectopic Secretion of Corticotropin-Releasing Hormone

Nonendocrine tumors rarely cause Cushing's syndrome by secretion of CRH. Patients have increased CRH levels in tumor tissue or in plasma and high plasma corticotropin levels. It is important to document that the site of corticotropin secretion is the pituitary gland because many nonendocrine tumors that secrete CRH also secrete corticotropin itself. Presumptive evidence of a pituitary source of corticotropin may come from demonstration that the gradient of corticotropin between the inferior petrosal sinus and peripheral blood is more than 3:1, from finding pituitary corticotropic hyperplasia in patients who underwent pituitary surgery for a presumed corticotropic adenoma, or from the failure to detect corticotropin in the nonendocrine tumor. When the nonendocrine tumor secretes both CRH and corticotropin, the true role of CRH in the clinical syndrome may be indeterminate.

Cushing's syndrome resulting from ectopic secretion of CRH does not have a distinctive presentation. In most cases, the hypercortisolism is unresponsive to dexamethasone suppression, but a normal response to high-dose dexamethasone has also been reported. The response to metyrapone is also variable. Tumors that secrete CRH include small cell carcinomas of the prostate and lung, medullary thyroid carcinoma, carcinoids, and a hypothalamic gangliocytoma. These neuroendocrine tumors are similar to the tumors that cause Cushing's syndrome by direct secretion of corticotropin.

The diagnosis of ectopic CRH secretion as the cause of Cushing's syndrome is usually made retrospectively. In view of the rarity of the disorder, it is probably inappropriate to measure CRH routinely in Cushing's syndrome. However, it may be worthwhile to determine the plasma CRH level when pituitary surgery has disclosed diffuse corticotropic hyperplasia in a patient with Cushing's syndrome.
HYPOGLYCEMIA WITH NONISLET CELL TUMORS

Clinical Features

Fasting hypoglycemia produced by nonislet cell tumors typically causes neuroglycopenic symptoms of obtundation, confusion, or behavioral aberrations, which may have been present for some time before the diagnosis is made. Nonislet cell tumors rarely secrete insulin, but a case of small cell cervical carcinoma with high levels of insulin, proinsulin, and C peptide has been reported; the tumor was found to contain insulin mRNA by in situ hybridization and immunoreactive insulin by immunohistochemical methods.

Most extrapancreatic tumors that cause hypoglycemia do so by secreting IGF-II. The offending neoplasms are usually bulky, slow-growing mesenchymal tumors. Fibrosarcomas, rhabdomyosarcomas, leiomyosarcomas, mesotheliomas, and hemangiopericytomas account for more than 50% of cases. Hepatocellular carcinomas (hepatomas), carcinoid tumors, and adrenocortical carcinomas account for about 25% of cases, and the remainder are made up of various carcinomas, leukemias, and lymphomas. More than one third of the tumors are retroperitoneal, about one third are intra-abdominal, and the remainder are intrathoracic.
Pathogenesis

Fasting hypoglycemia produced by nonislet cell tumors results from increased peripheral utilization of glucose, primarily in skeletal muscle, coupled with decreased hepatic glucose output.\textsuperscript{220,221,222} Lipolysis is inhibited, and free fatty acid levels are low. Although it had been suspected that bulky tumors themselves, sometimes weighing many kilograms, might metabolize enough glucose to exceed the capacity for hepatic glucose production, this phenomenon has not been documented. Despite insulin-like effects on glucose utilization, hepatic glucose production, and lipolysis, fasting insulin levels during hypoglycemia are appropriately suppressed. For this reason, it has appeared that an insulin-like factor is probably responsible for hypoglycemia.

Sera from patients with nonislet cell tumors contain elevated levels of an insulin-like activity by radioreceptor assay.\textsuperscript{223} The level of IGF-II mRNA in nonislet cell tumors is often increased, even in patients with normal serum IGF-II levels.\textsuperscript{224,225,226} IGF-II levels are sometimes elevated during hypoglycemia but may be normal,\textsuperscript{227} and the levels of IGF-I are typically suppressed.\textsuperscript{228} Although not all patients have high IGF-II levels, it appears that IGF-II is in fact the causative agent of hypoglycemia and can cause hypoglycemia at normal total serum levels as a consequence of altered processing and increased bioavailability.

Altered binding of IGF-II in the tumor-hypoglycemia syndrome increases its bioavailability to peripheral receptors. In normal serum, IGFs are bound largely in one of two complexes. Most IGF is normally bound to a heterotrimeric 150-kd complex consisting of the IGF, the binding protein IGFBP3, and an acid-labile glycoprotein. The large complex is retained in the circulation, and as a result the half-life of the IGF-II complex is relatively long, 12 to 15 hours. A minority of IGF circulates in a smaller 50-kd complex that contains mainly IGF and a different binding protein, IGFBP2. The small complex can cross capillaries and deliver IGF to tissue receptors, and IGF-II bound to this complex has a half-life of only about 30 minutes.\textsuperscript{230} In sera from patients with nonislet cell tumors and hypoglycemia, the fraction of IGF-II bound to the small, bioavailable complex is increased, on average by threefold.\textsuperscript{231,232,233} Presumably increasing the access of IGF-II to the receptor, even in the setting of normal total IGF-II levels.

A substantial fraction of IGF-II in both tumors and sera is present in a high-molecular-weight form, big IGF-II,\textsuperscript{225,226,227} a partially processed form that contains a 21-amino-acid carboxyl-terminal extension from the E domain.\textsuperscript{227} Big IGF-II was reported to lack O-linked glycosylation,\textsuperscript{234} which may give it increased bioactivity,\textsuperscript{235} but O-linked glycosylation was reported to be normal in another study.\textsuperscript{236} Whether a decreased ability of big IGF-II to form a normal ternary complex contributes directly to its increased bioavailability remains to be determined.

Current concepts of the alteration in IGF-II binding are summarized in Figure 40-3.\textsuperscript{8,216} Oversecretion of big IGF-II suppresses the secretion of insulin, growth hormone (GH), and IGF-I.\textsuperscript{237} In turn, suppression of GH and IGF-I down-regulates the synthesis of IGFBP3 and the acid-labile subunit, both of which are GH-dependent,\textsuperscript{238} and up-regulates the synthesis of IGFBP2. Consistent with this proposal regarding the role of GH is the response of a patient to GH therapy.\textsuperscript{239} Thus, IGF-II oversecretion leads to altered binding and increased bioactivity of IGF-II and can cause hypoglycemia even when total IGF-II levels are normal. The level of free IGF-II in serum is also increased.\textsuperscript{240}
Laboratory Diagnosis

The fasting levels of insulin and C peptide are appropriately suppressed in samples obtained during hypoglycemia (insulin < 36 pmol/L [6 µU/mL], C peptide < 0.2 nmol/L [0.6 ng/mL]). The IGF-II level may be normal or increased. In patients with normal levels of IGF-II, the diagnosis is supported by finding low levels of IGF-I, GH, and IGFBP3.
Treatment

The mainstay of treatment is resection of the tumor. Even partial debulking may ameliorate hypoglycemia. In patients with unresectable tumors, several maneuvers based on the pathogenetic scheme have been attempted. Therapy with GH, glucagon, glucocorticoids, or somatostatin has been effective in individual patients with unresectable tumors. These measures are temporary, however, until the unresectable tumor can be treated with chemotherapy.
SYNDROMES CAUSED BY GROWTH HORMONERELEASING HORMONE, GROWTH HORMONE, AND HUMAN PLACENTAL LACTOGEN

Since 1980, more than 40 cases of acromegaly have been associated with nonpituitary tumors. There are only two well-documented cases of acromegaly resulting from secretion of GH by a nonpituitary tumor: the other tumors caused acromegaly by secreting growth hormonereleasing hormone (GHRH), which was first isolated from extracts of pancreatic tumors.

Overall, secretion of GHRH accounts for less than 1% of cases of acromegaly. The clinical findings, aside from the presence of a nonpituitary tumor, do not differ from those in acromegaly caused by somatotropin adenomas. The mean duration of acromegalic features before diagnosis is 7.9 years, about the same as in pituitary acromegaly. Diabetes mellitus, amenorrhea, and galactorrhea are common. In about 50% of cases, the extrapituitary neoplasm is symptomatic. Other syndromes of hormone excess, including Cushings syndrome, primary hyperparathyroidism, and the Zollinger-Ellison syndrome, may occur in conjunction with acromegaly.

Carcinoids are the most common extrapituitary tumors that produce acromegaly (69% of cases), followed by islet cell tumors (23%), pheochromocytoma, and paraganglioma. GHRH immunoreactivity can frequently be demonstrated in neuroendocrine tumors from patients without acromegaly, usually in smaller amounts than in tumors associated with acromegaly. However, high plasma levels of GHRH have been reported in SCLC patients without acromegaly. Some of these patients have abnormal GH secretory dynamics, such as a paradoxical GH increase after administration of thyrotropin-releasing hormone (TRH), suggesting that subclinical or incomplete forms of acromegaly may be present. All three isoforms of GHRH have been identified in nonpituitary tumors, but the predominant species in most tumors is GHRH(140), whereas the dominant hypothalamic form is GHRH(144).

Serum levels of GHRH in acromegaly caused by extrapituitary tumors are markedly elevated, from 0.3 to 5 µg/L (0.3 to 50 ng/mL). Normal fasting GHRH levels are less than 60 ng/L (0.06 ng/mL), and the peripheral level is less than 200 ng/L (0.2 ng/mL) in typical acromegaly.

The dynamics of GH secretion in acromegaly induced by nonpituitary secretion of GHRH are not distinctive. GH and IGF-I levels are high, and the normal circadian rhythm of GH secretion is lost. Prolactin levels are elevated in 80% of patients. Virtually all patients display a paradoxical increase of GH after administration of TRH, compared with approximately 40% of patients with classical acromegaly. Many patients with GHRH-induced acromegaly do not respond to exogenous GHRH, but this is not a uniform finding and cannot be used diagnostically. In most cases, the nonpituitary tumor can be identified by imaging studies of the chest and abdomen. About 90% of carcinoid tumors that cause acromegaly are located in the chest (see Chapter 8).

The primary therapy is surgical. About half of patients have resectable tumors. For patients with nonresectable disease, the therapy of choice is octreotide, the somatostatin agonist. In about half of patients, GH levels return to normal with octreotide or lanreotide treatment, and most of the remainder have a partial response. The level of GHRH is often reduced less than that of GH, which suggests that the drug affects primarily the pituitary response to GHRH.

One case of extrapituitary acromegaly caused by nonpituitary secretion of GH itself involved a pancreatic islet cell tumor that contained both GH and GH mRNA. At surgery, an arteriovenous GH gradient was demonstrated across the tumor, and tumor cells in culture secreted immunoreactive GH. GH was not detectable in plasma. The other well-documented case was a follicular non-Hodgkin’s lymphoma in which the cells expressed the GH gene, but not the GHRH gene, and secreted large amounts of GH in culture. Hypersecretion of GH was abolished by successful chemotherapy of the lymphoma.

The propensity of other members of the GH family for secretion by nonendocrine tumors is variable. Prolactin has not been conclusively shown to be secreted into the blood by nonpituitary tumors. However, prolactin and its receptor are expressed in human breast carcinoma cells, and an autocrine pathway has been described in which prolactin induces constitutive phosphorylation of erbB-2 (Her/Neu). Neoplastic production of human placental lactogen (hPL) (or chorionic somatomammotropin) appears to be relatively common. In large series, hPL was detectable in plasma in 9% of patients with malignant disease, most commonly lung carcinoma but also carcinoma of the thyroid, breast, stomach, pheochromocytoma, carcinoids, and leukemia; 14% of patients with breast carcinoma had increased blood hPL levels. hPL has weak GH activity but substantial lactotrophic activity. Patients with elevated hPL levels in blood do not have galactorrhea, however, because the circulating hPL levels in such patients are lower than the equivalent levels of prolactin that produce galactorrhea. It is also possible that neoplasms secrete hPL in biologically inactive forms.
SYNDROMES CAUSED BY HUMAN CHORIONIC GONADOTROPIN

hCG is produced eutopically by trophoblastic and germ cell tumors, including testicular embryonal carcinoma and extragonadal germinomas. For these tumors, hCG is a useful tumor marker. Gynecomastia has been reported in a few adult patients with nontrophoblastic malignancies, and isosexual precocious puberty has occurred in children (see Chapter 21). The associated tumors include lung carcinoma, hepatocellular carcinoma, adrenocortical carcinoma, and renal carcinoma.

Although hCG is secreted by approximately 18% of nontrophoblastic tumors (Table 40-5), it is not useful as a tumor marker for screening for nontrophoblastic neoplasms. A significant number of normal individuals, including 2.4% of blood donors and 3.6% of patients with various benign diseases, also have detectable levels of hCG (assayed as hCG) in serum, decreasing the positive predictive value of a detectable hCG level.

Some tumors secrete free subunits of the glycoprotein hormones. For example, about 50% of malignant islet cell tumors secrete the subunit of glycoprotein hormones, whereas benign islet cell tumors rarely do so. Immunohistochemical staining for the subunit has also been used to distinguish benign from malignant islet cell tumors histologically. A degradation product of hCG in urine, the -core fragment, has been reported in about 50% of patients with lung cancer, but the fragment is also detected at low levels in 6% to 14% of individuals with benign disorders; its clinical value remains to be established.

ONCOGENOUS OSTEOMALACIA

More than 50 cases of hypophosphatemic osteomalacia or rickets have been reported in patients with tumors of mesenchymal origin, usually small, benign skeletal tumors of the extremities or head. Histologically, the causative tumors include hemangiopericytoma, ossifying and nonossifying fibroma, and giant cell tumors. Hypophosphatemic osteomalacia has also been reported in patients with disseminated prostatic carcinoma, a situation in which the disorder may be due to phosphate uptake by osteoblastic metastases.

Most patients with oncogenous osteomalacia are middle-aged and present with bone pain and proximal myopathy, which may have been present for years before diagnosis. However, the disorder has been described in children. The serum phosphorus level is markedly reduced because of renal phosphate wasting. The serum alkaline phosphatase is increased, but the serum calcium and PTH levels are normal. The level of 1,25(OH)₂ D is typically low and the level of 25-hydroxyvitamin D is normal. Osteomalacia is present in bone biopsies. The fact that the syndrome is reversed by resection of the tumor indicates that it has a humoral basis.

Although rare, oncogenous osteomalacia is probably the most common cause of acquired hypophosphatemic osteomalacia. The manifestations are similar to those of hereditary phosphate-wasting disorders such as X-linked hypophosphatemic rickets, and the primary event is probably the induction of severe phosphaturia by a humoral factor, phosphatonin, secreted by the tumor.

The mutation responsible for one of the hereditary forms of renal phosphate wasting, autosomal dominant hypophosphatemic rickets, has been localized to a new member of the fibroblast growth factor family, FGF-23. Each of six tumors from patients with oncogenous osteomalacia expressed high levels of FGF-23 mRNA or protein, and FGF-23 induces phosphate wasting. The gain-of-function mutations in FGF-23 that cause autosomal dominant hypophosphatemic rickets prevent its degradation. It is likely that the responsible protease is Phex; loss of this protease produces a third form of phosphate wasting, X-linked hypophosphatemia.
SYNDROMES CAUSED BY OTHER HORMONES

Erythropoietin and Erythrocytosis

Erythrocytosis occurs in 1% to 4% of renal carcinomas, 5% to 10% of hepatocellular carcinomas, and 10% to 20% of cerebellar hemangioblastomas. It has been observed in patients with uterine fibromyomas, adrenocortical carcinomas, or ovarian tumors. Renal and hepatocellular carcinomas account for 71% of cases; thus, erythrocytosis is most common in tumors arising from the tissues that normally secrete erythropoietin (the fetal liver and by the adult kidney).

The association of erythropoietin and vascular endothelial growth factor secretion from cerebellar hemangioblastoma and renal carcinoma raised the possibility that both of these hypoxia-responsive genes are specifically activated by loss of the von Hippel-Lindau tumor suppressor gene VHL. The VHL protein appears to stabilize mRNA for hypoxia-inducible proteins. VHL-negative renal carcinomas display constitutively high levels of the hypoxia-inducible factor-1 (HIF-1), a heterodimeric member of the bHLH PAS family of transcription factors, composed of \( \alpha \) and \( \beta \) subunits. The action of the VHL protein to increase the proteasome-mediated degradation of the HIF-1 protein and other proteins may prove central to many manifestations of VHL gene alteration.

The VHL gene also displays loss of heterozygosity in some hepatocellular carcinomas, and tissue-specific inactivation of the VHL gene in hepatocytes gives rise to cavernous hemangioma of the liver and up-regulation of the erythropoietin gene. It is thus likely that inactivation of VHL plays a central role in the induction of erythropoietin synthesis in each of the tumors classically associated with erythropoietin-dependent polycythemia, by either transcriptional or post-transcriptional mechanisms.

Early studies reported that erythropoietic bioactivity was frequently present in tumor extracts from polycythemic patients; erythropoietin mRNA has been demonstrated in extracts of renal carcinomas, hepatocellular carcinoma, and cerebellar hemangioblastoma. Erythrocytosis has been produced in nude mice by transplantation of erythropoietin-positive renal carcinoma cells and hepatocarcinoma cells. Some patients with tumors and erythrocytosis have increased serum erythropoietin levels. However, in the best studied group, patients with hepatocellular carcinoma, it has been difficult to demonstrate a consistent relationship between the red blood cell mass and serum levels of erythropoietin. Increased serum levels of erythropoietin are common in patients with hepatocellular carcinoma; however, few of the patients with high erythropoietin levels have erythrocytosis, and some patients with erythrocytosis have normal levels of erythropoietin. Absence of erythrocytosis in the presence of high erythropoietin levels could reflect secretion of biologically inactive (e.g., precursor) forms of erythropoietin.
Calcitonin

Calcitonin is present in neuroendocrine cells of the normal bronchial epithelium and is frequently secreted by neuroendocrine tumors, including 18% to 60% of SCLCs. Calcitonin is also secreted by other lung carcinomas, breast cancers, leukemias, and a broad spectrum of other neoplasms. Estimates of the frequency of calcitonin secretion are lower in studies that rigorously control for assay artifacts, but it is clear that some tumors express the gene for calcitonin/calcitonin generelated peptide (CGRP) and secrete calcitonin in vitro.

Tumors frequently secrete large forms of calcitonin and are less sensitive to stimulation than in patients with hypercalcitoninemia resulting from medullary thyroid carcinoma. CGRP, which is derived from alternative splicing of the calcitonin gene, is expressed in normal bronchial epithelium and has been detected in tumor extracts and serum. The levels of calcitonin in the sera of patients with lung carcinoma are lower than those in medullary thyroid carcinoma, and no clinical syndrome is associated with the secretion of calcitonin or CGRP.
Endothelin

The potent vasoconstrictor peptide endothelin is expressed in hepatocellular carcinoma, breast carcinoma, ovarian carcinoma, and prostate carcinoma. Endothelin receptors are often coexpressed on tumor cells, and endothelin-1 was reported to have paracrine effects on tumor cell growth. Increased serum levels of endothelin-1 and a partially processed form of the peptide big endothelin-1 have been found in hepatocellular carcinoma. Arteriovenous differences, albeit small, have been found across the liver of patients with hepatocellular carcinoma. No clinical manifestations of systemic secretion of endothelin have been reported, but endothelin-1 has been implicated as the factor causing the osteoblastic response to bone metastasis in breast carcinoma, and a similar role was suggested in prostate carcinoma.
Vasoactive Intestinal Peptide

Inappropriate secretion of VIP produces pancreatic cholera, also known as the WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria) or Verner-Morrison syndrome (see Chapter 33). In addition to pancreatic islet cell tumors, other neuroendocrine tumors, including ganglioneuroma, ganglioneuroblastoma, neuroblastoma, pheochromocytoma, and medullary thyroid carcinoma, can produce the syndrome. These tumors stain for VIP, and removal of the tumor causes return of peripheral VIP levels to normal and reverses the clinical syndrome. Increased VIP levels have also been reported in lung carcinoma and in a neuroendocrine tumor of the kidney. VIP is present in the central and peripheral nervous systems; thus, its production by neuroendocrine tumors may be regarded as eutopic rather than ectopic.
Other Gut Hormones

Somatostatin is frequently detectable in extracts of lung tumor [305] but is secreted by cultured SCLC cells, [306] but elevated serum somatostatin concentrations are uncommon in lung cancer (see Chapter 35). [307] Only one case of the somatostatinoma syndrome has been attributed to SCLC. [308] The glucagonoma syndrome occurred in a patient with a renal neuroendocrine tumor [309] and in a patient with a large cell lung carcinoma. [310] The glucagonoma syndrome occurred in a patient with a renal neuroendocrine tumor and in a patient with a large cell lung carcinoma.

GRP is often found in lung carcinomas, cultured SCLC cells, and other tumors but elevated serum levels are uncommon. [311] Pro-GRP may be a better tumor marker. [312] The peptide is a mitogen for SCLC cells, [313] and neutralizing studies with antibodies and antagonists suggested that it has an autocrine role as a growth factor. GRP was also reported to affect the motility of tumor cells. A variant form of the GRP receptor is expressed in human lung carcinoma cell lines. GRP is expressed in neuroendocrine cells of bronchial mucosa, particularly at branch points, and appears to have a developmental role in the regulation of branching morphogenesis of airways. Pancreatic polypeptide is occasionally detectable in the sera of patients with carcinoid tumors.

Pancreatic polypeptide is occasionally detectable in the sera of patients with carcinoid tumors.

Chapter 41 - Carcinoid Tumors, Carcinoid Syndrome, and Related Disorders

Kjell öberg

The first clinical and histopathologic description of carcinoid tumor was made by Otto Lubarsch in 1888. He was impressed by the multicentric origin of carcinoid tumors of the gastrointestinal tract, their lack of gland formation, and their lack of similarity with the usual adenocarcinoma of the alimentary system.

The term Karzinoide was introduced in 1907 by the pathologist Oberndorffer as a descriptive name for what he considered to be a "benign" type of neoplasm of the ileum, which could nevertheless behave like a carcinoma. It was subsequently generally accepted that the carcinoid tumor was a very-slow-growing and benign neoplasm with no potential for invasiveness and no tendency to give rise to metastases. This myth of benignity has survived to the present, even though in 1949 Pearson and Fitzgerald described a large series of metastasizing carcinoid tumors.

Carcinoid tumors have subsequently been reported in a wide range of organs, but they most commonly involve the lungs and gastrointestinal tract. Carcinoid tumors of the thymus, ovaries, testes, heart, and middle ear have also been described. The clinically well-known carcinoid syndrome was described by Thorson and associates in 1954; 1 year earlier, Lembeck had extracted serotonin from a carcinoid tumor.
PHYLOGENESIS AND EMBRYOLOGY

Carcinoid tumors are derived from neuroendocrine cells, and Gosset and Masson in 1914 were the first to point out the neuroendocrine properties of carcinoid tumors. Masson later described the remarkable affinity for silver salts displayed by intracytoplasmic granules in tumor cells and noted that carcinoid tumors originate from enterochromaffin cells, the so-called Kulchitsky cells in the crypts of Lieberkühn in the intestinal epithelium. Furthermore, he suggested that the tumors were of endocrine origin (Fig. 41-1).

The mammalian gastrointestinal tract and pancreas contain a large number of endocrine cell types, which initially were thought to originate from the neuroectoderm. This observation gave rise to the APUD concept (amine precursor uptake and decarboxylation) because of the ability of these cells to take up and decarboxylate amino acid precursors of biogenic amines such as serotonin and catecholamines. It was later revised by others who postulated that these endocrine cells might also be derived from mesoderm and endoderm. The neuronal phenotype is clearly seen when culturing carcinoid tumor cells in vitro. The enterochromaffin cells, from which many carcinoid tumors derive, have the property of producing and secreting amines (such as serotonin) and polypeptides (such as neurokinin-A and substance P).

Carcinoid tumors may also originate from other neuroendocrine cells, such as the enterochromaffin-like (ECL) cells of the gut and endocrine cells in the bronchi. The tumors derived from these cells are able to produce a wide range of hormones, such as gastrin, gastrin-releasing peptide (GRP), calcitonin, pancreatic polypeptide, adrenocorticotropic hormone (ACTH), corticotropin-releasing hormone (CRH), and growth hormonereleasing hormone (GHRH) as well as somatostatin, glucagon, and calcitonin gene related peptide (CGRP). A common secretory product from all types of carcinoid tumors is the glycoprotein chromogranin-A (CgA) the most important general tumor marker in these patients (see later).
MOLECULAR GENETICS

Despite advances in the diagnosis, localization, and treatment of carcinoid tumors, no etiologic factor associated with the development of these tumors has been identified. Little is known about molecular genetic changes underlying tumorigenesis. Sporadic foregut carcinoids as well as the familial-type multiple endocrine neoplasia type 1 (MEN-1) frequently display allelic losses at chromosome 11q13, and somatic MEN-1 gene mutations has been reported in one third of sporadic foregut tumors. In contrast with foregut carcinoids, molecular and cytogenetic data for midgut carcinoids are quite limited, and these tumors are not included in MEN-1 syndrome. Deletions of chromosomes 18q and 18p have been reported in 38% and 33%, respectively, of gastrointestinal carcinoids.

In one recent publication, deletions on chromosome 18 were found in 88% of midgut carcinoid tumors but Smad 4/DPC4 locus was not deleted. In addition to the consistent finding of deletions on chromosome 18, multiple deletions on other chromosomes (4, 5, 7, 9, 14, 20) were noticed in single tumors. The region telomeric to Smad 4/DPC 4/DCC loci must be further explored for possible losses of a tumor suppressor gene in this area.

| TABLE 41-1 -- Classification of Carcinoid Tumors |
|---------------------|---------------------|---------------------|
| **Histopathology**  | **Foregut**          | **Midgut**          | **Hindgut**         |
| Argyrophilic        | Argentaffin-positive | Argyrophilic        |
| CgA-positive        | CgA-positive         | SVP-2-positive      |
| NSE-positive        | NSE-positive         | (CgA-positive NSE-positive) |
| Synaptophysin-positive | Synaptophysin-positive | (Synaptophysin-positive) |
| **Molecular Genetics** | Chromosome 11q13 deletion | Chromosome 18q, 18p deletion | Unknown |
| **Secretory Products** | CgA, 5-HT, 5-HTP, histamine, ACTH, GHRH, CGRP, somatostatin, AVP, glucagon, gastrin, NKA, substance-P, neurotensin, GRP | CgA, 5-HT, NKA, substance-P, prostaglandins E₁ and F₂ , bradykinin | PP, PYY, somatostatin |
| **Carcinoid Syndrome** | Present (30%) | Present (70%) | Absent |

ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin; CgA, chromogranin-A, CGRP, calcitonin gene-related peptide; GHRH, growth hormone-releasing hormone; GRP, gastrin-releasing peptide; 5-HT, 5-hydroxytryptamine; 5-HTP, 5-hydroxytryptophan; NKA, neurokinin; NSE, neuron-specific enolase; PP, pancreatic peptide; PYY, peptide YY; SVP2, synaptic vesicle protein 2.
CLASSIFICATION

In 1963, Williams and Sandler reported a relationship between the embryonic origin of carcinoid tumors and the histologic, biochemical, and, to some extent, clinical features of the tumors. Three distinct groups were formed:

1. Foregut carcinoids (i.e., intrathoracic, gastric, and duodenal carcinoids).
2. Midgut carcinoids (carcinoids of the small intestine, appendix, and proximal colon).
3. Hindgut carcinoids (carcinoid tumors of the distal colon and rectum).

Although this original classification has been useful in the clinical assessment of patients with carcinoid tumors, it has demonstrated significant shortcomings. As a result, many investigators have adopted a new classification system that takes into account not only the site of origin but also variations in the histopathologic characteristics of carcinoid tumors. In this revised system, typical tumors are classified as well-differentiated neuroendocrine tumors with their characteristic growth pattern. These tumors are usually slow-growing, with low proliferation capacity (proliferation index <2%). They are usually confined to the mucosa and submucosa and are less than 1 to 2 cm in diameter. Tumors with increased nuclear atypia and high proliferation index (>10%) have been termed atypical or anaplastic carcinoids and have been subclassified to well-differentiated and poorly differentiated neuroendocrine carcinomas, depending on the growth pattern.

The incidence of carcinoid tumors is similar in Western countries and is estimated to be 2.8 to 21 per 1 million people. Because many carcinoid tumors are indolent, the true incidence may be higher. In particular, appendiceal carcinoids have not been included in many studies, but the high incidence of 21 per 1 million was found in an autopsy study when appendiceal carcinoids were included. The incidence of patients with a carcinoid syndrome is about 0.5 per 100,000. Data from the United States, based on results from the End Results Group and the Third National Cancer Survey, 1950 to 1969 and 1969 to 1971, respectively, found that the appendix was the most common site of carcinoid tumors, followed by the rectum, ileum, lungs, and bronchi.

An analysis done in the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute between 1973 and 1991 reported an increase in the proportion of pulmonary and gastric carcinoids and a decrease in the proportion of appendiceal carcinoids.
BIOCHEMISTRY

The production of hormones appears to be a highly organized function of carcinoid cells. In 1953, Lembeck isolated serotonin from a carcinoid tumor; since then, the carcinoid syndrome has been related to serotonin overproduction. The biosynthesis of serotonin and its metabolic degradation are outlined in Figure 41.3.

Carcinoid tumors of the midgut and foregut region with metastatic disease secrete serotonin and show elevated urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA) in 75% and 30%, respectively. Carcinoid tumors arising from the foregut, however, frequently have low levels of L-amino-acid decarboxylase, which converts 5-hydroxytryptophan (5-HTP) to serotonin. Thus, these tumors secrete primarily 5-HTP.

For many years, it was believed that the entire carcinoid syndrome could be explained by the secretion of these biologically active amines. However, further studies have indicated that serotonin is mainly involved in the pathogenesis of diarrhea and that other biologically active substances play a more important part in the carcinoid flush and bronchoconstriction.

Oates and associates proposed that kallikrein, an enzyme found in carcinoid tumors, is released in association with flush and stimulates plasma kininogen to liberate lysyl-bradykinin and bradykinin. These are biologically active substances that cause vasodilation, hypotension, tachycardia, and edema. Furthermore, prostaglandins (E1, E2, F1α, F2α) may also play a role in the carcinoid syndrome. Gastric carcinoids as well as lung carcinoids have been found to contain and secrete histamine, which might be responsible for the characteristic bright red flush seen in these patients. Metabolites of histamine are frequently present in high concentration in the urine from these patients. Dopamine and norepinephrine have also been found in carcinoid tumors.

The occurrence of substance-P in carcinoid tumors was first demonstrated by Håkansson and co-workers in 1977. Substance-P belongs to a family of polypeptides that share the same carboxyl terminus and are called tachykinins (Fig. 41.4). A number of tachykinin-related peptides have been isolated from carcinoid tumors, such as neuropeptide-A, neuropeptide-K, and eledin. During stimulation of flush in patients with midgut carcinoids, multiple forms of tachykinins are released to the circulation (Fig. 41.5).

Many different polypeptides (e.g., insulin, gastrin, somatostatin, S-100 protein, polypeptide YY, pancreatic polypeptide, human chorionic gonadotropin alpha subunit [HCGα], motilin, calcitonin, vasointestinal polypeptide [VIP], and endorphins) have been demonstrated in carcinoid tumors by immunohistochemical staining and sometimes in tumor extracts. Ectopic ACTH or CRH production may be found in foregut carcinoids; in particular, patients with bronchial carcinoids seem susceptible to Cushing’s syndrome. Patients with carcinoid tumors of the foregut type might also present with acneormega due to ectopic secretion of growth hormone-releasing hormone from the tumor. Duodenal carcinoids as part of von Recklinghausen’s disease can secrete somatostatin.

The chromogranin/secretogranin family consists of CgA, CgB (sometimes called secretoglobin I), secretoglobin II (sometimes called CgC), and some other members. CgA was first isolated in 1965 as a water-soluble protein present in chromaffin cells from bovine adrenal medulla. Its immunoreactivity has been found in all parts of the gastrointestinal tract and pancreas and has also been isolated from all endocrine glands.

CgA is an acidic glycoprotein of 439 amino acids with a molecular weight of 48 kD. It can be spliced into smaller fragments at dibasic cleavage sites, generating multiple bioactive fragments such as vasostatins, chromostatin, and pancreastatin. Both amines and peptides are co-released (Fig. 41.6).

Amines and hormones are stored intracellularly in two types of vesicles: (1) large dense core vesicles and (2) small synaptic-like vesicles. These vesicles are released on stimulation. Large dense-core vesicles contain the hormones and one or more members of the chromogranin/secretoglobin family of proteins. Both amines and peptides are co-released (Fig. 41.7).

The physiologic function of CgA is not fully elucidated. Its ubiquitous presence in neuroendocrine tissues and its co-secretion with peptide hormones and amines indicate a storage role of the peptide within the secretory granule. It also acts as a prohormone that can generate bioactive smaller fragments. CgA is an important tissue and serum marker for different types of carcinoid tumors, including those of the foregut, midgut, and hindgut (see Table 41-1 and later discussion).
CLINICAL PRESENTATION

The clinical presentation of carcinoid tumors depends on localization, hormone production, and extent of the disease. Usually, a lung carcinoid is diagnosed incidentally on routine pulmonary radiography, whereas a midgut carcinoid may be identified as a bowel obstruction or as a cause of abdominal discomfort or pain. Rectal carcinoids may cause bleeding or obstruction. However, lung carcinoids may also present clinically with Cushing's syndrome, due to secretion of CRH or ACTH, or with the carcinoid syndrome, due to production of serotonin, 5-HTP, or histamine. A midgut carcinoid often presents with the carcinoid syndrome, due to production of serotonin and tachykinins.

The clinical manifestations at referral depend on the type of referral center. At our institution, which cares for patients with malignant tumors, 74% of the patients present with the carcinoid syndrome, 13% with abdominal pain, 12% with carcinoid heart disease, and 2% with bronchial constriction. When unbiased material is analyzed, bowel obstruction is the most frequent problem leading to the diagnosis of ileal carcinoid tumor. The second most frequent symptom is abdominal pain. Flushing and diarrhea, which are components of the carcinoid syndrome, make up only the third most frequent presentations. Because many patients have vague symptoms, however, diagnosis of the tumor may be delayed by approximately 2 to 3 years.

The syndrome rarely occurs in patients with rectal carcinoids. This is the classic carcinoid syndrome, but some patients may display only one or two of the features. Other symptoms related to the syndrome are weight loss, sweating, and pellagra-like skin lesions.

In 1954, Thorson and co-workers for the first time described the carcinoid syndrome as having the following features: malignant carcinoid of the small intestine with metastasis to the liver; valvular disease of the right side of the heart (pulmonary stenosis and tricuspidal insufficiency without septal defect); peripheral vasomotor symptoms; bronchial constriction; and an unusual type of cyanosis. One year later, Dr. William Bean gave this colorful description of the carcinoid syndrome:

This witch's brew of unlikely signs and symptoms, intriguing to the most fastidious connoisseur of clinical esoteric, the skin underwent rapid and extreme changes resembling in clinical miniature the febrile phantasmagoria of the aurora borealis.

The syndrome is thus well characterized and includes flushing, diarrhea, right-sided heart failure, and sometimes bronchial constriction and increased urinary levels of 5-HIAA. This is the classic carcinoid syndrome, but some patients may display only one or two of the features. Other symptoms related to the syndrome are weight loss, sweating, and pellagra-like skin lesions.

Development of the carcinoid syndrome is a function of tumor mass, extent and localization of metastases, and localization of the primary tumor. The syndrome is most common in tumors originating in the small intestine and proximal colon; 40% to 60% of patients with these tumors experience the syndrome. The disorders are less frequent in patients with bronchial carcinoids and do not occur in patients with rectal carcinoids. The syndrome rarely occurs in patients with midgut carcinoids and a small tumor burden, such as only regional lymph node metastases. Patients with the full syndrome usually have multiple liver metastases. The association with hepatic metastases is due to inefficient inactivation by the liver of amines and peptides released into the portal circulation. The venous drainage of liver metastases is directly into the systemic circulation and bypasses hepatic inactivation.

Other carcinoid tumors likely to be associated with the carcinoid syndrome in the absence of liver metastases are ovarian carcinoids and bronchial carcinoids, which release mediators directly into the systemic rather than the portal circulation. Retroperitoneal metastases from classic midgut carcinoid also release mediators directly into the circulation and might cause the carcinoid syndrome without any liver metastases.
Flushing

Four types of flushing have been described in the literature.  

The first and most well-known type is the sudden, diffuse, erythematous flush, usually affecting the face, neck, and upper chest (i.e., the normal flushing area) (Fig. 41-8A and B) (see also Color Plate). This type of flush is commonly of short duration, lasting from 1 to 5 minutes, and is related to early-stage midgut carcinoids. Patients usually experience a sensation of warmth during flushing and sometimes heart palpitations. This type of flushing is reported in 20% to 70% of patients with midgut carcinoid at presentation of the disease.  

The second type is the violaceous flush, which affects the same area of the body. It has roughly the same time course or sometimes lasts a little longer. Patients may also have facial telangiectasia. This flush is related to the later stages of midgut carcinoid (Fig. 41-9) (see also Color Plate) and is normally not felt by patients because they have become accustomed to the flushing reaction.  

The third type is prolonged flushing that usually lasts a couple of hours but may last up to several days. This flush sometimes involves the whole body and is associated with profuse lacrimation, swelling of the salivary gland, hypotension, and facial edema (Fig. 41-10) (see also Color Plate). These symptoms are usually associated with malignant bronchial carcinoids.  

The fourth type of flushing is a bright red, patchy flush, seen in patients with chronic atrophic gastritis and ECL-cell hyperplasia, or so-called ECL-oma (derived from ECL cells). This type of flushing is related to an increased release of histamine and histamine metabolites.

Flushes may be spontaneous or may be precipitated by (1) stress (physical and mental); (2) infection; (3) alcohol; (4) certain foods (spicy); or (5) drugs, such as by injections of cate-cholamines, calcium, or pentagastrin (see later). The pathophysiology of flushing in the carcinoid syndrome is not yet elucidated. It was previously thought to be totally related to excess production of serotonin or serotonin metabolites. However, several patients with high levels of plasma serotonin did not have any flushing, nor did a serotonin antagonist (e.g., methysergide, cyproheptadine, or ketanserin) have any effect on the flushing.  

In a study from our own group in which we measured the release of tachykinins, neuropeptide-K, and substance-P during flushing provoked by pentagastrin or alcohol, a clear correlation was found between the onset and intensity of the flushing reaction and the release of tachykinins (see Fig. 41-5). Furthermore, when the release of tachykinins was blocked by pretimulatory administration of octreotide, little or no flushing was observed in the same patient (Fig. 41-11). Other mediators of the flushing reaction may be kallikrein and bradykinins, which are released during provoked flushing. Histamine may be a mediator of the flushes seen both in lung carcinoids and in gastric carcinoids (ECL-omas). Tachykinins, bradykinins, and histamines are well-known vasodilators, and somatostatin analogues may alleviate flushing by reducing circulating levels of these agents (see later). Furschgott and Zawadski have suggested that flushing is caused by an indirect vasodilatation mediated by endothelium-derived relaxing factor (EDRF) or by nitric oxide released by 5-HTP during platelet activation.  

The facial flushing associated with carcinoid tumors should be distinguished from idiopathic flushing and menopausal "hot flashes." Patients with idiopathic flushes usually have a long history of flushing starting rather early in life and sometimes with a family history without occurrence of a tumor. Menopausal hot flashes usually involve the whole body and are accompanied by intense sweating. Postmenopausal women in whom a true carcinoid syndrome is developing can tell the difference between the two types of flushes.
Diarrhea

Diarrhea occurs in 30% to 80% of patients with the carcinoid syndrome. Its pathophysiology is poorly understood but is probably multifactorial. The diarrhea is frequently accompanied by abdominal cramping, and endocrine, paracrine, and mechanical factors contribute to this condition. A variety of tumor products, including serotonin, tachykinins, histamines, kallikrein, and prostaglandins, can stimulate peristalsis, electromechanical activity, and tone in the intestine.

Secretory diarrhea may occur with fluid and electrolyte imbalance. Malabsorption may result from intestinal resections, lymphangiectasia, secondary to mesenteric fibrosis, bacterial overgrowth, and secondary to a tumor partially obstructing the small bowel or rapid intestinal transit. Increased secretion by the small bowel, malabsorption, or accelerated transit may overwhelm the normal storage and absorptive capacity of proximal colon and result in diarrhea, which may be aggravated if the reabsorbed function of the colon is impaired.

In a study of patients with elevated serotonin levels and the carcinoid syndrome, transit time in the small bowel and colon was significantly decreased in comparison with that of normal subjects. The volume of the ascending colon was significantly smaller than in normal subjects, and the postprandial colonic tone was markedly increased. This indicates that in patients in whom the carcinoid syndrome is associated with diarrhea, major alterations in gut motor function occur that affect both the small intestine and the colon. Many patients with carcinoid tumors have undergone wide resection of the small intestine, and they may be affected by the symptoms of short-bowel syndrome.

Serotonin is thought to be responsible for the diarrhea in the carcinoid syndrome by its effects on gut motility and intestinal electrolyte and fluid secretion. Serotonin receptor antagonists, such as ondansetron and ketanserin, relieve the diarrhea to a certain degree.
Carcinoid Heart Disease

A unique endocrine effect of carcinoid tumors is the development of plaque-like thickenings of the endocardium of the heart, valve leaflets, atria, and ventricles in 10% to 20% of the patients. This fibrotic involvement causes stenosis and regurgitation of the blood flow. Findings of new collagen beneath the endothelium of the endocardium is almost pathognomonic for carcinoid heart disease. The incidence of these lesions depends on the diagnostic methodology. Echocardiography can demonstrate early lesions in about 70% of patients with the carcinoid syndrome, whereas routine clinical examinations detect them in only 30% to 40%. These figures have significantly dropped to 10% to 15%, probably because of earlier diagnosis and the use of biologic antitumor treatments such as somatostatin analogues and -interferons. Both of these agents control the hormonal release and excess that might be involved in the fibrotic process. In a study performed 15 years ago, 40% of patients with carcinoid tumors died of cardiac complications related to the carcinoid disease. More recent data reveal that this complication is a rare event, and patients usually die of the effects of a progressive tumor.

The precise mechanism behind the fibrosis in the right side of the heart has not been solved at the moment, but it occurs mainly in patients with liver metastases who usually also have the carcinoid syndrome. Substances inducing fibrosis are thought to be released directly into the right side of the heart and are then neutralized or degraded through the lung circulation because few patients present with similar lesions on the left side. However, patients with lung carcinoids occasionally display the same fibrotic changes on the left side. Histologically, the plaque-like thickenings in the endocardium consist of myofibroblasts and fibroblasts embedded in a stroma that is rich in mucopolysaccharides and collagen.

We have previously shown that the transforming growth factor (TGF-) family of growth factors is up-regulated in carcinoid fibrous plaques on the right side of the heart. The TGF- family of growth factors is known to stimulate matrix formation and collagen deposition. The substances that induce TGF- locally in the heart are not known, but serotonin, tachykinins, and insulin-like growth factor I (IGF-I) may be mediators.

A correlation has been found between circulating levels of serotonin and tachykinins and the degree and frequency of carcinoid heart lesion. The weight-reducing drugs fenfluramine and dexfenfluramine appear to interfere with normal serotonin metabolism and have been associated with valvular lesions identical to those seen in carcinoid heart disease. However, treatment resulting in decreased urinary 5-HIAA excretion does not result in regression of cardiac lesions.

Another possible mediator might be IGF-I, which is released from carcinoid tumor cells. Treatment with somatostatin analogues, which down-regulate circulating IGF-I, has been able to prevent further development of carcinoid heart disease in two patients (data to be published).
Bronchial Constriction

A true asthma episode is a rare event in patients with the carcinoid syndrome. The causative agents of bronchial constriction are not known, but both tachykinins and bradykinins have been suggested as mediators. These agents can constrict smooth muscles in the respiratory tract and may also cause local edema in the airways.
Other Manifestations of the Carcinoid Syndrome

Fibrotic complications other than heart lesions may be found in patients with carcinoid tumors. These include (1) intra-abdominal and retroperitoneal fibrosis, (2) occlusion of the mesenteric arteries and veins, (3) Peyronie's disease of the penis, and (4) carcinoid arthropathy. Intra-abdominal fibrosis can lead to intestinal adhesions and bowel obstruction and is a more common cause of bowel obstruction than is the primary carcinoid tumor itself. Retroperitoneal fibrosis can result in urethral obstruction that impairs kidney function, which sometimes requires treatment with urethral stents. Narrowing and occlusion of arteries and veins by fibrosis are potentially life-threatening. Ischemic loops of the bowel may have to be removed, and this procedure ultimately causes short-bowel syndrome. Other rare features of the syndrome are pellagra-like skin lesions with hyperkeratosis and pigmentation, myopathy, and sexual dysfunction.
Carcinoid Crisis

Carcinoid crisis has become a rare event since the introduction of treatment with somatostatin analogues. It might occur spontaneously or during induction of anesthesia, embolization procedures, chemotherapy, or infection. Carcinoid crisis is a clinical condition characterized by severe flushing, diarrhea, hypotension, hyperthermia, and tachycardia. Without treatment, patients might die during the crisis.

Intravenous (IV) and/or subcutaneous somatostatin analogues are given before, during, and after surgery to prevent the development of carcinoid crisis. Patients with metastatic lung carcinoids are particularly difficult to treat during crisis. IV infusions of octreotide at doses of 50 to 100 µg/hour, supplemented with histamine H₁-receptor and H₂-receptor blockers and IV sodium chloride, are recommended.
Other Clinical Manifestations of Carcinoid Tumors

Ectopic secretion of CRH and ACTH from pulmonary carcinoid tumors and thymic carcinoids accounts for 1% of all cases of Cushing's syndrome. Acromegaly due to ectopic secretion of GHRH has also been reported in foregut carcinoids. Gastric carcinoid tumors make up less than 1% of gastric neoplasms. They can be separated into three distinct groups on the basis of both clinical and histologic characteristics and originate from gastric ECL cells:

1. Those associated with chronic atrophic gastritis type A (80%) (type I).
2. Those associated with Zollinger-Ellison syndrome as part of MEN-1 syndrome (6%) (type II).
3. Sporadic gastric carcinoids (type III), which occur without hypergastrinemia and pursue a more malignant behavior, with 50% to 60% developing metastases.

About 80% of gastric carcinoids are associated with chronic atrophic gastritis type A, and more than 50% of patients with these carcinoids also have pernicious anemia. These tumors are more common in women than in men and are usually identified endoscopically during diagnostic evaluation for anemia or abdominal pain. They are often multifocal and localized in the gastric fundus area, and they are derived from ECL cells. Patients have hypochlorhydria and hypergastrinemia. Gastrin hypersecretion has been postulated to result in hyperplasia of the ECL cells, which might later develop into carcinoid tumors. Hyperplasia of ECL cells has been noticed in patients with long-standing proton-pump inhibitor therapy.
DIAGNOSIS

The diagnosis of a suspected carcinoid tumor must take into consideration tumor biology, histopathology, biochemistry, and localization. The diagnosis of a carcinoid may be suspected from clinical symptoms suggestive of the carcinoid syndrome or from the presence of other clinical symptoms, or it can be made in relatively asymptomatic patients from the histopathology at surgery or after liver biopsy for unknown hepatic lesions.

In one study involving 154 consecutive patients with gastrointestinal carcinoids found at surgery, 60% were asymptomatic. In patients with symptomatic tumors, the time from onset of symptoms until diagnosis is frequently delayed, varying from 1 to 2 years. The current tumor biology program includes growth factors (platelet-derived growth factor, epidermal growth factor, IGF-I, TGF-), and proliferation factors (measurements of the nuclear antigen Ki-67) as a proliferation index. Such index correlates with tumor aggressiveness and survival. Adhesion molecules such as CD-44, particularly exon-V6 and exon-V9, have been related to improved survival. Determination of the expression of angiogenic factors basic fibroblast growth factor (b-FGF) and vascular endothelial growth factor (VEGF) should also be included in a tumor biology program. Somatostatin analogues are cornerstones in the treatment of the carcinoid syndrome; therefore, determination of the different subtypes of somatostatin receptors (sst-1 to sst-5) with specific antibodies is warranted.

The histopathologic diagnosis of carcinoids is based on immunohistochemistry using antibodies against CgA, synaptophysin, and neuron-specific enolase. These immunohistochemical stainings have replaced the old silver stainings by Grimelius and Sevier-Munger. The argentaffin staining by Masson to demonstrate content of serotonin has also been replaced by immunocytochemistry with serotonin antibodies. These neuroendocrine markers can be supplemented by specific immunocytochemistry to different hormones such as substance-P, gastrin, and ACTH.

Biochemical Diagnosis

In patients with flushing and other manifestations of the carcinoid syndrome, the diagnosis can be established by measuring the urinary excretion of 5-HIAA because levels are invariably elevated under these circumstances. Patients with carcinoid tumors usually have urinary 5-HIAA levels of 100 to 3000 µmol/24 hours (15 to 60 mg/24 hours) (reference range <50 µmol/24 hours [10 mg/24 hours]). Assays for urinary 5-HIAA include high-pressure liquid chromatography (HPLC) with electrochemical detection and colorimetric and fluorescence methods. Various foods and drugs can interfere with the measurement of urinary 5-HIAA, and patients should avoid these agents during the 24-hour sampling. Normally, two 24-hour urine collections are recommended. In a study of patients with malignant midgut carcinoid tumors, 60% to 73% presented with increased urinary 5-HIAA levels, with a specificity of almost 100%.

Today measurement of urinary 5-HIAA for diagnosis of carcinoid tumor is the predominant biochemical analytic procedure. However, urinary and platelet measurement of serotonin itself may give additional information. In some studies, platelet serotonin levels were more sensitive than urinary 5-HIAA and urinary serotonin levels and were not affected by the patient’s diet, as are 5-HIAA levels.

In a comparative study of 44 consecutive patients with carcinoid, the platelet serotonin, urinary 5-HIAA, and urinary serotonin levels were measured. In foregut carcinoids the sensitivities were 50%, 29%, and 55%, respectively. For midgut carcinoids, the sensitivities were 100%, 92%, and 82%, respectively, and for hindgut carcinoids, 20%, 0%, and 60%, respectively.

Elevations of 5-HIAA can occur in malabsorption states and a number of other conditions. Foregut carcinoids tend to produce an atypical carcinoid syndrome with increased plasma 5-HTP, but not serotonin, because they lack the appropriate decarboxylase. That results in normal urinary 5-HIAA. However,

| TABLE 41-3 -- Factors That Interfere with Determination of Urinary 5-HIAA |
|--------------------------|-----------------------------------------------|
| **Foods**                |                                               |
| Avocado                  |                                               |

Methenamine mandelate

Methyldopa

Monoamine oxidase inhibitors

Phenothiazine

Promethazine

Figure 41-12 Plasma levels of chromogranin-A (CgA), CgB, and CgC in patients with various neuroendocrine tumors. EPTs, endocrine pancreatic tumors; MEN-1, multiple endocrine neoplasia type 1.

some of the 5-HTP is decarboxylated in the intestine and other tissues, and many of these patients have slightly elevated U-5-HT or 5-HIAA levels.

Attempts have been made to identify more specific and sensitive serum markers for carcinoid that may allow earlier diagnosis. One such marker is CgA. It has been shown previously that CgA and CgB are more abundant than CgC in human neuroendocrine tissues. In 44 patients with carcinoid tumors, CgA was increased in 99%, CgB in 88%, and CgC in only 6%. In a study of 75 patients with midgut carcinoids and the carcinoid syndrome, CgA was elevated in 87% of carcinoid patients. Furthermore, a correlation between levels of plasma chromogranin and extent of disease was found (P < .0001). In the same study, urinary 5-HIAA was elevated in 76% of midgut carcinoids, and there were no correlations with tumor size or extent of disease.

CgA is a more sensitive marker than urinary 5-HIAA in detection of carcinoid tumors, but because CgA is released and secreted from various types of neuroendocrine tumors, the specificity is lower. Therefore, in a work-up of patients with the carcinoid syndrome, one should combine the determination of plasma CgA with urinary 5-HIAA or serotonin. Plasma neuron-specific enolase shows a lower sensitivity and specificity than does plasma CgA. Serum hCG- has been reported to be increased in 60% of patients with foregut carcinoid tumors and 50% of hindgut carcinoids but in only 11% of those patients with midgut carcinoids and the carcinoid syndrome. Plasma neuropeptide-K levels have been reported to be elevated in 46% of patients with midgut carcinoids, whereas only 9% of patients with foregut carcinoids displayed elevated levels. Plasma substance-P has a sensitivity of 32% and a specificity of 85%. Pancreatic polypeptide levels are also elevated in about one third of patients with midgut carcinoids and in as many with foregut carcinoids.

During therapy with somatostatin analogues, neither plasma CgA nor urinary 5-HIAA is a reliable marker of tumor size because somatostatin inhibits the synthesis and release of the hormones without changes in tumor size.
Localization Procedures

Numerous imaging techniques, including endoscopy, barium enema, chest radiography, ultrasonography, computed tomography, magnetic resonance imaging (MRI), and angiography, have been used to determine the location of the primary tumor as well as the metastases in patients with carcinoid tumors. In more recent years, somatostatin-receptor scintigraphy (SRS) and iodinated meta-iodobenzylguanidine (131I-MIBG) scanning have been used to localize and stage the disease. Bronchial carcinoids are usually detected by chest radiography, CT, or, occasionally, by bronchoscopy. The primary midgut tumor is usually small and difficult to localize with traditional diagnostic methods such as barium enema, CT scan, or MRI. Some of these tumors can be localized by angiography or SRS. Liver metastases are usually detected by CT or MRI. At present, CT or MRI and SRS are the primary diagnostic modalities for tumor staging (Fig. 41-13 A and B) (see also Color Plate).

A more sensitive method is positron emission tomography (PET) using 11C-5-HTP, the precursor of serotonin synthesis (Fig. 41-14) (see also Color Plate). This isotope is accumulated in carcinoid tumors, and with the recent development of PET cameras, tumors as small as 0.3 cm in diameter can be detected. During treatment a close relationship has been found among changes in the PET scan, transport rate constant, and urinary 5-HIAA, suggesting that PET scanning may be useful in monitoring the results of therapy. PET scanning using fluorodeoxyglucose 18 (18FDG) is not useful in detecting low-proliferating neuroendocrine tumors but can be beneficial in identifying poorly differentiated anaplastic tumors.

Carcinoid tumors contain high-affinity receptors for somatostatin in 80% to 100% of cases. The receptors are present in both the primary tumor and metastases. Five subtypes of somatostatin receptors have been cloned (sst-1 to sst-5), and somatostatin receptor type 2 is the predominant subtype expressed in carcinoid tumors.

The most commonly available somatostatin analogue, octreotide, binds with high affinity to sst-2 and with lower affinity to sst-3 and sst-5. SRS with 111In-DTPA-Phe-octreotide has been reported with a sensitivity of 80% to 90% in patients with carcinoids. Many studies have demonstrated that SRS has greater sensitivity for localizing carcinoids compared with conventional imaging studies. False-positive scans can be encountered in patients with granulomas (e.g., sarcoidosis, tuberculosis), activated lymphocytes (lymphomas, chronic infection), thyroid diseases (goiter, thyroiditis), endocrine pancreatic tumors, and other endocrine tumors. Because of its high sensitivity and ability to image, whole-body SRS should be the initial imaging procedure to localize and establish the stage of the disease. Bone metastases, which are common in carcinoid tumors, are efficiently picked up by SRS, which is as sensitive as traditional bone scanning with technetium.

A diagnostic algorithm is outlined in Figure 41-15.
TREATMENT

Treatment of carcinoid tumors with the carcinoid syndrome requires a multimodal approach, including symptomatic control as well as tumor reduction. Most patients with the carcinoid syndrome have metastatic disease. The therapeutic goals are to ameliorate and improve clinical symptoms, abrogate the tumor growth, improve quality of life, and if possible, prolong overall survival.

Symptomatic control of the carcinoid syndrome includes lifestyle changes, dietary supplementations, and specific medical treatment that reduces the clinical symptoms related to the different components of the carcinoid syndrome. Avoiding stress, both psychological and physical, as well as substances such as alcohol, spicy food, and medication that precipitate a flushing reaction might be sufficient in early cases. Production of serotonin by the tumor consumes tryptophan. Normally, about 1% of the tryptophan is used for the synthesis of serotonin, which can result in tryptophan and niacin deficiency. Therefore, supplemental niacin to prevent the development of pellagra has been recommended over the years. Because many patients have undergone resection of the terminal ileum, which may result in vitamin B₁₂ and folic acid deficiency, vitamin B₁₂ supplementation is needed in those patients.

Heart failure due to carcinoid heart disease may require diuretics or angiotensin-converting enzyme (ACE) inhibitors. A small number of patients need bronchodilators such as salbutamol, which interacts with -adrenergic receptors and does not induce flushing. The diarrhea seen in the carcinoid syndrome might be controlled by loperamide or diphenoxylate. If patients still have the carcinoid syndrome, they receive somatostatin analogue treatment, which has replaced most of the earlier types of serotonin and serotonin receptor inhibitors. Serotonin inhibitors (e.g., parachlorophenylalanine and -methyldopa), which inhibit serotonin synthesis, and serotonin receptor antagonists (e.g., ciproheptadine, methysergide, and ketanserin) are not used routinely clinically. These earlier treatments had limited efficacy in terms of inhibiting flushing and diarrhea and were accompanied by significant side effects. A combination of histamine H₁ and H₂-receptor antagonists is effective in the carcinoid syndrome that is caused by foregut carcinoids due to concomitant secretion of histamine and serotonin. Prednisolone in doses of 15 to 30 mg/day gives occasional relief in some cases with severe flushing and diarrhea.

Somatostatin Analogues

Although natural somatostatin-14 reduces symptoms in patients with the carcinoid syndrome, its use is limited by its short half-life (2.5 minutes). During the last two decades, synthetic somatostatin analogues (octapeptides) have been developed for clinical use. Octreotide is the most commonly available drug; other analogues are lanreotide and vapreotide.

The somatostatin analogues used in clinical practice (octreotide, lanreotide) both bind to receptors sst-1 and sst-5 and, with lower affinity, to sst-3. They exert their cellular action through interaction with specific cell and transmembrane receptors belonging to the superfamily of G protein-coupled membrane receptors. They inhibit adenylate cyclase activity, activate phosphotyrosine phosphatases (PTPs), and modulate mitogen-activated protein kinases (MAPKs). Receptor subtypes 2 and 5 modulate K⁺ and Ca²⁺ fluxes in the cell. Activation of all these pathways results in inhibition of known growth factor production and release as well as antiproliferative effects.

Somatostatin receptor subtype 3 is known to mediate PTP-dependent apoptosis accompanied by activation of p53 and Bax. Four of the five somatostatin receptor subtypes (sst-2 to sst-5) undergo rapid internalization after ligand binding, which has been explored by tumor-targeted radioactive somatostatin analogue therapy. An antiproliferative effect has been reported, probably through a combination of receptor subtype 2 and 5 activities, which inhibits MAPK and K⁺ and Ca²⁺ fluxes leading to cell cycle arrest; the precise antitumor mechanism, however, is not known.

It is now known that different subtypes of somatostatin receptors form heterodimers (sst-1 and sst-5) and heterodimers with dopamine receptor D2R. This cross-talk...
modulates the intracellular signal and gives a “fine tuning” of the mediated effects. \[148\]

All five subtypes of somatostatin receptors are expressed in carcinoid tumors; they are expressed in various combinations, although some tumors express all five subtypes.\[148\] \[149\] The receptors are expressed not only on tumor cells but also in periluminal veins. \[148\] Antiangiogenesis might be another antitumor mechanism of somatostatin analogues. \[152\]

Subcutaneous administration of octreotide and lanreotide every 8 to 12 hours can control the clinical symptoms in about 60% to 70% of patients with the carcinoid syndrome; these agents are considered the drugs of choice.\[153\] Octreotide and lanreotide decrease serotonin and urinary 5-HIAA levels as well as plasma tachykinin and CgA levels. The recommended dose for octreotide is 100 µg two or three times a day, a standard treatment for controlling clinical symptoms. \[154\] However, some patients may require higher doses, up to a total of 3000 µg/day, to control the clinical symptoms and tumor growth, particularly during long-term therapy.

Tachyphylaxis (reduced sensitivity) to somatostatin analogues may develop during long-term therapy. \[158\] Long-acting, slow-release formulations of octreotide and lanreotide have been developed, and doses of 20 to 30 mg given once a month (octreotide) or every 2 weeks (lanreotide) control clinical symptoms and hormone levels in 50% to 60% of patients with the carcinoid syndrome. \[158\] The long-acting formulations of somatostatin analogues have clearly improved the quality of life of patients by reducing the number of injections and provide more stable control of clinical symptoms. \[159\]

High-dose therapy with lanreotide (12 mg/day) and octreotide (3 mg/day) has generated an increased number of significant tumor reductions (12% versus 5% for the standard dose).\[164\] \[165\] Induction of apoptosis has been reported during high-dose therapy, \[166\] possibly mediated through activation of receptor subtype 3.

For patients at risk for carcinoid crisis, somatostatin analogue therapy is the treatment of choice. Carcinoid crisis is a life-threatening complication of the carcinoid syndrome and may occur spontaneously or may be associated with stress and anesthesia, chemotherapy, and infections (see earlier). Patients usually experience severe flushing, diarrhea, abdominal pain, and hypotension. Continuous infusion with somatostatin analogues, 50 to 100 µg/hour, is recommended and usually alters the life-threatening condition. It is also recommended that patients be given subcutaneous somatostatin analogues before surgery or before other stressful situations.

Side effects of somatostatin analogue therapy have been of a low-grade variety, occurring in 20% to 40% of patients. These include pain at the injection site, gas formation, diarrhea, and abdominal cramping. Significant long-term side effects include gallstone formation, “sludge” in the gallbladder, steatorrhea, deterioration of glucose tolerance, and hypocalcemia.\[168\] \[169\] The incidence of gallstones in patients treated over the long term has varied from 5% to 70%, and the incidence of symptomatic gallstones requiring surgical treatment is less than 10%. \[168\]
Interferons

Interferon alone or in combination with somatostatin analogues effective in the treatment of the carcinoid syndrome. Symptomatic and biochemical control may be obtained in 40% to 50% of the patients with the recommended doses of 3 to 5 million units of recombinant interferon alfa-2a or alfa-2b three to five times per week subcutaneously. Significant tumor reduction is reported in 10% to 20% of the patients. Interferon exerts a direct effect on the tumor cells by blocking cell division in the G1/S-phase, by inhibiting protein and hormone synthesis, and by reducing angiogenesis through inhibition of angiogenic factors b-FGF and VEGF. It has also an indirect effect through stimulation of the immune system, particularly T cells and natural killer cells. Response to interferon can be predicted by analyzing induction of 2’5’-oligoadenylate synthetase or P68 (PKR) protein kinase, enzymes involved in cell cycle regulation and protein synthesis.

Treatment with interferon induces an intratumoral fibrosis that is not picked up by regular CT scanning or ultrasonography; therefore, tumor size may remain unchanged. The side effects of interferons are more pronounced than with somatostatin analogues and include chronic fatigue syndrome, anemia, leukopenia, and thrombocytopenia as well as the development of autoimmune reactions in 10% to 15% of the patients. Most of the side effects are dose-dependent and can be managed by individualizing the dose.

Patients with the carcinoid syndrome who have not responded to octreotide or interferon alone may be given a combination of both agents. Such combinations have generated symptomatic control in 70% of patients and stabilization of tumor growth in 40% to 50% of patients. The combination also offers better tolerance of interferons when somatostatin analogues are added. Moreover, somatostatin analogue treatment is hampered by development of tachyphylaxis with time, which means less sensitivity to the somatostatin analogue, necessitating escalating doses and, finally, withdrawal of the compound for several months, when interferon therapy can continue. Conversely, interferon can be withdrawn and somatostatin analogue can be continued if severe side effects to interferon (mainly chronic fatigue syndrome or mental depression) develop.
Chemotherapy

Most agree that patients with classic midgut carcinoids and the carcinoid syndrome, in which tumors show low proliferation capacity, should not receive chemotherapy. The results in various studies have been disappointing, with response rates not more than 5% to 10%, short-lasting, and accompanied by considerable side effects. The combination of streptozotocin and 5-fluorouracil, which has demonstrated antitumor effect in endocrine pancreatic tumors, has not shown similar effects in classic midgut carcinoids. In foregut carcinoids, which usually present a more malignant behavior, however, cytotoxic treatment may be attempted. Such combinations include streptozotocin plus 5-fluorouracil, doxorubicin, cisplatin plus etoposide, and dacarbazine plus 5-fluorouracil. All of these cytotoxic treatments can be combined with a somatostatin analogue.
Surgery

Because most patients with the carcinoid syndrome already have malignancy at clinical presentation, surgical cure is seldom obtained. Resection of local disease or regional nodular metastatic disease can cure some patients; however, even if radical surgery cannot be performed, debulking procedures and bypass should always be considered and can be performed at any time during the course of treatment. In recent years, a more proactive attitude among surgeons has emerged, and wider resections and debulking procedures are being performed today than 10 years ago. In contrast to other metastatic tumors to the liver, in which liver transplantation has generally given poor results, an interest in liver transplantation is increasing for patients with metastatic carcinoids. In a review of 103 patients with malignant neuroendocrine tumors, including both carcinoids and pancreatic endocrine tumors, 5- and 2-year survival rates were 16% and 47%, respectively; however, recurrence-free survival was less than 24%. Liver transplantation might be considered in younger patients (<50 years of age) with a life-threatening uncontrolled carcinoid syndrome during medical therapy or tumor-targeted radioactive treatment without known metastatic spread outside the liver.

Another means of tumor reduction is hepatic artery embolization, which not only improves the carcinoid syndrome in about 50% of the patients but also reduces the tumor size in as many. The therapeutic effect may last for 9 to 12 months, and the procedure can be repeated. Chemoembolization, simultaneous embolization with surgical gel (Gelfoam), and chemotherapy (doxorubicin, mitomycin C, cisplatin, 5-fluorouracil), or interferon has resulted in symptomatic improvement in a significant number of patients with the carcinoid syndrome. However, hepatic artery occlusion or embolization may result in serious side effects (nausea, vomiting, liver pain, fever) and major complications (hepatorenal syndrome, sepsis, gallbladder perforation, and intestinal necrosis). Complications are seen in 5% to 7% of patients.

Other cytoreductive treatments may include cryotherapy and radiofrequency ablation. However, this procedure is limited to patients with smaller tumor burden, tumors less than 3 cm in diameter, and a limited number of metastases.
Irradiation

External irradiation has demonstrated limited efficacy and is used mainly to palliate symptoms related to bone and brain metastases. MIBG is taken up by carcinoids and is concentrated. The possibility of radiolabeled MIBG therapy has been evaluated in a limited number of patients. The response rate has been reported to be about 30% with 125I-MIBG or 131I-MIBG.

Somatostatin analogue-based tumor-targeted radioactive treatment has been applied through the last few years using 111In-DTPA-octreotide. Symptomatic improvement is reported in about 40% of the patients and tumor stabilization in about 30%. Indium 111 (111In) is a weak irradiator (Auger electrons) and seems to be replaced by yttrium 90 (90Y) (β emitters).

Studies with 90Y-DOTA-octreotide have been reported with promising results. It is an attractive mode of treatment because the radioactive ligand, after binding to the receptor, is internalized and transported to the cell nucleus, causing DNA damage. Because tumor cells usually have higher-density somatostatin receptors (sst-2 and sst-5) than do surrounding normal tissues, the treatment might be better tolerated.
PROGNOSIS

Clinically, the carcinoid syndrome is generally a manifestation of advanced disease. Carcinoids from various sites differ not only in the percentage developing the carcinoid syndrome but also in their aggressiveness. Survival rates for patients with various carcinoids depend on the site and the extent of the tumor. In patients with only localized disease, the 5-year survival rate is about 65%, not essentially higher than that for patients with regional metastases. In patients with distant metastases, the 5-year survival rate is reduced to 36%.

One of the main determinants of survival in carcinoid patients is the presence of metastases. Female gender and a younger age are associated with a better prognosis. Other factors that correlate with impaired survival are high CgA level at diagnosis and high proliferation index (Ki-67). During the 1990s, there was a reduced incidence of death from carcinoid heart disease, possibly a result of earlier diagnosis, active surgery, and the introduction of somatostatin analogues and interferons. In an earlier study performed by our group, 30% of the patients died of carcinoid heart complications. In a more recent study, this rate was reduced to less than 10%. Clinically significant carcinoid heart disease is now a rare event. Five percent to 10% of patients with carcinoids are at an increased risk for development of synchronous adenocarcinoma of the large intestine. The occurrence of a second malignancy is associated with a worse prognosis.
OTHER FLUSHING DISORDERS

Medullary Thyroid Carcinoma and VIPoma

Other neuroendocrine tumors, such as medullary thyroid carcinoma (MTC) and VIP-producing tumors (ganglioneuroma, endocrine pancreatic tumors), may present with flushing syndromes. Patients may also have diarrhea, particularly those with VIP-producing tumors, which are accompanied by a severe secretory diarrhea. In patients with MTC, flushing and diarrhea are infrequent symptoms and are seen mainly in patients with high circulating levels of calcitonin and CGRP.

The mechanism behind the flushing and diarrhea is unknown, but it has been postulated to be mediated through prostaglandins stimulated by calcitonin. The frequency of flushing and diarrhea is usually less than 5% in patients with advanced metastatic MTC. Treatment is directed against tumor growth and may consist of surgical resection, embolization of liver metastases, and cytotoxic treatment (doxorubicin-based combination therapies). Somatostatin analogue therapy may alleviate the diarrhea.

VIPoma or WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome (Verner-Morrison syndrome) is associated with severe secretory diarrhea (up to 15 L/day), and some patients also display a continuous whole-body violaceous flushing and hypotension. The syndrome also includes achlorhydria, hypokalemia, and metabolic acidosis and is related to overproduction of VIP and a related peptidyl peptide histidine methionine. These patients have tumors in the pancreas, lung, or sympathetic ganglia.

The diagnosis is confirmed by measuring plasma VIP, usually exceeding 70 pmol/L. Treatment is directed against the tumor and hormone excess. Administration of somatostatin analogues by either subcutaneous or intravenous infusion in the worst cases can control clinical symptoms. Cytotoxic treatment with streptozotocin-based combinations, 5-fluorouracil, or doxorubicin is recommended for malignant cases.
Mastocytosis and Related Disorders

Mastocytosis as well as other systemic mast cell activations is clinically related to flushing disorders. Most patients with mastocytosis have an indolent course, but some forms of mastocytosis are aggressive. Symptoms are attributed primarily to paroxysmal mast cell activation. [219][220]

Most patients with mastocytosis have evidence of cutaneous involvement, the most common being multiple, small pigmented lesions that produce urticaria on stroking with a blunt object (Darier's sign); this condition is called urticaria pigmentosa. [221] Another form of cutaneous mastocytosis is a more telangiectatic form called telangiectasia macularis eruptiva perstans. Hepatomegaly and splenomegaly can be due to infiltration of mast cells, and hepatic fibrosis is also common. [222][223]

Bone involvement can be manifested by either osteoporosis or osteosclerosis. [224] Systemic mastocytosis can also involve the gastrointestinal tract with mucosal nodules in the ileum, stomach, and large bowel. [225]

Hematologic abnormalities are nonspecific with marked mast cell infiltration of the bone, anemia, leukocytosis, eosinophilia, sometimes lymphadenopathy, and eosinophilia. [226] In a subgroup of patients, the mastocytosis is secondary to primary hematologic disorders, usually myeloproliferative or myelodysplastic disease. [227][228]

Mast cell leukemia has been reported in rare cases. [229] Mast cell leukemia has been reported in rare cases. [229] The diagnosis is made by measurement of histamine and histamine metabolites in the urine. [230][231] Quantification of histamine metabolites (N-methylhistamine and methylimidazole-acetic acid) appears to be more sensitive for overproduction of histamine in patients with mastocytosis. [231] Measurement of endogenous production of prostaglandin D$_2$ can be assessed by quantifying the major urinary metabolite (9-hydroxy-11,15-dioxo-2,3,18,19-tetranorprost-5-ene-1,20-dioic acid). [232] However, these measurements can be done only in specialized laboratories. Measurement of the tryptase release is easier to perform, and increased quantities of this granula-associated enzyme tryptase can be detected by immunoassay. [233]

Clinical signs of systemic mastocytosis include flushing, tachycardia, hypotension, and sometimes nausea, vomiting, and diarrhea. This syndrome resembles the carcinoid syndrome. Histamine is a potent vasodilator and is released from mast cells. Other mediators of the syndrome are the release of prostaglandin D$_2$, tryptase, and heparin. [234] Prostaglandin D$_2$ is a more potent mediator than is histamine.

The diagnosis is made by measurement of histamine and histamine metabolites in the urine. [235][236] Treatment depends on the severity of the disease. As in the treatment of allergic anaphylaxis, epinephrine is effective in reversing the hypotension associated with mast cell mediator release; thus, these patients should have constant access to epinephrine in the form of subcutaneous injection or inhalation. Chronic therapy to prevent acute attacks includes antihistamine therapy combined with inhibition of prostaglandin biosynthesis. Blockade of both histamine H$_1$ and H$_2$ receptors is required to prevent the vasodilator effect of histamine. [237]

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the cyclooxygenase enzyme that catalyzes the formation of prostaglandins. Aspirin has been used, but some patients cannot tolerate it because of side effects in the gut and allergic reactions. [238] In patients resistant to both antihistamine and NSAIDs, interferon has been attempted with a reduction in mast cell numbers as well as excretion of mast cell mediators. Treatment with interferon is still considered experimental. [239]

APPENDIX: Reference Values

The reference values are meant to be used only with this text because values and ranges vary among laboratories. In preparing the book and the reference values, the editors have taken into account the fact that the system of international units (SI, Système International d'Unités) is used in most medical and scientific journals and in clinical laboratories in many countries. However, clinical laboratories in some countries, including the United States, report results in conventional units. Therefore, in the book and in the Reference Values section, we use both systems. In the text, values in SI units appear first, and conventional units appear in parentheses after the SI units.

For some assays that measure mixtures of products in serum (growth hormone, luteinizing hormone), both the SI and the conventional units are given as units of weight rather than as molarity. Most conversions from one system to the other can be made as follows:

Conversion of mEq/L to mmol/L is made by dividing mEq/L by the valence of the molecule. For the convenience of the reader, factors for converting conventional to SI units are included (see Young DS. Implementation of SI units for clinical laboratory data. Ann Intern Med 106:114128, 1987). For the Units of Radiation, 1 bequerel (Bq) = 2.7 × 10^{-11} curies (Ci), 37 mBq = 1 mCi, 1 gray (Gy) = 100 rad, 1 sievert (Sv) = 100 rem.

Figure 1-1 Comparison of determinants of endocrine (A) and paracrine (B) signaling.
Figure 1-3 Diseases caused by mutations in G-protein-coupled receptors. All are human conditions with the exception of the final two entries, which refer to the mouse. (AD = autosomal dominant; AR = autosomal recessive inheritance.) Loss of function refers to inactivating mutations of the receptor, and gain of function to activating mutations. Abbreviations for G-protein-coupled receptors: ACTH = adrenocorticotropic hormone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone; PTH-PTHrP = parathyroid hormone and parathyroid hormone-related peptide; MSH = melanocyte-stimulating hormone; GHRH = growth hormone-releasing hormone; FSH = follicle-stimulating hormone. (Reproduced from Mayo K. In Conn PM, Melmed S (eds), Endocrinology: Basic and Clinical Principles. Totowa, NJ, Humana Press, 1997, page 27.)
**Figure 1-4** Peripheral feedback mechanism and a million-fold amplifying cascade of hormonal signals. Environmental signals are transmitted to the central nervous system, which innervates the hypothalamus, which responds by secreting nanogram amounts of a specific hormone. Releasing hormones are transported down a closed portal system, pass the blood-brain barrier at either end through fenestrations, and bind to specific anterior pituitary cell membrane receptors to elicit secretion of micrograms of specific anterior pituitary hormones. These enter the venous circulation through fenestrated local capillaries, bind to specific target gland receptors, trigger release of micrograms to milligrams of daily hormone amounts, and elicit responses by binding to receptors in distal target tissues. Peripheral hormone receptors enable widespread cell signaling by a single initiating environmental signal, thus facilitating intimate homeostatic association with the external environment. Arrows with a black dot at their origin indicate a secretory process. *(Reproduced from Normal AW, Litwack G. Hormones, 2nd edn. New York, Academic Press, 1997, p 14.)*
Figure 1-5 Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones impinge directly on their respective target cells. Intrapituitary cytokines and growth factors regulate tropic cell function by paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition of respective pituitary trophic hormone synthesis and secretion. (Reproduced with permission from Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. Endocrin Rev 1997; 18:206228.)
Figure 2-1 Simple pedigree of the propositi (arrow) and first-order relatives should be the standard family history in a new patient workup. If the patient has children, their health status should be included as well.
Figure 3-1 Different modes of utilization of polypeptide hormones in expression of their biologic actions. The peptide hormones are expressed in at least four ways in fulfilling their functions as cellular messenger molecules: (1) endocrine mode, for purposes of communication among organs (e.g., pituitary-thyroid axis); (2) paracrine mode, for communication among adjacent cells, often located within endocrine organs; (3) neuroendocrine mode, for synthesis and release of peptides from specialized peptidergic neurons for action on distant organs through the blood stream (e.g., neuroendocrine peptides of hypothalamus); and (4) neurotransmitter mode, for action of peptides in concert with classical amino acid-derived amnergic transmitters in the neuronal communication network. Identical polypeptides are often utilized in the nervous system both as neuroendocrine hormones and as neurotransmitters. In some instances, the same gene product is used in all four modes of expression.
Figure 3-2 Steps in the cellular synthesis of polypeptide hormones. Steps that take place within the nucleus include transcription of genetic information into a messenger ribonucleic acid (mRNA) precursor (pre-mRNA) followed by post-transcriptional processing, which includes RNA cleavage, excision of introns, and rejoicing of exons, resulting in formation of mRNA. Ends of mRNA are modified by addition of methylguanosine caps at the 5' end and addition of poly(A) tracts at the 3' ends. The cytoplasmic mRNA is assembled with ribosomes. Amino acids, carried by aminoacylated transfer RNAs (tRNAs), are then polymerized into a polypeptide chain. The final step in protein synthesis is that of post-translational processing. These processes take place both during growth of the nascent polypeptide chain (cotranslational) and after release of the completed chain (post-translational), and they include proteolytic cleavages of polypeptide chain (conversion of pre-prohormones or prohormones to hormones), derivatizations of amino acids (e.g., glycosylation, phosphorylation), and cross-linking and assembly of the polypeptide chain into its conformed structure. The diagram depicts post-translational synthesis and processing of a typical secreted polypeptide, which requires vectorial, or unidirectional, transport of the polypeptide chain across the membrane bilayer of the endoplasmic reticulum, thus resulting in sequestration of the polypeptide in the cisternae of the endoplasmic reticulum, a first step in the export of proteins destined for secretion from the cell (see Fig. 3-6). Most translational processing occurs within the cell as depicted (presecretory) and in some instances outside the cell, when further proteolytic cleavages or modifications of the protein may take place (postsecretory). CHO, carbohydrate.
Figure 3-3 Diagrammatic depiction of two configurations of precursors of polypeptide hormones. Diagrams represent polypeptide backbones of protein sequences encoded in mRNA. One form of precursor consists of the NH₂-terminal signal, or presequence, followed by the apoprotein portion of the polypeptide that needs no further proteolytic processing for activity. A second form of precursor is a pre-prohormone that consists of the NH₂-terminal signal sequence followed by a polyprotein, or prohormone, sequence consisting of two or more peptide domains linked together that are subsequently liberated by cleavages during post-translational processing of the prohormone. The reason for synthesis of polypeptide hormones in the form of precursors is only partly understood. Clearly, NH₂-terminal signal sequences function in the early stages of transport of polypeptide into the secretory pathway. Prohormones, or polyproteins, often serve to provide a source of multiple bioactive peptides. However, many prohormones contain peptide sequences that are removed by cleavage and have no known biologic activity, and they are referred to as cryptic peptides. Other peptides may serve as spacer sequences between two bioactive peptides (e.g., the C peptide of proinsulin). In instances in which a bioactive peptide is located at the COOH terminus of the prohormone, the NH₂-terminal prohormone sequence may simply facilitate cotranslational translocation of polypeptide in endoplasmic reticulum.
Figure 3-4 Diagrammatic illustration of primary structures of several prohormones. The *darkly shaded areas* of prohormones denote regions of sequence that constitute known biologically active peptides after their post-translational cleavage from prohormones. Sequences indicated by hatching denote regions of precursor that alter the biologic specificity of that region of precursor. For example, the precursor contains the sequence of -melanocyte-stimulating hormone (-MSH), but when the latter is covalently attached to the clip peptide, it constitutes adrenocorticotropic hormone (corticotropin, ACTH). Somatostatin-28 (SS-28) is an NH$_2$-terminally extended form of somatostatin-14 (SS-14) that has higher potency than somatostatin-14 on certain receptors. The neurophysin sequence linked to the COOH terminus of vasopressin (ADH) functions as a carrier protein for hormone during its transport down the axon of neurons in which it is synthesized. Precursor proenkephalin represents a polyprotein that contains multiple similar peptides within its sequence, either met-enkephalin (M) or leu-enkephalin (L). Procalcitonin and procalcitonin gene-related product (CGRP) share identical NH$_2$-terminal sequences but differ in their COOH-terminal regions as a result of alternative splicing during the post-transcriptional processing of the RNA precursor. -LPH, -lipotropin; GLP, glucagon-like peptide; IP, intervening peptide.
Figure 3-5 Schematic representation of subcellular organelles involved in transport and secretion of polypeptide hormones or other secreted proteins within a protein-secreting cell. (1) Synthesis of proteins on polyribosomes attached to endoplasmic reticulum (RER) and vectorial discharge of proteins through the membrane into the cisterna. (2) Formation of shuttling vesicles (transition elements) from endoplasmic reticulum followed by their transport to and incorporation by the Golgi complex. (3) Formation of secretory granules in the Golgi complex. (4) Transport of secretory granules to the plasma membrane, fusion with the plasma membrane, and exocytosis resulting in the release of granule contents into the extracellular space. Note that secretion may occur by transport of secretory vesicles and immature granules as well as mature granules. Some granules are taken up and hydrolyzed by lysosomes (crinophagy). Golgi, Golgi complex; RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum. (From Habener JF. Hormone biosynthesis and secretion. In Felig P, Baxter JD, Broadus AE, et al. [eds]. Endocrinology and Metabolism. New York, McGraw-Hill, 1981, pp 2959. Copyright © 1981 by McGraw-Hill, Inc. Used by permission of McGraw-Hill Book Company.)
Figure 3-6 Diagram depicting cellular events in initial stages of synthesis of a polypeptide hormone according to the signal hypothesis. In this schema, a signal recognition particle, consisting of a complex of six proteins and an RNA (7S RNA), interacts with the NH₂-terminal signal peptide of the nascent polypeptide chain after approximately 70 amino acids are polymerized, which results in the arrest of further growth of the polypeptide chain. The complex of the signal recognition particle and the polyribosome nascent chain remains in a state of translational arrest until it recognizes and binds to a docking protein, which is a receptor protein located on the cytoplasmic face of the endoplasmic reticular membrane. This interaction of the signal recognition particle complex with docking protein releases the translational block, and protein synthesis resumes. The nascent polypeptide chain is discharged across the membrane bilayer into the cisterna of the endoplasmic reticulum and is released from the signal peptide by cleavage with a signal peptidase located in the cisternal face of the membrane. In this model, the signal peptide is cleaved from the polypeptide chain by signal peptidase before the chain is completed (cotranslational cleavage). The configuration of the polypeptide during transport across the membrane and the forces and mechanisms responsible for its translocation are unknown. The loop, or hairpin, configuration of the chain that is shown is an arbitrary model; other models are equally possible.
Figure 3-7 Regulatory feedback loops of the hypothalamic-pituitary-target organ axis. Being a combination of both stimulatory and inhibitory factors, hormones often act in concert to maintain homeostatic balance in the presence of physiologic or pathophysiologic perturbations. The concerted actions of hormones typically establish closed feedback loops by stimulatory and inhibitory effects coupled to maintain homeostasis.
Figure 3-8 Diagrammatic structure of a "consensus" gene encoding a prototypical polypeptide hormone. Such a gene typically consists of a promoter region and a transcription unit. The transcription unit is the region of deoxyribonucleic acid (DNA) composed of exons and introns that is transcribed into a messenger ribonucleic acid (mRNA) precursor. Transcription begins at the cap site sequence in DNA and extends several hundred bases beyond the poly(A) addition site in the 3' region. During post-transcriptional processing of the RNA precursor, the 5' end of mRNA is capped by addition of methylguanosine residues. The transcript is then cleaved at the poly(A) addition site approximately 20 bases 3' to the AATAAA signal sequence, and the poly(A) tract is added to the 3' end of the RNA. Introns are cleaved from the RNA precursor, and exons are joined together. Dinucleotides GT and AG are invariably found at the 5' and 3' ends of introns. Translation of mRNA invariably starts with the codon ATG for methionine. Translation is terminated when the polyribosome reaches the stop codon TGA, TAA, or TAG. The promoter region of the gene located 5' to the cap site contains numerous short regulatory DNA sequences that are targets for interactions with specific DNA-binding proteins. These sequences consist of the basal constitutive promoter (TATA box), metabolic response elements that modulate transcription (e.g., in response to cAMP, steroid hormone receptors, and thyroid hormone receptors), and tissue-specific enhancers and silencers that permit or prevent transcription of the gene, respectively. The enhancer and silencer elements direct expression of specific subsets of genes to cells of a given phenotype. Whether a gene is or is not expressed in a particular cellular phenotype depends on complex interactions of the various DNA-binding proteins among themselves and, most important, with the TATA box proteins of the basal constitutive promoter.
Figure 3-9 Diagram of the pancreatic glucagon gene and its encoded messenger RNA (mRNA) (complementary DNA). The glucagon gene is an example of a gene in which exons precisely encode separate functional domains. The gene consists of six exons (E1 to E6) and five introns (1A to 1E). The mRNA encoding pre-proglucagon, the protein precursor of glucagon, consists of 10 specific regions: from left to right, a 5'-untranslated sequence (UN-TX, unshaded), a signal sequence (S, stippled), an NH₂-terminal extension sequence (N, hatched), glucagon (Gluc, shaded), a first intervening peptide (IP-I, hatched), a first glucagon-like peptide (GLP-I, shaded), a second intervening peptide (IP-II, hatched), a second glucagon-like peptide (GLP-II, shaded), a dilysyl dipeptide (hatched) after the glucagon-like peptide II sequence, and an untranslated region (UN-TX, unshaded). Exons from left to right encode the 5'-untranslated region, signal sequence, glucagon, glucagon-like peptide I, glucagon-like peptide II, and 3'-untranslated sequence. Letters shown above the mRNA denote amino acids located at positions in pre-proglucagon that are cleaved during cellular processing of precursor. The amino acid methionine (M) marks the initiation of translation of mRNA into pre-proglucagon. H, histidine; K, lysine; Q, glutamine; R, arginine.
Figure 3-10 Diagram of an endocrine cell showing potential control points for regulation of gene expression in hormone production. Specific effector substances bind either to plasma membrane receptors (peptide effectors) or to cytosolic or nuclear receptors (steroids), which leads to initiation of a series of events that couple the effector signal with gene expression. In the illustration shown, peptide effector-receptor complex interactions act initially through activation of adenylate cyclase (AC) coupled with a guanosine triphosphate-binding protein (G). Coupling factors and substances such as glucose, cyclic adenosine monophosphate, and cations activate protein kinases, resulting in a series of phosphorylations of macromolecules. As discussed in the text, specific effectors for various endocrine cells appear to act at one or more of the indicated five levels of gene expression, with the possible exception of post-translational processing of prohormones, for which no definite examples of metabolic regulation have yet been found.
Figure 3-11 Diagram showing three cell-surface receptor-coupled signal transduction pathways involved in the activation of a superfamily of nuclear transcription factors. Peptide hormone molecules (H1, H2, and H3) interact with sensor receptors (R1, R2, and R3) coupled to the diacylglycerol (DAG)-protein kinase C (PKC), the cyclic adenosine monophosphate (cAMP)-protein kinase A (PKA), and the calcium-calmodulin pathways in which small diffusible second messenger molecules are generated (DAG, cAMP, Ca$^{2+}$). The third messengers or effector protein kinases are generated and phosphorylate transcription factors such as members of the CREB/ATF and jun/AP-1 families of DNA-binding proteins to modulate DNA-binding affinities or transcriptional activation, or both. The various proteins bind as dimers determined by a poorly understood code that is not promiscuous in as much as only certain homodimer or heterodimer combinations are permissible. AP-1, activator protein 1; ATF, activating transcription factor; CaMK, calcium/calmodulin-dependent protein kinase; CREB, cAMP response element-binding protein.
Figure 3-12 Schema indicating levels in expression of genetic information at which diversification of information encoded in a gene may take place. The three major levels of genetic diversification are (1) gene duplication, a process that occurs in terms of evolutionary time; (2) variation in the processing of ribonucleic acid (RNA) precursors, which results in formation of two or more messenger RNAs (mRNAs) by way of alternative pathways of splicing of transcript (see Fig. 3-13 and Fig. 3-14); and (3) use of alternative patterns in processing of protein biosynthetic precursors (polypeptides, or prohormones). These three levels in gene expression provide a means for diversification of gene expression at levels of deoxyribonucleic acid (DNA), RNA, or protein. One or a combination of these processes leads to formation of the final biologically active peptide or hormone. In the diagram, loops depicted in transcripts denote introns; in diagrammatic structures of proteins, the stippled, shaded, and unshaded areas denote exons. See text for details.
Figure 3-13 Utilization of alternative promoters in the expression of genes as a means to generate biologic diversification of gene expression. The use of alternative promoters allows a gene to be expressed in a variety of unique contexts that alter the properties of the messenger ribonucleic acid (mRNA) that is expressed. Such alternative promoter usage may render the mRNA more or less stable, affect translational efficiencies, or switch the translation of one protein isoform to another. The use of alternative promoters in genes characteristically occurs during development, or after development is completed, to designate tissue-specific patterns of expression of the gene. Exons are shown as boxes whose protein-coding regions are shaded. Introns are designated by horizontal lines. Dashed lines indicate introns that are spliced out. (Adapted from Ayoubi TAY, Van De Ven WJM. Regulation of gene expression by alternative promoters. FASEB J 1996; 10:453460.)
Figure 3-14  Alternative exon splicing provides a means to generate biologic diversification of gene expression. Mechanisms of exon skipping or switching and intron slippage are frequently utilized in the alternative processing of premessenger ribonucleic acids (mRNAs) to provide unique mRNAs and encoded proteins during development and in a tissue-specific pattern of expression in the fully differentiated tissues or organs. Exons are shown as boxes with protein-coding regions shaded to designate origin of protein isoforms. Introns are depicted as horizontal lines. Dashed lines denote spliced-out introns.
Figure 3-15 Alternative translational initiation sites are used to change the coding sequences of messenger ribonucleic acids to encode different protein isoforms. The two mechanisms illustrated involve loose scanning and reinitiation of translation. See text.
Figure 4-1 Signal transduction by hormones and other ligands that act via nuclear receptors. HRE, hormone response element; mRNA, messenger ribonucleic acid.
Figure 4-2 Domain structure of nuclear receptors.
Figure 4-3 Structural basis of nuclear receptor ligand binding and cofactor recruitment.
Figure 4-4 Structural basis of nuclear receptor (NR) DNA binding specificity. Ribbon diagrams of receptor DNA-binding domains (DBDs) are shown. A, Steroid hormone receptor binding as homodimer to inverted repeat (arrows) of AGAACA half-site. B, RXR-NR heterodimer binding to direct repeat of AGGTCA. The position of the P-box, the region of the DBD that makes direct contact with DNA, is shown. N, number of base pairs between the two half-sites; RXR, retinoid X receptor.
Figure 4-5 Coactivators and corepressors in transcriptional regulation by nuclear receptors. CBP, calcium-binding protein; DRIP, D receptor-interacting protein; HRE, hormone response element; HAT, histone acetyltransferase; HDAC, histone deacetylase; N-CoR, nuclear receptor corepressor; NR, nuclear receptor; PCAF, p300/CBP-associated factor; SMRT, silencing mediator of retinoid and thyroid receptors; TRAP, thyroid hormone receptor-associated protein.
Figure 4-6 Repression and activation functions augmenting the dynamic range of transcriptional regulation by nuclear receptors. HRE, hormone response element.
Figure 5-1 Receptor tyrosine kinases. This diagram illustrates 3 of the 16 families of receptor tyrosine kinases. All receptor tyrosine kinases possess an extracellular domain containing the ligand-binding site, a single transmembrane domain, and an intracellular domain containing the tyrosine kinase domain. Several structural motifs (i.e., cysteine-rich domain, immunoglobulin-like domain, tyrosine kinase domain) in these receptor tyrosine kinases are indicated on the right side of the figure. Cys, cysteine; EGF, epidermal growth factor; Ig, immunoglobulin; PDGF, platelet-derived growth factor.
Figure 5-2 Ligand-induced dimerization of receptors. Two molecular mechanisms of ligand-induced receptor dimerization are illustrated. In the case of the platelet-derived growth factor, the ligand is dimeric and therefore contains two receptor binding sites. In the case of growth hormone, a single ligand molecule contains two binding sites so that it can bind simultaneously to two receptor molecules.
Figure 5-3: Phosphorylation of tyrosine residues in the activation loop leads to activation of the insulin receptor tyrosine kinase. A hypothetical mechanism for ligand-stimulated activation of the insulin receptor tyrosine kinase is illustrated. The model is based on the three-dimensional structure of the isolated insulin receptor tyrosine kinase as determined by x-ray crystallography. In the inactive insulin receptor kinase (left), Tyr1162 blocks the active site so that substrates cannot bind. In contrast, when the tyrosine residues in the activation loop (including Tyr1162) become phosphorylated (right), Tyr1162 moves out of the way, and there is a conformational change that allows binding of adenosine triphosphate (ATP) and protein substrate so that the kinase reaction can proceed.
Figure 5-4 Simplified model of signaling pathways downstream from the insulin receptor. Insulin binds to the insulin receptor, thereby activating the receptor tyrosine kinase to phosphorylate tyrosine residues on insulin receptor substrates (IRSs) including IRS-1 and IRS-2. Consequently, phosphorylated tyrosine residues in IRS molecules bind to Src homology 2 (SH2) domains in molecules such as growth factor receptor-binding protein 2 (Grb-2) and the p85 regulatory subunit of phosphatidylinositol (PI) 3-kinase. These SH2 domain-containing proteins initiate two distinct branches of the signaling pathway. Activation of PI 3-kinase leads to activation of phosphoinositide-dependent kinases (PDKs) 1 and 2, which activates multiple protein kinases including Akt/protein kinase B, atypical protein kinase C (PKC) isoforms, and serum/glucocorticoid-activated protein kinases (Sgk). Grb-2 interacts with m-SOS, a guanine nucleotide exchange factor that activates Ras. Activation of Ras triggers a cascade of protein kinases leading to the activation of mitogen-activated protein (MAP) kinase.
Figure 5-5 Mutations leading to constitutive activation of Ret. "Wild-type" Ret has intramolecular disulfide bonds formed by two cysteine residues in the same receptor molecule (left). When one of the two cysteine residues is mutated, the unpaired cysteine residue is available to form an intermolecular disulfide bond with a cysteine residue on another receptor molecule. This leads to receptor dimerization (right), which in turn leads to constitutive activation of the receptor tyrosine kinase. This type of mutation has been identified in patients with multiple endocrine neoplasia type 2.
Figure 5-6 Cytokine receptors are composed of multiple subunits and bind to one or more members of the Janus kinase (JAK) family of tyrosine kinases. A, Growth hormone (GH), like prolactin and leptin, binds to receptor homodimers and activates JAK2. B, Interferon (IFN) homodimers bind to their ligand-binding R1 subunits. The R2 subunits are then recruited, leading to activation of JAK1, which binds to R1 subunit, and JAK2, which binds to R2 subunit. Both subunits and both JAKs are necessary for responses to IFN. C, Interleukin-2 (IL-2) binds to receptors composed of three subunits: a c subunit shared with receptors for ILs 4, 7, 9, and 15; an IL-2R subunit shared with the IL-15 receptor; and a noncytokine receptor subunit, IL-2R subunit. IL-2 activates both JAK3, bound to the c subunit, and JAK1, bound to IL2-R. Extracellular regions of homology are indicated by the black lines and patterns. Intracellular regions of homology are indicated by the white boxes.
Cytokines activate signal transducers and activators of transcription (STATs). STAT proteins are latent cytoplasmic transcription factors. STATs bind, through their Src homology 2 (SH2) domains, to one or more phosphorylated tyrosines in activated receptor-JAK complexes. Once bound, they themselves are tyrosyl phosphorylated, presumably by the receptor-associated JAKs. STATs then dissociate from the receptor-JAK complexes, homodimerize or heterodimerize with other STAT proteins, move to the nucleus, and bind to gamma-activated sequence-like elements (GLES) in the promoters of cytokine-responsive genes. (Adapted from figure by J. Herrington, with permission.)
**Figure 5-8** The G protein-coupled receptor (GPCR) superfamily: diversity in ligand binding and structure. Each panel depicts various members of the GPCR superfamily in cartoon form. The seven membrane-spanning helices are shown as cylinders with the extracellular amino terminus and three extracellular loops above and the intracellular carboxyl terminus and three intracellular loops below. The superfamily can be divided into three subfamilies on the basis of amino acid sequence conservation within the transmembrane helices. Family 1 includes (A) the opsins, in which light (jagged arrow) causes isomerization of retinal covalently bound within the pocket created by the transmembrane helices (bar); (B) monoamine receptors, in which agonists (arrow) bind noncovalently within the pocket created by the transmembrane helices (bar); (C) receptors for peptides such as vasopressin, in which agonist binding (arrow) may involve parts of the extracellular amino terminus and loops as well as the transmembrane helices (bar); and (D) glycoprotein hormone receptors, in which agonists (oval) bind to the large extracellular amino terminus, thereby activating the receptor through as yet undefined interactions with the extracellular loops or transmembrane helices (arrow). Family 2 includes receptors for peptide hormones such as parathyroid hormone (PTH) and secretin. Agonists (arrow) may bind to residues in the extracellular amino terminus and loops as well as transmembrane helices (bar). Family 3 includes the extracellular Ca$^{2+}$ sensing receptor and metabotropic glutamate receptors. Agonists (sphere) bind in a cleft of the Venus flytrap-like domain in the large extracellular amino terminus, thereby activating the receptor through as yet undefined interactions with the extracellular loops or transmembrane helices (arrow).
**Figure 5-9** The G protein guanosine triphosphatase (GTPase) and G protein-coupled receptor (GPCR) desensitization-resensitization cycle. In each panel, the stippled region denotes the plasma membrane with extracellular above and intracellular below. In the basal state, the G protein is a heterotrimer with guanosine diphosphate (GDP) tightly bound to the subunit. The agonist-activated GPCR catalyzes release of GDP, which permits guanosine triphosphate (GTP) to bind. The GTP-bound subunit dissociates from the dimer. Arrows from subunit to effector and from dimer to effector indicate regulation of effector activity by the respective subunits. Arrow from effector to subunit indicates regulation of its GTPase activity by effector interaction. Under physiologic conditions, effector regulation by G protein subunits is transient and is terminated by the GTPase activity of the subunit. The latter converts bound GTP to GDP, thus returning the subunit to its inactivated state with high affinity for the dimer, which reassociates to form the heterotrimer in the basal state. In the basal state, the receptor kinase and arrestin are shown as cytosolic proteins. Dissociation of the GTP-bound subunit from the dimer permits the latter to facilitate binding of receptor kinase to the plasma membrane (arrow from dimer to receptor kinase). Plasma membrane binding permits the receptor kinase to phosphorylate the agonist-bound GPCR (depicted here as occurring on the carboxyl-terminal tail of the GPCR, but sites on intracellular loops are also possible). GPCR phosphorylation in turn facilitates arrestin binding to GPCR, resulting in desensitization. Endocytic trafficking of arrestin-bound GPCR and recycling to the plasma membrane during resensitization are not depicted here.
Figure 6-1 Seven-logarithm range of normal concentrations for the plasma concentrations of endocrine tests. DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; FT₄, free thyroxine; FT₃, free triiodothyronine; LH, luteinizing hormone; T₃, triiodothyronine; T₄, thyroxine; TSH, thyrotropin.

Figure 7-1 Three types of hypothalamic neurosecretory cells. Left, A magnocellular neuron that secretes arginine vasopressin or oxytocin (AVP, OXY). The cell body, which is located in the supraoptic or paraventricular hypothalamic nucleus (SON, PVH), projects its neuronal process into the neural lobe, and neurohormone is released from nerve endings. Center, Similar peptidergic neurons are located in the medial basal hypothalamus in nuclear groups including the PVH and arcuate nucleus of the hypothalamus (Arc). The neuropeptides in this case are released into the specialized blood supply to the pituitary to regulate its secretion. Similar in plan are neurosecretory neurons that terminate in relation to another neuron (right). These projection neurons are found in sites including the PVH, Arc, and lateral hypothalamic area (LHA) that project to autonomic preganglionic neurons in the brain stem and spinal cord. Such substances act as neurotransmitters or neuromodulators. ACTH, corticotropin; CART, cocaine and amphetamine-regulated transcript; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; MCH, melanin-concentrating hormone; ORX, orexin-hypocretin; POMC, pro-opiomelanocortin; TRH, thyrotropin-releasing hormone; TSH, thyrotropin.
Neurobiologic features of the peptidergic neuron. Neurosecretory neurons can be regarded as having secretory functions that are in many ways analogous to those of glandular cells. A secretory product, which is formed on the endoplasmic reticulum under the direction of messenger ribonucleic acid, is packaged in granules and transported along the axon by axoplasmic flow to reach nerve terminals, where the granules are released. Virtually all neurons carry out similar functions. Some secrete neurotransmitters, such as acetylcholine or norepinephrine; others, such as motor nerves, secrete acetylcholine and myotropic factors. In all neurons there is a constant orthodox (forward) flow of cytoplasm and formed elements such as mitochondria. Retrograde flow also takes place to bring substances that enter nerve endings back to the body of the cell. In typical neurotransmitter neurons, the neurotransmitters are synthesized by enzymes and are packaged into secretory granules. These granules are transported in a manner similar to that of neuropeptide-containing granules. In many neurons cosecretion of one or two peptides may occur in association with secretion of a classic neurotransmitter. (From Reichlin S. Summarizing comments. In Gotto AM Jr, Peck EJ Jr, Boyd AE III, et al [eds]. Brain Peptides: A New Endocrinology. New York, Elsevier/North-Holland, 1979, pp 379-403.)

Midsagittal nuclear magnetic resonance scan of the brain of a normal woman, which corresponds to the diagram in A. Note the location of the pituitary stalk, the intense signal from the posterior pituitary, and the anatomic relationship to the optic commissure and the optic nerve. (See also Fig. 7-4A.) (Courtesy of Dr. Samuel Wolpert.)
Figure 7-4a A. Midsagittal view of the human brain showing the hypothalamus and neighboring structures.
Figure 7-4b. Base of the human brain, showing the hypothalamus and neighboring structures. On gross inspection, several landmarks outline the hypothalamus. It is bounded anteriorly by the optic chiasm, laterally by the sulci formed with the temporal lobes, and posteriorly by the mammillary bodies (in which the mammillary nuclei are located). Dorsally, the hypothalamus is delineated from the thalamus by the hypothalamic sulcus. The smooth, rounded base of the hypothalamus is the tuber cinereum; the pituitary stalk descends from its central region, which is termed the median eminence. The median eminence stands out from the rest of the tuber cinereum because of its dense vascularity, which is formed by the primary plexus of the hypophyseal portal system. The long portal veins run along the ventral surface of the pituitary stalk. (From Nauta WJ, Haymaker W. Hypothalamic nuclei and fiber connections. In Haymaker W, Anderson E, Nauta WJ [eds]. The Hypothalamus. Springfield, Ill, Charles C Thomas, 1969, pp 136209.)
Figure 7-7 The paraventricular nucleus of the hypothalamus (PVH). A series of photomicrographs illustrate distinct subdivisions of the PVH and the presence of multiple neuropeptide mediators. Magnocellular neurons project to the posterior lobe of the pituitary gland to release arginine vasopressin or oxytocin (AVP, OT). Parvicellular hypophyseotropic neurons project to the median eminence and release releasing factors such as corticotropin-releasing hormone (CRH). In addition to neurons that make neuropeptides within the nucleus, the PVH receives a dense innervation from neurotransmitters and neuropeptide neurons, including neuropeptide Y (NPY). Note the subdivisions of the PVH including the dorsal (dp), ventral (vp), and medial (mp) parvicellular and posterior magnocellular (pm) divisions. IR, immunoreactivity; 3v, third ventricle.
Figure 7-8 The median eminence is the functional connection of the hypothalamus and the pituitary gland. A and B, Distribution of corticotropin-releasing hormone and thyrotropin-releasing hormone (CRH-IR and TRH-IR) immunoreactivity in the external layer of the median eminence (ME ext) of the rat. CRH and TRH cell bodies reside in the medial division of the paraventricular hypothalamic nucleus. C, Arginine vasopressin (AVP) immunoreactivity in nerve endings in the internal layer of the median eminence (ME int). Arc, arcuate nucleus; 3v, third ventricle.
Figure 7-9 The tuberoinfundibular system is revealed by retrograde transport of cholera toxin subunit B (CtB). The location of hypothalamic cell bodies of neurons projecting to the median eminence (ME) and the posterior pituitary can be identified by microinjecting a small volume of retrograde tracer (CtB) into the median eminence of the rat (see Wiegand,112 Lechan113). A, Retrogradely labeled cells can be seen in the paraventricular and supraoptic nuclei of the hypothalamus (PVH, SON). B, Magnocellular neurons are observed in the SON. C, Labeled neurons are found in the posterior magnocellular group (pm) as well as the medial parvicellular subdivision (mp). The labeled cells in the PVH include those that contain corticotropin-releasing hormone and thyrotropin-releasing hormone. D, Retrogradely labeled cells are also found in the arcuate nucleus of the hypothalamus (Arc). These include neurons that release growth hormone-releasing hormone and dopamine. 3v, third ventricle; ot, optic tract.

N
Figure 7-15 Prolactin (PRL) and thyrotropin (TSH) secretory responses to intravenous injection of 800 µg of thyrotropin-releasing hormone (TRH) in humans. This figure shows that TRH induces discharge of both PRL and thyrotropin, that the effect in females is greater than that in males (presumably owing to estrogen sensitization of the pituitary), and that thyrotoxicosis inhibits the response of both PRL and thyrotropin to TRH. An inhibitory effect on the TRH response is noted at the upper limit of the normal range of thyroid hormone levels and is a sensitive test of minor degrees of thyroid hormone excess. Although TRH is a potent prolactin-releasing factor (PRF), there is evidence that there is another PRF physiologically connected to PRL regulation. (Replotted from data of Bowers C, Friesen HG, Hwang P, et al. Prolactin and thyrotropin release in man by synthetic pyroglutamylhistidyl-prolinamide. Biochem Biophys Res Commun 1971; 45:1033-1041.)
Figure 7-16 Regulation of the hypothalamic-pituitary-thyroid axis. AGRP, agouti-related protein; CART, cocaine and amphetamine-regulated transcript; CRH, corticotropin-releasing hormone; NPY, neuropeptide Y; POMC, proopiomelanocortin; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyrotropin; OB-R, leptin receptor.
Figure 7-17 Relationship between plasma thyrotropin levels and thyroid hormone as determined by plasma protein-bound iodine (PBI) measurements in humans and rats. These curves illustrate, in the human (A) and the rat (B), that plasma thyrotropin levels are a curvilinear function of plasma thyroid hormone level. Human studies were carried out by giving myxedematous patients successive increments of thyrotropin $T_4$ at approximately 10-day intervals. Each point represents simultaneous measurements of plasma PBI and plasma thyrotropin at various times in the six patients studied. The rat studies were performed by treating thyroidectomized animals with various doses of $T_4$ for 2 weeks before assay of plasma thyrotropin and plasma PBI. These curves illustrate that the secretion of thyrotropin is regulated over the entire range of thyroid hormone levels. At the normal set point for $T_4$, the small changes above and below the control level are followed by appropriate increases or decreases in plasma thyrotropin. TSH, thyrotropin; $T_4$, thyroxine. (A from Reichlin S, Utiger RD. Regulation of the pituitary thyroid axis in man: relationship of TSH concentration to concentration of free and total thyroxine in plasma. J Clin Endocrinol Metab 1967; 27:251255, copyright by The Endocrine Society. B from Reichlin S, Martin JB, Boshans RL, et al. Measurement of TSH in plasma and pituitary of the rat by a radioimmunoassay utilizing bovine TSH: effect of thyroidectomy or thyroxine administration on plasma TSH levels. Proc Natl Acad Sci USA 1991; 88:87498753.)
Figure 7-28 Response of normal men to growth hormonereleasing hormone (GHRH)(129) (1 µg/kg), ghrelin (1 µg/kg), or GHRH(129) and ghrelin administered by intravenous injection. Note the prompt release of GH, followed by a rather prolonged fall in hormone level in response to both secretagogues. Ghrelin alone was more efficacious than GHRH(129), and there was an additive effect from the two peptides administered simultaneously. (From Arvat E, Macario M, Di Vito L, et al. Endocrine activities of ghrelin, a natural growth hormone secretagogue (GHS), in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. J Clin Endocrinol Metab 2001; 86:11691174.)
Figure 7-30 Regulation of the hypothalamic-pituitary-growth hormone (GH) axis. GH secretion by the pituitary is stimulated by GH-releasing hormone (GHRH) and is inhibited by somatostatin (SRIF). Negative feedback control of GH secretion is exerted at the pituitary level by insulin-like growth factor I (IGF-I) and by free fatty acids (FFA). GH itself exerts a short-loop negative feedback by the activation of SRIF neurons in the hypothalamic periventricular nucleus. These SRIF neurons directly synapse on arcuate GHRH neurons and project to the median eminence. Neuropeptide Y (NPY) neurons in the arcuate nucleus also indirectly modulate GH secretion by integrating peripheral GH, leptin, and ghrelin signals and projecting to periventricular SRIF neurons. Ghrelin is secreted from the stomach and is a putative natural ligand for the GH secretagogue receptor that stimulates GH secretion at both the hypothalamic and pituitary levels. On the basis of indirect pharmacologic data, it appears that release of GHRH is stimulated by galanin, -aminobutyric acid (GABA), and 2-adrenergic and dopaminergic stimuli and inhibited by somatostatin. Secretion of somatostatin is inhibited by acetylcholine (muscarinic receptors) and 5-HT (type 1D receptors), and increased by 2-adrenergic stimuli and corticotropin-releasing hormone (CRH). ACh, acetylcholine; CNS, central nervous system; DA, dopamine.
Somatostatin and the somatostatin receptor 2 subtype are involved in the short-loop inhibitory feedback of growth hormone (GH) on arcuate neurons. Activation of neurons in the arcuate nucleus was determined by the quantification of immunoreactive c-Fospositive cells after administration of the growth hormone secretagogue MK-0677 (MK). Preliminary treatment of wild-type mice (SSTR2$^{+/+}$) with either GH or the somatostatin analogue octreotide (Octreo) significantly attenuated the neuronal activation by MK-0677. In contrast, GH and octreotide had no effect on MK-0677 neuronal activation in somatostatin receptor 2-deficient mice (SSTR2$^{-/-}$). (Adapted from Zheng H, Bailey A, Jian M-H, et al. Somatostatin receptor subtype 2 knockout mice are refractory to growth hormone-negative feedback on arcuate neurons. Mol Endocrinol 1997; 11:17091717.)
Figure 7-32 Neural pathways involved in growth hormone (GH) regulation. This diagram illustrates the varied pathways by which impulses from the limbic system and brain stem ultimately impinge on the hypothalamic periventricular and arcuate nuclei to stimulate GH release through the mediation of somatostatin (SRIF) and growth hormone-releasing hormone (GHRH). Psychological stress modulates hypothalamic function indirectly through the bed nucleus of the stria terminalis (BNST) and amygdalar complex (Amyg). Circadian rhythms are entrained in part by projections from the suprachiasmatic nucleus (SCN). Complex reciprocal interactions between sleep stage and GHRH release involve cortex and subcortical nuclei, but the detailed mechanisms are not known. Dopaminergic and histaminergic input are from neurons located in the arcuate and mammillary nuclei, respectively, of the hypothalamus (HYP). Ascending catecholaminergic projections arise in both the nucleus of the tractus solitarius (NTS) and ventral lateral medulla (VLM). Serotonergic (5-HT) afferents are from the raphe nuclei. In addition to these neural pathways, a variety of peripheral hormonal and metabolic signals and cytokines influence GH secretion by actions within the medial basal hypothalamus and pituitary gland.
Figure 7-33 Diagram illustrating the genomic organization, messenger ribonucleic acid structure, and post-translational processing of the human somatostatin prohormone. Transcriptional regulation of the somatostatin gene, including the identification of tissue-specific elements (TSE), upstream elements (UE), and the cyclic adenosine monophosphate (cAMP) response element (CRE) that are binding sites for specific factors, has been studied extensively in pancreatic islet cell lines. It is not known whether all or some of these factors are also involved in the neural-specific expression of somatostatin. SST-28 and SST-14 are cyclic peptides containing a single covalent disulfide bond between a pair of Cys residues. A beta turn containing the tetrapeptide Phe-Trp-Lys-Thr is stabilized by hydrogen bonds to produce the core receptor binding epitope. This minimal structure has been the model for conformationally restrained analogues of somatostatin including octreotide. CPE, carboxypeptidase E; PC1/PC2, prohormone convertases 1 and 2; UTR, untranslated region. (Compiled from data by Shen LP, Rutter WJ. Sequence of the human somatostatin 1 gene. Science 1984; 224:168171; Goudet G, Delhalle S, Biemar F, et al. Functional and cooperative interactions between the homeodomain PDX1, Pbx, and Prep1 factors on the somatostatin promoter. J Biol Chem 1999; 274:40674073; and Milner-White EJ. Predicting the biologically active conformations of short polypeptides. Trends Pharmacol Sci 1989; 10:7074.)
Figure 7-34 The use of $^{111}$In-labeled diethyleneetriaminepentaacetic acid (DTPA)-octreotide (radioactive somatostatin analogue) and external imaging techniques to localize a carcinoid tumor expressing somatostatin receptors. Pictures were taken 24 hours after administration of labeled tracer.  
A, Anterior view of the abdomen showing nodular metastases in an enlarged liver and the primary carcinoid tumor (arrow) in the wall of the jejunum of a patient with severe flushing and diarrhea.  
B, Posterior view of the chest and neck showing a metastasis in a lymph node on the left side of the neck (arrow) and multiple metastases in the ribs and pleura.  
Figure 7-35 Regulation of the hypothalamic-pituitary-prolactin (PRL) axis. The predominant effect of the hypothalamus is inhibitory, an effect mediated principally by dopamine secreted by the tuberohypophyseal dopaminergic neuron system. The dopamine neurons are stimulated by acetylcholine (ACh) and glutamate and inhibited by histamine and opioid peptides. One or more prolactin releasing factors (PRFs) probably mediate acute release of PRL as in suckling and stress. There are several candidate PRFs, including thyrotropin-releasing hormone (TRH), vasoactive intestinal polypeptide (VIP), and oxytocin. PRF neurons are activated by serotonin (5-HT). Estrogen sensitizes the pituitary to release PRL, which feeds back on the pituitary to regulate its own secretion (ultrashort-loop feedback) and also influences gonadotropin secretion by suppressing the release of luteinizing hormone-releasing hormone (LHRH). Short-loop feedback is also mediated indirectly by prolactin receptor regulation of hypothalamic dopamine synthesis, secretion, and turnover. CNS, central nervous system; DA, dopamine; GABA, -aminobutyric acid.
**Figure 7-36** Schematic diagram of the gene for pre-pro-gonadotropin-releasing hormone (GnRH) and the GnRH peptide. Diagrams for the enhancer and promoter regions are specific to the rat gene.
Figure 7-37a Regulation of the hypothalamic-pituitary-gonadal axis.  A, Gonadotropin-releasing hormone (GnRH) neurons in a coronal section of the rat hypothalamus at 4× magnification. The inset is at 20× magnification. (Micrograph provided by Patricia Williamson and Kevin Grove, Oregon National Primate Center.)
Figure 7-37b Schematic diagram of the hypothalamic-pituitary-gonadal axis showing neural systems that regulate GnRH secretion and feedback of gonadal steroid hormones at the level of the hypothalamus and pituitary. CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, -aminobutyric acid; LH, luteinizing hormone; NPY, neuropeptide Y.
Figure 7-39 The influence of gonadotropin-releasing hormone (GnRH) pulse frequency on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion in a female rhesus monkey with an arcuate nucleus lesion ablating endogenous GnRH support of the pituitary. Decreasing GnRH pulse frequency from 1 pulse/hour to 1 pulse/3 hours leads to a decrease in plasma LH concentrations but an increase in plasma FSH concentrations. (Redrawn from Wildt L, Haulser A, Marshall G, et al. Endocrinology 1981; 109:376385.)
Figure 7-40 Pulsatile luteinizing hormone (LH) secretion in an ovariectomized rhesus monkey (A) and an ovariectomized rhesus monkey treated with estradiol (B). Estradiol causes a rapid and sustained suppression of LH secretion. (Redrawn from Yamaji T, Dierschke DJ, Knobil E. Endocrinology 70: 771777.)
Figure 7-41 Dose and duration requirements for estradiol-induced negative and positive feedback on luteinizing hormone (LH) secretion. Varying amounts of estradiol were implanted into ovariectomized rhesus monkeys. Short-term exposure to estradiol led to negative feedback on LH secretion, 36 hours of exposure led to positive feedback in 6 of 11 monkeys, and 42 hours of exposure led to robust positive feedback resulting in a surge of LH secretion in all monkeys. (*Redrawn from Karsch F, Weick RF, Butler WR, et al. Endocrinology 1973; 92:17401747.*)
Figure 7-42 Diagrammatic representation of changes in plasma levels of estradiol, progesterone, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and portal levels of gonadotropin-releasing hormone (GnRH) over the human menstrual cycle.
Figure 7-43 Regulation of energy homeostasis by the brain-gut-adipose axis. CCK, cholecystokinin; GLP-1, glucagon-like peptide 1; PYY, peptide YY.
Figure 7-44 Structure of the human leptin gene. cDNA, complementary deoxyribonucleic acid; UTR, untranslated region; rectangle, SP-1 site; triangle, CCAAT/enhancer binding protein (C/EBP); circle, cyclic AMP-responsive element (CRE); diamond, glucocorticoid response element (GRE).
Figure 7-45 Role of the hypothalamus as a sensory organ in the regulation of energy homeostasis. CRH, corticotropin-releasing hormone; DA, dopamine; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; NPY, neuropeptide Y; POMC, pro-opiomelanocortin; SRIH, somatotropin release-inhibiting hormone; TRH, thyrotropin-releasing hormone. (Modified with permission from Cone RD, Cowley MA, Butler AA, et al. The arcuate nucleus as a conduit for diverse signals relevant to energy homeostasis. Int J Obes 2001; 25:563-567.)
Figure 7-46 Organization of pro-opiomelanocortin (POMC), the precursor hormone of corticotropin (ACTH on figure), -LPH, and related peptides. The precursor protein contains a leader sequence (signal peptide), followed by a long fragment that includes sequence 5162 corresponding to -MSH. This fragment is cleaved at Lys-Arg bonds to form corticotropin 1B39, which in turn includes the sequences for -MSH (corticotropin 1B13) and corticotropin-like intermediate lobe peptide (CLIP) (corticotropin 1739), and a sequence corresponding to -LPH (191) that includes -LPH 158), and -endorphin (61B91). The -endorphin sequence also includes a sequence corresponding to met-enkephalin. The precursor molecule in the anterior lobe of the pituitary is processed predominantly to corticotropin and -LPH. In the intermediate pituitary lobe (in the rat), corticotropin and -LPH are further processed to -MSH and a -endorphinlike material. In all extrapituitary tissues, post-translational processing of the prohormone resembles that in the intermediate lobe. Hypothalamic processing is similar but not identical to that in the intermediate lobe. In the latter, -endorphin and -MSH are present predominantly in their acetylated forms. -LPH, -lipotropin; -MSH, -melanocyte-stimulating hormone; -LPH, -lipotropin; -endorphin, -melanocyte-stimulating hormone; -LPH, -lipotropin.
Figure 7-48 Average plasma ghrelin, insulin, and leptin concentrations during a 24-hour period in 10 human subjects consuming breakfast (B), lunch (L), and dinner (D) at the times indicated (0800, 1200, and 1730 hours, respectively). (Reprinted with permission from Cummings DE, et al. A preprandial rise in plasma ghrelin levels suggest a role in meal initiation in humans. Diabetes 2001; 50:17141719.)
Figure 7-50 A model of the central nervous system circuitry mediating the activation of the paraventricular hypothalamic nucleus (PVN or PVH) and the hypothalamic-pituitary-adrenal (HPA) axis by immune system stimulation. The immune system probably uses several pathways and sites of entry to communicate with the brain. This model predicts that circumventricular organs (organs devoid of blood-brain barrier; CVOs) and the blood vessels (bv) are crucial target sites of cytokines of systemic origin produced during the acute-phase response, whereas activated regions of the brain stem and deep limbic system might play a determinate role in the integration of information received from the periphery. Among these integrative structures, the PVN is critical in coordinating autonomic and endocrine responses including the activity of the HPA axis. For example, corticotropin-releasing factor (CRF) neurons of the parvicellular PVN expressed c-fos messenger ribonucleic acid, and that transcription of the gene coding CRF is activated essentially in this hypothalamic nucleus indicates the importance and the specificity of this neuroendocrine nucleus in endotoxin-treated animals. The mechanisms and the circuitry controlling the CRF release and the activity of the HPA axis might also be different from those involved in the biosynthetic machinery of CRF during immune challenge. ACTH, adrenocorticotropic hormone; AP, area postrema; ARC, arcuate nucleus; BnST, bed nucleus of the stria terminalis; bv, blood vessels; chp, choroid plexus; CeA, central nucleus of the amygdala; COX-2, cyclooxygenase-2; DMH, dorsomedial nucleus of the hypothalamus; EP, prostaglandin E receptor; IL-1, interleukin-1; IL-1R1, IL-1 type 1 receptor; IL-6, interleukin-6; IB, NF-B inhibitor; LC, locus coeruleus; LDT, laterodorsal tegmental nucleus; LPS, lipopolysaccharide; LRNm, lateral reticular nucleus medial; ME, median eminence; MPOA, medial preoptic area; NF-B, nuclear factor B; NTS, nucleus of the solitary tract; OVLT, organum vasculosum of the lamina terminalis; PGE2, prostaglandin E2; PB, parabrachial nucleus; PP, posterior pituitary; PVN, paraventricular nucleus of the hypothalamus (parvicellular [pc] and magnocellular [mc] divisions); SFO, subfornical organ; SON, supraoptic nucleus; TNF-, tumor necrosis factor; VLM, ventrolateral medulla. (Modified from Rivest S, Lacroix S, Vallieres L, et al. How the blood talks to the brain parenchyma and the paraventricular nucleus of the hypothalamus during systemic inflammatory and infectious stimuli. Proc Soc Exp Biol Med 2000; 223:2238.)
Figure 7-51 Immune stimulation activates key brain regions. A series of photomicrographs demonstrating the distribution of Fos-like immunoreactivity (Fos-IR) in the rat brain 2 hours after intravenous injections of lipopolysaccharide (LPS; 125 µg/kg). LPS administration is a commonly used model of immune stimulation, and Fos-IR is a widely used marker of neuronal activation. LPS activates (induces Fos-IR) in the ventral medial preoptic area and organum vasculosum of the lamina terminalis (VMPO and OVLT; A), in the subfornical organ (SFO; B), in the paraventricular nucleus of the hypothalamus (PVH; C), and in the area postrema and nucleus of the solitary tract in the brain stem (AP, NTS; D). Note that prominent Fos-IR is seen throughout the subdivisions of the PVH including the dorsal (dp), ventral (vp), and medial (mp) parvicellular and posterior magnocellular (pm) divisions. Also note that LPS activates neurons in the circumventricular organs (OVLT, SFO, AP). 3v, third ventricle.
**Figure 7-52** Typical pituitary response to thyrotropin-releasing hormone (TRH) administration in patients with hypothalamic-pituitary disease that has caused hypothyroidism. If there is intrinsic pituitary damage, the response is abnormally low. If there is hypothalamic damage, the response is normal or exaggerated. It must be emphasized that some patients with hypothalamic disease may not respond to TRH and that some patients with pituitary disease may respond to TRH. 

T<sub>4</sub>, thyroxine; TSH, thyrotropin. (From Jackson IMD. Diagnostic tests for the evaluation of pituitary tumors. In Jackson IMD, Reichlin S [eds]. The Pituitary Adenoma. New York, Plenum, 1980, pp 219-238.)
Figure 7-53 Effect of hypothalamic-pituitary disconnection on the growth hormone (GH) secretory responses to GH-releasing hormone (GHRH) (1 µg/kg) and hexarelin (2 µg/kg) administered intravenously to children with GH deficiency. Top, mean responses in a group of 24 prepubertal children with short stature secondary to familial short stature or constitutional growth delay. Children with GH deficiency and an intact vascular pituitary stalk as visualized by dynamic magnetic resonance imaging exhibited a clear, but blunted, GH response to both secretagogues (middle). In contrast, children with pituitary stalk agenesis (both vascular and neural components) had no or a markedly attenuated response to both peptides (bottom). (From Maghnie M, Spica-Russotto V, Cappa M, et al. The growth hormone response to hexarelin in patients with different hypothalamic-pituitary abnormalities. J Clin Endocrinol Metab 1998; 83:3886-3889.)
Figure 7-54 A neuroendocrine syndrome of adrenocorticotropic hormone insufficiency, obesity, and red hair resulting from a null mutation in the pro-opiomelanocortin gene. (Photo kindly provided by Dr. A. Gruters, Berlin.)
Figure 8-5 Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones traverse the portal system and impinge directly upon their respective target cells. Intrapituitary cytokines and growth factors regulate tropic cell function by paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition of respective pituitary trophic hormone synthesis and secretion. (From Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. Endocr Rev 1997; 18:206228.)
Figure 8-7 Magnetic resonance coronal section of a normal pituitary gland (top). A large pituitary adenoma is seen lifting and distorting the optic chiasm (arrow) and is also invading the sphenoid sinus (middle). A sagittal section of a large macroadenoma with bone invasion and impinging brain structures is shown (bottom).
Figure 8-10 Pathogenesis of Rathke's cysts. Schematic of the embryologic progenitors of sellar and parasellar structures. Rathke's pouch arises from an outpocketing of stomodeum (ectoderm) and gives rise to the adenohypophysis. The pharyngohypophyseal stalk, which connects the stomodeum and Rathke's pouch, is divided by the sphenoid bone as it grows together (arrows), isolating Rathke's pouch and the neurohypophysis within the sella. (From Harrison MJ, Morgello S, Post KD. Epithelial cystic lesions of the sellar and parasellar region: a continuum of ectodermal derivatives? J Neurosurg 1994; 80:1018–1025.)

Figure 8-32 Effects of pulsatile or continuous administration of gonadotropin-releasing hormone (GnRH) to ovariectomized monkeys rendered GnRH-deficient by placement of a lesion in the hypothalamus. Gonadotropin secretion was restored by hourly GnRH pulses, reduced during a continuous GnRH infusion, and again increased after reinstatement of pulsatile GnRH administration. FSH, follicle-stimulating hormone. (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophyseal responses to continuous and intermittent delivery of hypothalamic gonadotropin-releasing hormone. Science 1978; 202:631633. Copyright 1978 by the American Association for the Advancement of Science.)
Figure 8-33 Serum luteinizing hormone (LH) levels (open symbols) and follicle-stimulating hormone (FSH) levels (solid symbols) in men as a function of age from three studies. (From Tenover JL. Male hormone replacement therapy including "andropause." Endocrinol Metab Clin North Am 1998; 27:969987; Bhasin. In Melmed S (ed). The Pituitary, 2nd ed. Malden, Mass, Blackwell Scientific, 2002.)
Figure 8-35 Management of nonfunctioning pituitary adenomas. Skilled MRI interpretation is crucial to diagnose non-adenomatous mass (e.g., meningioma, aneurysm, or other sellar lesion). MRI, magnetic resonance imaging.
Figure 8-37 Effect of growth hormone (GH) secretagogues on GH, adrenocorticotrophic hormone (ACTH) and prolactin (PRL) secretion in healthy subjects. Mean (+ SEM) curve responses after administration of ghrelin (1.0 µg/kg), hexarelin (HEX) (1.0 µg/kg), growth hormone-releasing hormone (GHRH) (1.0 µg/kg), or placebo. (Adapted from Arvat E, Maccario M, Di Vito L, et al. Endocrine activities of ghrelin, a natural growth hormone secretagogue (GHS), in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. J Clin Endocrinol Metab 2001; 86:11691174.)
Figure 8-38 Growth hormone (GH) axis. Simplified diagram of GH/IGF-I axis involving hypophysiotropic hormones controlling pituitary GH release, circulating GH-binding protein and its GH receptor source, IGF-I and its largely GH-dependent binding proteins, and cellular responsiveness to GH and IGF-I interacting with their specific receptors. FFA, free fatty acids. IGFR, insulin-like growth factor I (IGF-I) receptor. Ghrelin, probably of predominantly gastric origin, also stimulates pituitary GH secretion. (From Rosenbloom A. Growth hormone insensitivity: physiologic and genetic basis, phenotype and treatment, J Pediatr 1999; 135:280289.)
Figure 8-39 Effect of fasting on growth hormone (GH) secretion patterns in a healthy male subject. (From Hartman ML, Veldhuis JD, Johnson ML, et al. Augmented growth hormone (GH) secretory burst frequency and amplitude mediate enhanced GH secretion during a two-day fast in normal men. J Clin Endocrinol Metab 1992; 74:757-765.)
Figure 8-40 Integrated model of the growth hormone-insulin-like growth factor binding protein-IGF (GHIGF-BP-IGF) axis in the growth process. Three mechanisms are proposed: (1) GH stimulates IGF-I production, and circulating IGF-I (endocrine IGF-I) acts at the growth plate; (2) GH regulates hepatic production of IGF-BP3 and acid-labile subunit (ALS): IGF-I binds to IGFBP-3 and thereafter with ALS, forming the 150-kd ternary complex; proteases cleave into fragments that release IGFBP3 into fragments that release IGF-I in the intravascular space and at the growth plate; and (3) GH induces differentiation local IGF-I production, and IGF-I acts through an autocrine and paracrine mechanism to stimulate cell division. (From Spagnoli A, Rosenfeld RG. The mechanism by which growth hormone brings about growth: The relative contributions of growth hormone and insulin-like growth factors. Endocrinol Metab Clin North Am 1996; 25:615631.)
Figure 8-41 Growth hormone (GH) receptors. A. Model of GH activation of JAK2 tyrosine kinase. GH binding to two GH receptors increases the affinity to each receptor for JAK2. The two receptor-associated JAK2 molecules are in close proximity, so that each JAK2 can phosphorylate the activating tyrosine of the other JAK2 molecule (blue arrows), thereby activating it. Activated JAK2 then phosphorylates itself (red arrow) and the cytoplasmic domain of the GH receptor (purple arrows) on tyrosines. These phosphotyrosines within the GH receptor and JAK2 form binding sites for signaling proteins. GH, growth hormone; GHR, growth hormone receptor; JAK2, Janus kinase 2; P, phosphate. B. Regulation of GH receptor-JAK2 signaling. SH2 enhances GH receptor signaling by increasing the activity of JAK2. GH-induced expression of SOCS proteins inhibits further GHR signaling by decreasing the activity of JAK2. Tyrosine phosphatases, such as SHP-2, might also contribute to inhibiting GH receptor signaling by dephosphorylating tyrosines in the GH receptor and/or JAK2. GH, growth hormone; GHR, growth hormone receptor; JAK2, Janus kinase 2; P, phosphatase; SHP-2, src homology 2 domain-containing protein tyrosine phosphatase 2; SOCS, suppressor of cytokine signaling. C. GH receptors signaling pathways. Some of the signaling pathways initiated by GH activation of JAK2 are shown. JAK2 phosphorylates SHC, leading to activation of MAPK (blue arrows). JAK2 also phosphorylates STAT transcription factors. MAPK and STATs are important for GH regulation of gene transcription (purple arrows). JAK2 phosphorylates IRS proteins, which are thought to lead to activation of PI 3'-kinase (PI3 K; red arrows). GH activation of PI 3'-kinase via IRS protein might be important for GH stimulation of glucose transport. GH, growth hormone, GHR, growth hormone receptor; IRS, insulin receptor substrates; JAK2, Janus kinase 2; MAPK, mitogen-activated protein kinase; P, phosphate; PI 3K, phosphatidylinositol 3-kinase, STAT, signal transducers and activators of transcription. (AC, From Herrington J, Carter-Su C. Signaling pathway activated by the growth hormone receptor. Trends Endocrinol Metab 2001; 12:252257.)
**Figure 8-42** Individual growth hormonereleasing hormone (GHRH) plus GHRP-6-mediated GH peaks in control subjects (*black dots*) and GH-deficient adults (*white dots*). GH secretion was a continuum between excessive secretion and abnormally low secretion, although a transition concentration between normality and abnormality may be seen at about the 15 µg/L concentration. Logarithmic representation. (*From Popovic V, Leal A, Micic D, et al. GH-releasing hormone and GH-releasing peptide-6 for diagnostic testing in GH-deficient adults. Lancet 2000; 356:11371142.*)
Figure 8-43 Effect of treatment with human growth hormone (hGH) on body fat in eight studies. (Adapted from Newman CB, Kleinberg DL. Adult growth hormone deficiency. Endocrinologist 1998; 8:178186.)
**Figure 8-44** Abdominal subcutaneous and visceral adipose tissue determined with computed tomography at the level of L45 in one man before (top) and after (bottom) 9 months of rhGH treatment. The scan shows the reduction in both visceral and subcutaneous adipose tissue. (Figures and caption kindly provided by B.A. Bengtsson.)
Figure 8-45  Time course of growth hormone (GH) dose and serum insulin-like growth factor I (IGF-I) concentration in a representative patient (38-year-old female) who was switched from oral to transdermal estrogen therapy during the course of GH replacement.  (From Cook DM, Ludlam WH, Cook MB. Route of estrogen administration helps to determine growth hormone [GH] replacement dose in GH-deficient adults. J Clin Endocrinol Metab 1999; 84:3956-3960.)
Figure 8-46 Management of adult somatotropin deficiency. Patients older than 60 years require lower maintenance doses. Women receiving transdermal estrogen require lower doses than those receiving oral estrogen preparations. GH, growth hormone; IGF-I, insulin-like growth factor I; Rx, treatment.
Figure 8-48 Harvey Cushing's first acromegaly patient. (A) Some years before presentation and (B) at admission. (From Jane JA, Laws ER. History of Acromegaly. In Wass JAH (ed). Handbook of acromegaly. Bristol, UK, BioScientifica, 2001, pp 315.)
Figure 8-49 Clinical features of acromegaly. A to C, Features of acromegaly or gigantism in two identical twins. A 22-year-old man with gigantism related to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (A) and enlarged hand (B) and foot (C) of the affected twin are apparent. Their clinical features began to diverge at the age of approximately 13 years. D to F, Increased incisor spacing and prognathism (D), macroglossia (E), and a normal tongue (F). (AC, From Gagel R, McCutcheon IE. Images in clinical medicine: pituitary gigantism. N Engl J Med 1999; 324:524; DF, from Turner. Clinical features, investigation and complications of acromegaly. In Wass J [ed]. Handbook of Acromegaly. Bristol, UK, BioScientifica, 2001.)
Figure 8-51 Radiation treatment of acromegaly. Long-term effects of radiation therapy on growth hormone (GH) secretion using a GH nadir after an oral glucose load below 2 µg/L as the cure criterion and the probability of not being cured with time after radiotherapy. The numbers of patients not cured at 5, 10, and 20 years after pituitary irradiation are indicated in parentheses. Each step represents one cure; each cross (+) denotes a patient not cured at the latest follow-up. (From Barrande G, Pittino-Lungo M, Coste J, et al. Hormonal and metabolic effects of radiotherapy in acromegaly: long term results in 128 patients followed in a single center. J Clin Endocrinol Metab 2000; 85:37793785.)
Figure 8-53 Medical management of acromegaly. A, Growth hormone (GH) and insulin-like growth factor I (IGF-I) concentrations with long-term octreotide treatment. Comparison of primary octreotide treatment in 25 previously untreated patients and in 80 patients who had previously undergone surgical resection or irradiation, or both. (From Newman C, Melmed S, George A, et al. Octreotide as primary therapy for acromegaly. J Clin Endocrinol Metab 1998; 83:3034-3040.) B, Pharmacodynamics of octreotide LAR twelve-hour mean serum octreotide and GH concentrations in a representative patient treated with a single 30-mg injection of Sandostatin LAR and observed for 60 days. After injection, drug levels peak at 28 days, and nadir GH levels are sustained for 4 weeks. (Adapted from Lancranjan I, Bruns C, Grass P, et al. Sandostatin LAR: a promising therapeutic tool in the management of acromegalic patients. Metabolism 1996; 45:6771.) C, Mean growth hormone (GH) concentration with octreotide (long-acting release) long-term treatment. Serum GH levels in acromegaly following monthly LAR octreotide injections in 12 patients for 1 year, and 8 patients for 31 months. (From Davies PH, Stewart SE, Lancranjan I, et al. Long-term therapy with long-acting octreotide [Sandostatin-LAR] for the management of acromegaly. Clin Endocrinol (Oxf) 1998; 48:311316.) D, Clinical impact of octreotide in reducing soft tissue swelling. Acromegaly in a patient suffering from obstructive sleep apnea before octreotide. Note the macroglossia, tracheotomy for airway obstruction, and intranasal feeding tube. After 6 months of treatment with octreotide, tongue size was reduced by half. Tracheotomy and nasal tube have been removed and sleep apnea has resolved. (Courtesy of S. Reichlin.)
**Figure 8-54** Action of growth hormone (GH) receptor antagonist. A, Normally, a single molecule of GH binds two GH receptors through sites 1 and 2, and the GH signal transduction pathway is activated. B, Pegvisomant increases binding of GH receptor to site 1 and blocks binding at site 2 to prevent functional GH-receptor dimerization, initiation of GH action, and induction of insulin-like growth factor I (IGF-I) synthesis and secretion. The peripheral effects of excess GH are antagonized at the cellular level, independent of the presence of somatostatin or dopamine receptors on the pituitary tumor. (Adapted from van der Lely AJ, Lamberts S. Medical therapy for acromegaly. In Wass J [ed]. Handbook of Acromegaly. Bristol, UK, BioScientifica, 2001, pp 5154.)
Figure 8-59 Structure of pro-opiomelanocortin (POMC) gene. Exon 1 encodes the RNA leader sequence, exon 2 encodes the initiator methionine (ATG), the signal peptide and several N-terminal residues of the precursor peptide, the remainder of which is encoded by exon 3. Corticotroph expression is determined by the upstream "pituitary" promoter (longer white arrowhead), whereas peripheral expression of the short POMC mRNA is determined by the "downstream" promoter (shorter white arrowhead). Translation of these shorter transcripts initiates from the initiator methionines (ATG) indicated in exon 3. The precursor peptide coding region is shaded light gray and the ACTH coding region is black. (From Clark AJL, Swords FM. Molecular pathology of corticotroph function. In Rappaport R, Amselem S [eds]. Hypothalamic-Pituitary Development: Genetic and Clinical Aspects. Basel, Karger, 2001, pp 140161.)
Figure 8-60 Processing and cleavage of pro-opiomelanocortin (POMC). The mature POMC precursor peptide is sequentially cleaved by PC-1 in the anterior pituitary corticotroph. In the neurointermediate lobe and other cell types, cleavage by PC2 allows release of -MSH and/or -endorphin. Carboxypeptidase H (not shown) removes residual basic amino acids at cleavage sites. -LPH, -lipotropin; JP, joining peptide; -LPH, -lipotropin, CLIP, corticotropin-like intermediate lobe peptide. (From Clark AJL, Swords FM. Molecular pathology of corticotroph function. In Rappaport R, Amselem S [eds]. Hypothalamic-Pituitary Development: Genetic and Clinical Aspects. Basel, Karger, 2001, pp 140161.)
Figure 8-63 Management of thyroid-stimulating hormone (TSH)-secreting pituitary tumors. PTU, propylthiouracil; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone.
Figure 8-64 Life-table analysis indicating probabilities of initially normal hypothalamic-pituitary-target gland axes remaining normal after radiotherapy (3750 to 4250 cGy). Growth hormone (GH) secretion is the most sensitive of the anterior pituitary hormones to the effects of external radiotherapy, and TSH secretion is the most resistant. In two thirds of patients, gonadotropin deficiency develops before adrenocorticotropic hormone (ACTH) deficiency. The reverse occurs in the remaining third. (From Littley MD, Shalet SM, Beardwell CG, et al. Hypopituitarism following external radiotherapy for pituitary tumors in adults. Q J Med 1989; 70:145160.)
Figure 8-65 Incidence of growth hormone (GH) deficiency in children receiving 27 to 32 Gy or 35 Gy of cranial irradiation for a brain tumor in relation to time from irradiation (dxt). This illustrates that the speed at which individual pituitary hormone deficits develop is dose-dependent; the higher the radiation dose, the earlier GH deficiency occurs. (Courtesy of the Department of Medical Illustrations, Wilkington Hospital, Manchester, England. From Shalet S. Pituitary failure. In DeGroot LJ, Jameson JL [eds]. Endocrinology, 4th ed. Philadelphia, WB Saunders, 2001.)
Figure 9-1 Magnicellular neurons and axon tracts in the hypothalamus. A, Coronal section of the hypothalamus in which neurophysin antibodies are used in an immunoperoxidase technique to demonstrate the magnicellular neurons and axons. The paired paraventricular nuclei (PVN) are at the top in the walls of the third ventricle (V). The axons course laterally and ventrally to the supraoptic nucleus (SON) at the lateral extremes of the optic chiasm (OC) and then inferiorly to the median eminence. (Adapted from Zimmerman EA, Anatomy of vasopressin in producing cells. In Czernichow P, Robinson AG [eds]. Diabetes Insipidus in Man. Basel, Karger, 1985, pp 121. Modified to add right SON by A. G. Robinson, University of California, Los Angeles.) B, In the median eminence, the axons from the two sides coalesce to form the supraopticohypophyseal tract that descends through the stalk to the axon terminals in the posterior pituitary. (Adapted from Robinson AG, Zimmerman EA. Cerebrospinal fluid and ependymal neurophysin. J Clin Invest 1973; 52:12601267. Modified to remove tissue tear by A. G. Robinson, University of California, Los Angeles.)
Figure 9-2 Comparison of the chemical structures of arginine vasopressin, oxytocin, and desmopressin. The differences are illustrated by the shaded areas. Oxytocin differs from vasopressin in position 3 (Ile for Phe) and position 8 (Leu for Arg). Desmopressin differs from arginine vasopressin in that the terminal cystine is deaminated and the arginine in position 8 is a d rather than an l isomer. (© 2003, UCLA, AG Robinson.)
Figure 9-3 Vasopressin synthesis in a magnicellular neuron.  A. The vasopressin gene is located on the short arm of chromosome 20. In the nucleus, the gene is transcribed to heteronuclear ribonucleic acid (RNA).  B. The introns are then excised, and the three exons are spliced to form mature RNA, which consists of exon A, exon B, and exon C. The mature RNA exits the nucleus to the cytoplasm. It is targeted to the endoplasmic reticulum, where it is attached to ribosomes.  C and D. There is translation of the three exons into pre-provasopressin. Exon A is translated to the 19-amino-acid signal peptide (SP), the nonapeptide arginine vasopressin (AVP), and the amino-terminal portion of the 93- to 95-amino-acid neurophysin (NP). Exon B encodes the highly conserved middle region of neurophysin. Exon C encodes the variable carboxyl terminus of neurophysin and a 39-amino-acid glycopeptide (GP). The pre-provasopressin is transferred across the endoplasmic reticulum, the glycopeptide is glycosylated, and the signal peptide is cleaved (D).  E. Provasopressin enters the Golgi apparatus, where the entire provasopressin complex is packaged into neurosecretory granules. The neurosecretory granules attach to microtubules and are transported along the microtubules to the posterior pituitary, where the neurosecretory granules are stored.  F. During transport, enzymes in the acidic granules cleave the prohormone to vasopressin (which is amidated), to neurophysin, and to the glycopeptide. Neurophysins form dimers and, subsequently, tetramers with one vasopressin attached to each neurophysin. There is an auxiliary fifth binding site for vasopressin, which spans the four neurophysin molecules of the tetramer.  G. When there is an action potential signaling release, a neurosecretory granule fuses with the axon membrane and the vasopressin, neurophysin, and glycopeptide are secreted into the extracellular space and, hence, into plasma, where they circulate independently of each other.  (© 2003, UCLA, AG Robinson.)
**Figure 9-4** Comparison in humans of the release of vasopressin in response to percentage changes of osmolality (increase) and pressure or volume (decrease). Note: To increase plasma vasopressin, the change in osmolality is much more sensitive, responding to as little as a 1% increase in osmolality, whereas volume and pressure require greater than a 10% to 15% change to stimulate release of vasopressin. (Redrawn from Robertson GL, Berl T. Water metabolism. In Brenner BM, Rector FC Jr [eds]. The Kidney, vol 1, 3rd ed. Philadelphia, WB Saunders, 1986, p 385.)
Figure 9-5 Relationship of plasma osmolality (mOsm/kg of H₂O) to plasma vasopressin (pg/mL) to urine osmolality (mOsm/kg of H₂O) to urine volume (L/day). AVP, arginine vasopressin; P, plasma; U, urine. A, Small changes in osmolality induce changes in vasopressin from less than 0.5 to 5 to 6 pg/mL. B, These small changes in plasma vasopressin induce changes in urine osmolality through the full range from maximally dilute to maximally concentrated urine. Plasma vasopressin can rise to higher levels than 6 pg/mL, as illustrated in A, but this does not translate into increased urine osmolality, which has a maximum determined by the osmolality of an inner medulla of the kidney. C, The relationship of volume to urine osmolality is logarithmic, assuming a constant osmolar load and the urine volume that would excrete that osmolar load at the urine osmolality indicated. The interrelationship between the three graphs is illustrated by the shaded area that represents the normal range. Urine volume changes relatively little with small changes in the other parameters until there is nearly complete absence of vasopressin, and the urine volume then increases dramatically. (Calculated from formulas in Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. Kidney Int 1976; 10:2537.) (© 2003, UCLA, AG Robinson.)
Figure 9-6 Comparison of the normal response of plasma vasopressin to plasma osmolality (A) with that in midgestation (B) and late gestation (C). During midgestation (B), there is a reset of the osmostat to a lower level, shifting the curve to the left. In late gestation, the osmotic threshold remains the same but there is a change in the slope and less vasopressin is secreted. (Adapted from Davison JM, Shields EA, Phillips PR, Lindheimer MD. Serial evaluation of vasopressin release and thirst in human pregnancy: role of human chorionic gonadotrophin in the osmoregulatory changes of gestation. J Clin Invest 1988; 81:798806.)
Figure 9-7 Typical triphasic response of urine volume after section of the pituitary stalk induced by surgery or head trauma. The first phase of diabetes insipidus occurs immediately after operation and continues to day 6. The second phase of antidiuresis occurs from day 7 and continues to day 12. The third stage is the recurrence of diabetes insipidus on day 13. (Durations vary; see text for discussion.)
Figure 9-9 Plasma arginine vasopressin (AVP) levels in patients with syndrome of inappropriate antidiuretic hormone secretion as a function of plasma osmolality. Each point depicts one patient at a single point in time. The shaded area represents AVP levels in normal subjects over physiologic ranges of plasma osmolality. The lowest measurable plasma AVP level using this radioimmunoassay was 0.5 pg/mL. (From Robertson GL, Aycinena P, Zerbe RL. Neurogenic disorders of osmoregulation. Am J Med 1982; 72:339-353.)
Figure 9-10 Schematic summary of different patterns of arginine vasopressin (AVP) secretion in patients with syndrome of inappropriate antidiuretic hormone secretion. Each line (a to d) represents the relation between plasma AVP and plasma osmolality of individual patients in whom osmolality was increased by infusion of hypertonic NaCl. The shaded area represents plasma AVP levels in normal subjects over physiologic ranges of plasma osmolality. (From Robertson GL. Thirst and vasopressin function in normal and disordered states of water balance. J Lab Clin Med 1983; 101:351371.)
**Figure 10-1** Structure of thyroid hormone and related compounds. The thyronine nucleus, the precursor iodinated amino acids, and the secreted hormones, thyroxine (T₄) and triiodothyronine (T₃). Iodinated thyronines are formed by the oxidative coupling of the precursor iodotyrosines monoiodotyrosine (MIT) and diiodotyrosine (DIT) in the thyroglobulin molecule.
Figure 10-2 Schematic illustration of a thyroid follicular cell showing the key aspects of thyroid iodine transport and thyroid hormone synthesis. AMP, adenosine monophosphate; cAMP, cyclic AMP; DIT, diiodotyrosine; MIT, monoiodotyrosine; NIS, sodium iodide symporter; T₃, triiodothyronine; T₄, thyroxine; Tg, thyroglobulin; TPO, thyroid peroxidase; TSH, thyrotropin; TSHR, thyrotropin receptor. (Modified from Spitzweg C, Heufelder AE, Morris JC. Thyroid iodine transport. Thyroid 2000; 10:321330.)
Figure 10-3 Pathways for thyroid hormone activation and inactivation catalyzed by human iodothyronine selenodeiodinases. Numbers refer to the iodine positions in the iodothyronine nucleus. The iodothyronine deiodinases are abbreviated D1, D2, and D3 for types 1, 2, and 3 deiodinases, respectively. Arrows refer to monodeiodination of the outer or inner ring of the iodothyronine nucleus, termed 5' or 5 by convention. The parentheses around D1 emphasize that D3, not D1, is probably the major enzyme catalyzing inner ring deiodination of T_4 and T_3.
Figure 10-5  Schematic diagram of thyroxine (T₄) 5'-deiodination reaction as catalyzed by the type 1 iodothyronine deiodinase (D1). The reaction assumes the formation of a selenyl-iodide intermediate, which requires a cystolic cofactor that is likely to be an -SH compound, such as reduced glutathione (GSH). Heavy metals with a single positive charge, such as gold (Au⁺), inhibit deiodination by interaction with the negatively charged selenium atom. Propylthiouracil (PTU) is thought to form a relatively stable Se-S complex, thereby blocking regeneration of the active enzyme. (Modified from Leonard JL, Visser TJ. Biochemistry of deiodination. In Hennemann G [ed]. Thyroid Hormone Metabolism. New York, Marcel Dekker, 1986, pp 189-229.)
Figure 10-6  Schematic diagram of the origin of the specifically bound nuclear triiodothyronine (T₃) in various rat tissues. Data are derived from studies in which double-isotope labeling techniques were used to estimate the sources of specifically bound nuclear T₃. In tissues having a receptor saturation significantly greater than 50%, the additional T₃ is provided by D₂-catalyzed T₄ to T₃ conversion. T₃ in rat plasma is derived from thyroid secretion (40%) with the remainder from D₁- and D₂-catalyzed T₂ to T₃ conversion. BAT, brown adipose tissue; PIT, pituitary gland.
Figure 10-7 Comparison of the chemical structure of thyroxine (T₄) with the structures of two agents that block the deiodination of the iodothyronines. The inhibition of T₄ to triiodothyronine (T₃) conversion, which occurs in patients receiving amiodarone, may be due to the drug itself or to a metabolic product. Iopanoic acid and related iodoanilines are competitive inhibitors of all three iodothyronine deiodinases.
Figure 10-8 Schematic diagram of thyroid hormone activation and inactivation in a cell expressing D2 and D3, such as an astroglial cell or a neuron. The triiodothyronine (T₃) that enters the cell can either be deiodinated to 3,3′ T₂ (diiodothyronine) or can enter the nucleus and bind to the thyroid hormone receptor. An additional source of T₃ is that generated by outer ring deiodination of thyroxine (T₄) within the cell. The interaction of T₃ with the thyroid hormone receptor (TR) bound as a heterodimer with a retinoid X receptor (RXR) to the thyroid hormone response element (TRE), causes either an increase or a decrease in the transcription of that gene. This leads to parallel changes in the concentrations of critical proteins, thus producing the thyroid hormone response of a given cell. mRNA, messenger RNA; rT₃, reverse T₃. (See Chapter 4 for specific details.)
Figure 10-9 The functional domains in the thyroid hormone receptor are similar in both α and isoforms of the thyroid hormone receptors. These isoforms differ primarily in their NH₂-terminal domains. AF, activating factor; DBD, DNA-binding domain; T₃, triiodothyronine.
Figure 10-10 Role of thyroxine and triiodothyronine (T\(_4\) and T\(_3\)) in the feedback regulation of thyrotropin-releasing hormone (TRH) and thyrotropin (TSH) secretion. Secreted T\(_4\) must be converted to T\(_3\) to produce its effects. This conversion may take place in tissues such as the liver (L) and kidney (K) and thyroid (T) catalyzed by D1 or D2 in the human thyroid gland (T), skeletal muscle (SM), and, possibly, cardiac muscle (CM). SRIH, somatostatin.
Figure 10-11 The log/linear relationship between thyrotropin (TSH) (vertical axis) and free thyroxine (FT₄) concentrations. Typical free T₄ concentrations in hypothyroid, euthyroid, and hyperthyroid patients are shown. (Modified from Spencer CA, LoPresti JS, Patel A, et al. Applications of a new chemiluminometric thyrotropin assay to subnormal measurement. J Clin Endocrinol Metab 1990; 70:453460.)
Figure 10-12 Effects of acute depletion of dietary iodine on serum triiodothyronine (T₃), thyroxine (T₄), and thyrotropin (TSH) in rats. Animals received a low-iodine diet (LID) without or with supplementation of potassium iodide (KI) in drinking water. (From Riesco G, Taurog A, Larsen PR, Krulich L. Acute and chronic responses to iodine deficiency in rats. Endocrinology 1977; 100:303313. © The Endocrine Society.)
**Figure 10-13** Newborn infant with iodide-induced goiter due to Lugol's solution treatment of the mother during the third trimester. This illustration shows the danger of chronic excess iodide administration during gestation.
Figure 10-14 Changes in various critical components of the thyroid-pituitary axis during pregnancy. Note the early increase in free thyroxine (T₄), probably due to thyroidal stimulation by human chorionic gonadotropin (hCG), which causes a reciprocal modest suppression of serum thyrotropin (TSH) during the late first trimester. TBG, thyroxine-binding globulin. (From Burrow GN, Fisher DA, Larsen PR. Mechanisms of disease: maternal and fetal thyroid function. N Engl J Med 1994; 331:10721078. © 1994, Massachusetts Medical Society.)
Figure 10-15 With the development of modern thyrotropin (TSH) assays with greater sensitivity, it is possible to distinguish between normal thyrotropin concentrations and the suppressed values of hyperthyroidism. Each generation of assays represents a 10-fold improvement in functional sensitivity, that is, 20% interassay coefficient of variation (CV) value. Black bars denote the 95% confidence limits of measurement at different thyrotropin concentrations. (From Nicoloff JT, Spencer CA. Clinical review 12: the use and misuse of the sensitive thyrotropin assays. J Clin Endocrinol Metab 1990; 71:553558.)
Figure 10-16 Pattern of changes in total serum thyroxine (T4) concentrations and thyroid hormone-binding ratio (THBR) in euthyroid patients with alterations in circulating concentrations of thyroxine-binding globulin (TBG). To convert T4 from nmol/L to µg/dL (total) or pmol/L (free), divide by 12.87.
Figure 10-17 Pattern of changes in total serum thyroxine (T₄) concentration and thyroid hormone-binding ratio (THBR) in patients with hyperthyroidism or hypothyroidism with normal serum thyroxine-binding globulin (TBG) concentration.
Figure 10-18 Examination of the thyroid gland. A. Sagittal section demonstrates relations of the isthmus of the normal thyroid gland. The superior border is inferior to the cricoid cartilage. The inferior thyroid border is essentially at the level of the superior surface of the manubrium. The inferior portions of the lateral lobes (not shown) extend more inferiorly than the isthmus. B. The cricoid cartilage is regarded as an important landmark. Especially when the thyroid gland is thought to be essentially normal or subnormal in size, the cricoid should be located. This is easily accomplished. The index fingers are then inserted so that their superior portion rests against the inferior portion of the cricoid while the inferior portion of these fingers is over the superior portion of the thyroid. The second and third fingers are rotated over other portions of the gland to evaluate its size, contour, consistency, possible adherence to surrounding structures, and other features. Because there is marked variation among different subjects in the length and thickness of the neck and in the length of the trachea superior to the level of the manubrium, the relative position of the thyroid may vary. In some cases, essentially all of the thyroid gland rests posterior to the sternum. In most instances, however, by having the patient moderately extend the neck (short of tightening the anterior neck muscles) and swallow repeatedly, it is possible to palpate most or all of the gland. Despite marked variations in neck-chest relations, thyroid tissue, when present, is found within 1 cm of the cricoid. By concentrating the palpation meticulously in the area where the thyroid is normally found, with rare exceptions the examiner can outline small as well as enlarged glands.
Figure 11-1  Inhibition of the binding of $^{125}\text{I}$-labeled thyrotropin (TSH) to human thyroid TSH receptors by increasing concentrations of bovine TSH (†) and by increasing concentrations of immunoglobulin G (IgG)-containing TSH receptor antibodies referred to here as TSH-binding inhibitory immunoglobulin (TBII) activity (and . (From Endo K, Kashagi K, Konishi J, et al. Detection and properties of TSH-binding inhibitor immunoglobulins in patients with Graves’ disease and Hashimoto’s thyroiditis. J Clin Endocrinol Metab 1978; 46:734739. © 1978, The Endocrine Society.)
Figure 11-2 Stimulation of adenylate cyclase activity in human thyroid membranes by serum immunoglobulin G in normal control subjects and patients with thyroid disease. (From Bech K, Nishup Madsen SN. Thyroid adenylate cyclase stimulating immunoglobulins in thyroid disease. Clin Endocrinol 1979; 11:4758.)
Figure 11-3 Schematic diagram of thyroid cell stimulation and blockade by antibodies to the thyrotropin-stimulating hormone receptor. Such autoantibodies may act as agonists or antagonists, depending on how they interact within the extracellular domain.
Figure 11-4 Section of thyroid gland of four patients with Graves' disease. A, Untreated. B, After therapy with potassium iodide for 3 weeks. C, After treatment with thiouracil for 5 weeks. D, Three months after three treatments with radioiodine. Note the marked hypertrophy and hyperplasia of the acinar cells and scant amount of colloid in sections A, C, and D. A lymph follicle is present in C. Note the broad bands of scar tissue in D. Section B is almost normal in appearance. Each patient, except the first one, was euthyroid at the time of thyroidectomy.
Figure 11-6  Human thyrotropin receptor (hTSH-R) exon structure. Outline structure of the TSHR (A) in comparison with the porcine luteinizing hormone receptor (pLH-R) and rat follicle-stimulating hormone receptor (rFSH-R) genes and (B) the exon/intron organization of the TSHR gene. A shows the similarity (%) between the hTSHR and the pLH and rFSH receptors, respectively. (From Gross B, Misrahi M, Sar S, et al. Composite structure of the human TSH receptor gene. Biochem Biophys Res Comm 1991; 177:679687.)
Figure 11-7 A current model of the human thyrotropin-stimulating hormone receptor structure. The TSHR has seven transmembrane domains, a large extracellular domain, and a small intracellular domain. The receptor is cleaved, probably after activation, into A (or A) and B (or B) subunits. The subunit is thought to be shed from the cell surface.
Figure 11-8 T cells from a patient with Graves' disease demonstrate a dose-related proliferative response to a thyrotropin-stimulating hormone receptor peptide (aa 181200). Data shown as $^3$H-thymidine uptake at 18 hours.
Figure 11-9 Schematic diagram of a T-cell receptor dimer showing the alpha and beta chains retained by transmembrane regions. V, variable region; C, constant region. (From Davis MM, Chien YH, Gascoigne NR, et al. A murine T cell receptor gene complex. Immunol Rev 1984; 81:235258.)
**Figure 11-10** Possible mechanisms involved in the cause and precipitation of Graves’ disease. MHC, major histocompatibility complex.
Figure 11-11 Photomicrograph of Graves' thyroid tissue stained for HLA class II (DR) antigen expression using the immunoperoxidase technique. Note the brown thyroid epithelial cells indicating the presence of DR antigen. Note also the relative lack of lymphocytic infiltration in this region.
Figure 11-12 CT scans of orbits in two patients with Graves’ orbitopathy. A, Note the obviously grossly swollen medial rectus extraocular muscles in both orbits and the resulting proptosis. B, The patient shows considerable proptosis with only minimal muscle enlargement, suggesting the presence of a large amount of retro-orbital fat. (Courtesy of Dr. Peter Som, New York, NY.)
**Figure 11-13** Section of extraocular muscle from a biopsy taken from a patient with severe Graves’ orbitopathy. Note that within the muscle fibers is a patch of lymphocytic infiltration. (Courtesy of Dr. D. Kendler, University of British Columbia, Vancouver, Canada.)
Figure 11-14 Chronic pretibial myxedema in a patient with Graves’ disease and orbitopathy. The lesions are firm and nonpitting, with a clear edge to feel. (Courtesy of Dr. Andrew Werner, New York, N.Y.)
Figure 11-15 Characteristic signs of Graves’ orbitopathy (A) subsequently corrected by orbital decompression surgery (B). Note the thyroid stare, the asymmetry, the proptosis, and the periorbital edema prior to correction. (Courtesy of Dr. Jack Rootman, University of British Colombia, Vancouver, Canada.)
Figure 11-16 Graves' orbitopathy. A, Palpebral edema. This patient's eyes protruded anteriorly 1 cm more than normal, but there is no "popeye" appearance, owing to edema of the surrounding structures. B, Marked widening of palpebral fissures and slight palpebral swelling. C, Unequal degrees of ophthalmopathy. D, Unilateral lid retraction. E, Palpebral swelling, presumably because of fat pads and edema, and paralysis of the right external rectus muscle. F, Marked conjunctival injection and chemosis, together with ophthalmoplegia. G, Failure to close lid on the right because of marked exophthalmos, corneal scarring, and panophthalmitis; the eye had to be enucleated.
Figure 11-17 Ophthalmoplegia in Graves' disease. Other than slight conjunctival injection, the only ocular abnormality was paralysis of upward gaze on the right in this woman with severe Graves' disease.
Figure 11-18 Rare thyroid acropachy in a patient with Graves' disease. The hypermetabolic state leads to axial bone destruction, presumably secondary to enhanced osteoclast activity. Acropachy is not to be confused with clubbing, which is usually painless. (Courtesy of Dr. Andrew Werner, New York, N.Y.)
**Figure 11-19** Effects of antithyroid agents on the serum levels of triiodothyronine (T\(_3\)) and thyroxine (T\(_4\)) in patients with Graves' disease. The **left panels** show the effects of potassium iodide (SSKI, 5 drops every 8 hours). A rapid reduction in T\(_3\) concentration occurs in all patients over the first 5 days of therapy. Methimazole (MMI) at the indicated doses has a variable effect on serum T\(_3\) concentrations. In one patient the serum T\(_3\) level falls rapidly over the first 3 days, whereas in the other two individuals, despite an even larger dosage, there is no change. Serum T\(_4\) concentration does not change significantly over this time interval. The **right panels** show that the administration of high-dose propylthiouracil (PTU) causes a marked decrease in serum T\(_3\) concentrations to one third to one half of initial levels. This decrease is due to the PTU-induced inhibition of type 1 iodothyronine 5'-deiodinase. *(Data from Abuid J, Larsen PR. Triiodothyronine and thyroxine in thyrotoxicosis: acute response to therapy with antithyroid agents. J Clin Invest 1974; 39:263-268.)*
Figure 11-20 Influence of carbimazole and placebo treatment on thyroid peroxidase antibody levels (measured as antimicrosomal antibodies) in patients with Hashimoto's thyroiditis. These data illustrate the immunosuppressive effect of carbimazole in patients who remained euthyroid throughout observation. SEM, standard error of the mean. (From McGregor AM, Ibbertson HK, Smith BR, Hall R. Carbimazole and autoantibody synthesis in Hashimoto's thyroiditis. Br Med J 1980; 281:968-970.)
Figure 11-21 Incidence of postradioiodine hypothyroidism in relation to the duration of follow-up. The total number of patients followed for each of the indicated time periods is shown in parentheses. (From Dunn JT, Chapman EM. Rising incidence of hypothyroidism after radioactive iodine therapy in thyrotoxicosis. Reprinted by permission of The New England Journal of Medicine, 1964; 271:10371042.)
Figure 11-22 Probability of the development of worsening of orbitopathy in patients with Graves’ disease. The serum triiodothyronine (T₃) levels are shown before treatment, and the type of therapy is shown as a variable. (From Tallestedt L, Lundell G, Torring O, et al. Occurrence of ophthalmopathy after treatment for Graves’ disease. N Engl J Med 1992; 326:17331738. Copyright © 1992, Massachusetts Medical Society. All rights reserved.)
**Figure 11-24** $^{131}$I scanning of a hyperfunctioning hot nodule corresponding to physical examination with a faint outline of the remaining suppressed gland. In this unusual case, Graves’ disease developed a few months later after an oral contrast agent load. *(From Soule J, Mayfield R. Graves' disease after $^{131}$I therapy for toxic nodule. Thyroid 2001; 11:9192.)*
Figure 11-25 Subacute thyroiditis. Intrafollicular giant cell surrounding a central core of colloid. (From Meachim G, Young MH. De Quervain’s subacute granulomatous thyroiditis: histological identification and incidence. J Clin Pathol 1963; 16:189199.)
Figure 11-26 Thyroid function in a patient in the course of de Quervain's (subacute) thyroiditis. During the thyrotoxic phase (days 10 to 20) the serum thyroglobulin (TG) concentration was elevated, the free thyroxine index (FTI) was high, and thyrotropin (TSH) was suppressed. The erythrocyte sedimentation rate was 86 mm/hour, and the thyroidal radioactive iodine uptake was 2%. The Tg level and FTI declined in parallel. During the phase of hypothyroidism (days 30 to 63), when the FTI was below normal, the serum Tg level transiently increased in parallel with the increase in serum TSH. All parameters of thyroid function were normal by day 150, 5 months after the onset of symptoms. (From DeGroot LJ, Larsen PR, Hennemann G [eds]: Acute and subacute thyroiditis. In The Thyroid and Its Diseases, 6th ed. New York, Churchill Livingstone, 1996, p 705.)
**Figure 11-27** Low-power (A) and high-power (B) magnification of a thyroid gland biopsy during the hypothyroid phase of "silent thyroiditis." Note the extensive lymphocytic infiltration and patchy distribution of poorly preserved follicles. (From Woolf PD. Transient painless thyroiditis with hyperthyroidism: a variant of lymphocytic thyroiditis? Endocr Rev 1980; 1:411420. © 1980, The Endocrine Society.)
Figure 11-28 Schematic of the typical course in chronic thyroiditis with transient thyrotoxicosis. The duration of each phase may vary, and some patients do not experience a discernible hyperthyroid or hypothyroid phase. (From Woolf PD. Transient painless thyroiditis with hyperthyroidism: a variant of lymphocytic thyroiditis? Endocr Rev 1980; 1:411-420. © 1980, The Endocrine Society.)
Figure 11-29 Changes in free thyroxine in various types of postpartum thyroid disease. Numbers indicate the number of months post partum. (Adapted from Davies TF [ed]. Autoimmune Endocrine Disease. New York, John Wiley & Sons, 1963, p 255.)
Figure 11-30 The structure of amiodarone illustrating the characteristics of thyroid hormone. The molecule is 37% iodine by weight.
Figure 12-1 A and B, Typical appearance of patients with moderately severe primary hypothyroidism or myxedema. Note dry skin, sallow complexion, with the absence of scleral pigmentation differentiating the carotenemia from jaundice. Both individuals demonstrate periorbital myxedema. The patient in B illustrates the loss of the lateral aspect of the eyebrow, sometimes termed Queen Anne's sign. That finding is not unusual in the age group that is commonly affected by severe hypothyroidism and should not be considered to be a specific sign of the condition.
Figure 12-2 A and B. Chest roentgenograms in a patient with myxedema heart disease. The patient had signs of severe congestive heart failure and was given thyroid hormone alone. Within 4 months, the heart had returned to normal size and there was no evidence of underlying heart disease.
Figure 12-3 The consequences of untreated congenital hypothyroidism are demonstrated in this 17-year-old girl. Her condition had been diagnosed at birth but, through a series of misunderstandings, was not treated with thyroid hormone. Note her size, the poorly developed nasal bridge, the wide-set eyes, and the ears, which are larger than are appropriate for head size. Her tongue is enlarged, and her extremities are inappropriately short in relation to her trunk. (Courtesy of Dr. Ronald B. Stein.)
Figure 12-4 X-ray films of the skull and hand of the 17-year-old patient illustrated in Figure 12-3. A, Skull film showing that the posterior and anterior fontanelles are open and that the sutures are not fused. The deciduous and permanent teeth are present. B, Radiograph of the wrist and hand showing the delayed appearance of the epiphyseal centers of the bones of the hand and the absence of the distal radial epiphysis. The estimated bone age is 9 months. (Courtesy of Dr. Ronald B. Stein.)
Figure 12-5 Frequency of hypothyroid symptoms and signs (percentage) in 50 patients with overt hypothyroidism and in 80 euthyroid controls. Two symptoms (pulse rate and cold intolerance, marked by asterisks) showed positive and negative predictive values of less than 70% and were thus excluded from the new score. (From Zulewski H, Müller B, Exer P, et al. Estimation of tissue hypothyroidism by a new clinical score: evaluation of patients with various grades of hypothyroidism and controls. J Clin Endocrinol Metab 1997; 82:771776.)
Figure 12-6 Strategy for the laboratory evaluation of patients with suspected hypothyroidism. The principal differential diagnosis is between primary and central hypothyroidism (see Chapter 8). The serum thyrotropin (TSH) concentration is the critical laboratory determination that, in general, allows recognition of the cause of the disease. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH) in whom a low free thyroxine (T₄) level may be associated with a reduced TSH level for several months after relief of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of thyroid peroxidase (TPO) antibodies raises a possible diagnosis of transient hypothyroidism following an undiagnosed episode of subacute or postviral thyroiditis. In such patients, a trial of a reduced levothyroxine dosage after 4 months may reveal recovery of thyroid function thus avoiding permanent levothyroxine replacement. MRI, magnetic resonance imaging.
Figure 12-7 Possible involvement of Fas-FasL in the apoptosis of Hashimoto's thyroiditis. In Graves' disease, the thyroid follicles thrive because the thyroid cells do not express many functional Fas molecules (shown in red) and, therefore, the thyroid cells are resistant to the FasL (Fas ligand) on both the thyroid cells themselves and on the Th2 T cells (shown in blue). Further apoptotic resistance may be driven by Th2 cytokines, such as interleukin-4 (IL-4) and IL-10. However, the Th2 cells express Fas and may themselves be deleted by the FasL constitutively expressed on the thyroid cells. The result is thyroid cell survival with T-cell destruction. In contrast, in Hashimoto's disease, the thyroid cell expresses many functional Fas molecules, perhaps induced by gamma interferon from the Th1 type T cells associated with this disease. The expression of thyroid cell Fas may lead to self (homophilic) apoptosis via thyroid cell FasL, or apoptosis may result from attack by the Fas1 armed Th1 cells. The result is thyroid follicle destruction and T-cell proliferation.
Figure 12-8 A T-cell clone (G) from a patient with Hashimoto's disease was able to specifically lyse autologous thyroid cells. Data are shown as percent cytotoxicity from a radioactive chromium release assay. Note that clone C was able to lyse all cell targets and was, therefore, not thyroid cellspecific. (From McKenzie WA, Davies TF. An intrathyroid T-cell clone specifically cytotoxic for human thyroid cells. Immunology 1987; 61:101103).
Figure 12-9 Hashimoto's disease. A. Note the exaggeration of the normal lobular pattern. B. Interfollicular infiltration by lymphocytes and plasma cells. C. Granular, oxyphilic changes in the cytoplasm of the follicular epithelium (Askanazy cells). (From Woolner LB, McConahey WM, Beahrs OH. Struma lymphomatosa [Hashimoto’s thyroiditis] and related thyroidal disorders. J Clin Endocrinol Metab 1959; 19:5363. © 1959, The Endocrine Society.)
**Figure 13-1** Transverse composite sonogram (A) and corresponding anatomic map (B) of the normal thyroid gland. C, common carotid artery; CVII, seventh cervical vertebra; LC, longus colli muscle; SM, strap muscles; SCM, sternocleidomastoid muscle; T, thyroid; TR, trachea. (From Rifkin MD, Charboneau JW, Laing FC. Special course: ultrasound 1991. In Reading CC [ed]. Syllabus: Thyroid, Parathyroid, and Cervical Lymph Nodes. Oak Brook, Ill, Radiological Society of North America, 1991, pp 363-377.)
**Figure 13-2** Cervical map, derived from sonographic images, helps to communicate anatomic relationships of pathology to clinicians and serves as a reference for follow-up examinations. SMG, submandibular gland. (From James EM, Charboneau JW, Hay ID. The thyroid. In Rumack CM, Wilson SR, Charboneau JW [eds]. Diagnostic Ultrasound, vol 1. St. Louis, Mosby Year Book, 1991, pp 507528.)
Figure 13-3 Outer and cut surfaces of a nontoxic nodular goiter of 15 years' duration. Note variations in size and structure of the nodules; there are thick areas of fibrous tissue, flecks of calcium, scattered areas of thyroid tissue, cysts, and small hemorrhages.
**Figure 13-5** Sonographically guided thyroid nodule fine-needle aspiration. Transverse sonogram of the right thyroid lobe (A, left panel) shows a 1.5-cm solid thyroid nodule (arrows) containing a central cystic component. C, common carotid artery; J, jugular vein. Palpation-guided aspiration biopsy obtained nondiagnostic fluid only. B, right panel, shows sonographically guided needle aspiration biopsy (curved arrow) of the solid portion of the nodule, which proved that this was a benign adenomatous nodule. (From Rifkin MD, Charboneau JW, Laing FC. Special course: ultrasound 1991. In Reading CC [ed]. Syllabus: Thyroid, Parathyroid, and Cervical Lymph Nodes. Oak Brook, Ill, Radiological Society of North America, 1991, pp 363377.)
Figure 13-6 Management of nodular goiter based on fine-needle aspiration (FNA) biopsy as the first diagnostic test. Subsequent management is based on cytologic results. Percentages in parentheses indicate satisfactory or unsatisfactory biopsy results. (From Gharib H. Fine needle aspiration biopsy of thyroid nodules: advantages, limitations, and effect. Mayo Clin Proc 1994; 69:4449.)
Figure 13-7 Genetic events in thyroid tumorigenesis. Activating point mutations of the RAS genes are found with a similar frequency in follicular adenomas and follicular carcinomas and are considered an early event in follicular tumorigenesis. The PPAR-PAX8 rearrangement was found only in follicular carcinomas. Rearrangements of transmembrane receptors with tyrosine kinase activity (RET, TRK genes) are found only in papillary thyroid carcinomas. Inactivating point mutations of the P53 gene are found only in poorly differentiated and anaplastic thyroid carcinomas. Activation of the cyclic adenosine monophosphate pathway, by point mutation of the thyrotropin receptor (TSH-R) or the subunit of the G protein genes, leads to the appearance of hyperfunctioning thyroid nodules. Gs stimulatory guanyl nucleotide protein.
Figure 13-8 Distribution of pathologic-Tumor-Node-Metastases (pTNM) stages in 2284 patients with papillary thyroid carcinoma (upper left), 218 patients with medullary thyroid cancer (lower left), 141 patients with follicular thyroid cancer (upper right), and 125 patients with Hurthle cell cancer (lower right) undergoing primary surgical treatment at the Mayo Clinic from 1940 to 1997.
Figure 13-9 Cause-specific survival according to pathologic-Tumor-Node-Metastases (pTNM) stage in a cohort of 2284 patients with papillary thyroid carcinoma treated at the Mayo Clinic from 1940 to 1997. The numbers in parentheses represent the percentages of patients in each pTNM stage grouping.
**Figure 13-10** Development of neck nodal metastases, local recurrences, and distant metastases in the first 20 years after definitive surgery for papillary thyroid cancer (PTC) or medullary thyroid cancer (MTC) performed at the Mayo Clinic from 1940 to 1997. Based on 2150 consecutive PTC (left) and 194 MTC (right) patients who had complete surgical resection (i.e., had no gross residual disease) and were without distant metastases on initial examination. Postop, postoperative.
**Figure 13-11** Development of neck nodal metastases (NM), local recurrences (LR), and distant metastases (DM) in the first 20 years after definitive surgery for follicular thyroid cancer (FTC) or Hürthle cell cancer (HCC) performed at the Mayo Clinic from 1940 to 1997. Based on 110 consecutive FTC patients (left) and 115 HCC patients (right) who had complete surgical resection and were without distant metastases on initial examination.
Figure 13-12 Cumulative cause-specific mortality rates for patients with differentiated thyroid carcinoma in the first 25 years after treatment with initial surgery performed at the Mayo Clinic from 1940 to 1997. Based on 2768 consecutively treated patients (2284 with papillary thyroid carcinoma [PTC], 141 with follicular thyroid cancer [FTC], 125 with Hurthle cell cancer [HCC], and 218 with medullary thyroid cancer [MTC]).
Figure 13-13 Survival to death from all causes and to death from thyroid cancer (cause-specific mortality) in 2284 consecutive patients with papillary thyroid carcinoma undergoing initial management at the Mayo Clinic from 1940 to 1997. Also plotted is the expected survival (all causes) of persons of the same age and sex and with the same date of treatment but living under mortality conditions of the northwest central United States.
Figure 13-14 Lack of influence of nodal metastases at initial operation on cumulative mortality from papillary thyroid carcinoma in 1941 patients with pT1-3 intrathyroidal tumors (completely confined to the thyroid gland) and 209 pT4 patients with extrathyroidal (locally invasive) tumors. All patients had initial surgical treatment at the Mayo Clinic from 1940 to 1997. DM, distant metastases.
Figure 13-15 Cumulative mortality from papillary thyroid carcinoma in patients at either minimal risk or higher risk of cancer-related death as defined by International Union Against Cancer (UICC) pathologic-Tumor-Node-Metastases (pTNM) stages (upper left), AGES scores (upper right), AMES risk groups (lower left), and MACIS scores (lower right). The minimal risk group constitutes 81% of the 2284 patients when defined by pTNM stages I and II, 86% as defined by AGES scores less than 4, 88% as defined by AMES low-risk, and 83% when defined by a MACIS score less than 6. The cause-specific mortality (CSM) rates at 20 years were 25% for stages III and IV, 36% for AGES scores of 4+, 39% for AMES high-risk, and 32% for patients with MACIS scores of 6+. The CSM ratios between the high-risk and low-risk groups at 20 years were 19 for pTNM, 36 for AGES, 35 for AMES, and 40 for MACIS.
Figure 13-16 Cause-specific survival according to MACIS (metastases, age, completeness of resection, invasion, and size) scores of less than 6, 6 to 6.99, 7 to 7.99, and 8+ in a cohort of 2284 consecutive patients with papillary thyroid carcinoma (PTC) undergoing initial treatment at the Mayo Clinic from 1940 to 1997. The numbers in parentheses represent the numbers and percentages of PTC patients in each of the four risk groups.
Figure 13-17 Postoperative recurrence (any site) in the first 20 years after definitive surgery for differentiated thyroid carcinoma performed at the Mayo Clinic from 1940 to 1997. Based on 2569 consecutive patients (2150 papillary thyroid carcinoma, 110 follicular thyroid carcinoma, 115 Hurthle cell carcinoma, and 194 medullary thyroid carcinoma) who had complete tumor resection and had no distant metastases at presentation. The ages in parentheses represent the median age at diagnosis for each of the four histologic subtypes.
Figure 13-18 Cause-specific survival according to pathologic-Tumor-Node-Metastases (pTNM) stages in a cohort of 141 patients with follicular thyroid carcinoma (left panel) and 125 patients with Hürthle cell carcinoma (right panel) treated at the Mayo Clinic from 1940 to 1997. Numbers in parentheses represent the number of patients in each pTNM stage grouping.
Figure 13-19 Comparison of cause-specific survival in 1472 papillary thyroid carcinoma (PTC) and 250 follicular thyroid carcinoma (FTC) patients treated at the Mayo Clinic from 1940 to 1990. 138 of the PTCs were “pure” papillary in histotype (no follicular elements). 97 of the FTC patients had predominantly oxyphilic tumors. There is a significant difference ($P = .0001$) between the PTC and the FTC survival curves. However, within either the PTC or FTC groups, the two survival curves are insignificantly different. (From Grebe SKG, Hay ID. Follicular thyroid cancer. Endocrinol Metab Clin North Am 1995; 24:761801.)
Figure 13-20 Survival to death from all causes in 141 consecutive patients with follicular thyroid carcinoma (left) and 125 patients with Hürthle cell cancer (right) undergoing initial management at the Mayo Clinic from 1940 to 1997. Also plotted is the expected survival (all causes) of persons of the same age and sex and with the same date of treatment but living under mortality conditions of the northwest central United States.
Figure 13-21 Cumulative cause-specific survival among 100 patients with nonoxyphilic follicular thyroid carcinoma treated at the Mayo Clinic from 1946 to 1970, plotted by high-risk and low-risk categories. High risk means that two or more of the following factors were present: age older than 50 years, marked vascular invasion, and metastatic disease at time of initial diagnosis. (From Brennan MD, Bergstralh EJ, van Heerden JA, et al. Follicular thyroid cancer treated at the Mayo Clinic, 1946 through 1970: initial manifestations, pathologic findings, therapy, and outcome. Mayo Clin Proc 1991; 66:1122.)
**Figure 13-22** Survival differences in low-risk, intermediate-risk, and high-risk groups for 228 consecutive patients with follicular thyroid carcinoma who were seen and treated at the Memorial Sloan-Kettering Cancer Center during a period of 55 years from 1930 to 1985. (From Shaha AR, Loree TR, Shah JP. Prognostic factors and risk group analyses in follicular carcinoma of the thyroid. Surgery 1995; 118:1131-1138.)
Figure 13-23 Cause-specific survival according to pathologic-Tumor-Node-Metastases (pTNM) stage in a cohort of 218 patients with medullary thyroid carcinoma treated at the Mayo Clinic from 1940 to 1997. Numbers in parentheses represent the percentages of patients in each pTNM stage grouping.
Figure 13-24  Total-body scan performed 5 days after administration of 100 mCi (3700 MBq) of radioactive iodine ($^{131}$I). The chest radiograph of this asymptomatic 34-year-old patient, who was being monitored for a papillary thyroid carcinoma, was normal; the only abnormality was an elevated serum thyroglobulin level, at 45 ng/mL, during levothyroxine suppressive treatment. Note the presence of diffuse uptake in the lungs (L) and in the left iliac bone (I). After four treatments with 100 mCi of $^{131}$I, metastatic uptake disappeared and the thyroglobulin level became undetectable during levothyroxine therapy. B, bladder; M, mouth; N, nose; S, stomach.
Figure 13-25 The patient was being monitored for a papillary thyroid carcinoma. The serum thyroglobulin level was 22 ng/mL during levothyroxine suppressive treatment, and local imaging modalities were not interpretable because of three previous extensive neck operations. Left, Total-body scan performed 4 days after administration of 100 mCi (3.7 GBq); there is no visible uptake in the neck. Right, Positron emission tomography scan using $^{18}$F-fluorodeoxyglucose ($^{18}$FDG) demonstrating significant uptake in a paratracheal lymph node (arrow) that measured 12 mm in diameter at surgery.
Figure 13-26 Follow-up of high-risk patients with papillary or follicular thyroid carcinoma after near-total thyroidectomy based on serum thyroglobulin (Tg) measurements and ¹³¹I ablation, total-body scanning. LT₄, levothyroxine; TBS, total-body scan; TSH, thyrotropin. Thyroglobulin values are method specific, and the normal range should be determined in each assay. For the total-body scan, above 0 is positive, with ¹³¹I uptake indicative of neoplastic foci; below 0 is negative.
Figure 14-1 Schematic diagram of the structure of the human adrenal cortex, depicting the outer zona glomerulosa and inner zona fasciculata and zona reticularis.
Figure 14-2 The cyclopentanoperhydrophenanthrene structure of corticosteroid hormones highlighting the structure of some endogenous steroid hormones together with their nomenclature.
Figure 14-3 Adrenal steroidogenesis. After the steroidogenic acute regulatory (SIAR) proteinmediated uptake of cholesterol into mitochondria within adrenocortical cells, aldosterone, cortisol, and adrenal androgens are synthesized through the coordinated action of a series of steroidogenic enzymes in a zone-specific fashion. Androstenedione, DHEA, dehydroepiandrosterone, DOC, deoxycorticosterone.
Figure 14-4  A, Electron shuttle system for the mitochondrial enzymes, CYP11A1 and CYP11B1. Adrenodoxin reductase receives electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduces adrenodoxin, which transfers reducing equivalents to the CYP enzyme. The enzyme then transfers electrons, by way of oxygen, to the steroid. Fp, flavoprotein; Fp, reduced form of flavoprotein.  B, Electron shuttle system for the microsomal enzymes, CYP17 and CYP21A2. P450 reductase, a flavoprotein, accepts electrons from NADPH and transfers them to the NADPH-P450 enzyme. The enzyme then transfers electrons, by way of oxygen, to the steroid. A second reducing equivalent may be supplied to CYP17 by NADPH-P450 reductase or cytochrome b5.
Figure 14-5 Synthesis and cleavage of pro-opiomelanocortin (POMC) within the human anterior pituitary gland. Prohormone convertase enzymes sequentially cleave POMC to adrenocorticotropic hormone (ACTH). Shaded areas represent melanocyte-stimulating hormone (MSH) structural units. -LPH, -lipoprotein; N-POC, amino-terminal pro-opiomelanocortin.
Figure 14-6 Normal regulation of adrenal glucocorticoid secretion. Adrenocorticotropic hormone (ACTH) is secreted from the anterior pituitary under the influence of two principal secretagogues, corticotropin-releasing hormone (CRH) and arginine vasopressin; other factors including cytokines also play a role. CRH secretion is regulated by an inbuilt circadian rhythm and additional stressors operating through the hypothalamus. Secretion of both CRH and ACTH is inhibited by cortisol, highlighting the importance of negative feedback control.
Figure 14-7 Circadian and pulsatile secretion of adrenocorticotropic hormone (ACTH) and cortisol in a normal subject (top two panels) and in a patient with Cushing's disease. In a normal subject, secretion of ACTH and cortisol is highest in early morning and falls to a nadir at midnight. ACTH pulse frequency and pulse amplitude are increased in Cushing's disease, and circadian rhythm secretion is lost.
Figure 14-8 The normal renin-angiotensin-aldosterone regulatory system. Renin, secreted by the kidney, cleaves angiotensin I (A I) from renin substrate (angiotensinogen), an \( \alpha \)-globulin produced by the liver. Angiotensin I is converted into biologically active angiotensin II by angiotensin-converting enzyme (ACE), mainly in the lung. Angiotensin II increases peripheral vascular resistance, and, together with angiotensin III, stimulates aldosterone (ALDO) secretion, which results in sodium retention and increased plasma volume.
Figure 14-9 Schematic structure of the human genes encoding the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR). In both cases splice variants have been described; in the case of the GR, there is evidence that the GR isoform can act as a dominant negative inhibitor of GR action. mRNA, messenger ribonucleic acid.
Figure 14-10 The anti-inflammatory action of glucocorticoids. Cortisol binds to the cytoplasmic glucocorticoid receptor (GR). Conformational changes in the receptor-ligand complex result in dissociation from heat shock proteins (HSPs) 70 and 90 and migration to the nucleus. Binding occurs to specific DNA motifs, glucocorticoid response elements in association with the activator protein-1 (AP-1) comprising c-fos and c-jun. Glucocorticoids mediate their anti-inflammatory effects through several mechanisms: (1) The inhibitory protein IB, which binds and inactivates nuclear factor B (NFB), is induced. (2) The GR-cortisol complex is able to bind NFB and thus prevent initiation of an inflammatory process. (3) Both GR and NFB compete for the limited availability of coactivators that include cyclic adenosine monophosphate response element binding protein (CREB) binding protein and steroid receptor coactivator-1.
**Figure 14-11** Mineralocorticoid hormone action. An epithelial cell is depicted in the distal nephron or distal colon, or both. The much higher concentrations of cortisol are inactivated by the type 2 isozyme of 11-hydroxysteroid dehydrogenase (11-HSD2) to cortisone, permitting the endogenous ligand, aldosterone, to bind to the mineralocorticoid receptor (MR). Relatively few mineralocorticoid target genes have been identified, but these include serum and glucocorticoid-induced kinase (SGK), subunits of the epithelial sodium channel (ENaC), and basolateral Na⁺,K⁺-adenosine triphosphatase.
Figure 14-12 The principal pathways of cortisol metabolism. Interconversion of hormonally active cortisol to inactive cortisone is catalyzed by two isozymes of 11-hydroxysteroid dehydrogenase (11-HSD). 11-HSD1 principally converting cortisone to cortisol and 11-HSD2 the reverse. Cortisol can be hydroxylated at the C6 and C20 positions. A ring reduction is undertaken by 5-reductase or 5-reductase and 3-hydroxysteroid dehydrogenase.
Figure 14-13 The principal sites of action of glucocorticoids in humans highlighting some of the consequences of glucocorticoid excess. CNS, central nervous system; GI, gastrointestinal; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.
Figure 14-14 Structures of the natural glucocorticoid cortisol, some of the more commonly prescribed synthetic glucocorticoids, and the mineralocorticoid fludrocortisone. Note that triamcinolone is identical to dexamethasone except that a 16-hydroxyl group is substituted for the 16-methyl group. Betamethasone, another widely used glucocorticoid, has a 16-methyl group.
Figure 14-15 Minnie G., Cushing's index patient, at age 23 years. (From Cushing H. The basophil adenomas of the pituitary body and their clinical manifestations [pituitary basophilism]. Bull Johns Hopkins Hosp 1932; 50:137195.)
Figure 14-16 Clinical features of Cushing's syndrome. A. Centripetal and some generalized obesity and dorsal kyphosis in a 30-year-old woman with Cushing's disease. B. Same woman as in A, showing moon facies, plethora, hirsutism, and enlarged supraclavicular fat pads. C. Facial rounding, hirsutism, and acne in a 14-year-old girl with Cushing's disease. D. Central and generalized obesity and moon facies in a 14-year-old boy with Cushing's disease. E and F. Typical centripetal obesity with livid abdominal striae seen in a 41-year-old woman (E) and a 40-year-old man (F) with Cushing's syndrome. G. Striae in a 24-year-old patient with congenital adrenal hyperplasia treated with excessive doses of dexamethasone as “replacement” therapy. H. Typical bruising and thin skin of Cushing's syndrome. In this case, the bruising has occurred without obvious injury.
**Figure 14-18** Patterns of cortisol secretion in three patients with cyclical Cushing’s syndrome. In each case, ratios of early morning urinary cortisol (nmol/L) to creatinine (mmol/L) are plotted against time. Variable periodicity in cortisol hypersecretion is shown. (From Atkinson AB, McCance DR, Kennedy L, et al. Cyclical Cushing’s syndrome first diagnosed after pituitary surgery: a trap for the unwary. Clin Endocrinol 1992; 36:297-299.)
Figure 14-19 Investigation of a patient with suspected Cushing's syndrome. The laboratory diagnosis of Cushing's syndrome and the differential diagnosis of its cause are debatable and differ in any given center depending on many factors, including familiarity, turn-around time of hormone assays, and local expertise in techniques such as inferior petrosal sinus sampling (IPSS). Depicted here is an algorithm in use within many endocrine units based upon the reported sensitivity and specificity of each endocrine test.
Figure 14-20 Plasma adrenocorticotropic hormone (ACTH) concentrations in patients with Cushing's disease and Cushing's syndrome associated with adrenocortical tumors and ectopic ACTH syndrome. To convert values to pmol/L, multiply by 0.2202. (From Besser GM, Edwards CRW. Cushing's syndrome. Clin Endocrinol Metab 1972; 1:451490.)
Figure 14-21 Comparison of the cortisol and adrenocorticotropic hormone (ACTH) responses to an intravenous injection of ovine corticotropin-releasing hormone (1 µg/kg) in normal subjects, patients with Cushing's disease, and patients with ectopic ACTH. (From Chrousos GP, Schulte HM, Oldfield EH, et al. The corticotropin-releasing factor stimulation test: an aid in the evaluation of patients with Cushing's syndrome. N Engl J Med 1984; 310:624-626.)
**Figure 14-22** Anatomy of the venous drainage of the pituitary gland through the inferior petrosal venous sinuses. (From Oldfield EH, Chrousos GP, Schulte HM, et al. Preoperative lateralization of ACTH-secreting pituitary microadenomas by bilateral and simultaneous inferior petrosal sinus sampling. Reprinted by permission of The New England Journal of Medicine 1985; 312:100103.)
Figure 14-23 A. Magnetic resonance imaging (MRI) scan of pituitary demonstrating the typical appearance of a pituitary microadenoma. A hypodense lesion is seen in the right side of the gland with deviation of the pituitary stalk away from the lesion. After a biochemical diagnosis of Cushing's disease, this patient was cured following transsphenoidal hypophysectomy. B. MRI scan of the pituitary gland demonstrating a large macroadenoma in a patient with Cushing's disease. In contrast to smaller tumors, these tumors are invariably invasive and recur after surgery.
Figure 14-24  A, Adrenal computed tomographic (CT) scan demonstrating bilateral adrenal hyperplasia in a patient with Cushing’s disease.  B, CT scan of a typical solitary left adrenal adenoma causing Cushing's syndrome.  C, Cushing’s syndrome caused by massive macronodular hyperplasia. Adrenal glands are replaced by multiple nodules (arrows). Combined weight of adrenal glands was over 100 g.  D, Cushing’s syndrome caused by surgically proven primary pigmented nodular adrenal disease in a 21-year-old patient. Notice the multiple small nodules with the relatively atrophic internodular adrenocortical tissue involving the medial limb of the right adrenal gland (arrow). (C and D from Findling JW, Doppman JL. Biochemical and radiologic diagnosis of Cushing’s syndrome. Endocrinol Metab Clin North Am 1994; 23:511537.)
Figure 14-25 Computed tomographic scan of a patient with rapidly progressing Cushing's syndrome caused by an adrenal carcinoma. An irregular right adrenal mass is shown (A) with a large liver metastasis (B).
Figure 14-27 A young woman with Cushing's disease, photographed initially beside her identical twin sister (A). In this case, treatment with bilateral adrenalectomy was undertaken. Several years later, the patient presented with Nelson's syndrome and a right third cranial nerve palsy (B and C) related to cavernous sinus infiltration from a locally invasive corticotropinoma (D). Hypophysectomy and radiotherapy were performed with reversal of the third nerve palsy (E). Note the advancing skin pigmentation of Nelson's syndrome.
Figure 14-28  Selective removal of a microadenoma and its effect on the hypothalamic-pituitary-adrenal axis. Because the surrounding normal pituitary corticotrophs are suppressed in a patient with an adrenocorticotropic hormone (ACTH)-secreting pituitary adenoma, successful removal of the tumor results in ACTH and hence adrenocortical deficiency with an undetectable (<50 nmol/L [2 µg/dL]) plasma cortisol level. A plasma cortisol level higher than 50 nmol/L (2 µg/dL) postoperatively implies that the patient is not cured. (Courtesy of Dr. Peter Trainer.)
Figure 14-29 Gradual recovery of function of the hypothalamic-pituitary-adrenal axis after removal of a pituitary adrenocorticotropic hormone-secreting microadenoma. The insulin hypoglycemia test (I.H.T.) eventually demonstrated the return of a normal stress response.
Figure 14-30 Pigmentation in Addison's disease. **A**, Hands of an 18-year-old woman with autoimmune polyendocrine syndrome and Addison's disease. Pigmentation in a patient with Addison's disease before (**B**) and after (**C**) treatment with hydrocortisone and fludrocortisone. Note the additional presence of vitiligo. **D**, Similar changes also seen in a 60-year-old man with tuberculous Addison's disease before and after corticosteroid therapy. **E**, Buccal pigmentation in the same patient. (**B** and **C**, courtesy of Professor C.R.W. Edwards.)
Figure 14-31  Computed tomographic (CT) scans of patients with primary adrenal insufficiency. The affected adrenal glands are indicated by arrows. A, CT scan of a 59-year-old man with histoplasmosis. Note the subcapsular calcium in both glands. B, CT scan of a 59-year-old man with metastatic melanoma. C, CT scan of an 80-year-old man with bilateral adrenal hemorrhage resulting from anticoagulation for pulmonary emboli. D, Bilateral adrenal tuberculomas in a 79-year-old man with tuberculosis affecting the urogenital tract. (A and B courtesy of Dr. William D. Salmon, Jr.; C courtesy of Dr. Craig R. Sussman.)
Figure 14-32 Congenital adrenal hyperplasia related to 21-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition resulting in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, variable mineralocorticoid deficiency, and excessive secretion of adrenal androgens. DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory protein.
Figure 14-33 Map of the short arm of human chromosome 6 (upper bar), showing the relative positions of the genes encoding the major histocompatibility proteins A, C, B, DR, DQ, and DP. The detail (lower bar) shows the approximately 120-kilobase region containing the genes for complement component C2, properdin factor B (Bf), and the duplicated complement C4 gene (C4A and C4B). The pseudogene CYP21A1 and the functional gene CYP21A2 are in tandem array with the two C4 genes. HLA, human leukocyte antigen.
Figure 14-34  Basal and stimulated plasma 17-hydroxyprogesterone (17OHP) concentrations in patients with CYP21A2 (21-hydroxylase) deficiency. To convert values to nmol/L, multiply by 0.0303. The mean for each group is indicated by a large cross and the adjacent letter: c, patients with classical CYP21A2 deficiency; v, patients with nonclassical (acquired and cryptic) CYP21A2 deficiency; h, heterozygotes for all forms of CYP21A2 deficiency; p, general population; u, known unaffected persons (e.g., siblings of patients with CYP21A2 deficiency who carry neither affected parental haplotype as determined by human leukocyte antigen typing). (From White PC, New MI, Dupont B. Congenital adrenal hyperplasia: part 1. Reprinted by permission of The New England Journal of Medicine 1987; 316:15191524.)
Congenital adrenal hyperplasia related to 11-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition resulting in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, mineralocorticoid excess related to excessive deoxycorticosterone (DOC) secretion, and excessive secretion of adrenal androgens. DHEA, dehydroepiandrosterone; SIAR, steroidogenic acute regulatory protein.
Figure 14-36 Congenital adrenal hyperplasia related to 17-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition resulting in an increase in adrenal steroid precursors proximal to the block. The result is cortisol deficiency and mineralocorticoid excess usually related to deoxycorticosterone (DOC) excess. Because gonadal 17-hydroxylase activity is also absent, sex steroid secretion in addition to adrenal androgen secretion is severely impaired, resulting in hypogonadism. DHEA, dehydroepiandrosterone; STAR, steroidogenic acute regulatory protein.
Figure 14-37 Congenital adrenal hyperplasia related to 3-hydroxysteroid dehydrogenase (3-HSD) deficiency resulting in cortisol deficiency and variable mineralocorticoid deficiency. Gonadal 3-HSD activity is also absent, resulting in male pseudohermaphroditism and hypogonadism or primary amenorrhea in females. ACTH, adrenocorticotropic hormone; DOC, deoxycorticosterone; DHEA, dehydroepiandrosterone; STAR, steroidogenic acute regulatory protein.
Figure 14-38  A. Adrenal incidentaloma discovered in a woman undergoing investigation for abdominal pain.  B. Incidentally discovered right adrenal myelolipoma.
Figure 15-1 Organization of the sympathoadrenal system. Sympathetic preganglionic axons arise in large part from cells located in the thoracolumbar spinal cord. These preganglionic sympathetic neurons in turn have synapses with descending tracks from neurons in the pons, medulla, and hypothalamus, allowing regulation of sympathetic activity by the brain. In turn, these central nervous system neurons that influence sympathetic activity are regulated by a variety of factors, including substrates (glucose) and hormones (corticotropin-releasing hormone). (From Landsberg L, Young JB. Catecholamines and the adrenal medulla. In Bondy PK, Rosenberg JE (eds). Metabolic Control and Disease, 8th ed. Philadelphia: WB Saunders, 1980:1621693.)
Figure 15-2 Sympathoadrenomedullary efferent autonomic pathways. The axons of the preganglionic neurons synapse with postganglionic cell bodies located in the paravertebral and preaortic ganglia as well as neurons in the celiac and superior and inferior mesenteric ganglia. Postganglionic axons from the cell bodies located in these ganglia in turn innervate the visceral organs. The splanchnic outflow of the lower thoracic and lumbar preganglionic axons also directly innervates the cells of the adrenal medulla.
Figure 15-3 Biosynthetic pathway for catecholamines (left to right). All catecholamines contain the catechol nucleus. L-Tyrosine is converted to L-3,4-dihydroxyphenylalanine (L-dopa) in the rate-limiting step by tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts L-dopa to dopamine. Dopamine is hydroxylated to L-norepinephrine by dopamine-beta-hydroxylase (DBH). L-Norepinephrine is converted to L-epinephrine by phenylethanolamine N-methyltransferase (PNMT).
Figure 15-4  Catecholamine metabolism. Metabolism of catecholamines occurs through two enzyme pathways. Catechol-O-methyltransferase (COMT) converts epinephrine to metanephrine and converts norepinephrine to normetanephrine by meta-O-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid (DOMA), which is then converted by COMT to VMA.
Figure 15-5 Algorithm for diagnosis of pheochromocytoma. CT, computed tomography; MRI, magnetic resonance imaging.
Figure 15-6. A, Axial in-phase gradient-echo image demonstrates left adrenal mass (arrow). B, Axial image from the out-of-phase gradient-echo sequence demonstrates the left adrenal mass. In comparison to the in-phase image, no suppression of the adrenal mass is present. Suppression is the rule in lipid-containing cortical adenomas.
Figure 15-7 Components of the renin-angiotensin system. (Redrawn from Williams GH, Chao J, Chao L. Kidney hormones. In Conn PM, Melmed S [eds]. Endocrinology: Basic and Clinical Principles. Totowa, NJ, Humana Press, 1997, pp 393404.)
Figure 15-9 Modification of vascular and aldosterone response to angiotensin II by dietary salt intake. Sodium intake has a reciprocal influence on vascular and adrenal responses to angiotensin II. On a high salt intake the vascular response is enhanced while the adrenal response is suppressed. Sodium restriction has the opposite effect. (Redrawn from Williams GH, Hollenberg NK. "Sodium-sensitive" essential hypertension: emerging insights into pathogenesis and therapeutic implications. In Klahr S, Massry SG [eds]. Contemporary Nephrology. Vol 3. New York, Plenum Press, 1985, p 303, with permission.)
Figure 15-10 Relationship between the activity of the renin-angiotensin system and the mechanisms underlying the hypertension. (Redrawn from Laragh JH, Sealey JE, Niarchos AP, et al. The vasoconstrictor volume spectrum in normotension and in the pathogenesis of hypertension. Fed Proc 41:2415-2423, 1982.)
Figure 15-11 Effect of angiotensinogen genotype on renal blood flow responses to angiotensin II infusions. Subjects were classified according to their alleles at the 235 codon of the angiotensinogen gene as to whether they were homozygous for the wild type (MM), heterozygous (MT), or homozygous for the hypertensive-link (TT) alleles. The subjects with the TT235 genotype had a renal blood flow response to angiotensin II similar to that of nonmodulators. (Redrawn from Hopkins P, Lifton RP, Hollenberg NK, et al. Blunted renal vascular response to angiotensin II is associated with a common variant of the angiotensinogen gene and obesity. J Hypertens 1996; 14:199207. Copyright 1996, Rapid Science Publishers.)
Figure 15-12 Pathogenesis of nonmodulating hypertension. ANG II, angiotensin II.
Figure 15-13 Relationship of arterial pressure to insulin resistance in normotensive ethnic subgroups. An index of insulin sensitivity, the glucose disposal rate, was determined with an insulin clamp and fasting insulin levels were measured in normotensive blacks, whites, and Pima Indians. There was a significant negative correlation between arterial blood pressure and glucose disposal rates in whites but not in the other subgroups.  

Figure 15-14 Mechanisms by which insulin resistance may produce hypertension.
**Figure 15-15** Diagnostic and therapeutic flow chart for evaluating patients for renovascular hypertension. BP, blood pressure; MR, magnetic resonance.* Stenting of renal arteries is commonly done following angioplasty.
Figure 15-16 Diagnostic flow chart for evaluating the hypokalemic hypertensive patient. Differentiation of APA versus IHA. PRA, plasma renin activity; PAC, plasma aldosterone concentration; APA, aldosterone-producing adenoma; IHA, idiopathic hyperaldosteronism; CT, computed tomography. *Suppressed values: PAC < 280 pmol/L (< 10 ng/dL) following IV saline; aldosterone excretion rate 39 nmol/d (< 14 µg/d) after oral salt loading.
Figure 16-1 Endocrine interactions in the female reproductive axis. Some of the well-characterized endocrine interactions between the hypothalamus, pituitary, ovary, and endometrium for regulation of the menstrual cycle are depicted. \( E_2 \), estradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; LHRH, luteinizing hormonereleasing hormone; P, progesterone.
**Figure 16-2** Luteinizing hormone-releasing hormone (LHRH) production.  

A. The LHRH gene encodes a precursor protein named pre-pro-LHRH in the neuronal body. LHRH is released from this protein by proteolytic processing, which gives rise to LHRH and LHRH-associated protein (GAP) within the neuronal body. Both LHRH and GAP are transported in an axon to the nerve terminal and secreted into the portal circulation.  

B. Pre-pro-LHRH is a 92-amino-acid (aa) protein. The biologically active decapeptide (aa 1 to 10) is sandwiched between the 23-aa signal peptide and the Gly-Lys-Arg sequence. The arrow indicates the site of proteolytic processing. The C-terminal 56-aa peptide is cleaved to produce GAP. (From Yen SSC. Endocrine regulation of the reproductive system. In Yen SSC, Jaffe RB, Barbieri RL [eds]. Reproductive Endocrinology, 4th ed. Philadelphia, WB Saunders, 1999, p 44.)
Figure 16-3 Effect of pulsatile or continuous administration of luteinizing hormonereleasing hormone (LHRH) to ovariectomized monkeys rendered them LHRH-deficient by placement of a lesion in the hypothalamus. Release of LH and follicle-stimulating hormone (FSH) was restored by hourly LHRH infusion, inhibited during a continuous infusion, and again restored after reinstitution of pulsatile LHRH administration. (Adapted from Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. Science 1978; 202:631633. Copyright © 1978, by American Association for the Advancement of Science.)
Figure 16-4 Regulation of luteinizing hormone-releasing hormone (LHRH), LH, and follicle-stimulating hormone (FSH) secretion. Locally synthesized and systemic hormones regulate the pulsatile secretion of LHRH from the hypothalamus into the portal circulation. In turn, LHRH together with a number of steroid and peptide hormones regulate the synthesis of and gonadotropin subunits and the formation and secretion of FSH and LH. CRH, corticotropin-releasing hormone; E₂, estradiol; P₄, progesterone.
Figure 16-7 Transverse section of the caudal region of a 5-week embryo showing the location of gonadal ridges, the primordium of the adrenal glands, and the migration path of primordial germ cells. From the third week on, germ cells arising from the yolk sac cross the dorsal mesentery of the hindgut and migrate to the gonadal ridges. By the end of the fifth week, rapid division of primordial germ cells, gonadal epithelium, and mesenchyme starts the early gonad that differentiates subsequently to the ovary in a 46,XX fetus. CC, coelomic cavity. (Modified from Moore K. The Developing Human. Philadelphia, WB Saunders, 1983.)
Figure 16-8 Age-dependent changes in germ cell number in the human ovary. The highest number of oocytes is found in the ovaries of a human fetus at midgestation. This number decreases sharply during the third trimester. After birth, the progressive decline in the number of ovarian follicles containing oocytes continues until complete depletion at the menopause. (From Baker TG. A quantitative and cytological study of germ cells in the human ovaries. Proc R Soc Biol Sci 1963; 158:417433.)
Figure 16-9 Meiotic cell division. Meiosis occurs exclusively in germ cells and serves two critical purposes: (1) generation of germ cells genetically distinct from the somatic cells and (2) generation of a mature egg with a reduction in the number of chromosomes from 46 to 23. Genetic recombination through crossing over of genes between homologous chromosomes and random assortment of (original) maternal and paternal chromosomes into daughter cells during the first meiotic division are responsible for the first function of meiosis, maintenance of genetic diversity. The second function is provided by a reduction in the number of chromosomes so that each daughter cell, or ovum, receives randomly one chromosome from each of the 23 pairs. During fertilization, the fusion of ovum and sperm, each of which has 23 chromosomes, produces a genetically novel individual with 46 chromosomes. The chromosome marked as white in the oogonium (upper left corner) originates from the father of the fetus, whereas the black chromosome comes from the mother of the fetus. The random exchange of genes (alleles) between homologous chromosomes (crossing over) takes place before the meiotic arrest in the prophase I stage before birth. During postnatal life, these oocytes remain in meiotic arrest until puberty. In the developing oocyte in the graafian follicle, meiosis I is resumed immediately after the preovulatory luteinizing hormone (LH) surge during each ovulatory cycle. Meiotic maturation is defined as the period from the breakdown of the oocyte's nucleus (germinal vesicle, GV) until the oocyte reaches metaphase II (i.e., transition from oocyte to egg). A second and short meiotic arrest occurs at metaphase II until the oocyte is fertilized by a sperm. DNA, deoxyribonucleic acid; GVBD, germinal vesicle breakdown; mat, maternal; n, the amount of DNA material in haploid number (23) of chromosomes; pat, paternal.
Figure 16-14 Complete follicular growth trajectory. Class 1 follicle is a secondary follicle with theca cells and is presumed to become responsive to gonadotropins. Although the tonic (early) stage of follicle development (class 1 to 4) is likely to be gonadotropin-dependent (albeit to a lesser extent), the final stages of follicular development (class 5 to 8) are the ones heavily dependent on gonadotropins. According to this view, late luteal phase, class 5 follicles constitute the cohort from which the follicle destined to ovulate in the following cycle is recruited. The exponential gonadotropin-dependent growth phase (class 5 to 8) takes place during the follicular phase of the cycle following the third menses from initiation of the growth phase. During this time, follicular selection and dominance are accomplished. The total duration of the process wherein a class 1 follicle is converted into preovulatory class 8 follicle is estimated to be 85 days and spans three ovulatory cycles. M, menses; Ovul, ovulation; Gn, gonadotropin. (Courtesy of A. Gougeon.)
**Figure 16-15** Gonadotropin-dependent (exponential) follicular growth phase: recruitment, selection, and the attainment of dominance. At and At, atretic follicle; H, healthy follicle. (Courtesy of A. Gougeon.)
**Figure 16-19** Schematic representation of the human gonadotropin receptor genes. The structure of the genes is depicted at the top of the drawings. The open bars indicate sections of the exons that encode untranslated regions of the messenger ribonucleic acid; the closed bars indicate the sequences that encode the protein. Both genes are at least 80 kb in size. The relation between the intron-exon structure of the gene and the domains on the protein is indicated by the lines connecting the gene to the protein. The horizontally hatched part of the protein indicates the signal peptide, and the crosshatched bars signify the seven segments of the transmembrane domain. The numbers below the protein indicate the start and end of the signal peptide and the length of the total protein product including the signal peptide. Note that the receptor genes are similar in structure with the exception of an additional exon in the luteinizing hormone (LH) receptor gene. Exon 1 encodes the signal peptide and a small part of the extracellular domain; the following eight or nine exons encode the rest of the extracellular domain, including the leucine-rich repeat motifs. In both receptor genes, the final exon is the largest and contains the information for the transmembrane signal transduction domain. FSH, follicle-stimulating hormone. (From Themmen APN, Huhtaniemi IT. Mutations of gonadotropins and gonadotropin receptors: elucidating the physiology and pathophysiology of pituitary-gonadal function. Endocr Rev 2000; 21:455-1583. Copyright © 2000 by The Endocrine Society.)
Figure 16-20  Two-cell hypothesis for ovarian steroidogenesis.  A, The preovulatory follicle produces estradiol through a paracrine interaction between theca and granulosa cells. In response to stimulation with a gonadotropin, steroidogenic factor-1 (SF-1, a member of the orphan nuclear receptor family) acts as a master switch to initiate transcription of a series of steroidogenic genes in each cell type. Because granulosa cells do not have a direct connection to the circulation, aromatase (P450arom) in granulosa cells is dependent for substrate on androstenedione that diffuses from theca cells. Two critical steps in estradiol formation seem to be the entry of cholesterol into mitochondria facilitated by steroidogenic acute regulatory protein (StAR) in theca cells and the conversion of androstenedione to estrone catalyzed by P450arom in granulosa cells.  B, In the corpus luteum, granulosa-lutein cells are heavily vascularized, which is critical for the entry of cholesterol into this cell type through primarily low-density lipoprotein receptors and for secretion of large amounts of progesterone into the circulation. The entry of cholesterol into mitochondria (by StAR) is likely to be the most critical steroidogenic step for progesterone formation in granulosa lutein cells. Androstenedione produced in theca-lutein cells serves as a substrate for estradiol produced in granulosa-lutein cells. Gonadotropins and the transcription factor SF-1 play key roles for important steroidogenic steps in both cell types. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FSH-R, follicle-stimulating hormone receptor; HSD, hydroxysteroid dehydrogenase; LH-R, luteinizing hormone receptor.
Figure 16-21 Steroidogenic pathway in the ovary. Biologically active steroids progesterone and estradiol are produced primarily in the ovary of a woman of reproductive age. Estradiol production requires the activity of six steroidogenic proteins including StAR and six enzymatic steps. P450c17, product of the CYP17 gene, catalyzes two enzymatic reactions. The four rings of the cholesterol molecule and its derivative steroids are identified by the first four letters in the alphabet, and the carbons are numbered in the sequence shown in the insert. 3-HSD-II, 3-hydroxysteroid dehydrogenase [5][4] isomerase type II; 17-HSD-1, 17-hydroxysteroid dehydrogenase type 1; P450arom, aromatase; P450c17, 17-hydroxylase/17,20-lyase; StAR, steroidogenic acute regulatory protein.
Figure 16-22 Changes in the ovarian follicle, endometrial thickness, and serum hormone levels during a 28-day menstrual cycle. Menses occur during the first few days of the cycle. E$_2$, estradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; Inh, inhibin; P, progesterone.
Figure 16-23 Estrogen biosynthesis in women. The biologically active estrogen estradiol (E$_2$) is produced in at least three major sites: (1) by direct secretion from the ovary in reproductive-age women; (2) by conversion of circulating androstenedione (A) of adrenal or ovarian origins, or both, to estrone (E$_1$) in peripheral tissues; and (3) by conversion of A to E$_1$ in estrogen target tissues. In the latter two instances, estrogenically weak E$_1$ is further converted to E$_2$ within the same tissue. The presence of the enzyme aromatase and 17-hydroxysteroid dehydrogenase (17-HSD) is critical for E$_2$ formation at these sites. E$_2$ formation by peripheral and local conversion is particularly important in post-menopausal women and in estrogen-dependent diseases such as breast cancer, endometriosis, and endometrial cancer.
Figure 16-24 Functional anatomy of the endometrium. Endometrium is a multilayered mucosa specialized for implantation and support of pregnancy. A single, continuous layer of epithelial cells lines the surface of the stroma and penetrates the stroma with deep invaginations almost all the way down to the myometrium-endometrium junction. The entire thickness of the endometrium is penetrated by the spiral arteries and their capillaries. Spiral arteries originate from the radial branches of arcuate arteries, which in turn arise from uterine arteries. The superficial layer (functionalis) is shed during menstruation, whereas the permanent bottom layer (basalis) gives rise to the regeneration of endometrium after each menstruation. The striking changes in the spiral arteries (coiling, stasis, vasodilatation followed by intense vasoconstriction) are consistently observed before the onset of every menstruation episode. (Courtesy of Kristof Chwalisz.)
Figure 16-25 Cyclic changes in thickness and morphology of endometrium and the relation of these changes to those of the ovarian cycle. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In Williams Obstetrics, 19th ed. Stamford, Conn, Appleton & Lange, 1993, pp 81109.)
Figure 16-26 Dating the endometrium by morphology. (From Noyes RW, Hertig AW, Rock J. Dating the endometrial biopsy. Fertil Steril 1950; 1:325.)
Critical epithelial effects of estrogen (e.g., deoxyribonucleic acid [DNA] synthesis, proliferation, and gene expression) are mediated primarily by estrogen receptor (ER) in stromal cells in a paracrine manner in the endometrium.
**Figure 16-28** The antiestrogenic effects of progesterone on epithelial cells (e.g., decreased proliferation and enhanced differentiation) are mediated primarily by progesterone receptors (PRs) in stromal cells in a paracrine manner in the endometrium. DNA, deoxyribonucleic acid; ER, estrogen receptor.
Figure 16-29 Diagrammatic representation of donation of excess oocytes by a woman undergoing in vitro fertilization (IVF) to a woman with ovarian failure treated with exogenous estrogen and progesterone. A, Woman with ovarian failure treated with increasing doses of estrogen during days 1 through 14 of the cycle. Exogenous progesterone was added to the estrogen treatment on days 15 through 28 and continued if pregnancy was diagnosed. Seven donor eggs were fertilized with sperm from the recipient's husband, and five embryos were transferred to the uterus on day 16 to 18. B, The IVF patient-donor was treated with human menopausal gonadotropin (hMG) until day 8, when human chorionic gonadotropin (hCG) was given, and oocytes were harvested 32 to 36 hours later. Half of the eggs were donated to the recipient, and the other half were fertilized with sperm from the donor's husband; the five fertilized eggs were transferred to the uterus of the IVF donor. Serum levels of E$_2$ (estradiol) and P$_4$ (progesterone) in both women are shown. To convert estradiol values to picomoles per liter, multiply by 3.671. To convert progesterone values to nanomoles per liter, multiply by 3.180. (Adapted from Rosenwaks Z. Donor eggs: their application in modern reproductive technologies. Fertil Steril 1987; 47:895909.)
Figure 16-31 Severe clitoromegaly resulting from a testosterone-secreting ovarian tumor.  

A. The entire length of the clitoris is approximately 4 cm (normal < 1 cm).  
B. The transverse diameter of the clitoris measures 1.5 cm (normal < 0.7 cm).
Androgen biosynthesis in women. There are two biologically active androgens, testosterone (T) and dihydrotestosterone (DHT). Depending on the menstrual cycle phase or postmenopausal status, 20% to 30% of T is secreted by the ovary. The rest of T production (blood) is accounted for by the conversion of circulating androstenedione (A) to T in various peripheral tissues. Both the adrenal and ovary contribute to circulating A directly or indirectly depending on the cycle phase, reproductive-age versus postmenopausal status, and chronologic age. Moreover, T may also be formed locally in androgen target tissues. Finally, T is converted to the more potent androgen DHT within the target tissues and cells. For example, local conversion of T to DHT in sex skin fibroblasts and hair follicles amplifies androgenic action for clitoral enlargement and hirsutism. DHEA, dehydroepiandrosterone; HSD, hydroxysteroid dehydrogenase.
Figure 16-33 Polycystic ovaries. A, Operative findings of classical enlarged polycystic ovaries. The uterus is located adjacent to the two enlarged ovaries. B, Sectioned polycystic ovary with numerous follicles. C, Histologic section of a polycystic ovary with multiple subcapsular follicular cysts and stromal hypertrophy (low power, left). At higher power (× 100), islands of luteinized theca cells are visible in the stroma (right). This morphologic change is called stromal hyperthecosis and appears to be directly correlated with circulating insulin levels. (C, From Dunaif A. Insulin resistance and the polycystic ovary syndrome: mechanism and implications for pathogenesis. Endocr Rev 1997; 18:774800. Copyright © 1997 by The Endocrine Society.)
Figure 16-34 Acanthosis nigricans. A, Moderate acanthosis nigricans (darkening and thickening of skin) at the lateral lower fold of the neck. Note facial hirsutism (sideburns) in the same patient. B, Severe acanthosis nigricans in another patient with severe insulin resistance. (B, courtesy of Dr. R. Ann Word.)
Figure 16-36 Pathologic mechanisms in polycystic ovary syndrome (PCOS). A deficient in vivo response of the ovarian follicle to physiologic quantities of follicle-stimulating hormone (FSH), possibly because of an impaired interaction between signaling pathways associated with FSH and insulin-like growth factors (IGFs) or insulin, may be an important defect in PCOS. This ovarian defect may be the key event responsible for anovulation in PCOS. Insulin resistance associated with increased circulating and tissue levels of insulin and bioavailable estradiol (E₂), testosterone (T), and IGF-I gives rise to abnormal hormone production in a number of tissues. Oversecretion of luteinizing hormone (LH) and decreased output of FSH by the pituitary, decreased production of testosterone-binding globulin (TeBG) and IGF-binding protein 1 (IGFBP-1) in the liver, increased adrenal secretion of dehydroepiandrosterone sulfate (DHEAS), and increased ovarian secretion of androstenedione (A) all contribute to the vicious circle that maintains anovulation and androgen excess in PCOS. Excessive amounts of E₂ and T arise primarily from the conversion of A in peripheral and target tissues. 17-HSD, 17-hydroxysteroid dehydrogenase; 5-red, 5-reductase.
Figure 16-37 Extraovarian conversion of androstenedione to androgen and estrogen. Androstenedione of adrenal or ovarian origin, or both, acts as a dual precursor for androgen and estrogen. Five percent of circulating androstenedione is converted to circulating testosterone, whereas 1.3% of circulating androstenedione is converted to circulating estrone in peripheral tissues. Testosterone and estrone are further converted to biologically potent steroids, dihydrotestosterone and estradiol, in peripheral and target tissues. Biologically active amounts of estradiol in serum are measured in pg/mL (pmol/L), whereas biologically active levels of testosterone in serum are measured in ng/mL (nmol/L). Thus, 1.3% conversion of normal quantities of androstenedione to estrone may have a critical biologic impact in settings such as postmenopausal endometrial or breast cancer. Furthermore, significant androgen excess is observed in conditions with abnormally increased androstenedione formation (e.g., polycystic ovary syndrome).
Figure 16-38 Hormonal monitoring in clomiphene citrate-initiated ovulation: use of the triple-7 regimen. Please see text.

Figure 16-39 Variation of the duration of the menstrual cycle in women with regular cycles. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In Williams Obstetrics, 19th ed. Stamford, Conn, Appleton & Lange, 1993, pp 81109.)
Figure 16-40 Tissue sources of estrogen in postmenopausal breast cancer. This figure exemplifies the important pathologic roles of extraovarian (peripheral) and local estrogen biosynthesis in an estrogen-dependent disease in postmenopausal women. The estrogen precursor androstenedione (A) originates primarily from the adrenal in the postmenopausal woman. Aromatase expression and enzyme activity in extraovarian tissues such as fat increase with advancing age. The aromatase activity in skin and subcutaneous adipose fibroblasts gives rise to formation of systemically available estrone (E₁) and to a smaller extent estradiol (E₂). The conversion of circulating A to E₁ in undifferentiated breast adipose fibroblasts compacted around malignant epithelial cells and subsequent conversion of E₁ to E₂ in malignant epithelial cells provide high tissue concentrations of E₂ for tumor growth. The clinical relevance of these findings is exemplified by the successful use of aromatase inhibitors to treat breast cancer.
Figure 16-41 Regimens of hormone replacement therapy (HRT). Estrogen (E) is replaced in a postmenopausal woman to prevent osteoporosis, urogenital atrophy, and hot flashes. In the postmenopausal woman with a uterus, a progestin (P) is added to estrogen to prevent endometrial hyperplasia and cancer. E and P can be administered in a number of ways. A and B. The postmenopausal women receiving hormone replacement have predictable withdrawal bleeding episodes after each P course. C. These women take E and P together continuously. After a year of continuous combination therapy, the rate of unpredictable breakthrough spotting is 20%.
Figure 17-1 The growth of the world population (billion) and increments by decades (million).  () Publication of Malthus' essay on population. Since then, the world population has increased six times.  () Publication of Paul Ehrlich's *The Population Bomb*. Since then, the world population has increased from 4 billion to 6 billion. (Modified from Raleigh VS. Trends in world population: how will the millennium compare with the past? Hum Reprod Update 1999; 5:500.)
**Figure 17-2** The population growth in individual continents. *(From United Nations Population Division. World Population Prospects: The 2000 Revision. New York, United Nations, 2000.)*
**Figure 17-3** Birth rates from 1950 to 2000 and projections for the first half of the 21st century. *(From United Nations Population Division. World Population Prospects: The 2000 Revision. New York, United Nations, 2000.)*
Figure 17-4 The decrease of the birth rate is inversely proportional to the percentage of the population practicing contraception and positively related to the standard of living. (Modified from Potts M. The unmet need for family planning. Sci Am 2000; 282[1]:69.)
Figure 17-5 Intended and unintended pregnancies in the United States, 1994. (Data adapted from Henshaw SK. Unintended pregnancy in the United States. Fam Plann Perspect 1998; 30:2429, 46.)
Figure 17-6  Attachment of the ethinyl group to C-17 of estradiol creates an orally highly active estrogen, ethinylestradiol (EE). Mestranol has a methyl group on C-3 of EE. Mestranol is a prohormone because it must be metabolically converted to EE to be able to bind to estrogen receptors. Modification of the estradiol molecule on C-17 provides long-acting 17-cypionate, used in injectable preparations. For numbering of the steroid molecule, see Figure 17-8.
Figure 17-7 Development of norethindrone from testosterone. Splitting off the C-19 radical from the testosterone molecule changes this androgen to a progestagen. Attachment of the ethinyl group to C-17 enhances the progestagenic activity of the compound and makes it orally active. For numbering of the steroid molecule, see Figure 17-8.
Figure 17-8 Contraceptive progestagens are derived from three skeleton structures, pregnane, estrane, and gonane (see details in the text). The pregnane molecule shows the numbering system of contraceptive steroids.
Figure 17-9 Classification of contraceptive steroids. Hybrid progestagens are in gray boxes. In parentheses are the active progestagenic metabolites of norgestimate and desogestrel.
**Figure 17-10** Progestagens derived from progesterone. Progesterone loses its activity when a hydroxyl group is attached to C-17. Formation of an acetate restores the progestational activity, which is further enhanced by manipulations at C-6. Derivatives of hydroxyprogesterone acetate are potent progestagens as well as antiandrogens.
Figure 17-11 Norethindrone (NET) and its derivatives. In order to become biologically active, the individual derivatives must be converted into NET.
Figure 17-12 Early gonanes: levonorgestrel and norgestrel.
Figure 17-13 Progestagens of the advanced gonane group. Norgestimate and desogestrel are prohormones, metabolically converted into the active progestagenic substances, norelgestromin and etonogestrel, respectively. Gestodene is active without metabolic conversion.
Figure 17-14 Hybrid progestagens: nonpregnanes nomegestrol and nesterone, dienogest, and drospirenone. Drospirenone is a spironolactone derivative.
**Figure 17-15** Relative binding affinities of contraceptive progestagens for progesterone receptors. The assay measures displacement of $^3$H-labeled R5020 from progestagen receptors isolated from the rabbit uterus. The $[^3]$H$^3$H]R5020 is a radiolabeled synthetic progestagen used in in vitro studies. (Data from Phillips A, Demarest K, Hahn DW, et al. Progestational and androgenic receptor binding affinities and in vivo activities of norgestimate and other progestins. Contraception 1990; 41:399.)
Figure 17-16 Relative binding affinity of contraceptive progestagens for androgen receptors. The assay measures displacement of $^{3}$H-labeled dihydrotestosterone from rat prostatic androgen receptors. (Data from Phillips A, Demarest K, Hahn DW, et al. Progestational and androgenic receptor binding affinities and in vivo activities of norgestimate and other progestins. Contraception 1990; 41:399.)
Figure 17-17 Contrasting effects of oral contraceptives containing levonorgestrel (LNG) and norgestimate (NGM) on high-density and low-density lipoproteins (HDL and LDL). (Modified from Henzl M. Norgestimate: from the laboratory to three clinical indications. J Reprod Med 2001; 46:647-661.)
Figure 17-18 Menstrual patterns during 5 years of using contraceptive hormonal implant with levonorgestrel. (From Speroff L, Darney PD. A clinical guide for contraception, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

**Figure 17-20** Types of intrauterine devices (IUDs). The copper T380 and the levonorgestrel-releasing IUD are clinically used in the United States. The frameless copper IUD is available in Europe.
Figure 18-1 Schematic diagram of sexual differentiation beginning with formation of the bipotential gonads from intermediate mesoderm, differentiation of the testes and ovaries from the bipotential gonads, and formation of the sexual phenotypes. The genes known to be involved and their presumed sites of action are indicated. 
5-red, steroid 5-reductase 2; AMH, antimüllerian hormone; AMHR, antimüllerian hormone receptor; AR, androgen receptor; DAX-1, dosage-sensitive sex reversaladrenal hypoplasia congenital gene; DHT, dihydrotestosterone; SF-1, steroidogenic factor 1; SOX3, SRY-related gene HMGbox 3; SOX9, SRY-related gene HMGbox 9; SRY, sex-determining region of the Y chromosome; WT1, Wilms' tumorrelated gene 1.
Figure 18-2 Germ cells. A, Schematic drawing of a 3-week-old embryo showing the site of origin of germ cells in the wall of the yolk sac. B, Migration path of primordial germ cells along the wall of the yolk sac and along the dorsal mesentery into the genital ridge. (From George FW, Wilson JD. Embryology of the genital tract. In Walsh PC, Gittes RF, Perlmutter AD, et al [eds]. Campbell's Urology, 5th ed. Philadelphia, WB Saunders, 1986, pp 1804-1818.)
Figure 18-3 Descent of the testis. (From George FW, Wilson JD. Embryology of the genital tract. In Walsh PC, Gittes RF, Perlmutter AD, et al [eds]. Campbell's Urology, 5th ed. Philadelphia, WB Saunders, 1986, pp 18041818.)
Figure 18-4 Diagram of the Sertoli cell showing the relation between Sertoli cell cytoplasm and developing spermatocytes.
Figure 18-7 Pathways of testosterone synthesis in human testis. Cholesterol for testosterone synthesis can arise from three sources: (1) plasma cholesterol, (2) cholesterol newly synthesized within the Leydig cell, and (3) cholesterol stored as cholesterol esters in Leydig cells. The delivery of cholesterol to the inner mitochondrial membrane for side-chain cleavage to pregnenolone is the rate-limiting reaction and under control of luteinizing hormone. Conversion of pregnenolone to testosterone can take place by two theoretical pathways—one in which side-chain cleavage and reduction of the 17-keto group are accomplished before A-ring oxidation and the other in which this sequence is reversed. As indicated by bold arrows, the former pathway is predominant in the human. DHEA, dehydroepiandrosterone; HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory protein. (Modified from Griffin JE, Wilson JD. The testis. In Bondy PK, Rosenberg LE [eds]. Metabolic Control and Disease, 8th ed. Philadelphia, WB Saunders, 1980, pp 1535-1578.)
Figure 18-9 Metabolism of plasma testosterone in extraglandular tissues. Testosterone can be metabolized to either active or excretory metabolites. Active metabolites such as dihydrotestosterone may be further metabolized to excretory metabolites. HSD, hydroxysteroid dehydrogenase. (From Griffin JE, Wilson JD. The testis. In Bondy PK, Rosenberg LE [eds]. Metabolic Control and Disease, 8th ed. Philadelphia, WB Saunders, 1980, pp 1535-1576.)
Figure 18-10 Schematic diagram of androgen action. Testosterone, secreted by the testis, binds to the androgen receptor in a target cell, either directly or after conversion to dihydrotestosterone. Dihydrotestosterone binds more tightly than testosterone. The major actions of androgens, shown on the right, are mediated by testosterone (solid lines) or by dihydrotestosterone (broken lines). (From Griffin JE. Androgen resistance: the clinical and molecular spectrum. N Engl J Med 326:611618, 1992. Copyright 1992, Massachusetts Medical Society. All rights reserved.)
Figure 18-11 Schematic diagram of the normal androgen receptor.
Figure 18-12 Cell divisions during spermatogenesis. The overall number of cell divisions is much higher than that during oogenesis.
Figure 18-13 Schematic diagram illustrating conversion of spermatocyte to spermatid to spermatozoon.
Figure 18-14 Schematic diagram of the different phases of male sexual function during life as indicated by mean plasma testosterone level and sperm production at different ages. (From Griffin JE, Wilson JD. The testis. In Bondy PK, Rosenberg LE [eds]. Metabolic Control and Disease, 8th ed. Philadelphia, WB Saunders, 1980, pp 1535-1578.)
Figure 18-15 Ontogeny of luteinizing hormone (LH) secretion. Plasma LH concentrations were sampled every 20 minutes for 24 hours in three normal males at different stages of development. Top, Pattern in an adult man with frequent secretory episodes throughout the 24-hour period and no significant sleep-related augmentation. Middle, Secretory pattern in midpuberty in which marked secretory episodes occur during sleep. Bottom, Pattern in prepuberty in which there are no significant secretory episodes at any time throughout the sampling period. (From Griffin JE, Wilson JD. The testis. In Bondy PK, Rosenberg LE [eds]. Metabolic Control and Disease, 8th ed. Philadelphia, WB Saunders, 1980, pp 1535-1578. Courtesy of R.M. Boyar.)
Figure 18-17 Diagram of sequence of events at puberty. The ranges of age during which changes occur in normal boys are indicated by figures below each bar.  (Data from Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. Arch Dis Child 1970: 45:1323.)
Four different patterns of abnormal androgen-estrogen dynamics can result in the development of gynecomastia. The altered component in each pattern is highlighted in black, and specific examples of each type of abnormality are listed at the bottom of each panel. Details of normal androgen-estrogen dynamics are shown in Figure 18-8 (Figure Not Available). HCG, human chorionic gonadotropin; HSD, hydroxysteroid dehydrogenase.
Figure 18-19 Types of androgen preparations available for clinical use. Type A derivatives are esterified in the 17 position. Type B steroids have alkyl substitutions in the 17 position. Type C derivatives involve a variety of alterations of ring structure that enhance activity, impede catabolism, or influence both functions. Most androgen preparations involve combinations of type AC or type BC changes.
Figure 18-20 Effect on penile size of 200 mg of testosterone cypionate intramuscularly every 2 weeks for 11 months in a previously untreated 22-year-old man with microphallus caused by hypogonadotropic hypogonadism. (From Griffin JE, Wilson JD. Disorders of sexual differentiation. In Walsh PC, Retik AB, Stamey TA, et al [eds]. Campbell’s Urology, 6th ed. Philadelphia, WB Saunders, 1992, pp 1509-1542.)
Figure 19-2 Biochemical mechanisms of penile smooth muscle relaxation. A, Relaxation of the cavernosal smooth muscle is regulated by intracellular cyclic adenosine monophosphate (cAMP) and cyclic guanidine monophosphate (cGMP). The intracellular second messengers, by activation of specific protein kinases, cause sequestration of intracellular calcium (Ca$^{2+}$), closure of calcium channels, and opening of potassium (K$^+$) channels. This results in a net decrease in intracellular calcium, causing smooth muscle relaxation. Nitric oxide, released by noradrenergic, noncholinergic nerve endings (NANC), stimulates guanyl cyclase. By inhibiting phosphodiesterase type 5 (PDE5), sildenafil increases the amount of intracellular cGMP. Prostaglandin E$_1$ (PGE$_1$) stimulates generation of cAMP. Papaverine inhibits PDE$_2$, PDE$_4$, and PDE$_5$ and thereby increases the amount of intracellular cAMP. AMP, adenosine monophosphate; GTP, guanosine triphosphate; IP$_3$, inositol 1,4,5-triphosphate; NO, nitric oxide; PKA, protein kinase A; PKG, cGMP-specific protein kinase. B, Interconnection of cavernosal smooth muscle cells in the penis. The smooth muscle cells in the corpora cavernosa are interconnected through connexin 43-derived gap junctions. Therefore, alterations in action potential and potassium channel activity in any myocyte affect the adjacent myocytes. (A and B, Adapted and redrawn from Melman A, Christ GJ. Integrative erectile biology: the effects of age and disease on gap junctions and ion channels and their potential value to the treatment of erectile dysfunction. Urol Clin North Am 2001; 28:28:217231.)
Figure 19-3 Arterial supply of the perineum and clitoris in prearousal (A) and arousal (B) states.
Figure 20-1 A, Serum thyrotropin (hTSH) and human chorionic gonadotropin (hCG) concentrations throughout pregnancy. Between 8 and 14 weeks of gestation, there is a significant negative correlation between the individual hTSH and hCG levels (P < .001). Each point represents the mean (±SE). SE, standard error. B, Linear regression of maternal serum free thyroxine (T₄) and hCG concentrations during the first half of gestation (P < .001). (From Glinoer D, de Nayer P, Bourdoux P, et al. Regulation of maternal thyroid during pregnancy. J Clin Endocrinol Metab 1990; 71:276.)
Figure 20-2 Mean plasma concentrations of estrone (E₁), estradiol (E₂), estriol (E₃), and progesterone (P) during pregnancy. (Data from Tulchinsky D, Hobel CJ, Yeager E, et al. Plasma estrone, estradiol, estriol, progesterone, and 17-hydroxyprogesterone in human pregnancy: I. Normal pregnancy. Am J Obstet Gynecol 1972; 112:1095–1096; and Levitz M, Young BK. Estrogens and pregnancy. Vitam Horm 1977; 35:109.)
Figure 20-3 Steroidogenesis in the maternal-fetal-placental unit. SCC, cholesterol side-chain cleavage enzyme; DHEA, dehydroepiandrosterone; HSD, hydroxysteroid dehydrogenase; AROM, aromatase-enzyme complex.
Figure 20-4 Mean (±SE) maternal serum human chorionic gonadotropin (hCG) levels throughout normal pregnancy. (From Braunstein GD, Rasor J, Danzer H, et al. Serum human chorionic gonadotropin levels throughout normal pregnancy. Am J Obstet Gynecol 1976; 126:678.)
Figure 20-5 Proposed pathways for metabolism of human chorionic gonadotropin: , intact hCG; : N, hCG with nicked subunit; N, free nicked subunit; CTP fragment, carboxy-terminal fragment; mRNA, messenger RNA. (From Braunstein GD. Physiologic functions of human chorionic gonadotropin during pregnancy. In Mochizuki M, Hussa R [eds]. Placental Protein Hormones. Amsterdam, Elsevier Science, 1988, p 33.)
Figure 20-6  Placental weight (Pl. wt.) and maternal serum concentrations of human placental lactogen (hPL) during pregnancy.  (From Selenkow HA, Saxena BN, Dana CL. Measurement and pathophysiologic significance of human placental lactogen. In Pecile A, Finzi C [eds]. The Feto-Placental Unit. Amsterdam, Excerpta Medica, 1969, p 340.)
Figure 20-7. Mean (± standard error) of plasma human growth hormone (hGH) (A) and insulin-like growth factor-1 (IGF-1) (B) levels throughout pregnancy. The number of individual assays of growth hormone (GH) and IGF-1 at each gestational stage is indicated in A on top of vertical bars. GH 5 B4 indicates placental GH (hGH-V); GH 5 24 indicates pituitary GH. (From Mirlesse V, Frankenne F, Alsat E, et al. Placental growth hormone levels in normal pregnancy and in pregnancies with intrauterine growth retardation. Pediatr Res 1993; 34:39.)
Figure 21-1 Diagrammatic representation of a chorionic villus extending into the maternal blood lake and showing fetal capillaries in the fetal mesenchyme. The villus is sheathed by the syncytiotrophoblast. The residual sparse areas of cytotrophoblast provide cells to renew and maintain the syncytiotrophoblast layer. The villus is surrounded by maternal blood in the maternal intervillous space. The placenta serves as an important endocrine organ. Hormones are produced by cytotrophoblast and syncytiotrophoblast cells. Neuropeptides appear to modulate syncytiotrophoblast production of placental protein hormones, and decidual prostaglandins and cytotrophoblast growth factors may participate in regulation of syncytiotrophoblast steroid hormone production. See text for details.
Figure 21-2 Diagrammatic representation of the fetoplacental unit composed of the fetal adrenal cortex and the placenta. The placenta is deficient in 17-hydroxylase activity and cannot synthesize estrogens from progesterone. The fetal adrenal cortex has low 3-hydroxysteroid dehydrogenase (3HSD) and 17β isomerase activity and cannot synthesize progesterone. Sulfokinase activity is high in fetal adrenal tissue, and steroid sulfatase activity is high in placental tissue. Thus, the placenta produces progesterone, which is predominantly converted to dehydroepiandrosterone (DHEA) by the fetal adrenal cortex; the DHEA can be sulfated to form DHEA sulfate (DHEAS). Part of this is 16-hydroxylated by the fetal liver, and both DHEA and DHEAS are used by the placenta as substrates for estrone (E₁) and estradiol (E₂) synthesis, respectively. Placental sulfatase converts DHEAS and 16-hydroxy-DHEAS to DHEA and 17-hydroxy-DHEA. The 16-hydroxy-DHEA is used for estriol (E₃) synthesis. See text and references for details.
Figure 21-3 Cartoon illustrating the homeobox genes programming hypothalamic and pituitary embryogenesis and function. SHH and ZIC2 are the sonic hedgehog and Drosophila odd-paired homologues, mutations of which have been shown to cause human holoprosencephaly. RPX is the Rathke’s pouch homeobox gene involved in anterior pituitary gland embryogenesis. LHX3 and LHX4 are LIM class homeodomain transcription factors also essential for normal pituitary embryogenesis. PROP1 and PIT1 defects in mice and humans lead to growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH) deficiency. FSH, follicle-stimulating hormone; LH, luteinizing hormone; POMC, pro-opiomelanocortin. See text for details.
Figure 21-4 Patterns of change of fetal plasma human placental lactogen (hPL), growth hormone (GH), prolactin (PRL), insulin-like growth factor I (IGF I), and insulin-like growth factor II (IGF II) during gestation and in the neonatal period. The range of fetal plasma hPL concentrations is shown as the hatched area. (Data from Bennett A, Wilson DM, Liu R, et al. J Clin Endocrinol Metab 1983; 57:609612; Kaplan SL, Grumbach MM, Aubert ML. Recent Prog Horm Res 1976; 32:161243; Bala RM, Lopatka J, Leung A, et al. Clin Endocrinol Metab 1981; 52:508512.)
Figure 21-5 Hemi-cross-section of a 5-week human embryo with location of the adrenal primordia (suprarenal cortices) and gonadal ridges. The homeobox genes programming adrenal and gonadal embryogenesis are indicated. SF1 (steroidogenic factor 1) is involved in testicular and ovarian development, whereas SRY is the single critical regulator of testicular embryogenesis. Inactivation of the DAX1 gene leads to adrenal hypoplasia. The steroidogenic acute regulatory protein (StAR) is the rate-limiting factor for adrenal steroidogenesis. See text for details.
Figure 21-7 Cartoon showing the homeobox genes programming development of the thyroid and parathyroid glands. HOXB3 may be responsible for activation of thyroid transcription factor 1 (TTF1) during early embryogenesis, with TTF2 and PAX8 involved in a synergistic cascade programming thyroid gland embryogenesis. These factors are also involved in thyroid follicular cell function, promoting thyroglobulin (TG), thyroid peroxidase (TPO), and thyroid-stimulating hormone receptor (TSHR) gene transcription. HOX15 gene knockout in mice causes parathyroid gland aplasia. See text for details.
Figure 21-8 Patterns of change of fetal plasma thyroid-stimulating hormone (TSH), thyroxine (T₄), triiodothyronine (T₃), reverse T₃ (rT₃), and iodothyronine sulfate (T₄S, rT₃S, and T₃S) levels during gestation and in the neonatal period. The patterns for T₄S and rT₃S are based on limited 30-week data. (Data from Fisher DA, Klein AH. N Engl J Med 1981; 304:702712; Santini F, Chiovato L, Ghirri P, et al. J Clin Endocrinol Metab 1999; 84:493498; Burrow GN, Fisher DA, Larsen PR. N Engl J Med 1994; 331:10721078.)
Figure 21-9 Patterns of change of plasma levels of human chorionic gonadotropin (hCG), luteinizing hormone (LH), testosterone (T), and estradiol (E₂) in a male fetus during gestation and in the neonatal period. (Data from Reyes FI, Boroditsky RS, Winter JS, et al. J Clin Endocrinol Metab 1974; 38:612617; Kaplan SL, Grumbach MM, Aubert ML. Recent Prog Horm Res 1976; 32:161243; Winter JS, Faiman C, Hobson WC, et al. J Clin Endocrinol Metab 1975; 40:545551; Forest MG, Cathiard AM. J Clin Endocrinol Metab 1975; 41:977980; and Penny R, Parlow AF, Frasier SD. Pediatrics 1979; 64:604608.)
**Figure 21-10** Proposed actions of parathyroid hormone (PTH), PTH-related protein (PTHrP), and calcitonin (CT) in the fetus. PTHrP and perhaps PTH from the parathyroid glands and PTHrP from the placenta act on the placenta to promote calcium (Ca) and phosphate (PO$_4$) transport from the maternal to the fetal circulation to maintain the relative fetal hypercalcemia and the high rate of fetal bone formation during the last half of gestation. PTHrP also acts on the kidney to promote 1-hydroxylation of 25-hydroxycholecalciferol to 1,25-dihydroxyvitamin D, 1,25(OH)$_2$D, which augments placental calcium transport and promotes fetal bone growth. High fetal CT levels tend to promote bone accretion. See text for details.
Figure 21-11 Cartoon showing the homeobox genes programming development of the pancreas. IDX1 gene knockout in the mouse leads to pancreatic agenesis, whereas ISL1 knockout produces islet cell agenesis. Knockout of PAX4 and PAX6 leads to beta cell or alpha cell agenesis or hypogenesis; Beta2 gene disruption also produces beta cell hypoplasia. See text and Koshimizu et al. J Clin Endocrinol Metab 1995; 61:7882.
Figure 21-12 Actions of cortisol and catecholamines during fetal adaptation to the extrauterine environment. The prenatal cortisol surge acts to promote functional maturation of several organ systems as indicated. The neonatal catecholamine surge triggers or potentiates a number of the extrauterine cardiopulmonary and metabolic functional adaptations that are critical to extrauterine survival. See text for details. BAT, brown adipose tissue; E, epinephrine; NE, norepinephrine; T3, triiodothyronine; T4, thyroxine.
Figure 22-1 Typical G-banded karyotypes of patients with abnormal gonadal differentiation.  A, The 45,X karyotype of a patient with streak gonads, short stature, and physical stigmata of Turner's syndrome.  B, The 47,XXY karyotype of a phenotypic male with seminiferous tubule dysgenesis (chromatin-positive Klinefelter's syndrome).
Figure 22-2 A partial karyotype of C group (chromosome numbers 6 to 12) and X and Y in a patient with a 46,X,i(Y;7)(q11;q36) karyotype. Standard Giemsa staining, autoradiography, fluorescent (Q), and Giemsa (G) banding techniques were used to identify the chromosome anomaly. A, The standard staining technique for karyotype analysis revealed an enlarged C group chromosome and a deleted G group chromosome. B, Autoradiography after incubation of lymphocyte culture with tritiated thymidine showed a late-labeling segment on the distal arms of the C chromosome and absence of a late-labeling segment on the deleted long arm of the presumptive Y. C, Quinacrine hydrochloride staining and fluorescence microscopy demonstrated a translocation of the brightly fluorescent segment of the long arm of the Y chromosome to the long arm of chromosome 7. D, Giemsa banding confirmed that the C group chromosome involved in the translocation was chromosome 7.
**Figure 22-3** FISH for SRY analysis in metaphase and interphase 46,XY cells. FISH images illustrating localization of the Vysis SRY probe on the distal short arm of the Y chromosome (Yp11.3) shown in SpectrumOrange and Vysis CEPX, a probe for the X centromere shown in SpectrumGreen. Note the localization of the X (green) and Y (orange) in an interphase nucleus (right). (Courtesy of Philip Cotter and Helen Jenks.)
Figure 22-4 Daughter cell lines can arise from mitotic nondisjunction or anaphase lag during first mitotic division in the zygote. More complex mosaicism can result if the zygote is aneuploid or if replication errors arise beyond the one cell stage. In females, nondisjunction or anaphase lag may involve either the maternal or paternal X chromosome. Deductions regarding the origin of X chromosomes in aneuploid patients can be made by correlating sex-linked traits with those in parents and by using specific DNA probes for analysis.
Figure 22-5 A diagram of chromosome breakage and recombination to form long and short arm deletions and ring chromosomes. Deleted segments may also be transposed to terminal portions of other chromosomes as additions, or there may be reciprocal translocations of deleted segments with those from another chromosome.
Long arm isochromosomes of the X,Xqi, were postulated to result from centric fission, that is, transverse rather than longitudinal division of the centromere. A more likely mechanism is shown. A deletion occurs at the centromere on the short arm or above the centromere. Fusion of remaining chromatids of the short arm followed by division of the centromere and duplication of entire chromatid and centromere(s) results in an isochromosome with either one or two centromeres. The acentric fragment is lost.
Figure 22-7 Diagram of a G-banded Y chromosome. Y-linked genes are shown. SHOX/PHOG, short stature/pseudoautosomal homeobox-containing osteogenic gene on the X; MIC2, a cell-surface antigen recognized by the monoclonal antibody 12E7; SRY, sex-determining region Y; RPS4Y, ribosome protein S4Y; ZFY, zinc finger Y; TSPYA, TSPYB, testes-specific protein Y; PRKY, a member of the cyclic adenosine monophosphate-dependent serine threonine protein kinase gene family, homologous to PRKX. DAZ, deleted in azoospermia; AZF, azoospermic factor.
**Figure 22-8** A, Q staining and fluorescence microscopy of interphase cells from a normal male, illustrating typical Y bodies. B, An enlarged photograph of one cell, showing a fluorescent Y body at the periphery of the nucleus. C, Metaphase chromosomes from a normal male, illustrating the brightly fluorescent distal segment of the long arm of the Y chromosome. D, An interphase nucleus in a buccal smear of a patient with a 47,XXY karyotype. A brightly fluorescent Y body and an X chromatin body (which exhibits much weaker fluorescence) were identified by Q staining and fluorescence microscopy.
Figure 22-9 Diagram of a G-banded X chromosome. Selected X-linked genes are shown. SHOX/PHOG, short stature/pseudoautosomal homeobox-containing osteogenic gene; MIC2, a cell-surface antigen recognized by monoclonal antibody 12E7; PRKX, a member of the cyclic adenosine monophosphate-dependent serine threonine protein kinase gene family. Illegitimate X-Y interchange occurs frequently between PRKX and PRKY. DAX1, dosage-sensitive sex reversal congenital adrenal hypoplasia critical region on the X chromosome-1; GK, glycerol kinase; DMC, Duchenne's muscular dystrophy; USP9X, human X-linked homologue of the DFFRX (Drosophila fat facets related X gene); RPS4X, ribosomal protein S4X; Xist, Xi specific transcripts; XIC, X-inactivation center; ATRX, -thalassemia, X-linked mental retardation; DIAP2, human homologue of the Drosophila diaphanous gene, mutations of which affect oogenesis and spermatogenesis.
Figure 22-10  A and B, Photomicrographs showing the X chromatin body (Barr body, arrow) in the nucleus of buccal mucosal cells from a normal female (thionine stain, ×2000). Such cells are found in about 25% of well-preserved nuclei.  C, A buccal mucosal cell from a normal male, illustrating absence of this body (thionine stain, ×2000).  D, A typical “drumstick” nuclear appendage (arrow) found in a variable proportion of leukocytes of female subjects.
Figure 22-11 Characteristics of heterochromatin formation as exemplified by differential behavior of the two X chromosomes of the female in somatic cells. 1. Precocious condensation of a large part of one of the two X chromosomes in prophase and formation of the X chromatin body in interphase nuclei. 2. Delayed replication of DNA in one of the X chromosomes (arrow indicates silver grains overlying one X chromosome in the autoradiogram of metaphase chromosomes from a normal female exposed to tritiated thymidine late in the synthetic period). With some exceptions (PAR region, etc.) gene activity on the heterochromatic late-replicating X chromosome is silenced or modified. (From Grumbach MM. On the significance of sex chromatin. In Second International Conference on Congenital Malformations. New York, International Medical Congress, 1964, pp 6267.)
Figure 22-12 Diagram of the fixed differentiation or Lyon hypothesis of X chromosome behavior in somatic cells of the human female. At the late blastocyst stage (the time when X chromatin can first be identified), one of the two X chromosomes becomes heterochromatinized in each cell and gives rise to an X chromatin body; it is by chance in each cell whether this differentiation involves a maternally derived X (M) or a paternally derived X (P). Once differentiation has occurred, this characteristic is fixed in succeeding generations of somatic cells. Most of the genes on the heterochromatic portion of an X chromosome are suppressed or inactivated, thus serving as a means of "dosage compensation" for the greater number of X-linked genes in the female than in the male. This mechanism has an important bearing on expressivity and penetrance of an X-linked mutant gene in a heterozygous female. In the diagram, the maternally derived X carries a mutant gene (a) that is expressed only in cells in which this X is the isopyknotic, euchromatic active X (white X_M). Although the heterochromatinized X (black X) in this diagram is represented as wholly inactive, some loci on the heterochromatinized X do remain active and exert genetic effects. The female germ cell line beyond the oogonia stage is exempted from heterochromatinization.
Figure 22-13 Diploid somatic cells from a girl with a 49,XXXX karyotype. A, Four X chromatin bodies (arrows) in an interphase nucleus from a culture of skin fibroblasts. B, Autoradiogram of metaphase chromosomes, illustrating four areas of high grain density overlying four of the five X chromosomes. C, An autoradiogram of an interphase nucleus in a culture of skin fibroblasts; four peripheral "hot" areas (arrows) of high grain density overlie four X chromatin bodies and provide direct evidence that each X chromatin body is derived from one late-labeling X chromosome. (Modified from Grumbach MM, Morishima A, Taylor JA. Human sex chromosome abnormalities in relation to DNA replication and heterochromatization. Proc Natl Acad Sci USA 1963; 49:581589; and Grumbach MM. On the significance of sex chromatin. In Second International Congress on Congenital Malformations. New York: International Medical Congress, 1964, pp. 62-67.)
Figure 22-14 Diagram of the historical search for the testis-determining factor. The shaded area on the Y chromosome is the region to which this factor has been localized. ZFY, zinc finger Y; SRY, sex-determining region Y; numbers 1 to 4A indicate arbitrary deletion segments on the Y chromosome. (Modified from McLaren A. What makes a man a man? Reprinted by permission from Nature, vol. 346, pp. 216-217. © 1990 Macmillan Magazines Ltd.)
Figure 22-15 Localization of the putative sex-determining region, SRY, on the short arm of the Y chromosome. The zinc finger locus ZFY (the suggested site of the testis-determining factor in 1987) is shown, as well as the break points observed in four 46,XX males described by Palmer and co-workers. The break points of one 46,XX male and one 46,XY female studied by Page and colleagues are also indicated. Note that the 46,XY female has a noncontinuous deletion that involves both ZFY and SRY. (From Page DC, Fisher EMC, McGillivray B, et al: Additional deletion in the sex-determining region of the human Y chromosome resolves the paradox of X[t(y;22)] female. Nature 1990; 346:279-281.)
**Figure 22-16** Diagram of the human SRY protein. The HMG box is an 80 amino acid DNA-binding domain with two nuclear localization signals at either end: CaM, calmodulin and imp, importen. The last seven amino acids of SRY can bind to either of the PDZ domains found in SRY-interacting protein 1 (SIP-1). The solid circles indicate selected mutations reported in the SRY protein affecting testicular differentiation and consequent male development.
Figure 22-17 Diagram of the SOX9 protein. Unlike SRY, SOX9 has two introns. Like SRY it has two nuclear localization signals at the ends of the HMG box. SOX9, unlike SRY, binds to heat shock protein 70 (HSP70) and has a trans-activation domain at the carboxyl-terminal end. Selected mutations causing sex reversal and campomelic dysplasia are indicated by the solid circles, those causing only campomelia are indicated by the open triangles, whereas SRY mutations occur primarily on the HMG box. SOX9 mutations appear to occur throughout the gene.
Figure 22-18  Diagram of the SF1 protein. Mutations causing SF1 deficiency are shown. Gly35Glu (P box) and Arg255Leu are heterozygous mutations in a male and a female. Arg92Gln (A-Box) is a homozygous mutation in a male; heterozygotes are unaffected. P box, proximal box; D box, distal box; A-box is the FTZ-F1 box; PRR is a proline-rich region; regions II and III are conserved regions among SF1 proteins; AF-2 is an activation domain.
Figure 22-19 A and B, Hypothetical linear cascade and network of genes involved in human sex determination and differentiation (refer to manuscript for genes described in the mouse). WT1, Wilms' tumor suppressor gene; SF1, steroidogenic factor 1; DAX1, dosage-sensitive sex reversal adrenal hypoplasia critical region on the X gene 1; SOX9, autosomal gene containing SRY-like HMG box; SRY, sex-determining region Y; DMRT1, double sex, mab3-related transcription factor 1; WNT4, a member of the vertebrate homolog family of the Drosophila segment polarity gene, "wingless"; AMH, antimüllerian hormone; GATA4, transcription factor.
Types of cell division. A female somatic cell undergoing mitosis is represented. At the metaphase plate are two X chromosomes and two homologous autosomes of group 21 to 22. Division occurs through the centromere, giving rise to two daughter cells of identical chromosomal composition. Replication of each arm into two chromatids takes place while the chromosomes are extended and before the next metaphase. The first meiotic division involves pairing of homologous chromosomes. The centromere does not divide in this cell division. It is by chance whether the maternal (X<sup>M</sup>) or paternal (X<sup>P</sup>) member of each pair goes to the respective daughter cells. During the complex prophase of first meiotic division (not shown), multiple chiasmata are formed between the chromosomes of each pair, facilitating exchanges of chromosomal segments (crossing over) between them. During the second meiotic division, the centromere again divides, giving rise to daughter cells identical to the parent cell. This division more nearly resembles mitosis than the first meiotic division. Nondisjunction can take place in mitosis or in the first or second meiotic division; representative examples are illustrated.
Figure 22-21 Anatomic and schematic representations of gonadal differentiation. A and B. Transverse section through the urogenital ridge at the stage of the indifferent gonad. Note the proximity of a large fetal adrenal to the hilar portion of gonad. C and D. Transverse section through the fetal testis at 56-mm stage. E and F. Transverse section through the fetal ovary at 60-mm stage. In ovarian development, coelomic epithelium continues to proliferate for a much longer period. (Modified from Arey LB. Developmental Anatomy, 7th ed. Philadelphia, WB Saunders, 1965; and Witschi E. Development of Vertebrates. Philadelphia, WB Saunders, 1956.)
Figure 22-22 Comparison of the pattern of change of serum testosterone and human chorionic gonadotropin (hCG) and serum and pituitary luteinizing hormone (LH) (LER960) and follicle-stimulating hormone (FSH) (LER869) in the human male fetus during gestation with morphologic changes in the fetal testis. (Adapted from Kaplan SL, Grumbach MM. Pituitary and placental gonadotropins and sex steroids in the human and subhuman primate fetus. Clin Endocrinol Metab 1978; 7:487-511.)
**Figure 22-23** Comparison of the pattern of serum follicle-stimulating hormone (FSH), luteinizing hormone (LH), and human chorionic gonadotropin and pituitary FSH and LH in the human female fetus during gestation with the developmental histology of the fetal ovary. (Adapted from Kaplan SL, Grumbach MM. Pituitary and placental gonadotropins and sex steroids in the human and subhuman primate fetus. Clin Endocrinol Metab 1978; 7:487511.)
Figure 22-24 The sequence of sexual differentiation in the human fetus. The sequence as schematically depicted here emphasizes that testicular development in the male fetus precedes all other forms of sexual dimorphism. There is an inherent propensity of the gonads, genital ducts, and external genitalia to feminize, whereas masculinization requires Y chromosomemediated (SRY) differentiation of the fetal testes. (Modified from Jost A. Hormonal factors in the sex differentiation of the mammalian foetus. Philos Trans R Soc Lond [Biol] 1970; 259:119130.)
Figure 22-25 Embryonic differentiation of male and female genital ducts from wolffian and müllerian primordia. Left, An indifferent stage showing large mesonephric body. Middle, Female ducts. Remnants of mesonephros and wolffian ducts are now termed the epoöphoron, paroöphoron, and Gartner duct. Right, Male ducts before descent into scrotum. The only müllerian remnant is the testicular appendix. Prostatic utricle (vagina masculina) is derived from urogenital sinus. (Modified from Corning HK. Lehrbuch der Entwicklungsgeschichte des Menschen. Munich, JF Bergmann, 1921; and Wilkins L. The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence, 3rd ed. 1965. Courtesy of Charles C Thomas, Publisher, Springfield, IL.)
Figure 22-26 A schematic summary of Jost's experiments with rabbit embryos. The fetal testis plays a decisive role in determining the differentiation of the genital ducts. Testosterone stimulates wolffian development but fails to effect involution of müllerian structures. (Data from Jost A. Embryonic sexual differentiation [morphology, physiology, abnormalities]. In Jones HW, Scott WW [eds]. Hermaphroditism, Genital Anomalies and Related Endocrine Disorders, 2nd ed. Baltimore, Williams & Wilkins, 1971, p 16.)
Figure 22-27 Mechanism of action of anti-müllerian hormone (AMH/MIS). AMH/MIS binds to the ubiquitous AMH type I (ALK2) and the müllerian ductspecific AMH type II receptor, forming a heterodimer that induces signaling through the SMAD pathway and binding to DNA, resulting in the production of MMP2, matrix metalloprotein 2 in the müllerian duct mesenchyme. Pro MMP2 is secreted into the extracellular space, where it is activated by a membrane based metalloproteinase. Apoptosis (cell death) may occur as a result of activation of a death factor or inactivation of a survival factor. An alternate hypothesis is that MMP2 acts to cleanse the epithelial cell basement membrane. (Redrawn from Roberts LM, Visser JA, Ingraham HA. Involvement of a matrix metalloproteinase in MIS-induced cell death during urogenital development. Development 2002; 129:14571496).
Figure 22-28 Differentiation of male and female external genitalia from indifferent primordia. Male development occurs only in the presence of androgenic stimulation during the first 12 fetal weeks. (Adapted from Spaulding MH. The development of the external genitalia in the human embryo. Contrib Embryol Carnegie Inst 1921; 13:6968.)
**Figure 22-30** Linear representations of the steroid/thyroid hormone receptor superfamily are shown to illustrate sequence homology. hGR is the glucocorticoid receptor; hMR, the mineralocorticoid receptor; hAR, the androgen receptor; hPR, the progesterone receptor; hER, the estrogen receptor; hERR 1 and hERR 2, estrogen-related receptors; hRAR, the retinoic acid receptor; hTR, the thyroid hormone receptor; hVDR, the vitamin D receptor; and hCOUP, the chicken ovalbumin upstream promoter. The DNA-binding site (region I) and the hormone-binding regions (II and III) are shown. *(From O'Malley B. The steroid receptor superfamily: more excitement predicted in the future. Mol Endocrinol 1990; 4:363369. © by The Endocrine Society.)*
Figure 22-31 Type II zinc fingers. +++ indicates the amino acid skeleton of the zinc fingers, which specifies DNA binding in a sequence-specific manner.
Figure 22-32 A simplified scheme of male sex differentiation. (Modified from Grumbach MM. Genetic mechanisms of sex development. In Vallet HL, Porter IH [eds]. Genetic Mechanisms of Sexual Development. New York, Academic, 1979, pp 3373.)
Figure 22-34 A, A 19-year-old phenotypic male with chromatin-positive seminiferous tubule dysgenesis (Klinefelter's syndrome). The karyotype was 47,XXY, gonadotropin levels were elevated, and testosterone levels were low normal. Note normal virilization with long legs and gynecomastia (B, C). The testes were small and firm and measured 1.8 × 0.9 cm. Testicular biopsy revealed a severe degree of hyalinization of the seminiferous tubules and clumping of Leydig cells. D, A 48-year-old male with 47,XXY Klinefelter's syndrome with severe leg varicosities.
Figure 22-35  A. An 8½-year-old boy with a 48,XXXY chromosome constitution, mental retardation, precocious sexual development, and accelerated growth. The appearance of pubic hair was noted at age 6. By 8 years, acne, a deep voice, tall stature, and axillary hair were present. Height was 148 ± 2.9 cm, weight was 47.7 ± 3.9 kg, span was 140 cm, and upper segment/lower segment ratio was 0.87. Testes measured 2.1 × 1.3 cm. Note the long legs, prognathism, small hands and feet, gynecomastia, and secondary sexual characteristics. His I.Q. was 62. The urinary 17-ketosteroid level was 3.2 mg/day and urinary gonadotropin levels were elevated. Bone age was 13.5 years. Roentgenogram of chest was normal. The buccal smear contained nuclei with a maximum of two X chromatin bodies. Karyotype of cells derived from skin and blood was 48,XXXY. B. Testicular biopsy showed hyalinized tubules and clumping of Leydig cells; germ cells were absent. The findings suggest that true precocious puberty, with stimulation of juvenile testes by pituitary gonadotropin, led to premature appearance of typical histologic changes of seminiferous tubule dysgenesis. (Courtesy of M. M. Grumbach and A. Morishima, unpublished data.)
Figure 22-36 Origin of the 47,XXY karyotype. Superscripts M and P designate, respectively, maternal and paternal X chromosomes. The dashed circle indicates a nonviable cell line. (From Grumbach MM. The testes. In Beeson PB, McDermott W [eds]. Cecil Loeb Textbook of Medicine, 13th ed. Philadelphia, WB Saunders, 1971, pp 16041818.)
Figure 22-37 Diagram of the short arms of the X and Y chromosomes during meiotic pairing. A, A crossover (dashed lines) usually occurs between the pseudoautosomal regions of the X and Y chromosomes. Anomalous but equal crossovers (solid lines) can occur that result in an X chromosome with the sex-determining region (SRY) and a Y chromosome deficient in the SRY. It is estimated to occur at the PRKX and PRKY locus in 40% of SRY+XX males. Zygotes with these sex chromosomes will become XX males or XY females as indicated. B, Anomalous unequal crossovers (solid lines) during male meiosis can result in an X chromosome with an SRY gene as well as the pseudoautosomal regions of both the X and Y chromosomes. SRY, sex-determining region Y; ZFY, zinc finger Y.
Figure 22-38 Variation in physical appearance in five patients with the typical form of the syndrome of gonadal dysgenesis. All of these patients had a 45,X karyotype, and all had differences between height age and chronologic age of 3 years or more. (Modified from Grumbach MM. Some considerations of the pathogenesis and classification of anomalies of sex in man. In Astwood EB [ed]: Clinical Endocrinology. New York, Grune & Stratton, 1960, pp 407-436.)
A patient aged 14 years, 10 months with the typical form of the syndrome of gonadal dysgenesis. The X chromatin pattern was negative and the karyotype was 45,X. She was short (height, 134.5 cm; height age, 9 years, 5 months), was sexually infantile except for the appearance of sparse pubic hair, and exhibited characteristic stigmata of the syndrome: a short webbed neck, shield-like chest with widely separated nipples, bilateral short fourth metacarpals, puffiness over dorsum of fingers, cubitus valgus, and an increased number of pigmented nevi. The facies were characteristic and the ears low set. The bone age was 13.5 years. Plasma gonadotropin levels were elevated. Vaginal smears and urocytogram showed an immature pattern in which cornified squamous cells were absent. With estrogen therapy, female secondary sexual characteristics were induced; cyclic estrogen administration resulted in periodic estrogen-withdrawal bleeding.
Figure 22-40 A and B. An infant with the syndrome of gonadal dysgenesis (karyotype 45,X) and associated lymphedema of extremities. The term Bonnevie-Ullrich syndrome is applied when this characteristic swelling of the feet or hands or both is associated with other features of gonadal dysgenesis. (From Grumbach MM. Chromosomal sex and the prepubertal diagnosis of gonadal dysgenesis. Reproduced by permission of Pediatrics 20:740. Copyright 1957.)
Figure 22-41 A. The mean height (50th percentile) in untreated patients with gonadal dysgenesis (mainly 45,X karyotype), compared with the growth curve of normal females. B. The mean height velocity in patients with gonadal dysgenesis and in normal females. Data derived from various sources. Note the lack of a pubertal growth spurt. (B, Courtesy of J. Frame and K. Attie, Genentech, Inc.)
Figure 22-42. The pattern of plasma follicle-stimulating hormone (FSH) concentration in relation to age in 58 patients with the syndrome of gonadal dysgenesis. , patients with 45,X karyotype; , patients with structural abnormalities of the X chromosome and mosaics. The hatched area shows the mean to the lower limits of the assay for FSH values in normal females. (From Conte FA, Grumbach MM, Kaplan SL. A diphastic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. J Clin Endocrinol Metab 40:670674, 1975. © The Endocrine Society.)
Figure 22-43 The range of phenotypic and gonadal expression in variants of the syndrome of gonadal dysgenesis and its relation to sex chromosome constitution. Typical phenotypic and gonadal findings in monosomic 45,X gonadal dysgenesis may be modified by the presence of a mosaic chromosomal constitution or by the presence of a structurally abnormal second sex chromosome. For example, 45,X/46,XX and 45,X/47,XXX mosaicism may be associated with normal stature, minimal somatic features of gonadal dysgenesis, and varying degrees of ovarian differentiation, or with a clinical picture indistinguishable from that of classic 45,X gonadal dysgenesis. Phenotype and gonadal differentiation apparently depend on the proportion of 45,X to 46,XX or 47,XXX cells in somatic and germ cells during differentiation. Similarly, the presence of a structurally abnormal X chromosome frequently modifies some features of the classic syndrome. When 45,X/46,XY mosaicism or a structurally abnormal Y chromosome is present, varying degrees of testicular differentiation may be found. The spectrum of clinical findings may extend from phenotypic male through ambiguous genitalia to phenotypic female, depending on the degree of fetal testicular insufficiency. In addition, beneficial effects of a normal XY cell line or presence of some part of a Y chromosome may lead to normal stature and a modification of the somatic defects associated with 45,X monosomy. (From Jones HW Jr, Grumbach MM. Developmental disorders [females]. In Cooke RE [ed]. Biologic Basis of Pediatric Practice. New York, McGraw-Hill, 1968, pp 10871093. Reproduced with permission of McGraw-Hill, Inc.)
Figure 22-44 The loss of germ cells during migration to or after seeding of the indifferent gonad in a 45,X individual gives rise to a gonadal streak, because germ cells are necessary for ovarian development of the indifferent gonad; evidence suggests that loss occurs after implantation of germ cells. In the presence of 45,X/46,XX mosaicism, gonadal differentiation may vary from that of an ovary to that of a gonadal streak. Similarly, in 45,X/46,XY mosaics, depending on the sex chromosome constitution of the germ cells and gonadal blastema, gonadal differentiation may vary from that of a testis to that of a gonadal streak. In 47,XXY individuals, germ cells become implanted in the primitive testis, but a marked loss of spermatogonia seems to occur in the perinatal period and infancy. (From Jones HW Jr, Grumbach MM. Developmental disorders [females]. In Cooke RE [ed]. Biologic Basis of Pediatric Practice. New York, McGraw-Hill, 1968, pp 1087-1093. Reproduced with permission of McGraw-Hill, Inc.)
**Figure 22-45** Structural anomalies of the X chromosome. The normal X at the left is G banded. A dark band on the short arm and two major dark bands on the long arm are visible. The first Xq and the ring X chromosome (Xr) are not banded. They show late replication with tritiated thymidine. Note symmetry of the arms of the second Xq. Even with G banding, it is difficult to distinguish this chromosome from a possible short arm isochromosome. The long arm isochromosome (Xqi) appears to be dicentric. The two chromosomes to the far right are isodicentric X chromosomes. Both have two C bands but only one functional centromere. There is a mirror-like band pattern on both sides of a point between the two C bands. The first isodicentric X chromosome presumably represents a break in the long arm of X at q22 with fusion of chromatids and duplication of the entire chromatid. The second isodicentric X chromosome appears to represent a terminal break in the short arm so that reduplication of the chromatids has produced what appears to be almost two X chromosomes.
Figure 22-46 Variable gonadal function and phenotypic stigmata in three patients with a deletion of the short arm of the X chromosome (Xp) of different degrees.  

A 13-year-old phenotypic female of short stature (-3.5 SD) with low-set ears, high-arched palate, low hairline, broad chest with wide-spaced areolae, cubitus valgus, puffy hands and feet, and short fourth metacarpals. There was no evidence of secondary sexual characteristics. The plasma FSH level was elevated at 26 µg/L (LER-869); the plasma estradiol level was less than 22 pmol/L (6 pg/mL). The buccal smear contained a normal proportion of X chromatin bodies in interphase nuclei, which were conspicuously small. Karyotype analysis and autoradiography revealed a 46,XXp karyotype. The abnormal X chromosome appeared to lack the entire short arm.

B, A phenotypic female, aged 17 years, 4 months, with the stigmata of the syndrome of gonadal dysgenesis. Her height was 151 cm (-3 SD), and she had multiple nevi, cubitus valgus, and a short fourth metacarpal on the right hand. At age 13 the patient noted spontaneous onset of breast development, which did not progress. Plasma gonadotropin levels were elevated: LH 7.3 µg/L (LER-960) and FSH 53 µg/L (LER-869). The concentration of plasma estradiol was 70 pmol/L (19 pg/mL). On buccal smear, the cells had a normal proportion of X chromatin bodies, which appeared small. Karyotype analysis and autoradiography indicated an Xp chromosome that had been deleted close to the centromere, but a small segment of the short arm was visible distal to the centromere.

C, A 20-year-old phenotypic female with a chief complaint of dysfunctional uterine bleeding. She had short stature, slight puffiness of hands and feet, and short fourth metacarpals. Female secondary sexual characteristics appeared at age 11, and menarche at age 13 was followed by regular menses, which later became irregular. The buccal smear contained nuclei with a normal proportion of small sex chromatin bodies. Bilateral ovaries were identified grossly and histologically during an appendectomy. Karyotype was 46,XXp. The extent of deletion of the short arms of the abnormal X chromosome in this patient is less than that seen in patients in A and B. A segment of the short arm is readily discernible above the centromere. It appears that, in these three patients with Xp karyotypes, somatic and gonadal manifestations of the syndrome of gonadal dysgenesis correlated with the magnitude of deletion of the short arm of the X chromosome.
Figure 22-47  A. A 22-year-old tall female with a chief complaint of primary amenorrhea had a deletion of the long arm of one X chromosome, Xq. At age 12 she developed sparse pubic hair. Breast development did not occur, and she remained sexually infantile. Height was 178 cm (+2.6 SD), and weight was 70 kg (+1.2 SD). No somatic stigmata of the syndrome of gonadal dysgenesis were noted. Plasma gonadotropin levels were elevated: LH was 5.6 µg/L (LER-960), and follicle-stimulating hormone level was 36.5 µg/L (LER-869). The buccal smear showed a normal proportion of X chromatin bodies that were slightly small.  B. A Giemsa-stained Xq, which exhibited (C) the late-labeling pattern characteristic of an X chromosome.
Figure 22-48 Three patients with 45,X/46,XY sex chromosome mosaicism who illustrate the highly variable phenotype in this variant of the syndrome of gonadal dysgenesis. (Numbers of the patients refer to designation in Table 22-13.) A, Patient 1, a phenotypic female, was age 15 years, 4 months. She had short stature (-3.1 SD), an increased number of pigmented nevi, puffiness over the dorsa of fingers, and broad and short hands, and she was sexually infantile (breast development seen in photograph followed estrogen therapy) except for sparse pubic and axillary hair. The urinary gonadotropins were markedly elevated. B, Patient 3, aged 3 years, 1 month, had ambiguous external genitalia, perineal hypospadias, and undescended gonads. He was of average height and had a broad chest and a duplication of the left kidney. C, Patient 9, aged 8 years, 1 month, was a phenotypic male with a penile urethra and unilateral undescended gonad, average height, cubitus valgus, short fourth metacarpals, and puffiness of dorsa of fingers. By age 15, male secondary sexual characteristics were well advanced and a left scrotal testis, which was normal in histologic appearance, measured 4.0 × 2.4 cm.
Figure 22-49 The external genitalia of a normally differentiated male with 45,X/46,XY mosaicism. Karyotype analyses revealed 16% and 68% mosaicism for a 45,X cell line in blood and skin, respectively. Gonadotropin levels, both basal and LHRH stimulated, and plasma testosterone levels were normal. Fertility was documented in vitro and by the conception of a normal male fetus.
Figure 22-50 45,X/46,XY mosaicism with a feminizing gonadoblastoma. A, A 20-year-old female with many stigmata of the syndrome of gonadal dysgenesis, including short stature, multiple nevi, cubitus valgus, and hyperconvex, small nails. The buccal smear was X chromatin negative; on fluorescence microscopy, 30% of interphase nuclei had a single Y body. Karyotype was 45,X/46,XY. The patient had spontaneous development of pubic and axillary hair at age 12. At age 18, breast development was noted. Her height was 139 cm (-5.1 SD) and weight 39 kg (-2.5 SD). Bone age was 17 years; an intravenous pyelogram was normal. The concentration of plasma gonadotropins at 20 years of age was elevated; plasma luteinizing hormone was 6 µg/L (LER-960) and follicle-stimulating hormone was 50 µg/L (LER-869). The concentration of plasma estradiol was 95 pmol/L (26 pg/mL), and that of estrone was 117 pmol/L (32 pg/mL); the plasma testosterone level was less than 0.7 nmol/L (0.2 ng/mL). On exploratory laparotomy, normal-appearing fallopian tubes and a uterus were found. The right gonad was a typical "streak," with whorls of fibrous connective tissue. B, The left gonad was replaced by a 1.3 × 1 × 1 cm tumor mass, which, on histologic section, revealed well-defined nests and islands of Sertoli-Leydig-like cells and germ cells, as well as calcification consistent with diagnosis of gonadoblastoma. C, Higher magnification illustrates aggregates of germ cells and small epithelial cells resembling immature Sertoli cells, as well as cells indistinguishable from Leydig cells. After gonadectomy the concentration of plasma estradiol was prepubertal (<18 pmol/L [<5 pg/mL]).
Figure 22-51 Phenotypic male and female with syndrome of webbed neck, ptosis, congenital heart disease, short stature, and hypogonadism (pseudo-Turner's syndrome, Noonan's syndrome). A, A boy, aged 9 years, 7 months, exhibited characteristic abnormalities: triangular facies, prominent brow, hypertelorism, ptosis, antimongoloid slant of palpebral fissures, broad apex nasi, low-set ears, webbed neck, pectus excavatum, pulmonic stenosis and atrial septal defect, short stature (-3.5 SD), bilateral undescended testes, and high-grade mental retardation. At age 18, he was 154.0 cm in height (height age: 12 years, 5 months); the boy had Leydig cell hypofunction. Biopsy of testes showed germinal aplasia. (From Grumbach MM, Barr ML. Cytologic tests of chromosomal sex in relation to sexual anomalies in man. Recent Prog Horm Res 1958; 14:255334.) B, An 8-year-old girl with similar features. Height was 106.2 cm (height age: 4 years, 4 months). Pulmonic stenosis was present, and the karyotype was 46,XX.
Figure 22-52  A 17-year-old true hermaphrodite with bilateral scrotal ovotestes and a 46,XX sex chromosome constitution in cultures of peripheral blood and skin, perineal hypospadias (partially repaired in photograph), moderate bilateral gynecomastia and pubic hair (recently shaved in picture), sparse axillary hair, a high-pitched voice, and absent facial hair. Height was 168 cm. Urinary 17-ketosteroid level was 1.3 mg/day; urinary gonadotropin levels were elevated. A male type of urethra, bilateral scrotal fallopian tubes and ovotestes, and rudimentary bicornuate uterus and vagina attached to the posterior urethra were seen at operation. The photomicrographs show histopathology of the ovarian and testicular portion of one ovotestis.  B, Immature seminiferous tubules lined with Sertoli cells and spermatogonia and Leydig cells.  C, Ova and follicles.  (From Grumbach MM, Barr ML. Cytologic tests of chromosomal sex in relation to sexual anomalies in man. Recent Prog Horm Res 1958; 14:255-334.)
Figure 22-53 Female pseudohermaphroditism induced by prenatal exposure to androgens. Exposure after 12th fetal week leads only to clitoral hypertrophy (diagram on left). Exposure at progressively earlier stages of differentiation (depicted from left to right in drawings) leads to retention of the urogenital sinus and labioscrotal fusion. If exposure occurs sufficiently early, the labia fuse to form a penile urethra. (From Grumbach MM, Ducharme JR. The effects of androgens on fetal sexual development: androgen-induced female pseudohermaphroditism. Fertil Steril 1966; 11:157-180. Reproduced with permission of the publisher. © The American Fertility Society.)
Figure 22-54 Diagram of the steroid biosynthetic pathways and the biosynthetic defects that result in congenital adrenal hyperplasia. The defect in patients with "lipoid adrenal hyperplasia" is not (except for one reported case) in the CYP11A1 (cholesterol side-chain cleavage) enzyme but in STAR, the steroidogenic acute regulatory protein. This protein is involved in the transport of cholesterol from the outer mitochondrial membrane to the inner membrane where the CYP11A1 enzyme is located. CYP11B1 (11-hydroxylase) catalyzes 11-hydroxylation of deoxycorticosterone and 11-deoxycorticisol primarily. CYP17 (17-hydroxylase/17,20-lyase) catalyzes both 17-hydroxylation and splitting of the 17,20 bond, but for the latter it has preferential ♂-17,20-lyase activity (see text). CYP19 (aromatase) catalyzes the conversion of androstenedione to estrone and testosterone to estradiol. CYP11B2 (aldosterone synthetase) catalyzes the conversion of corticosterone to aldosterone. 3-HSD I and 3-HSD II, 3-hydroxysteroid dehydrogenase/4,5-isomerase types I and II; CYP21 (P450c21), 21-hydroxylase; 17-HSD 3, 17-hydroxysteroid dehydrogenase type 3. In the human, deletion of or a homozygous null mutation of CYP11A1 (P450scc) is probably lethal in utero but a heterogeneous mutation caused congenital lipoid adrenal hyperplasia (see text).
**Figure 22-55** Diagram of chromosome 6. Only the banding pattern of the short arm is shown. Numbers 11 to 25 delineate bands according to the Paris nomenclature. To right of the centromere, the sites of genes for the major histocompatibility complex (MHC), glyoxalase I (GLO), and phosphoglucomutase (PGM) are indicated on a recombinant unit scale. To left is a scheme of genes in the MHC complex. The gene for 21-hydroxylase is closely linked to HLA-B and resides between the HLA-B and HLA-D loci.
Figure 22-56 Pedigrees of two families with children with 21-hydroxylase deficiency. HLA haplotypes for HLA-A, HLA-B, and HLA-C are indicated for each individual. a, b indicate paternal haplotypes and c, d maternal haplotypes. Parents are heterozygotes for 21-hydroxylase deficiency. Patients with haplotype a, c are homozygous for 21-hydroxylase deficiency. Haplotype b, d indicates a child who has two normal genes for 21-hydroxylase activity. (Redrawn from Levine LS, Zachmann M, New MI, et al. Genetic mapping of the 21-hydroxylase deficiency gene within the HLA linkage group. Reprinted by permission of the New England Journal of Medicine 1978; 299:911915.)
Figure 22-58 Diagram of the CYP21B gene and the site of microconversions that cause 21-hydroxylase deficiency. The numbered black boxes are the exons. SW, salt wasting; SV, simple virilizing; NC, nondiagnostic form. AG indicates an adenine to guanine transition near the end of intron 2, which causes premature splicing, resulting in an aberrant 11-amino-acid string and a stop codon. 8nt indicates an eight-nucleotide deletion in exon 3. 306+1 indicates a thymidine insertion at codon 306, which causes a frameshift and stop. GGC is a guanine-to-cytosine transition at codon 484. As noted in the text, all of these deleterious mutations that inactivate or diminish 21-hydroxylase activity are normally present in the CYP21A pseudogene. The lengths of the arrows and the percentages in parentheses designate the magnitude of activity of the 21-hydroxylase enzyme in transfected cells.
Figure 22-59 Normal plasma 17-hydroxypregesterone levels in non-stressed infants from birth to 2 years of age. To convert 17-hydroxypregesterone values to nanomoles per liter, multiply by 0.03026. (From Jenner MR, Grumbach MM, Kaplan SL. Plasma 17-OH progesterone in maternal and umbilical cord plasma in children, and in congenital adrenal hyperplasia (CAH): application to neonatal diagnosis of CAH. Pediatr Res 1970; 4:380 [abstract].)
**Figure 22-60** A and B, An untreated girl with the nonsalt-losing form of congenital adrenal hyperplasia. Androgens caused disproportionate acceleration of bone maturation compared with stature. C, Virilized adult female with nonsalt-losing adrenal hyperplasia. The patient had a deep voice, shaved daily, and wore a toupee for baldness. After treatment with cortisone, her 17-ketosteroid levels fell to normal values, her breasts enlarged, she underwent a normal menarche, and hair regrew on her head. Note short stature and short extremities. D, Female pseudohermaphroditism caused by maternal ingestion of an oral progestational compound from the 8th to 12th week of pregnancy. Labioscrotal fusion is sufficient to obscure the vaginal orifice and create a urogenital sinus. Clitoris is enlarged. There is no progressive virilizing tendency. (C, from Wilkins L. The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence, 3rd ed. Springfield, IL, Charles C Thomas, 1965.)
Figure 22-61 Diagram of the CYP11B1 (P450c11) gene with representative mutations causing 11-hydroxylase deficiency. The exons are the numbered black boxes. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and then by the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation; Pro32C indicates the deletion of a cytosine in the proline 32 codon, causing a frameshift; Asn394 + 2nt designates the addition of two nucleotides in the asparagine 394 codon, causing a frameshift. Mutations in CYP11B1 are distinct from those in CYP11B2 (P450as).
Figure 22-62 Diagram of the 3-hydroxysteroid dehydrogenase type 2 (HSD3B2) gene with selected mutations that result in 3-HSD deficiency. The numbered solid boxes indicate the exons. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and then the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. GA, nt6651 is a guanine-to-adenine transition at nucleotide 6651 in intron 3 that creates a new splice junction. 186/InsC/187 is a single-nucleotide cytosine insertion after codon 186 (proline) that changes the reading frame and causes an aberrant 16-amino-acid sequence before a stop codon. 273AA is a deletion of two adenines in codon 273 (AAA), which encodes lysine. This deletion causes a frameshift resulting in a premature termination at residue 279 and results in a truncated protein 94 amino acids shorter than the wild type. Mutations with less than 1% 3-HSD activity are indicated below the gene and cause salt loss. Missense and splicing mutations, indicated above the gene, result in 2% to 4.7% enzymatic activity and are associated with the nonsalt-losing phenotype.
Figure 22-63 Diagram of selected mutations in the CYP17 gene (17-hydroxylase/17,20-lyase deficiency). The exons are the numbered black boxes. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. Phe53 or 54 is a deletion of phenylalanine at codon 53 or 54. 518/Ins469nt is a deletion of 518 nucleotides and an insertion of 469 nucleotides. His120 + 7nt is a seven-nucleotide duplication at codon 120 (histidine). +ILE112 is a duplication of isoleucine at codon 112. GC300,301 is a deletion of two nucleotides, guanine and cytosine, at codon 300 and 301. ILe480 + 4nt is a four-nucleotide duplication (cytosine-adenine-thymidine-cytosine) at codon 480. Asp487, Ser488, Phe489 indicates a deletion of aspartic acid (codon 487), serine (codon 488), and phenylalanine (codon 489). All of these mutations cause 17-hydroxylase deficiency. Missense mutations at codons 347 and 358 (indicated by the box) have been associated with "isolated" 17,20-lyase deficiency.
Figure 22-64 Model of the steroid-synthesizing cell (adrenal/gonadal) showing conversion of cholesterol to steroids.  

A, Cholesterol from low-density lipoprotein, from cholesterol esters stored in lipid droplets, and from endogenous synthesis in the endoplasmic reticulum is transported from the outer mitochondrial membrane to the inner membrane. This transport, which is a rate-limiting step in steroid synthesis, is facilitated by StAR (steroidogenic acute regulatory protein) as well as by other, StAR-independent mechanisms. In the mitochondria, steroid synthesis then ensues as a result of the conversion of cholesterol to 5α-pregnenolone by the enzyme CYP11A1 (P450scc).  

B, In patients with congenital lipoid adrenal hyperplasia, a mutation in the gene encoding StAR results in little or no activity of the mutant StAR, causing greatly diminished cholesterol transport into the mitochondria. Low levels of steroidogenesis via mechanisms independent of StAR can occur; however, increased ACTH (LH/FSH) secretion results in cholesterol accumulation in the cells as lipid droplets.  

C, Continued stimulation and resultant accumulation of cholesterol causes engorgement of these cells, with both mechanical and chemical perturbation of the cell function. Females with congenital lipoid adrenal hyperplasia feminize at puberty and menstruate but have progressive hypergonadotropic hypogonadism. It has been hypothesized by Bose and co-workers that this occurs because the follicular cells are relatively quiescent in utero and before puberty; hence, they are undamaged. At the beginning of each cycle, they are recruited, and a small amount of estradiol can be produced as a result of StAR-independent mechanisms. This can occur until the follicular cells are engorged and rendered nonfunctional. (From Bose HS, Sujiwara T, Strauss JF III, Miller WL. The pathophysiology and genetics of congenital lipoid adrenal hyperplasia. N Engl J Med 1996;335:1870-1878. Copyright 1996, Massachusetts Medical Society. All rights reserved.) (See text.)
**Figure 22-65** Diagram of the selected mutations identified in the StAR gene associated with congenital lipoid adrenal hyperplasia. Nucleotide (nt) and amino acid numbers are given according to the cDNA sequence. Missense mutations causing amino acid substitutions are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the protein and the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. 247/InsG/nt248 is an insertion of a guanine causing a frameshift between nucleotides 247 and 248. T nt261 is a deletion of a thymidine at nucleotide 261. 548/InsTT/nt549 is an insertion of two thymidines in exon 4 between nucleotides 548 and 549, causing a frameshift. T nt593 is a deletion of two thymidines at nucleotide 593, causing a frameshift. Cnt650 is a deletion of a cytosine at nucleotide 650, causing a frameshift. TA @ 11 is a thymidine-to-adenine transition minus 11 nucleotides (5') from the intron 4/exon 5 junction. 947/InsA/nt948 is the insertion of an adenine between nucleotides 947 and 948, which results in a frameshift. (Data from Bose H, Sugawara T, Stauss JF, Miller WL. The pathophysiology and genetics of congenital lipoid adrenal hyperplasia. N Engl J Med 1996; 335:1870-1878.)
Figure 22-66 The biosynthetic defects in converting C19-steroids (androgens, androgen precursors) to C18-steroids (estrogens) in the CYP19 (P450arom)-deficient fetal placental unit. 3-HSD, 3-hydroxysteroid dehydrogenase/4,5-isomerase; 17-HSD, 17-hydroxysteroid dehydrogenase; DHEA, dehydroepiandrosterone; DHEAS, DHEA sulfate; DHT, dihydrotestosterone; T, testosterone; A, androstenedione; E1, estrone; E2, estradiol; E3, estriol. (Modified and redrawn from Conte FA, Grumbach MM, Ito Y, et al. A syndrome of female pseudohermaphroditism, hypergonadotropic hypogonadism, and multicystic ovaries associated with missense mutations in the gene encoding aromatase (P450arom). J Clin Endocrinol Metab 1994; 78:1287-1292. © 1994, The Endocrine Society.)
Figure 22-67 Diagram of the CYP19 (P450arom) gene and selected mutations causing aromatase deficiency. The numbered black boxes represent translated exons. The septum in the open box in exon II represents the 3' acceptor splice junction for the untranslated exons. The multiple alternate promoters and the untranslated exons (open boxes) are indicated. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation.

GTAT 3nt X is a guanine-to-adenine transition at the splice junction between exon 3 and intron 3, resulting in a stop codon (X) three nucleotides downstream (3').

GTGC + 29 aa is a thymidine-to-cytosine transition at the splice junction between exon 6 and intron 6, giving rise to a 29-amino-acid insert in the protein. CPro408X, a deletion of a cytosine occurring in codon 408 (proline), results in a frameshift and a stop codon 3 nucleotides downstream (3N).

**Figure 22-68** hCG/LH resistance. Diagram of male sex determination and differentiation showing a defect in the hCG/LH receptor that causes Leydig cell unresponsiveness to hCG (LH) and results in male pseudohermaphroditism. Solid bar delineates defect, and stippled area designates general site of defect. Dashed lines indicate that subsequent processes may be completely or partially affected.
Figure 22-69 Diagram of the LH/hCG receptor with its seven transmembrane alpha helices and selected mutations that cause male pseudohermaphroditism. The open circles represent the amino acid residues on the LH/hCG receptor protein. The solid circles indicate the amino acid substitutions in patients with male pseudohermaphroditism. The mutations are indicated by the three-letter abbreviation of the wild-type amino acid, followed by the position number of the amino acid in the protein and the three-letter abbreviation for the substituted amino acid or the letter X, which indicates a nonsense (stop) mutation leading to an inactive, truncated receptor.
Figure 22-70 Diagram of male sex determination and differentiation showing the consequences of an enzymatic block in biosynthesis of testosterone that results in male pseudohermaphroditism. Solid bar indicates defect (see legend for Figure 22-63).
Figure 22-71 Defects in the biosynthetic pathway for testosterone. Five defects cause male pseudohermaphroditism in affected males (1 to 5). Even though all blocks affect both gonadal and adrenocortical steroidogenesis, only those at steps 1, 2, and 3 are associated with major abnormalities in biosynthesis of glucocorticoids and mineralocorticoids. StAR mutations impair transport of cholesterol to the inner mitochondrial membrane, the site of CYP11A1. In the human, null mutations in CYP11A1 are probably lethal in utero (see text). CYP17 (17-hydroxylase/17,20-lyase) primarily catalyzes the scission of 17-hydroxypregnenolone to dehydroepiandrosterone. Only minimal conversion of 17-hydroxyprogesterone to androstenedione occurs normally. Therefore, synthesis of gonadal steroids is mainly through the 5α-pathway.
Figure 22-72  A and B, Genitalia of male infant with congenital adrenal hyperplasia resulting from 3-HSD 2 deficiency. The boy was admitted at 9 days of age in a salt-losing crisis and died at 3 months of unexplained muscular paralysis. Paresis, resembling that of Werdnig-Hoffmann syndrome, became progressively more severe even though adrenal replacement therapy was adequate and blood electrolytes were normal. Biochemical findings revealed a severe block in the conversion of 5-3-hydroxysteroids to 4-3-ketosteroids.
Figure 22-73 The topology of 5-sterol reductase. Dark circles designate amino acid substitutions due to missense mutations in \textit{DHCR7}. The two arrows indicate site of stop codons. (From Witsch-Baumgartner M, Loffler J, Utermann G. Mutations in the human \textit{DHCR7} gene. Hum Mutat 2001; 17:172182.)
Figure 22-74 Diagram of the gene encoding 17-hydroxysteroid dehydrogenase type 3 with selected mutations reported to cause 17-HSD deficiency. The exons are the numbered black boxes. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and the three-letter abbreviation for the substituted amino acid. nt325 + 4 is a splice junction mutation, a transition of adenine (A) to thymidine (T), located four nucleotides downstream (3') of the boundary between exon 3 and intron 3; nucleotide 325 is the closest base pair in the exon to the mutation. nt326 is a splice junction mutation, a transition of guanine (G) to cytosine (C), located one nucleotide upstream (5') of the boundary between intron 3 and exon 4. nt665 is a splice junction mutation, a transition of guanine (G) to adenine (A), located one nucleotide upstream (5') of the splice junction between intron 8 and exon 9. nt777-783 indicates a deletion of nucleotides 777 to 783 in the gene. (Redrawn from Andersson S, Geissler WM, Wu L, et al. Molecular genetics and pathophysiology of 17-hydroxysteroid dehydrogenase 3 deficiency. J Clin Endocrinol Metab 1996; 81:130136. © 1996, The Endocrine Society.)
Figure 22-75 The syndrome of complete androgen resistance and its "variant" form.  

A, A 17-year-old patient with the complete syndrome. This phenotypic female was chromatin negative, had a 46,XY karyotype, and had total absence of sexual hair with female secondary sexual characteristics. A small vagina ended blindly.  

B, The testes exhibited Leydig cell hyperplasia and seminiferous tubules that lacked germinal elements. C, At laparotomy, abdominal testes, rudimentary wolffian structures, and no müllerian structures were found.  

D, The variant form of syndrome in a 25-year-old female. Sexual hair was present, although sparse.  

E, The testes exhibited Leydig cell hyperplasia.  

F, The clitoris was hypertrophied, but there was no labial fusion. A shallow vagina ended blindly. At laparotomy, hypoplastic wolffian structures and absent müllerian structures were noted.
Figure 22-76 Diagram of male pseudohermaphroditism caused by complete or partial androgen resistance illustrating defects in the androgen receptor that result in absent or reduced binding of DHT or impaired function of the ligand-bound receptor.
Figure 22-77. A, Diagram of the androgen receptor gene divided into its eight exons. Exon 1 codes for the NH₂-terminal domain and regulates transcription. Exons 2 and 3 code for two zinc fingers. Exons 4 through 8 code for the androgen-binding domain of the receptor. B, The organization of a steroid-responsive gene. Ligand binding activates the receptor, and it binds to the steroid response elements of the gene (as a dimer along with co-activators; not shown). Enhancers as well as a CAAT and a TATA box are present. Gene transcription begins 19 to 27 base pairs downstream of the TATA box.
Figure 22-78 Diagram of the androgen receptor gene (AR) with missense mutations that cause complete androgen resistance (CAR) and partial androgen resistance (PAR). Asterisks indicate mutations that have been found to cause both complete and partial androgen resistance. Each mutation is indicated by the three-letter abbreviation for the wild-type amino acid, followed by the position number of the amino acid in the protein and the three-letter abbreviation for the substituted amino acid. Exon 1 (open box) regulates transcription. Exons 2 and 3 (heavy diagonal lines) encode the DNA-binding region of the androgen receptor. Part of exon 4 (thin diagonal lines) encodes the "hinge region" of the androgen receptor, which contains a nuclear localization signal. The 3' end of exon 4 through exon 8 (stippled) encodes the ligand (androgen)-binding region. A mutational hot spot is located in exon 5 and can cause both CAR and PAR. Not shown are nonsense, frameshift, and splice junction mutations and deletions that can cause either CAR or PAR. (Redrawn from Quigley CA, De Bellis A, Marschke KB, et al. Androgen receptor defects: historical, clinical and molecular perspectives. Endocr Rev 1995; 16:271321. © 1995, The Endocrine Society.)
Figure 22-79 A patient with partial androgen resistance (Reifenstein's syndrome). Both the patient and his brother had hypospadias, poor masculinization, and marked gynecomastia. Both had a normal 46,XY karyotype, normal wolffian duct derivatives, and no müllerian structures. (Reproduced, with permission, from Bowen P, Lee CSN, Migeon CJ, et al. Hereditary male pseudohermaphroditism with hypogonadism, hypospadias, and gynecomastia [Reifenstein's syndrome]. Ann Intern Med 1965; 62:252270. Courtesy of Dr. E. C. Reifenstein, Jr.)
Figure 22-80 Diagram of male pseudohermaphroditism resulting from 5-reductase deficiency.
Figure 22-81  A. A prepubertal 46,XY child with 5-reductase-2 deficiency who was raised as a female.  B. A postpubertal male with 5-reductase-2 deficiency who has virilized and changed gender role behavior.  (From Peterson RE, Imperato-McGinley J, Gautier T, et al. Male pseudohermaphroditism due to 5-steroid deficiency. Am J Med 1977; 62:170191.)
Figure 22-82 Diagram of the gene encoding 5-reductase-2 with representative mutations causing 5-reductase-2 deficiency. The exons are the numbered black boxes. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the position number of the amino acid in the enzyme and the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. GT nt725 + 1 is a splice junction mutation of guanine (G) to thymidine (T) one nucleotide downstream of the boundary between exon 4 and intron 4. Nucleotide 725 is the closest nucleotide in the exon to the mutation. A cohort of patients from New Guinea has been described with complete deletion of the 5-reductase-2 gene. (Redrawn from Wilson JD, Griffin JE, Russell DW. Steroid 5-reductase deficiency. Endocr Rev 1993; 14:577-593. © 1993, The Endocrine Society.)
Figure 22-83 Diagram of the pathogenesis of dysgenetic male pseudohermaphroditism. This condition can result from a sex chromosome anomaly or from a mutant gene in the male sex determination or differentiation cascade. The degree of masculinization is dependent on the functional ability of the dysgenetic gonads to produce antimüllerian hormone and testosterone.
Figure 22-84 Diagram of the pathogenesis of the persistent müllerian duct syndrome.
Figure 22-85 Diagram of the mutations in the antimüllerian hormone gene that cause the persistent müllerian duct syndrome. Exons are the black numbered boxes. Mutations are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the position number of the amino acid in the protein and the three-letter abbreviation for the substituted amino acid or X for a nonsense (stop) mutation. nt2526 is a deletion of nucleotides 25 and 26; nt353-356, nt1074-1087, and nt2277-2292 indicate similar deletions of the respective nucleotides. (Redrawn from Imbeaud S, Carré Eusebe D, Rey R, et al. Molecular genetics of the persistent müllerian duct syndrome: a study of 19 families. Hum Mol Genet 1994; 3:125131. By permission of Oxford University Press.)
Figure 22-86 Diagram of selected mutations in the gene for the AMH receptor type II. Black numbered boxes are exons. Exons 1 to 3 encode the extracellular domain of the receptor. Exon 4 (diagonal lines) encodes the transmembrane domain, and exons 5 through 11 encode the intracytoplasmic domain. Mutations are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the position number of the amino acid in the receptor protein and the three-letter abbreviation for the substituted amino acid or X for a nonsense (stop) mutation. n8487 designates a deletion/insertion at nucleotides 8487. GA nt615 is a guanine-to-adenine transition at nucleotide 615, which is at the splice site between exon 2 and intron 2. 27nt (open box) is a 27-nucleotide deletion, the most common mutation causing the AMH-positive form of the persistent müllerian duct syndrome, a mutation present in 25% of the patients studied with this form. (Redrawn from Imbeaud S, Belville C, Messike-Zeitoun L, et al. A 27 base-pair deletion of the antimüllerian type II receptor gene is the most common cause of the persistent müllerian duct syndrome. Hum Mol Genet 1996; 5:12691277. By permission of Oxford University Press.)

**Figure 23-16** Covalent structure of human growth hormone. (From Chawla RK, Parks JS, Rudman D. Structural variants of human growth hormone: biochemical, genetic, and clinical aspects. *Annu Rev Med* 1983; 34:519547.)
Figure 23-17 Relation between 24-hour (24h) mean growth hormone (GH) levels and age in boys and men. Bars represent values for the 24-hour mean (± SE) levels of GH (left axis) from 60 24-hour GH profiles of healthy boys and men subdivided according to chronologic age. An idealized growth velocity curve reproduced from the 50th percentile values for whole-year height velocity of North American boys (9) is superimposed. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. J Clin Endocrinol Metab 1989; 69:563570.)
Figure 23-18. A, The mean (± SE) 24-hour (24h) levels of growth hormone (GH) for groups of normal boys at varied stages of pubertal maturation. B, The mean (± SE) area under the GH concentration versus time curve for individual GH pulses, as identified by the Cluster pulse detection algorithm. C, The number of GH pulses (± SE), as detected by the Cluster algorithm, in the 24-hour GH concentration profiles for boys in each of the pubertal study groups. Note: The mean 24-hour GH concentration changes are largely mediated by changes in the amount of GH secreted per pulse rather than the frequency of pulses. In each panel, bars bearing the same letter are statistically indistinguishable. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. J Clin Endocrinol Metab 1989; 69:563570.)
Figure 23-19 Levels of growth hormone (GH) and growth hormone-binding protein (GHBP) measured in normal pubertal boys throughout adolescence. GHBP levels do not significantly change during puberty, but there is a significant increment of GH production and, therefore, of GH levels during this same time. These data suggest that there may be greater amounts of "free GH" during this period, leading to greater production of insulin-like growth factor I. (Data from Martha PM Jr, et al. J Clin Endocrinol Metab 1989; 69:563570; and Martha PM Jr, et al. J Clin Endocrinol Metab 1991; 73:175181.)
Figure 23-21 Structure of the IGF-I gene. A, The organization of the genes encoding human, rat and chicken insulin-like growth factor I (IGF-I) is depicted. Exons are represented by boxes (coding regions are in black, noncoding regions are in white), polyadenylation sites by arrows, and promoter regions by a bracket and the letter P. The full extent of the second and last human exons and the second rat exon has not been determined, as indicated by the dotted lines. B, Structure and expression of the human IGF-I gene. The structure of the different human IGF-I messenger RNAs (mRNAs) is displayed below the map of the gene. Sites of pre-mRNA processing are indicated by the thin lines. Sites of differential polyadenylation are marked at the 3' end of the gene by vertical arrows and in the mRNAs by horizontal boxes of varying length. (A and B, From Rotwein P. Structure, evolution, expression, and regulation of insulin-like growth factors I and II. Growth Factors 1991; 5:318.)
**Figure 23-22** Structure of the *IGF-II* gene. A. The organization of human, rat, and mouse *IGF-II* genes is shown. Exons are represented by boxes (coding regions are in black, noncoding in white), polyadenylation sites by thick vertical arrows, and promoter regions by a bracket and the letter P. The multiple transcription initiation sites for mouse and rat exon 1 are marked by the thin vertical arrows. The locations of mouse pseudoexons 1 and 2 are indicated. B. Structure and expression of the human *IGF-II* gene. The structure of different human insulin-like growth factor II (IGF-II) messenger RNAs (mRNAs) is displayed below the map of the gene. The patterns of mRNA processing are indicated by the thin lines. Sites of differential polyadenylation are marked at the 3' end of the gene by vertical arrows and in the mRNAs by horizontal boxes of varying length. (A and B, From Rotwein P. Structure, evolution, expression, and regulation of insulin-like growth factors I and II. Growth Factors 1991; 5:318.)
Figure 23-23 Normal serum levels (micrograms per liter) of insulin-like growth factor I (IGF-I) for males (A) and females (B). Lines represent the mean ± 3 SD. (Data courtesy of Diagnostic Systems Laboratories, Inc., Webster, Texas.)
Figure 23-24 Serum insulin-like growth factor I (IGF-I) levels in normal subjects (a and d), normal short stature subjects (b and e), and subjects with growth disorders (c and f). (From Rosenfeld RG, Wilson DM, Lee PDK, Hintz RL. Insulin-like growth factors I and II in the evaluation of growth retardation. J Pediatr 1986; 109:428-433.)
Figure 23-25 Serum insulin-like growth factor II (IGF-II) levels in normal subjects (A), normal short stature subjects (B), and subjects with growth disorders (C). (From Rosenfeld RG, Wilson DM, Lee PDK, Hintz RL. Insulin-like growth factors I and II in the evaluation of growth retardation. J Pediatr 1986; 109:428-433.)
Figure 23-26 Structure of the insulin-like growth factor (IGF) receptors. The insulin and IGF-I receptors are both heterotetrameric complexes composed of extracellular subunits that bind the ligands and subunits that anchor the receptor in the membrane and that contain tyrosine kinase activity in their cytoplasmic domains. The tyrosine kinase domain of the insulin receptor-related receptor (IRR) is homologous to the tyrosine kinase domains of the insulin and IGF-I receptors. The C-terminal domain is deleted in the IRR. Hybrids consist of a hemireceptor from both insulin and IGF-I receptors. The IGF-II/mannose-6-phosphate (M6P) receptor is not structurally related to the IGF-I and insulin receptors or the IRR, having a short cytoplasmic tail and no tyrosine kinase activity. (From LeRoith D, Werner H, Geitner-Johnson D, Roberts CT Jr. Molecular and cellular aspects of the insulin-like growth factor I receptor. Endocr Rev 1995; 16:143-163. © The Endocrine Society.)
Figure 23-27 Structure of the human insulin-like growth factor I (IGF-I) receptor precursor. Molecular cloning of human IGF-I receptor complementary DNAs (cDNAs) isolated from a placental library revealed the presence of an open reading frame of 4101 nucleotides. The 1367-amino acid polypeptide contains, at its N-terminus, a 30-amino acid hydrophobic signal peptide, which is responsible for the transfer of the nascent protein chain into the endoplasmic reticulum. After digestion by endopeptidases at a proteolytic cleavage site (Arg-Lys-Arg-Arg) located at residues 707 to 710, and subunits are released and linked by disulfide bonds to give the configuration of the mature heterotetrameric receptor. Shown in this diagrammatic representation are, in addition, the cysteine-rich domain of the subunit and the transmembrane and tyrosine kinase domains of the subunit. (From LeRoith D, Werner H, Geitner-Johnson D, Roberts CT Jr. Molecular and cellular aspects of the insulin-like growth factor I receptor. Endocr Rev 1995: 16:143163. © The Endocrine Society.)
Figure 23-30 Amino acid sequences of human insulin-like growth factor binding proteins (IGFBPs) 1 to 6, deduced from nucleotide sequences. Sequences in the amino-terminal and carboxyl-terminal residues are aligned to show maximal homologies. Dashes indicate gaps. Residues that are identical in five or six of the six IGFBPs are shaded. (From Rechler MM. Insulin-like growth factor binding proteins. Vitam Horm 1993; 47:114.)
Figure 23-31 Schematic representation of the effect of insulin-like growth factor binding protein (IGFBP) proteases on IGF action. In this model, proteolysis of IGFBPs results in a reduction in their affinity for IGF ligands, resulting in enhanced binding of IGF peptides by IGF receptor. (From Cohen P, Rosenfeld RG. The IGF axis. In Rosenbloom AL [ed]. Human Growth Hormone: Basic and Scientific Aspects. Boca Raton, Fla, CRC Press, 1991, pp 4358.)
Figure 23-32 The effect of insulin-like growth factor binding protein 3 (IGFBP-3) proteolysis by prostate-specific antigen (PSA) on IGFBP-3 affinity for IGF-I (A) and IGF-II (B). (From Cohen P, Peehl DM, Graves HC, Rosenfeld RG. Biological effects of prostate-specific antigen as an insulin-like growth factor binding protein-3 protease. J Endocrinol 1994; 142:407-415.)
Figure 23-33 The effect of insulin-like growth factorbinding protein 3 (IGFBP-3) proteolysis by prostate-specific antigen (PSA) on the ability of IGFBP-3 to inhibit IGF-I (A) and IGF-II (B) action. (From Cohen P, Peehl DM, Graves HC, Rosenfeld RG. Biological effects of prostate-specific antigen as an insulin-like growth factorbinding protein-3 protease. J Endocrinol 1994; 142:407415.)
Figure 23-34  Affinity cross-linking of $[^{125}I]$IGF-I (A) and $[^{125}I]$IGF-II (B) to membranes from Hs578T breast cancer cells. In the absence of unlabeled insulin-like growth factor (IGF) peptide (lane 1), IGF was predominantly bound to 40- to 45-kd IGFBP-3; no type I or type II IGF receptors were observed. Iodinated IGF was readily displaceable by unlabeled IGF-I or IGF-II (lanes 2 to 5) but not by unlabeled IGF-I-insulin hybrid molecule (lanes 6 and 7) or by an IGF analogue with decreased affinity for IGF-binding proteins (QAYL, lanes 9 and 10 in A). However, addition of [Leu27] IGF-II, which has decreased affinity for the type I IGF receptor (lanes 11 and 12 in A and lanes 7 and 8 in B), resulted in "unmasking" of the 130-kd subunit of the type I IGF receptor (A) and the 250-kd type II IGF receptor. (From Oh Y, Muller HL, Lamson G, Rosenfeld RG. Insulin-like growth factor (IGF)-independent action of IGF-binding protein 3 in hs578T human breast cancer cells: cell surface binding and growth inhibition. J Biol Chem 1993; 268:1496414971.)
Figure 23-35 Effect of transfection of Balb/c fibroblasts with a human insulin-like growth factor binding protein 3 (IGFBP-3) complementary DNA (cDNA) (Tx-BP-3) or with the control plasmid (Tx-P) on cell growth. Transfection with the IGFBP-3 cDNA resulted in a decreased cell proliferation (A) and increased cell doubling time (B). The latter effect could not be overcome with insulin, supporting the concept that the inhibitory effects of IGFBP-3 are IGF independent. (From Cohen P, Lamson G, Okajima T, Rosenfeld RG. Transfection of the human insulin-like growth factor binding protein 3 gene into Balb/c fibroblasts inhibits cellular growth. Mol Endocrinol 1993; 7:380386. © The Endocrine Society.)
Figure 23-36 Theoretical mechanisms of cellular insulin-like growth factor binding protein (IGFBP) actions.
Figure 23-37 Inhibition of Hs578T breast cancer cell growth by insulin-like growth factor binding protein 3 (IGFBP-3) is IGF independent. Recombinant IGFBP-3 from *Escherichia coli* results in decreased cell number and cannot be overcome by the addition of an IGF analogue with normal affinity for IGF receptors but decreased affinity for IGFBP-3 (QAYL-Leu-IGF-II). On the other hand, IGF-II, which itself does not stimulate cell proliferation in Hs578T cells, partially releases cells from the growth-inhibitory effects of IGFBP-3, presumably by causing dissociation of IGFBP-3 from the cell membrane. (From Oh Y, Muller HL, Lamson G, Rosenfeld RG. Insulin-like growth factor [IGF]-independent action of IGF-binding protein 3 in Hs578T human breast cancer cells. J Biol Chem 1993; 268:14964-14971.)
Figure 23-38 Transforming growth factor-2 (TGF-2) inhibits Hs578T cell growth by transcriptional regulation of insulin-like growth factor binding protein 3 (IGFBP-3). Reduction in IGFBP-3 messenger RNA (mRNA) and protein levels through the use of an IGFBP-3 antisense oligodeoxynucleotide resulted in significant reduction in the growth inhibitory actions of TGF-2. (From Oh Y, Muller HL, Ng L, Rosenfeld RG. TGF-2-induced cell growth inhibition in human breast cancer cells is mediated through IGFBP-3 action. J Biol Chem 1995; 270:13589-13592.)
Figure 23-39 Schematic diagram of insulin-like growth factor (IGF)-independent and IGF-dependent actions of IGF-binding protein 3 (IGFBP-3), the latter being mediated through a putative membrane-associated IGFBP-3 receptor.
Figure 23-40 Normal serum levels of insulin-like growth factor binding protein 3 (IGFBP-3) (micrograms per milliliter) by age for males (A) and females (B). The lines represent the mean ± 3 SD. (Data courtesy of Diagnostic Systems Laboratories, Inc., Webster, Texas.)
Figure 23-41 Curves of weight and height of a child with growth failure resulting from prolonged self-imposed caloric restriction because of a fear of becoming obese. The crossing of percentiles on the weight curve preceded that for the height curve; when the caloric intake was normalized (arrow), the gain in weight occurred before the improvement in linear growth. At the end of the prolonged period of caloric restriction, weight age (10.2 years) was less than height age (12 years). (From Pugliese MT, Lifshitz F, Grad G, et al. Fear of obesity: A cause of short stature and delayed puberty. N Engl J Med 1983; 309:513518.)
Figure 23-42 Catch-up growth in a girl with gluten-induced enteropathy (celiac disease). After 8 years of growth impairment, the patient was placed on a gluten-free diet and demonstrated substantial catch-up growth. Note the return to the previous growth percentiles. (Courtesy of J. M. Tanner.)
Figure 23-43 Growth curves of two boys with obesity. The boy depicted by the circles had cortisol excess related to Cushing's disease. An onset of rapid weight gain was associated with a decrease in linear growth velocity at 7 years of age. The diagnosis was established, and an adrenalectomy (arrow) was performed at the age of 9½ years, with an almost immediate increase in growth rate and striking catch-up. The boy whose growth is depicted by triangles had exogenous obesity. At the age of 9½ years, his weight was approximately the same as that of the patient with Cushing's disease, but his height was at the 97th percentile, reflecting the enhancement of linear growth in this individual with exogenous obesity.
Figure 23-44 The hypothalamic-pituitary-IGF axis: sites of established and hypothetical defects. The established defects are shown as Roman numerals in the gray-shaded circles or ovals, and the hypothetical defects are shown in the white circles or ovals. ALS, acid-labile subunit; GH, growth hormone; GHBP, GH-binding protein; GHRH, GH-releasing hormone; IGF, insulin-like growth factor; IGFBP, IGF-binding protein; JAK, Janus kinase; MAPK, mitogen-activated protein kinase; STAT, signal transducer and activator of transcription. (From Lopez-Bermejo A, Buckway CK, Rosenfeld RG: Genetic defects of the growth hormone-insulin-like growth factor axis. Trends Endocrinol 2000; 11:43.)
Figure 23-45 Decision tree for the investigation of genetic defects in patients with IGF deficiency. Hypothetical genetic defects are presented in parentheses. In those defects shown with a # sign, abnormalities in other organs and structures besides the hypothalamus-pituitary-IGF axis are expected to occur as a result of these genetic defects. ACTH, adrenocorticotropic hormone; CPHD, combined pituitary hormone deficiencies; FSH, follicle-stimulating hormone; GH, growth hormone; GHR, GH receptor; GHRHR, GH-releasing hormone receptor; IGF, insulin-like growth factor; IGFR, IGF-I receptor; LH, luteinizing hormone; PRL, prolactin; STAT5, signal transducer and activator of transcription 5; TSH, thyrotropin (thyroid-stimulating hormone). (From Lopez-Bermejo A, Buckway CK, Rosenfeld RG: Genetic defects of the growth hormone-insulin-like growth factor axis. Trends Endocrinol 2000; 11:43.)
**Figure 23-46** Magnetic resonance image of infundibular dysgenesis. A, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area in a normal 8-year-old girl. The anterior pituitary (AP) and posterior pituitary (PP) lobes and the pituitary stalk (PS) are marked. B, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area of a 17-year-old boy with isolated human growth hormone deficiency. The anterior pituitary (AP) lobe is hypoplastic, the posterior pituitary (PP) lobe is ectopic, and the pituitary stalk is absent. (From Root AW, Martinez CR. Magnetic resonance imaging in patients with hypopituitarism. Trends Endocrinol Metab 1992; 3:283-287.)
Figure 23-47 Height measurements for Ecuadorian children with insulin-like growth factor deficiency resulting from growth hormone insensitivity.  (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. Endocr Rev 1994; 15:369390. © The Endocrine Society.)
Figure 23-48 Facial appearance of Ecuadorian patients with insulin-like growth factor deficiency due to growth hormone insensitivity. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. Endocr Rev 1994; 15:369-390. © The Endocrine Society; photography by A. L. Rosenbloom, M.D.)
Figure 23-49 The normal GH-IGF axis (A) and the GH-IGF axis showing four potential biochemical defects capable of causing GH insensitivity (B): (1) abnormalities of the GH receptor, binding protein, or both; (2) abnormal signal transduction, resulting from a defect in the intracellular domain of the GH receptor or postreceptor; (3) defect of IGF synthesis; and (4) defect of IGF secretion. GH, growth hormone; GH-BP, GH-binding protein; GHRH, GH-releasing hormone; IGF, insulin-like growth factor; IGFBP, IGF-binding protein; SMS, somatostatin. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. Endocr Rev 1994; 15:369-390. © The Endocrine Society.)
Figure 23-50  Serum growth hormone (GH) and GH-binding protein levels in sera of patients with GH receptor deficiency from Ecuador. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. Endocr Rev 1994; 15:369-390. © The Endocrine Society.)
**Figure 23-51** Serum levels of insulin-like growth factor I (IGF-I), IGF-II, IGF-binding protein 2 (IGFBP-2) and IGFBP-3 in patients with GH receptor deficiency from Ecuador. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to GH receptor deficiency. Endocr Rev 1994; 15:369-390. © The Endocrine Society.)
Figure 23-52 Clinical and biochemical evaluation of growth failure: seeking the diagnosis of IGF deficiency syndrome. The goal of Step 1 is to define the patient to be assessed. Step 2 seeks a wide array of "diseases" associated with poor growth. Step 3 relates to the possibility of GH provocative testing. Step 4 defines assessment of the hypothalamic-pituitary morphology and the consideration of adrenocorticotrophic hormone deficiency. Nonetheless, the primary evaluation is for "IGF deficiency," with studies designed to delineate hypothalamic or pituitary abnormalities or GH insensitivity. CRH, corticotropin-releasing hormone; GH, growth hormone; GHBP, growth hormone-binding protein; GHD, growth hormone deficiency; GHIS, growth hormone insensitivity syndrome; GHR, growth hormone receptor; GHRHR, growth hormone-releasing hormone receptor; HPA, hypothalamic-pituitary-adrenal; IGF, insulin-like growth factor; IGFBP-3, IGF-binding protein 3; ITT, insulin tolerance test; SDS, standard deviation score; T₄, thyroxine; TSH, thyrotropin (thyroid-stimulating hormone).
Figure 23-53 Annual growth velocity (mean ± SD) for prepubertal patients with growth hormone (GH) deficiency prior to and during 4 years of GH treatment, contrasting results with daily (QD) and thrice-weekly (TIW) injections. The mean annual growth velocity in the QD group was significantly greater than that of the thrice-weekly group during each year, although significance diminished from year 1 to year 4. (From MacGillivray MH, Baptista J, Johanson A, and Genentech Study Group. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal naive growth hormone-deficient children. J Clin Endocrinol Metab 1996; 81:18061809; reproduced by permission of M. H. MacGillivray.)
Figure 23-54 Height standard deviation score (SDS) (mean ± SD) for prepubertal patients with growth hormone deficiency (GHD) before and during 4 years of growth hormone (GH) treatment, contrasting results with daily (QD) and thrice-weekly injections (TIW). The mean SDS in the QD group was significantly greater throughout the treatment period. Younger patients had the greatest increase in height SDS, and the effect of age was more marked in the QD group. (From MacGillivray MH, Baptista J, Johanson A, and Genentech Study Group. Outcome of a four-year randomized study of daily versus three times weekly somatropin treatment in prepubertal naive growth hormonedeficient children. J Clin Endocrinol Metab 1996; 81:18061809 (1328). Reproduced by permission of M. H. MacGillivray.)
**Figure 23-55** Algorithm for transition to adult treatment of growth hormone deficiency (GHD). MPHD, multiple pituitary hormone deficiencies.
Figure 23-57 Height standard deviation score (SDS) (mean ± SD) in 20 growth-retarded prepubertal patients with chronic renal insufficiency. Note that the basal height is outside the normal range (at -2.6 SD), enters the normal range within 1 year of treatment, and does not differ from the mean by the 5th year of growth hormone therapy. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth-retarded children with chronic renal insufficiency with recombinant human growth hormone. Kidney Int 1996; 49:781785; reproduced by permission of R. N. Fine.)
Figure 23-58 Adult height of patients with Turner's syndrome who were treated with growth hormone (GH) (n = 17) or combination GH plus oxandrolone (n = 45), compared with historical Turner's controls (n = 25), relative to each subject's projected adult height (indicated by dotted zero line). The mean increments in adult height relative to the projected adult height are indicated. Diamond symbols in the combination group indicate two subjects with poor compliance who terminated treatment early. (From Rosenfeld RG, Attie KM, Frane J, et al. Growth hormone treatment of Turner syndrome: beneficial effect on adult height. J Pediatr 1998; 132:319-324.)
Figure 23-59 Growth during insulin-like growth factor I treatment of growth hormone insensitivity, relative to normal standards (Tanner) and median for untreated patients (Laron) in boys (A) and girls (B). Closed circles indicate growth and open circles indicate the onset of puberty. (From Ranke MB, Savage MO, Chatelain PG, et al. Long-term treatment of growth hormone insensitivity syndrome with IGF-I. Horm Res 1999; 51:128134.)
Figure 24-1  A summary and proposed scheme of the evolution of the human pattern of postnatal growth and development during the first 20 years of life. *A. afar*, *Australopithecus afarensis*, a "bipedal chimpanzee"; *A. africana*, *Australopithecus africanus*; *H. habilis*, *Homo habilis* (the toolmaker); *H. erect 1*, early *Homo erectus*; *H. erect 2*, late *Homo erectus*; *H. sapiens*, *Homo sapiens*. The early hominid *australopithecine* specimens from South Africa date to about 3.0 to 1.5 million years ago. *H. afarensis*, while a hominid (the family of all human species), retained many anatomic features of nonhominid species, for example, an adult brain size of about 400 mL compared with *H. habilis* (650 to 800 mL), early *H. erectus* (850 to 900 mL), late *H. erectus* (up to 1100 mL), and modern *H. sapiens* (about 1400 mL). Infancy is defined as the period when the mother's breast milk is the sole or most important source of nutrition and in preindustrialized societies ends at about 36 months. Childhood is the period after weaning, when the child is dependent on others for food and protection; this period ends when the growth of the brain in weight is almost complete, at about age 7 years. The juvenile stage is defined as prepubertal individuals who are no longer dependent on their parents for survival. The adolescent stage begins with the onset of puberty, when adult height is attained. The pattern in *A. afarensis* is no different from that in the chimpanzee (*Pan troglodytes*). Note the first appearance of the childhood stage, *H. habilis* (arising about 2 million years ago) and the first appearance of the adolescent stage in *H. erectus 2* (about 500,000 years ago); *H. sapiens* arose about 120,000 to 150,000 years ago. (Modified from Bogin B. Growth and development: recent evolutionary and biocultural research. In Boaz NT, Wolfe LD [eds]. Biological Anthropology: The State of the Science. Bend, Ore, International Institute for Human Evolutionary Research, 1995, pp 4970.)
Figure 24-2 Changes in age at menarche, 1840 to 1978, illustrating the advance in the age at menarche in Western Europe and the United States since 1840 and the slowing of this trend since about 1965. (Modified from Tanner M, Eveleth PB. Variability between populations in growth and development at puberty. In Berenberg SR [ed]. Puberty, Biologic and Psychosocial Components. Leiden, HE Stenfert Kroese, 1975, pp 256-273. Reprinted by permission of Kluwer Academic Publishers.)
Figure 24-3  Stages of breast development according to Marshall and Tanner and Reynolds and Wines. Stage 1: preadolescent; elevation of papilla only. Stage 2: breast bud stage; elevation of breast and papilla as a small mound, enlargement of areolar diameter. Stage 3: further enlargement of breast and areola with no separation of their contours. Stage 4: projection of areola and papilla to form a secondary mound above the level of the breast. Stage 5: mature stage; projection of papilla only, resulting from recession of the areola to the general contour of the breast. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. Growth Diagrams 1965 Netherlands: Second National Survey on 024 Year Olds. Netherlands Institute for Preventative Medicine TNO. Groningen, Wolters-Noordhoff, 1971. © Wolters-Noordhoff, Groningen.)
Figure 24-4 Stages of female pubic hair development, according to Marshall and Tanner, Reynolds and Wines, and Dupertuis and colleagues. Stage 1: preadolescent; the vellus over the pubes is not further developed than that over the anterior abdominal wall; that is, there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly along the labia. This stage is difficult to see on photographs. Stage 3: hair is considerably darker, coarser, and curlier. The hair spreads sparsely over the junction of the pubic region. Stage 4: hair is now adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle of the classical feminine pattern. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. Growth Diagrams 1965 Netherlands: Second National Survey on 624 Year Olds. Netherlands Institute for Preventive Medicine TNO. Groningen, Wolters-Noordhoff, 1971. © Wolters-Noordhoff, Groningen.)
Figure 24-5 Stages of male genital development and pubic hair development, according to Marshall and Tanner, Reynolds and Wines, and Dupertuis and colleagues. Genital development: Stage 1: preadolescent. Testes, scrotum, and penis are about the same size and proportion as in early childhood. Stage 2: the scrotum and testes have enlarged; the scrotal skin shows a change in texture and also some reddening. Stage 3: growth of the penis has occurred, at first mainly in length but with some increase in breadth; there is further growth of the testes and scrotum. Stage 4: the penis is further enlarged in length and breadth with development of the glans. The testes and scrotum are further enlarged. The scrotal skin has further darkened. Stage 5: genitalia are adult in size and shape. No further enlargement takes place after stage 5 is reached. Public hair development: Stage 1: preadolescent; the vellus over the pubic region is not further developed than that over the abdominal wall; that is, there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair, straight or slightly curled, appearing chiefly at the base of the penis. Stage 3: hair is considerably darker, coarser, and curlier and spreads sparsely over the junction of the pubes. Stage 4: hair is now adult in type, but the area it covers is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. Most men will have further spread of the pubic hair. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. Growth Diagrams 1965 Netherlands: Second National Survey on 024 Year Olds. Netherlands Institute for Preventative Medicine TNO. Groningen, Wolters-Noordhoff, 1971. © Wolters-Noordhoff, Groningen.)
Figure 24-6 Diagram of the sequence of events at puberty in males. An average is represented in relation to the scale of ages; the range of ages within which some of the changes occur is indicated by the figures below. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. Arch Dis Child 1970; 45:1323.)
Figure 24-7 The sequence of events at puberty in females. The design of the figure is described in the legend of Figure 24-6. (From Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. Arch Dis Child 1969; 44:291303.)
Figure 24-8 Schematic representation of the growth of ovarian follicles during infancy and childhood. Type 1 (primordial follicle) and type 2 (primary follicle) are composed of a small oocyte and a few to a ring of flat granulosa cells. In the diplotene (nestling) stage of prophase, primary follicles are the predominant form of oocyte and constitute the reservoir of cells from which follicular growth occurs. Types 3 to 5 (preantral follicles) are follicles that have entered the growth phase; the oocyte is enlarging and is surrounded by a zona pellucida, and granulosa cells increase in number and differentiate. The growth of the oocyte is complete by the end of the preantral stage, and the increased follicular size is due to follicular growth and fluid accumulation. Types 6 to 8 represent antral follicles (graafian follicles) and contain a fully grown oocyte, a large number of granulosa cells, a fluid-filled cavity, and a well-developed theca external to the basement membrane. Large preovulatory follicles are absent (10,000 to 15,000 µm). Follicular growth and atresia take place throughout childhood; all follicles that enter the growth phase become atretic, and this can occur at any stage in their development but mainly involves large antral follicles. (From Peters H, Byskov AG, Grinsted J. Follicular growth in fetal and prepubertal ovaries of humans and other primates. Clin Endocrinol Metab 1978; 7:469-485.)
Figure 24-9 High-resolution pelvic ultrasonography. Top left, Prepubertal uterus. Top right, Prepubertal ovary demonstrating four small follicular cysts (arrows). Bottom left, Pubertal postmenarchal uterus. Bottom right, Ovarian cyst in a girl with true precocious puberty.
Figure 24-10  **Left**, Diagram illustrating developmental stages of testicular germ cells based on electron microscopic findings in the rabbit. Note differences between prespermatogonium and spermatogonium.  **Right**, Diagram showing maturation of testicular cell types in the rabbit from prepubertal appearance at left to onset of spermatogenesis at right. Interstitial cells undergo changes in shape, size, and arrangement in the process of Leydig cell differentiation.  *(From Gondos B. Testicular development. In Johnson AD, Gomes WR [eds]. The Testis, vol 4. New York, Academic Press, 1977, pp 137.)*
Figure 24-11 The adolescent growth spurt in girls and boys (growth velocity curves). Note the later onset of the pubertal growth spurt in boys and the approximately 2-year difference in peak height velocity and the greater magnitude of peak height velocity compared with girls. The timing of the effects of estradiol is indicated. Progressive epiphyseal fusion terminates the growth spurt and leads to final or adult height. (From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. J Pediatr Endocrinol Metab 2000; 13[suppl 6]:14391455.)
**Figure 24-12** The infancy, childhood, and puberty (ICP) model of Karlberg for mean attained height (left) and height velocity (right) for boys. The mean value for each component (infancy, childhood, puberty) and their sums (combined growth, right; combined velocity, left) are plotted. The growth curve for an individual represents the additive effect of the three biologic phases of the growth process (ICP). Karlberg has provided mathematical functions for each component of his model. **Infancy:** This component starts before birth and falls off by age 3 to 4 years. It can be described by the exponential function \( y = a + b[1 \exp(ct)] \). Average total gain in height for Swedish boys is 79.0 cm (44.0% of final height) and for girls is 76.8 cm (46.2%). **Childhood:** This phase begins at the end of the first year of life and continues to mature height. A second-degree polynomial function describes this component: \( y = a + bt + ct^2 \). Average total gain in height for boys is 85.2 cm (47.4%) and for girls is 78.4 cm (47.3%). **Puberty:** The model for the pubertal growth spurt is a logistic function: \( y = a/[1 + \exp(b(t - t_v))] \). Average total gain in height for boys is 15.4 cm (8.6%) and for girls is 10.9 cm (6.5%); \( v \) designates attained height at time \( t \) in years from birth; \( a, b, \) and \( c \) are constants; \( t_v \) is the age at peak height velocity. (Adapted from Karlberg J. On the construction of the infancy-childhood-puberty growth standard. Acta Paediatr Scand Suppl 1989; 356:2637.)
Figure 24-13 A schematic male growth chart with the features of the ICP (infancy, childhood, puberty) pattern overlaid and illustrating the predominant endocrine mechanisms controlling each phase of growth. The first shaded area emphasizes the decreasing velocity of infantile growth as the individual leaves the rapid growth phase of fetal life. The clear area is the childhood phase, which continues and magnifies the decreased velocity of growth into a plateau of rather constant growth during childhood. These two phases depend, in large part, on the effects of growth hormone (GH) and thyroid hormone with no or little effect derived from gonadal steroids. Finally, there is the period of the pubertal growth spurt in which gonadal steroids exert their direct and indirect effects. Gonadal steroids exert direct effects on the bone by stimulating the generation of insulin-like growth factor I (IGF-I) and other growth factors locally, and exert indirect effects by stimulating increased GH secretion which, in turn, exerts its own effects on bone and stimulates the production of IGF-I. In the female, the major gonadal steroid involved in the pubertal growth spurt is estradiol, whereas in the male, testosterone and estradiol (arising mainly from the aromatization of testosterone) are the major gonadal steroids.
**Figure 24-14** Interactions of the major growth-promoting hormones during puberty. Plus (+) indicates stimulatory action, minus (-) inhibitory action. Circulating insulin-like growth factor I (IGF-I) arises mainly from liver, but other tissues also contribute (endocrine action). Growth hormone and gonadal steroids have a direct stimulatory effect on the generation of IGF-I (paracrine action) locally in bone and cartilage cells. For simplification, the feedback loops for IGF-I and gonadal steroids on the hypothalamic-pituitary unit are omitted.
Figure 24-15  Serum insulin-like growth factor I (IGF-I; also called somatomedin C, SMC) in females and males stratified by age (left) and by pubertal stage (right). Males attain peak IGF-I levels at 15 years (2.5 ± 0.2 U/mL) at pubertal (genital) stage 3 (2.3 ± 0.2 U/mL). IGF-I concentrations reach a plateau between ages 12 and 15 in females (about 2 U/mL) and peak at pubertal (breast) stage 3 (2.5 ± 0.2 U/mL). The mean concentrations during puberty are higher than both adult and prepubertal values.
Figure 24-16a. Spine bone mineral density (BMD) for females by age. Mixed effects and semiparametric models were used to create the mean curves, and robust nonparametric smoothing techniques were employed for estimations of standard deviation (SD) and by age. Mean BMD was significantly greater in black (right) than in nonblack (Asian, Hispanic, and white) subjects (left). The solid line represents the mean level for age, and the dashed lines indicate the SD as indicated.
Figure 24-16b B. Spine BMD for males by age. The curve for black males was significantly greater than the mean levels of all nonblacks; Asian and white males had greater mean spine BMD than Hispanics. Mean and SD curves are shown. (A and B, From Bachrach LK, Hastie T, Wang M, et al. Bone mineral acquisition in healthy Asian, Hispanic, black and caucasian youth: A longitudinal study. J Clin Endocrinol Metab 1999; 84:4707.)
Figure 24-17 Mean plasma estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) concentrations in prepubertal and pubertal females by pubertal stage of maturation (1 = prepubertal; 5 = menstruating adolescents) and the mean bone age for each stage. Single daytime values of gonadotropins have limited usefulness because of pulsatility of gonadotropin release and the increased amplitude of LH pulses during sleep through puberty. The gonadal steroid values, however, are useful in determining the stage of pubertal development. To convert FSH values (LER-869) to international units per liter, multiply by 8.4. To convert LH values (LER-960) to international units per liter, multiply by 3.8. To convert estradiol values to picomoles per liter, multiply by 3.671. (From Grumbach MM. Onset of puberty. In Berenberg SR [ed]. Puberty, Biologic and Social Components. Leiden, HE Stenfert Kroese, 1975, pp 121. Reprinted by permission of Kluwer Academic Publishers.)
Figure 24-18 Mean plasma testosterone and gonadotropin levels in normal boys by stage of maturation (1 = prepubertal) and mean bone age for each stage. (See legend for Fig 24-17.) To convert testosterone values to nanomoles per liter, multiply by 0.03467. (From Grumbach MM. Onset of puberty. In Berenberg SR [ed]. Puberty, Biologic and Social Components. Leiden, HE Stenfert Kroese, 1975, pp 121. Reprinted by permission of Kluwer Academic Publishers.)
Figure 24-19 Organization and characteristics of the hypothalamic-pituitary-gonadotroph-gonadal system. The medial basal hypothalamus (MBH) contains the transducer luteinizing hormone-releasing hormone (LHRH) neurosecretory neurons. These neurons translate neural signals into a periodic, oscillatory chemical signal, LHRH. This MBH complex functions as an LHRH pulse generator (oscillator), which is frequency coded and releases LHRH from its axon terminals at the median eminence as a largely synchronous intermittent discharge into the primary capillary plexus of the hypothalamo-hypophysial portal circulation. The LHRH pulse generator is influenced by biogenic amine neurotransmitters, peptidergic neuromodulators, neuroexcitatory amino acids, and neural pathways. During the follicular phase in the adult female and the adult male, an LHRH pulse (estimated indirectly by monitoring LH pulses in peripheral blood) occurs approximately every 90 to 120 minutes throughout the day. Changes in the frequency and probably in the amplitude of the LHRH secretory episodes modulate the pattern of LH and follicle-stimulating hormone (FSH). The major site of action of testosterone and progesterone is on the LHRH pulse generator, as these two classes of steroids decrease LH pulse frequency, but a pituitary site of action has also been described. Estrogens have major direct inhibitory and stimulatory effects on the LHRH-primed pituitary gonadotroph: the inhibitory, or negative, feedback action is associated with a decrease in both the frequency and the amplitude of pituitary LH secretion. On the other hand, evidence also supports a negative and positive feedback action of estrogen on the LHRH pulse generator. Inhibin has a direct inhibitory effect on the pituitary gland and the secretion of FSH. The secretion of gonadal steroids by the gonads is controlled mainly by the amplitude of the gonadotropin signal. (Adapted from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, The Williams & Wilkins Co., Baltimore.)
Figure 24-20 The immortalized hypothalamic luteinizing hormone-releasing hormone (LHRH) (LHRH) neuronal cell line. Left, Phase-contrast micrograph illustrating the neuronal phenotype (GT13 cell line) including the extension of multiple long neurites, cell-cell contacts, and growth cones. The neuroendocrine function of GT cells is limited to expression of LHRH and GAP. Magnification × 175. Right, Demonstration of autonomous LHRH (gonadotropin-releasing hormone, GnRH) pulses at about 20-minute intervals by the LHRH neurons in culture. This is the same frequency as that for LH pulses in vivo, in castrated adult mice and rats. To convert LHRH values to picomoles per liter, multiply by 0.8460. (Micrograph from Mellon PL, Windle II, Goldsmith PC, et al. Immortalization of hypothalamic GnRH neurons by genetically targeted tumorigenesis. Neuron 1990; 5:110. Copyright by Cell Press. Graph courtesy of G. Martinez de la Escalera and R. I. Weiner.)
Figure 24-21 Effect of pulsatile administration of luteinizing hormone-releasing hormone (LHRH) in contrast to continuous infusion of LHRH in adult oophorectomized rhesus monkeys in which gonadotropin secretion has been abolished by lesions that ablated the medial basal hypothalamic LHRH pulse generator. Note the high concentrations of plasma LH and follicle-stimulating hormone (FSH) in monkeys given one LHRH pulse per hour, the suppression of gonadotropin secretion by continuous infusion of LHRH even though the total dose of LHRH was the same, and the restoration of FSH and LH secretion when the pulsatile mode of LHRH administration was reinitiated. (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. Science 1978; 202:631633. Copyright 1978 by the AAAS.)
Figure 24-22 Ontogeny of luteinizing hormone-releasing hormone (LHRH) neurons in the mouse. The route of migration of the LHRH neurosecretory neurons (black dots) in the mouse embryo is shown from their origin in the medial olfactory placode (a plate-like thickening of embryonic ectoderm) in the nasal region through the forebrain into the hypothalamus and preoptic areas. At embryonic (E) day 11 to 11.5 LHRH cells are in the anlage of the vomeronasal organ and medial wall of the olfactory placode. By E day 13 the number of LHRH neurons has increased, and most are in the nasal septum with the nervus terminalis and the vomeronasal nerves; only a few cells are in the brain. By E day 14 the majority of LHRH cells are in the ganglion terminale and the central root of the nervus terminalis and arch through the forebrain to the hypothalamus. By E day 16 most of the LHRH neurons are in the hypothalamus and preoptic areas, and the migration is almost complete. GT, ganglion terminale; OB, olfactory bulb; POA, preoptic area, VNO, vomeronasal organ. (Adapted from Schwanzel-Fukuda M, Pfaff DW. Origin of luteinizing hormone-releasing hormone neurons. Nature 1989; 338:161-164. Reprinted by permission from Nature, Vol. 338, pp. 161-164. Copyright © 1989 Macmillan Magazines Ltd.)
Figure 24-23 Ontogeny of the luteinizing hormonereleasing hormone (LHRH) neurons in the rhesus monkey. In the 36-day embryo the LHRH cells (black dots) are located deep in the nasal septum along the path of the nervus terminalis but not within the brain. By day 38 LHRH cells are clustered along the dorsal region of the olfactory bulbs and nervus terminalis with a few cells arching back along the ventral surface of the forebrain. By 55 days the LHRH neurons are in the process of migration, but clusters of LHRH cells have entered the central nervous system and reached the basal hypothalamus. BH, basal hypothalamus; LT, lamina terminalis; LV, lateral ventricle; NA, nasal area; NE, nasal epithelium; NT, nervus terminalis; OB, olfactory bulb; OC, optic chiasm; Tu, olfactory tubercle. Ontogeny of gonadotropin-releasing hormonecontaining neurons in early fetal development of rhesus macaques, Endocrinology 1990; 126:498511. © by The Endocrine Society.)
**Figure 24-24** Comparison of the pattern of change of serum testosterone, human chorionic gonadotropin (hCG), and serum and pituitary luteinizing hormone (LH) (LER-960) and follicle-stimulating hormone (FSH) (LER-869) levels in the human male fetus during gestation in relation to the morphologic changes in fetal testes. The top graph illustrates the regression curve for the increment (Δ) between a baseline plasma LH and FSH level and the 15-minute response to administration of LHRH to the male fetus plotted as a function of gestational age. The scale masks the slight increase in plasma FSH. Data were recalculated from Takagi and colleagues. The evidence supports the hypothesis that the hypothalamic LHRH pulse generator is functional early in gestation and mediates the rise in serum concentration of fetal pituitary gonadotrophs. To convert plasma hCG values to international units per liter, multiply by 1.0. Other conversions are in the legends of Figure 24-17 and Figure 24-18. (Modified from Kaplan SL, Grumbach MM. Pituitary and placental gonadotropins and sex steroids in the human and subhuman primate fetus. Clin Endocrinol Metab 1978; 7:487511; and Gluckman PD, Grumbach MM, Kaplan SL. The human fetal hypothalamus and pituitary gland. In Tulchinsky D, Ryan KJ [eds]. Maternal-Fetal Endocrinology. Philadelphia, WB Saunders, 1980, pp 196232.)
Figure 24-25 Pattern of change of serum follicle-stimulating hormone (FSH), luteinizing hormone (LH), and human chorionic gonadotropin (hCG) levels; concentration of pituitary FSH and LH; and increment (Δ) between baseline FSH and LH and the 15-minute response to administration of LHRH in the human female fetus during gestation with the development of the fetal ovary. See legends of Figure 24-17, Figure 24-18, and Figure 24-24 for conversions to SI units. (Modified from Kaplan SL, Grumbach MM. Pituitary and placental gonadotropins and sex steroids in the human and subhuman primate fetus. Clin Endocrinol Metab 1978; 7:487-511.)
Figure 24-26  Pulsatile luteinizing hormone (LH) secretion in the ovine fetus. GA, gestational age. The length of gestation is 145 days in the sheep.  (From Clark SJ, Ellis N, Styne DM, et al. Hormone ontogeny in the ovine fetus. XVII. Demonstration of pulsatile luteinizing hormone secretion by the fetal pituitary gland. Endocrinology 1984; 115:17741779. © by The Endocrine Society.)
Figure 24-27 Left, The effect in the ovine fetus of administration for 7 days of luteinizing hormone-releasing hormone (LHRH) agonist (10 µg intravenously daily) on the acute LH response to LHRH agonist. Right, Recovery of the LH response was impaired 8 days after discontinuing LHRH agonist administration to the ovine fetus. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-28 Change in the pattern of pulsatile follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion in early infancy, childhood, and puberty. The data for early infancy are derived from Waldhauser and colleagues. Note the pulsatile secretion in the infant and the striking difference in the amplitude of FSH and LH pulses between male and female infants. After infancy, the amplitude and frequency of gonadotropin pulses decrease greatly for almost a decade (juvenile pause) until the onset of puberty. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-29 Mean leptin ±95% CI (log scale) by puberty stage in boys ( and ---) and girls ( and ), with significant sex differences marked. *, $P < 0.05$; **, $P < 0.005$; ***$, P < 0.0005$. (From Ahmed ML, Ong KK, Morrell NJ, et al. Longitudinal study of leptin concentrations during puberty. J Clin Endocrinol Metab 1999; 84:902.)
Figure 24-30 The postulated action of leptin secreted by adipocytes on the hypothalamic luteinizing hormone-releasing hormone (LHRH) pulse generator. Its indirect action through hypothalamic neural networks is illustrated as well as direct action. Leptin appears to function as a permissive factor, not a trigger, in the onset of human puberty. Although leptin is reported to advance puberty in rodents, its role in "triggering" puberty in humans has not been established and is speculative. FSH, follicle-stimulating hormone; mRNA, messenger ribonucleic acid. (See text.)
Figure 24-31 Postulated dual mechanism of restraint of puberty involves both gonadal steroid-dependent and gonadal steroid-independent (intrinsic central nervous system inhibitory mechanism) processes. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-32 Change in pattern of the plasma concentration of follicle-stimulating hormone (FSH) with age in 58 patients with the syndrome of gonadal dysgenesis. Mixed longitudinal (n = 23) and cross-sectional (n = 35) data. Triangles designate patients with 45,X karyotype. Circles indicate Turner's syndrome patients with X chromosome mosaicism or structural abnormalities of the X chromosome, or both. Note the values in the 2- and 3-day-old infants. The solid line represents a regression line of best fit. The hatched area indicates the mean plasma values in normal females. To convert FSH values to international units per liter, multiply by 8.4. (From Conte FA, Grumbach MM, Kaplan SL. A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. J Clin Endocrinol Metab 1975; 40:670674. © by The Endocrine Society.)
Figure 24-33 Effect of administration of ethinylestradiol (2 µg/day) on the urinary excretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in a prepubertal normal male aged 11 years, 2 months. Note the rapid and significant decrease in LH and FSH levels by day 3 after treatment with estradiol; by day 4 the excretion of FSH and LH is less than 0.01 IU. (From Kelch RP, Kaplan SL, Grumbach MM. Suppression of urinary and plasma follicle-stimulating hormone by exogenous estrogens in prepubertal and pubertal children. Reproduced from the Journal of Clinical Investigation, 1973, vol. 52, pp. 11221128 by copyright permission of the American Society for Clinical Investigation.)
Figure 24-34 Interaction of the negative feedback mechanism and the putative intrinsic central nervous system (CNS) inhibitory mechanism in restraining puberty as extrapolated from the pattern of change in the concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in agonadal infants, children, and adolescents. (See Figure 24-33 for key to symbols; the solid line is the regression curve of best fit; the solid bars connote the mean normal concentrations + 1 SD of FSH and LH.) For about the first 3 years of life the sensitive gonadal steroid, negative feedback mechanism has a dominant role in restraining gonadotropin secretion, as exemplified by the high gonadotropin concentrations in this age group in the absence of gonads (and gonadal steroid feedback). A major role of the intrinsic CNS inhibitory mechanism in this age group is unlikely in light of the rise in gonadotropins to castrate levels in the absence of functional gonads. From 4 to 6 years of age the postulated intrinsic CNS inhibitory mechanism is dominant, as indicated by the fall in FSH and LH concentrations in the absence of gonads. Even in this age group the augmented gonadotropin response evoked by LHRH and the slightly higher mean basal gonadotropin concentrations in agonadal individuals support a role, although a subsidiary one, for gonadal steroid negative feedback in the suppression of gonadotropin secretion during this period of the juvenile pause. The authors suggest that the intrinsic CNS inhibitory mechanism suppresses the functional LHRH pulse generator. Finally, after about 10 years of age the CNS inhibition gradually wanes, resulting in disinhibition of the LHRH pulse generator. The gonadal steroid negative feedback mechanism with an adult-type set point and inhibin play a dominant role in regulating the LHRH pulse generator-pituitary gonadotropin system. For conversion to SI units, see the legend of Fig. 24-17 (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-35 Postulated ontogeny of the dual mechanism for the inhibition of puberty. Interrupted arrows indicate inhibition. Note the action of both components during the juvenile pause (prepuberty). See Figure 24-34 for the relative role of these two mechanisms during development. LHRH is given as LRF in the figure; MBH, medial basal hypothalamus. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-36. A. True precocious puberty in a 2 9/12-year-old girl (SM) secondary to a large bilateral congenital suprasellar arachnoid cyst. Signs of sexual precocity were noted during the preceding year. The head circumference was +5 SD above the mean value for age, and frontal bossing was present. Breasts were Tanner stage 3. Serum estradiol, 26 pg/mL; estrone, 38 pg/mL; dehydroepiandrosterone sulfate (DHEAS), less than 3 µg/dL. The serum luteinizing hormone (LH) concentration rose from 1.4 to 8.7 ng/mL (LER-960) after IV administration of LH-releasing hormone (LHRH), a pubertal response. Bone age, 3 6/12 years. Pelvic ultrasonography showed pubertas-like uterus and ovaries. To convert estrone values to picomoles per liter, multiply by 3.899. To convert DHEAS values to micromoles per liter, multiply by 0.02714. For other conversions see legend of Figure 24-17. B. Cranial CT scans for SM showing low-density fluid collection in the middle cranial fossa, thinning of the cortex, and striking compression of the lateral and third ventricles. C. Cranial CT scans 8 months later, after decompression of the arachnoid cyst and creation of a communication between the cyst and the basal cerebrospinal fluid cisterns and a cystoperitoneal shunt. Note the striking decrease in size of the fluid collections and expansion of the cerebral cortex. D. Basal and peak LH and follicle-stimulating hormone (FSH) concentrations after LHRH administration in SM and serum estradiol values before and 2 weeks and 9 months after surgical decompression of the arachnoid cyst. Note prepubertal LH response to LHRH and fall in serum estradiol level by 9 months after surgery. The bone age had increased by 3 years over an 11-month period, but the velocity has now returned to normal. The patient remained prepubertal during follow-up. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-37 Hypothalamic hamartoma as an ectopic luteinizing hormone-releasing hormone (LHRH) pulse generator that escapes the intrinsic central nervous system inhibitory mechanism and results in true precocious puberty. Two possible mechanisms are proposed. **Left**, The LHRH neurosecretory neurons in the hamartoma functioning as an LHRH pulse generator without activation of the suppressed normally located LHRH pulse generator. **Right**, The hamartoma acting as an ectopic LHRH pulse generator but communicating with and activating (possibly through axonic connections or by LHRH itself) the normally located hypothalamic LHRH pulse generator, which then functions synchronously with the hamartoma.
Figure 24-38 The striking developmental changes in GABA and gonadotropin-releasing hormone (GnRH; luteinizing hormonereleasing hormone) release between the prepubertal and the pubertal rhesus monkey as measured in 10-minute perfusate samples from the stalk median eminence. In each animal, multiple samples were obtained. Mean ± SEM. ** $P < .01$; * $P < .05$ versus prepubertal monkeys. *(From Mitsushima D, Hei DL, Terasawa E. *Aminobutyric acid is an inhibitory neurotransmitter restricting the release of luteinizing hormonereleasing hormone before the onset of puberty. Proc Natl Acad Sci USA 1994; 91:395399.*)
Figure 24-39 The yin and the yang of the neuroendocrinology of the prepubertal juvenile pause and its intrinsic central inhibition of the luteinizing hormonereleasing hormone (LHRH) pulse generator and the reversal of this inhibition and termination of the juvenile pause, which leads to the onset of puberty. The GABAergic neuronal network and its neurotransmitter -aminobutyric acid (GABA) constitute the most ubiquitous inhibitory transmitter in the hypothalamus as well as the brain. During the prepubertal juvenile pause, this neurotransmitter system appears to play the major neural role in inhibiting the LHRH pulse generator. (Suppression of GABA inhibition during this period promptly results in reactivation of the suppressed LHRH pulse generator in the rhesus monkey.) With the approach of puberty GABA inhibition of the LHRH pulse generator wanes, and its reactivation gradually occurs. This reactivation is quite likely augmented by stimulatory neurotransmitters (e.g., excitatory amino acids), some of which are dependent on increased gonadal steroids for their activation, and by neurotrophic factors and growth peptides. As a consequence, the amplitude and, to a lesser extent, the frequency of LHRH pulses increase, which, in turn, leads to increased pulsatile secretion of follicle-stimulating hormone (FSH) and LH and the activation of the ovary and testis. As shown experimentally in the monkey, the LHRH pulse generator can function in the absence of hypothalamic stimulatory factors. The nature of and factor or factors responsible for this transition from central inhibition and the postulated dominance of GABA to the release of inhibition and reactivation of the LHRH pulse generator are unknown.
Figure 24-40 Plasma luteinizing hormone (LH) and testosterone sampled every 20 minutes in a 14-year-old boy in pubertal stage 2. The histogram displaying sleep stage sequence is depicted above the period of nocturnal sleep. Sleep stages are rapid eye movement (REM) with stages I to IV shown by depth of line graph. Plasma LH is expressed as mIU/mL. Plasma testosterone is expressed as nanograms per 100 mL. To convert LH values to international units per liter, multiply by 1.0. To convert testosterone values to nanomoles per liter, multiply by 0.03467. (From Boyar RM, Rosenfeld RS, Kapen S, et al. Human puberty: simultaneous augmented secretion of luteinizing hormone and testosterone during sleep. Reproduced from the Journal of Clinical Investigation, 1974, vol. 54, pp. 609618 by copyright permission of the American Society for Clinical Investigation.)
Figure 24-41  Changes in plasma luteinizing hormone (LH) (top) and follicle-stimulating hormone (FSH) (bottom) levels in prepubertal, pubertal, and adult individuals. Note the limited LH response in prepubertal children compared with that of pubertal and adult subjects. The FSH response to LH-releasing hormone (LHRH) is similar in prepubertal, pubertal, or adult males. In females, the FSH response is significantly greater than that of prepubertal, pubertal, or adult males. For conversion to SI units, see the legend of Figure 24-17. (Modified from Grumbach MM, Roth JC, Kaplan SL, et al. Hypothalamic pituitary regulation of puberty in man: evidence and concepts derived from clinical research. In Grumbach MM, Grave GD, Mayer FE [eds]. Control of the Onset of Puberty. New York, John Wiley & Sons, 1974, pp 115166.)
**Figure 24-42** Relation of plasma dehydroepiandrosterone sulfate (DHEAS [DHAS]) to growth of the zona reticularis and increase in adrenal volume with age. **Top,** The close correlation between the development of the zona reticularis and the increase in plasma DHEAS level. **Middle,** The age at which either focal islands of reticular tissue or a continuous reticular zone was found in a series of patients with sudden death who had not had an antecedent illness. **Bottom,** The increase in adrenal volume at the time of puberty. For conversion to SI units, see the legend of **Figure 23-37.** (From Grumbach MM, Richards HE, Conte FA, et al. Clinical disorders of adrenal function and puberty: assessment of the role of the adrenal cortex and abnormal puberty in man and evidence for an ACTH-like pituitary adrenal androgen stimulating hormone. In James VHT, Serio M, Giusti G, et al [eds]. The Endocrine Function of the Human Adrenal Cortex. New York, Academic Press, 1978, pp 583612.)
Figure 24-43 Adrenarche and the zona reticularis. The rise in circulating dehydroepiandrosterone sulfate (DHEAS) is the biochemical hallmark of adrenarche. The diagram compares and contrasts the major steroidogenic pathway in the zona fasciculata with that in the zona reticularis. In contrast to the zona fasciculata, the expression of 3-hydroxysteroid, 4,5-isomerase type 2 messenger ribonucleic acid (mRNA) and its activity (the enzyme that irreversibly traps 5-precursors into 4-steroids) is very low in the zona reticularis, whereas the expression of and activity of steroid sulfotransferase is high. A single gene, CYP17, encodes a single enzyme that has both 17-hydroxylase and 17,20-lyase activity, but the ratio of 17,20-lyase to 17-hydroxylase activity is relatively high in the zona reticularis compared with that in the zona fasciculata. Some of the factors that seem to augment the increased 17,20-lyase activity of CYP17 are the augmented serine phosphorylation of the enzyme and the apparent increased abundance of the electron-donating redox partner, including P450 reductase and of cytochrome b5. (See text.)
Figure 24-44 Hypothesis of the control of pituitary adrenal androgen secretion by a putative separate adrenal androgenstimulating hormone acting on a corticotropin (ACTH)-primed adrenal cortex. Although this diagram suggests that "AASH" arises from the pituitary gland, a distinct pituitary factor with AASH activity has not been isolated; an extrapituitary factor is not excluded. The lower part of the diagram shows the relationship of adrenarche to gonadarche, including dissociation in various clinical disorders of sexual development (+, present; -, absent). (Modified from Sklar CA, Kaplan SL, Grumbach MM. Evidence for dissociation between adrenarche and gonadarche: studies in patients with idiopathic precocious puberty, gonadal dysgenesis, isolated gonadotropin deficiency, and constitutionally delayed puberty. J Clin Endocrinol Metab 1980; 51:548556. © by The Endocrine Society.)
Figure 24-45 A boy 16 years, 2 months of age, with constitutional delay in growth and puberty. Height, 149.5 cm (4 SD below the mean value for age); upper/lower body ratio, 1.1 (retarded for age); phallus, 6.0 × 1.6 cm; testes, 2.5 × 1.4 cm; the scrotum showed early thinning. At a chronologic age of 15 years, 4 months the bone age was 11 years and the sella turcica was normal. The plasma concentration of luteinizing hormone (LH) was 0.7 ng/mL (LER-960); follicle-stimulating hormone (FSH), 0.5 ng/mL (LER-869). On LH-releasing hormone (LHRH) testing the plasma concentration of LH increased to 2.2 ng/mL (an increment of 1.5 ng/mL), and the testosterone level rose from 52 to 77 ng/dL. The testes subsequently spontaneously enlarged, and the patient progressed through puberty. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-46 The various patterns of pulsatile luteinizing hormone (LH) secretion that can occur in isolated hypogonadotropic hypogonadism (B to D) compared with LH secretion in a normal man (A). A, The discrete LH pulses occurring about every 2 hours in a normal 36-year-old man. B, Typical apulsatile LH pattern associated with a low testosterone concentration usually found in isolated hypogonadotropic hypogonadism. C, Pattern of developmental arrest with low-amplitude nocturnal LH pulses apparent only during sleep. D, Low-amplitude LH pulse pattern during sleep and wake periods. To convert LH values to international units per liter, multiply by 1.0. (From Spratt DI, Crowley WF. Hypogonadotropic hypogonadism: GnRH therapy. In Krieger DT, Bardin CW [eds]. Current Therapy in Endocrinology and Metabolism, 19851986. Toronto, BC Decker, 1985, pp 155159.)
Figure 24-47  Craniopharyngioma in a short 5-year-old girl with a history of frontal headaches, impaired vision, and poor growth.  Left, Midline sagittal T1-weighted image that shows a hyperintense region superiorly and an inferior hypointense region. The combination of hyper- and hypointense areas in a noncontrast-enhanced examination is the most characteristic finding in craniopharyngioma. Note erosion of dorsum sellae (solid white arrow) and posterior pituitary bright spot. Right, Coronal-weighted T1 image shows tumor extending upward to the inferior frontal horns, narrowing the foramen of Monro and causing mild hydrocephalus. The open white arrows indicate the upper border of the hyperintense area of the tumor.
Figure 24-48 A girl 18 years, 8 months of age, with isolated gonadotropin deficiency (sexual infantilism and primary amenorrhea). Height was 173 cm (+1 SD), weight was 66.5 kg (+1 SD), and skeletal age was 13 years. Adrenarche with pubic hair development occurred at age 13 ½ years. At the time of the photograph, pubic hair was in stage 3 and there was slight breast and nipple development resulting from a previous short course of estrogen therapy. Immature labia minora and majora were noted, and no estrogen effect was present on the vaginal mucosa. Olfactory testing was normal. The plasma luteinizing hormone (LH) (LER-960) level after LH-releasing hormone (LHRH) administration rose from 0.5 to 1.8 ng/mL (a prepubertal response). Serum estradiol was undetectable. The dehydroepiandrosterone sulfate (DHEAS) level was 92 µg/dL (appropriate for pubic hair stage 2). Note the discrepancy between adrenarche and gonadarche. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-36. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-49 A boy of 15 years, 10 months, with isolated gonadotropin deficiency and anosmia (Kallmann's syndrome). He had undescended testes, but after administration of 10,000 U of human chorionic gonadotropin (hCG) the testes descended and were palpable in the scrotum. Height, 163.9 cm (-1.5 SD); the upper/lower body ratio was 0.86, which is eunuchoid. The phallus measured 6.3 × 1.8 cm, and the testes were 1.2 × 0.8 cm. The concentration of plasma luteinizing hormone (LH) was less than 0.3 ng/mL; of follicle-stimulating hormone (FSH), 1.2 ng/mL; of testosterone, 16 ng/dL. After 100 µg of LH-releasing hormone (LHRH) the plasma LH (LER-960) was 0.7 ng/mL and FSH (LER-869) 2.4 ng/mL. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology; 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-50  Serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to the administration of LH-releasing hormone (LHRH) in 25 males with an isolated gonadotropin deficiency with or without anosmia, segregated according to whether the volume of the testes was prepubertal or greater than 2.5 cm$^3$; testicular volume in those with testes greater than 2.5 cm$^3$ were as large as 4 cm$^3$. Basal and LHRH-stimulated gonadotropin levels after the intravenous injection of 100 µg LHRH (peak value) are shown. *$P < .05$. For conversion to SI units, see the legend of Figure 24-17. (From Van Dop C, Burstein S, Conte FA, et al. Isolated gonadotropin deficiency in boys: clinical characteristics and growth. J Pediatr 1987; 111:684-692.)
Figure 24-51 Comparison of the brain and nasal cavities of a normal 19-week-old male fetus (upper left) and those of a male fetus of similar age with Kallmann's syndrome caused by an X chromosome deletion at Xp22.3 (upper right). In the normal fetal brain the luteinizing hormone-releasing hormone (LHRH) neurosecretory neurons (black dots) are located in the hypothalamic area including the medial basal hypothalamus; the anterior hypothalamic area; and, of interest regarding hypothalamic hamartoma as an ectopic LHRH pulse generator, the pre- and retro-mammillary areas. A small cluster of LHRH neurons is present among the fibers of the terminalis nerve on the floor of the nasal septum. In the male fetus with Kallmann's syndrome, no LHRH neurons were detected in the hypothalamic region including the basal hypothalamus, median eminence, and preoptic area. The LHRH cells fail to migrate to and enter the brain from their origin in the nose; these cells end in a tangle beneath the forebrain on the dorsal surface of the cribriform plate and in the nasal cavity. AC, anterior commissure; CG, crista galli; IN, infundibular nucleus; NT, terminalis nerve; OC, optic chiasm; POA, preoptic area. (Adapted from Schwanzel-Fukuda M, Bick D, Pfaff DW. Luteinizing hormone-releasing hormone (LHRH)-expressing cells do not migrate normally in an inherited hypogonadal (Kallmann) mouse. Mol Brain Res 1989; 6:311-326.) Lower panels show magnetic resonance imaging scans of brain (coronal section, TI-weighted image). Lower left, Normal olfactory sulci (open white arrows) and bulbs (small solid white arrows) in a 15-year-old boy. Lower right, Absent olfactory sulci (open white arrows) and bulbs in a 17-year-old anosmic, sexually infantile boy with Kallmann's syndrome.
A 20-year-old male with idiopathic hypopituitary dwarfism and deficiencies of gonadotropins, thyrotropin, corticotropin, and growth hormone, who had a history of arrested hydrocephalus. Height, 129 cm (-8 SD); the phallus was 2 cm in length, and the testes measured 1.5 × 1 cm. He had received thyroid and glucocorticoid replacement. Basal luteinizing hormone (LH) was less than 0.2 ng/mL (LER-960), follicle-stimulating hormone (FSH) was 0.5 ng/mL (LER-869), and testosterone was less than 0.1 ng/mL. In response to 100 µg of LH-releasing hormone (LHRH), the plasma LH concentration increased slightly to 0.6 ng/mL, and there was no increase in plasma testosterone. The excretion of urinary 17-ketosteroids was 1.1 mg/24 hours. The bone age was 10 years, and the volume of the sella turcica was small on skull radiographs. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-53 47,XXY Klinefelter's syndrome in 17-year-old identical twins. At age 15 gynecomastia was noted. The twins had a eunuchoid habitus and poorly developed male secondary sexual characteristics. Both were 187 cm in height; arm spans were 187 cm and 189.5 cm; the voices were high-pitched; the testes measured 1.8 × 1.5 cm; penis length was 7.5 cm. Gynecomastia and signs of androgen deficiency were more evident in the twin on the left. Urinary gonadotropins, greater than 50 mU/24 hours. The testes exhibited extensive tubular fibrosis, small dysgenetic tubules, and clumping or pseudoadenomatous formation of Leydig cells; germ cells were rare. The microscopic appearance was typical of seminiferous tubule dygenesis. (Patients are described in Grumbach MM, Barr ML. Cytologic tests of chromosome sex in relation to sexual anomalies in man. Recent Prog Horm Res 1958; 14:255324.)
Figure 24-54 Left, A 14 10/12-year-old patient with the typical form of the syndrome of gonadal dysgenesis (Turner's syndrome). The X chromatin pattern was negative, and the karyotype was 45,X. She was short (height 134.5 cm; height age 9 5/12 years) and sexually infantile except for the appearance of sparse pubic hair, and exhibited characteristic stigmata of the syndrome: a short webbed neck, shield-like chest with widely separated nipples, bilateral metacarpal signs, puffiness over the dorsum of the fingers, cubitus valgus, increased number of pigmented nevi, characteristic facies, and low-set ears. The bone age was 13 6/12 years; urinary 17-ketosteroids 5.1 mg/day; urinary gonadotropin greater than 100 mU/day. Vaginal smears and the urocytogram showed an immature pattern in which cornified squamous cells were absent. With estrogen therapy, female secondary sexual characteristics were induced; the cyclic administration resulted in periodic estrogen withdrawal bleeding. Right, A 45,X, 9 11/12-year-old patient with Turner's syndrome. Apart from short stature (height 118 cm; age 6 10/12 years), increased pigmented nevi, and subtle changes in the fingers and toes, she had few somatic anomalies. In contrast to the patient at the left, the main clinical feature was short stature.
Figure 24-55 The evaluation of delayed puberty in boys.
Figure 24-56 The evaluation of delayed puberty in girls.
Figure 24-57 Age at onset of idiopathic true precocious puberty in 106 children. Open bars, female; hatched bars, male. At all ages, the frequency is greater in females than in males. The peak prevalence in girls is between ages 6 and 8 years. (From Kaplan SL, Grumbach MM. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 168. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-58 Left, A boy 2 years, 5 months of age with idiopathic precocious puberty. He had pubic hair and phallic and testicular enlargement by 10 months of age. At 1 year of age, his height was 86 cm (+4 SD); the phallus measured 10 × 3.5 cm, and the testes measured 2.5 × 1.5 cm. Plasma luteinizing hormone (LH) was 1.9 ng/mL (LER-960); follicle-stimulating hormone (FSH) 1.2 ng/mL (LER-869); and testosterone 416 ng/dL. After 100 µg of LH-releasing hormone (LHRH), the plasma LH increased to 8.4 ng/mL and FSH to 1.8 ng/mL, a pubertal response. When photographed, the patient had been treated with medroxyprogesterone acetate for 1.5 years. His height was 95.2 cm (+1 SD), the phallus was 6 × 3 cm, and the testes were 2.4 × 1.3 cm. Basal concentrations of LH (LER-960) were 0.9 ng/mL; FSH (LER-869) 0.8 ng/mL; and testosterone 7 ng/dL. After 100 µg of LHRH, LH concentrations rose to 2.3 ng/mL, whereas FSH concentrations did not change when he was on treatment with medroxyprogesterone acetate. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (Left, From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB, [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.) Right, A 3 3/12-year-old girl with idiopathic true precocious puberty who had recurrent vaginal bleeding since 9 months of age. Height age, 4 5/12 years; bone age, 8 10/12 years.
Figure 24-59  **Left,** Mean basal plasma luteinizing hormone (LH) level (LER-960) and mean peak and increment after intravenous LH-releasing hormone (LHRH) (100 µg) in normal prepubertal and pubertal females and in females with idiopathic true precocious puberty. The mean peak and increments of plasma LH are higher in true precocious puberty than in normal puberty.  **Right,** Basal follicle-stimulating hormone (FSH) level (LER-1364) and mean peak and increment after intravenous LHRH (100 µg) in normal prepubertal and pubertal females with true precocious puberty. The concentration of FSH and the response to LHRH were greater in females with true precocious puberty and normal puberty than in prepubertal females.  (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620-660. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-60  Left, Serial determinations of plasma estradiol in three girls with idiopathic true precocious puberty. Note the striking fluctuations in values.  Right, Serial determinations of plasma testosterone in three boys with true precocious puberty (B.L. and J.C. have a hypothalamic hamartoma; M.D. has the idiopathic form). For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18.  (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620660. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-61 A, A 17-month-old male infant with hamartoma of the tuber cinereum and true precocious puberty. At 8 months of age, secondary sexual development was noted, and the patient was misdiagnosed as having congenital virilizing adrenal hyperplasia. He was treated with glucocorticoids, which slowed his growth but did not affect his sexual development and bone age advancement. When he was first seen at 17 months, height was 84.2 cm; weight was 14.8 kg; the pubic hair stage was stage II; the penis was 10.4 × 2.2 cm; the testes were 1.5 × 2.8 cm; and the scrotum was thinned and rugated. The bone age was 4 3/12 years. After luteinizing hormone-releasing hormone (LHRH) administration, the LH level rose from 0.5 to 3.1 ng/dL (LER-960), the follicle-stimulating hormone (FSH) level from 0.5 to 1.2 ng/mL (LER-869), and the testosterone level from 409 to 450 ng/dL. Dehydroepiandrosterone sulfate (DHEAS) was 17 µg/dL (preadrenarchal value). The patient was treated with a potent long-acting LHRH agonist deslorelin (D-Trp⁶ Pro⁹ NEt-LHRH), which resulted in arrest of his pubertal advancement and a striking decrease in the plasma concentration of testosterone, LH pulses, and the response to exogenous LHRH. B, Computed tomographic scan of the patient, demonstrating a 1.5-cm mass posterior and rostral to the dorsum sella, which depresses the flow of the third ventricle. For conversion to SI units, see the legends of Figure 24-17, Figure 24-18, and Figure 24-36. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SSC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 31384.)
Figure 24-62  **Left,** Magnetic resonance imaging scan demonstrating a hypothalamic hamartoma (solid white arrow) in a 4-year-old boy with true precocious puberty; sagittal T1-weighted image. The posterior pituitary hot spot is designated by the solid black arrow.  **Right,** Computed tomographic brain scan (coronal section) showing an isodense, pedunculated, collar button-shaped hypothalamic hamartoma (arrow) in a 2-year-old girl with true precocious puberty.
Figure 24-63 Pulsatile luteinizing hormone (LH) secretion before and during LH-releasing hormone (LHRH) agonist therapy in a boy (right) and a girl (left) with true precocious puberty secondary to a hypothalamic hamartoma. For conversion to SI units, see the legend of Figure 24-17.
Figure 24-64 A boy of 8 years, 8 months with neurofibromatosis and precocious puberty, secondary to a hypothalamic glioma. He had tonic-clonic seizures at 2½ years and rapid growth starting at 4 years; an enlarged penis and testes and the presence of public hair were first noted at 7½ years. At this time, his height was 139.9 cm (+ 1.4 SD); the phallus was 9 × 3 cm; the right testis measured 5.5 × 3.2 cm and the left measured 5.4 × 2.9 cm. He had stage 3 pubic hair and 24 large café-au-lait spots. Computed tomographic scans and pneumoencephalography revealed a 1.5 × 2.5 cm hypothalamic mass, which was treated with radiation. The plasma concentration of luteinizing hormone (LH) was 0.5 ng/mL (LER-960); follicle-stimulating hormone (FSH) 0.4 ng/mL (LER-869); testosterone 221 ng/dL. After 100 µg of intravenous LH-releasing hormone (LHRH) the peak concentration of LH was 4.9 ng/mL, and that of FSH 1.4 ng/mL, a pubertal response. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-65 Effect of administration of the luteinizing hormonereleasing hormone (LHRH) agonist deslorelin (4 µg/kg/day subcutaneously) on pulsatile secretion of LH (top), LH response to LHRH (middle), and plasma concentration of estradiol (bottom) in a 5 1/12-year-old girl with idiopathic true precocious puberty. This patient, who had a bone age of 13 years when treatment was begun, has been administered deslorelin for 7 years. During this period, the estimated predicted final height increased by 15 cm. Surprisingly, the bone age advanced by only about 6 months on serial examinations for several years. For conversion to SI units, see the legend of Figure 24-17. (Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. Acta Paediatr Jpn 1988; 30[supp]:155175.)
Figure 24-66 Deslorelin treatment (4 µg/kg/day subcutaneously) of girls and boys with true precocious puberty: effect during the first 12 weeks of treatment on the luteinizing hormone (LH) and follicle-stimulating hormone (FSH) response to a challenge with LH-releasing hormone (LHRH) (mean peak response and maximum increment) and on the maximal unstimulated concentration of plasma estradiol in the girls and of plasma testosterone in the boys. Note the relatively rapid change from pubertal values to prepubertal values. For conversion to SI units, see the legends of Figure 24-17 and Figure 24-18. (From Styne DM, Harris DA, Egli CA, et al. Treatment of true precocious puberty with a potent luteinizing hormone releasing factor agonist: effect on growth, sexual maturation, pelvic sonography, and the hypothalamic pituitary gonadal axis. J Clin Endocrinol Metab 1985; 61:142181. © by The Endocrine Society.)
Figure 24-67 A 2 5/12-year-old girl with true precocious puberty after 6 weeks of deslorelin therapy (4 µg/day subcutaneously). Note the regression in the size of the breasts; however, the rapid rate of growth had not decreased. At the end of 1 year of therapy, growth rate was suppressed to 4 cm/year, and bone age advanced only 1 year. CA, chronologic age; HT, height; WT, weight; BA, bone age. (From Styne DM, Grumbach MM. Puberty in the male and female: Its physiology and disorders. In Yen SCC, Jaffe RB [eds]. Reproductive Endocrinology, 2nd ed. Philadelphia, WB Saunders, 1986, pp 313384.)
Figure 24-68 Effect of luteinizing hormonereleasing hormone (LHRH) agonist therapy in true precocious puberty on growth. Left, Changes in mean height velocity (cm/year ± 1 SE) after the initiation of LHRH agonist therapy with DTrp⁶ Pro⁹ Net (LHRH) (filled bars) or with nafarelin (hatched bars). A sharp decrease in height velocity occurred within 1 year. Right, Mean (±1 SE) height for bone age before and during LHRH agonist treatment. The discrepancy between height and the more advanced bone age decreases (reverts to normal) with chronic LHRH agonist treatment. (From Kaplan SL, Grumbach MM. True precocious puberty: treatment with GnRH agonists. In Delemarre-Van de Waal H, Plant TM, van Rees GP, et al [eds]. Control of the Onset of Puberty III. Amsterdam, Elsevier, 1989, pp 357-373.)
**Figure 24-69** A 1 5/12-year-old boy with a human chorionic gonadotropin (hCG)secreting hepatoblastoma. Note the outline of the large liver (left) and the penile enlargement (right). The testes were 2 × 1 cm, and public hair was stage 2. The plasma hCG level was 50 mlU/mL, plasma testosterone 168 ng/dL, and plasma -fetoprotein 160,000 ng/mL. Metastatic lesions in both lungs were seen on the radiograph of the chest. To convert testosterone values to SI units, see the legend of Figure 24-17. To convert hCG values to international units per liter, multiply by 1.0. To convert -fetoprotein values to micrograms per liter, multiply by 1.0. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620660. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-70 Familial testotoxicosis. **Left,** A 5½-year-old boy and his 28-year-old father with the disorder. The boy exhibited signs of sexual precocity by 3 years of age. Height was 130.6 cm (+4.8 SD); bone age 12½ years. The plasma testosterone level was 267 ng/dL; dihydrotestosterone 46 ng/dL; dehydroepiandrostosterone sulfate (DHEAS) 23 µg/dL. The plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels were low, and neither rose after treatment. Pulsatile LH secretion was not demonstrable. Treatment with deslorelin, an LHRH agonist, was without effect. The father had begun sexual maturation by 3 years of age and had reached a final height of 162.6 cm in his early teens. The plasma testosterone level was 294 ng/dL; LH 0.5 ng/mL (LER-960); and FSH 0.5 ng/mL (LER-869). The father had an adult-type LH and FSH response to LHRH; the LH level increased to 7.5 ng/mL, and the FSH level to 2 ng/mL. At least 28 male family members over nine generations are affected. To convert dihydrotestosterone values to nanomoles per liter, multiply by 0.03467. For other conversions to SI units, see the legends of Figure 24-17 and Figure 24-18. **Center,** External genitalia of the 5½-year-old boy. The penis measured 12 × 2.8 cm; the right testis was 4 × 2 cm, and the left testis 3.5 × 2.5 cm. **Right,** Testis of the boy showed Leydig cell maturation without Reinke crystalloids and spermatogenesis (Mallory trichome).
Figure 24-71. A. The serpentine seven transmembrane Gₛ protein coupled hLH/hCG receptor with its large extracellular domain and the intracellular domain. The seven helical transmembrane domains are indicated by Roman numerals. B. The two-dimensional seven-transmembrane topology of the hLH/hCG receptor with positions of constitutively activating mutations causing testotoxicosis (male-limited autosomal dominant sexual precocity). The mutations are indicated by solid circles and the residue number. Note the cluster of mutations in the VI transmembrane helix and third cytoplasmic loop. The aspartine 578→glycine mutation is the most common. (Redrawn from Yano K, Kohn LD, Saji M, et al. A case of male limited precocious puberty caused by a point mutation in the second transmembrane domain of the luteinizing hormone choriogonadotropin receptor gene. Biochem Biophys Res Commun 1996; 220:1036-1042.)
Figure 24-73 A 10/12-year-old girl with recurrent "autonomous" follicular cysts of the ovary. MPA, medroxyprogesterone acetate (oral). For conversion to SI units, see the legend of Figure 24-17. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620-660. © 1990, the Williams & Wilkins Co., Baltimore.)
Figure 24-74  A 7 4/12-year-old girl with luteinizing hormone-releasing hormone (LHRH) independent sexual precocity associated with McCune-Albright syndrome. She had breast development since infancy, and it increased noticeably at about 3 years of age; 6 months later episodes of recurrent vaginal bleeding began. Growth of pubic hair was noted at about 4 to 5 years of age. At age 5 1/12 years the bone age was 6 11/12 years; height was +1 SD above the mean value for age. By 6½ years of age, when she was seen at the University of California, San Francisco, the bone age had advanced to 9 years, and height was at +1 SD. Breasts were at Tanner stage 4; pubic hair at stage 3. Extensive irregular café-au-lait macules cover the right side of the face, left lower abdomen and thigh, and both buttocks. A bone survey showed widespread involvement of the long bones with typical polyostotic fibrous dysplasia, and the floor of the anterior fossa of the skull was sclerotic and the diploetic space widened. She has had two pathologic fractures through bone cysts in the right upper femur. Note the osseous deformities. Plasma estradiol concentrations were consistently in the pubertal range; LH response to LHRH was prepubertal. Results of thyroid function studies were normal, including the thyrotropin response to thyrotropin-releasing hormone administration and antithyroid antibodies were not detected. Treatment with oral medroxyprogesterone acetate suppressed menses and arrested pubertal development but did not slow skeletal maturation. Her final height is 142 cm (-2.5 SD). Menstrual cycles are regular.
Figure 24-75a Bone lesions in McCune-Albright syndrome. A, The skull with severe thickening primarily at the base due to fibrous dysplasia. The auditory and optic nerves could be caught in narrowed foramina but that is not the case in these patients. B and C, distortions of the long bones, which can develop into a "shepherd's crook" appearance; note the multiple bone cysts.
Figure 24-75b D. Bone scan showing the areas of remodeling that "light up" depending upon the area affected in individual patients. There are examples of patients primarily affected in the craniofacial area, in the appendicular area, and in both areas as well as the axial skeleton.  (Courtesy of Michael T. Collins, M.D., National Institutes of Health, Bethesda, Maryland and Sandra Gorges, M.D., University of California, Davis.)
Figure 24-76 Serial pelvic ultrasonograms at 2-week intervals in a 6-year-old girl with McCune-Albright syndrome. Breast development and vaginal bleeding coincided with the enlargement of the ovarian cyst. With the spontaneous regression of the large ovarian cyst, the breasts regressed in size and vaginal bleeding ceased. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In Grumbach MM, Sizonenko PC, Aubert ML [eds]. Control of the Onset of Puberty. Baltimore, Williams & Wilkins, 1990, pp 620660. © 1990, the Williams & Wilkins Co., Baltimore.)
The G protein guanosine triphosphatase (GTPase) cycle. The heterotrimeric guanine nucleotide-binding proteins (G proteins) composed of three subunits (, , ) couple cell-surface receptors consisting of a single serpentine polypeptide having seven helical membrane-spanning domains with an effector, in this instance, adenylate cyclase (AC) that catalyzes the transformation of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). The G protein stimulation subunit , , mediates the stimulation of cAMP generation. In the inactive, unstimulated state, the G protein is a heterotrimer and GDP is tightly bound to the subunit. When the cell-surface receptor is activated by its cognate agonist, the receptor catalyzes the release of the tightly bound GDP, which enables GTP to bind to the subunit. The GTP-bound subunit (-GTP) dissociates from the tightly bound dimer, and both play a role in the G protein activation of the effector, adenylate cyclase. The intrinsic GTPase activity of the subunit ends the stimulation of the effector by converting the bound -GTP to -GDP; as a consequence, the subunit again returns to its inactive state and reassociates with high affinity with the subunit, yielding the , , heterotrimer. Disorders of signal transduction can arise from germ cell or somatic mutations at any of the five stages of the cycle. The gain-of-function, activating somatic mutations in the GNAS1 gene that encodes the G subunit and leads to McCune-Albright syndrome (shown in the bracket), involves the highly conserved arginine 201 residue. These mutations inhibit the intrinsic GTPase activity of the subunit and hence the conversion of the bound GTP to GDP. (See text.) Alanine 366 to serine mutation (shown in the bracket) was detected in two boys, both of whom had pseudohypothyroidism Ia (PHP) and testotoxicosis. The mutant protein was constitutively activated in the Leydig cells at the scrotal temperature (32 to 33°C), leading to testotoxicosis, but was rapidly degraded at body temperature, 37°C, which led to PHP1a. (See text.) (Modified from Spiegel AM. Mutations in G proteins and G protein-coupled receptors in endocrine disease. J Clin Endocrinol Metab 1996; 81:2432–2442.)
Figure 24-78 Left and center, Severe, chronic hypothyroidism of Hashimoto’s thyroiditis in a 7 1/12-year-old girl with sexual precocity (without pubic or axillary hair), episodic vaginal bleeding, and galactorrhea. She had symptoms of hypothyroidism and a sharply decreased rate of growth over the previous 2 years (height, -1 SD; bone age, 5 3/12 years). Breast development was Tanner stage 3; the labia minora were enlarged, and the vaginal mucosa was dull pink, thickened, and rugated with evidence of an estrogenic effect. No acne, seborrhea, or hirsutism was present. The uterus was of adolescent size, and the endometrial mucosa was in a proliferative phase. Urinary gonadotropins were barely detectable by bioassay. Right, Striking change in appearance after 8 months of thyroid hormone treatment. She had grown 7 cm in height and lost 8.1 kg in weight; the breasts had decreased in size, galactorrhea was no longer demonstrable, the labia minora had regressed, and the vaginal mucosa was pink and glistening (no estrogen effect). Ten weeks after the initiation of thyroid hormone replacement therapy, she developed a right slipped capital femoral epiphysis that was repaired surgically; recovery was uneventful.
Figure 24-79 Left. Radiograph of the skull of a patient with hypothyroidism illustrating an enlarged pituitary fossa in the lateral view. The dorsum sellae was thin and demineralized, and the floor had a double contour line. The area of the sella turcica was 150 mm$^2$. Pneumoencephalography showed a suprasellar mass impinging on the cisterna chiasmatica. After thyroid hormone treatment for 8 months, the area of the sella had decreased 30% in volume to 100 mm$^2$, the dorsum sellae had remineralized, and the double floor was no longer evident. Right. Growth curve illustrating the decrease in growth rate despite the sexual precocity and the catch-up growth induced by thyroid hormone therapy. (From Van Wyk JJ, Grumbach MM. Syndrome of precocious menstruation and galactorrhea in juvenile hypothyroidism: an example of hormonal overlap in pituitary feedback. J Pediatr 1960; 57:416435.)
Figure 24-80 The diagnosis of sexual precocity in girls.
Figure 24-81 The evaluation of pubic hair in normal phenotypic girls before 7 years.
Figure 24-82 The diagnosis of sexual precocity in a phenotypic male.
Figure 25-1 During aging, declines in the activities of a number of hormonal systems occur. PRL, prolactin; T<sub>4</sub>, thyroxine; TSH, thyrotropin. Left, A decrease in growth hormone (GH) release by the pituitary gland causes a decrease in the production of insulin-like growth factor I (IGF-I) by the liver and other organs (somatopause). Middle, A decrease in release of gonadotropin luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and decreased secretion at the gonadal level (from the ovaries, decreased estradiol [E<sub>2</sub>] from the testicle, decreased testosterone [T]) cause menopause and andropause, respectively. (Immediately after the initiation of menopause, serum LH and FSH levels increase sharply.) Right, The adrenocortical cells responsible for the production of dehydroepiandrosterone (DHEA) decrease in activity (adrenopause) without clinically evident changes in corticotropin (adrenocorticotropic hormone, ACTH) and cortisol secretion. A central pacemaker in the hypothalamus or higher brain areas (or both) is hypothesized, which together with changes in the peripheral organs (the ovaries, testicles, and adrenal cortex) regulates the aging process of these endocrine axes.
**Figure 25-2** Changes in the hormone levels of normal women (left) and men (right) during the aging process. A and B, Estrogen secretion throughout an individual normal woman’s life (expressed as urinary estrogen excretion) (A) and mean free testosterone (T) index (the ratio of serum total T to sex hormone-binding globulin levels) during the life span of healthy men (B). (From Guyton AC. In Guyton AC [ed]. Textbook of Medical Physiology, 8th ed. Philadelphia, WB Saunders, 1991, pp 899914.) C and D, Serum dehydroepiandrosterone sulfate (DHEAS) concentrations in 114 healthy women (C) and 163 healthy men (D). (Adapted from Ravaglia G, et al. J Clin Endocrinol Metab 1996; 81:11731178.) E and F, The course of serum insulin-like growth factor I (IGF-I) concentrations in 131 healthy women (E) and 223 healthy men (F) during aging. Note the difference in the distribution of ages in the different panels. (Adapted from Corpas E, et al. Endocr Rev 1993; 14:2039.)
Figure 25-3 Effect of raloxifene administration (60 to 120 mg/day) on the cumulative incidence of breast cancer in 7705 postmenopausal women (mean age, 66.5 years) with osteoporosis. Statistical significance of the difference between the groups was $P < .001$. (From Cummings SR, Eckert S, Krueger KA, et al. The effect of raloxifene on risk of breast cancer in postmenopausal women: results from the MORE randomized trial. Multiple Outcomes of Raloxifene Evaluation. JAMA 1999; 281:21892197.)
Figure 25-4 AC. Mean (± standard error) change from baseline in fat mass, lean mass, and bone mineral density of the lumbar spine (L2 to L4) as determined by dual-energy x-ray absorptiometry in 106 men older than 65 years who were treated with either testosterone or placebo (54 men each). The decrease in fat mass (P < .005) and the increase in lean mass (P < .01) in the testosterone-treated subjects were significantly different from those in placebo-treated subjects at 36 months. Bone mineral density increased significantly in both groups. (A and B, from Snyder PJ, et al. J Clin Endocrinol Metab 1999; 84:19661972; C, from Snyder PJ, et al. J Clin Endocrinol Metab 1999; 84:26472653.)
Figure 25-5 Serum total testosterone levels in a group of healthy young (n = 58; aged 21 to 35 years) and older (n = 96; aged 60 to 80 years) men. Mean ± standard deviation. Serum total testosterone is 18.2 ± 4.2 nmol/L (525 ± 122 ng/dL) for the young men and 14.5 ± 4.5 nmol/L (420 ± 12.9 ng/dL) for the older men. (From Tenover JS. Androgen administration to aging men. Endocrinol Metab Clin North Am 1994; 23:877-892.)
Figure 25-6 Human steroidogenic enzymes in peripheral intracrine tissues. DHEA, dehydroepiandrosterone; DHEAS, DHEA sulfate; DHT, dihydrotestosterone; 5-DIOL, androsten-5-ene-3,17-diol; 4-Dione, androstenedione; E₁, estrone; E₂, estradiol; 3-HSD, 3-hydroxysteroid dehydrogenase; 17-HSD, 17-hydroxysteroid dehydrogenase; Testo, testosterone. (Modified and adapted from Labrie F, Luu-The V, Lin SX, et al. Intracrinology: role of the family of 17 beta-hydroxysteroid dehydrogenases in human physiology and disease. J Mol Endocrinol 2000; 25:116.)
Figure 25-7  Percentage of healthy adult men and women who reported an improved sense of well-being after 12 weeks of oral administration of 50 mg of DHEA nightly in comparison with placebo: *** P < .005 compared with placebo values. Scored values of libido on a Visual Analogue Scale in men and women did not change during DHEA administration. (From Morales AJ, Nolan JJ, Nelson JC, et al. Effects of replacement dose of dehydroepiandrosterone in men and women of advancing age. J Clin Endocrinol Metab 1994; 78:13601367.)
Figure 25-8 Knee extension-flexion muscle strength at baseline (100%) and percentage change in response to placebo and DHEA (100 mg/day) in aging men ($n = 8$) and women ($n = 8$), expressed as number of feet. * $P < .05$, placebo versus baseline; ** $P < .05$, DHEA versus placebo. (From Yen SS, Morales AJ, Khorram O. Replacement of DHEA in aging men and women. Potential remedial effects. Ann NY Acad Sci 1995; 774:128142.)
Figure 26-1 Distribution and function of calcium and phosphate. Note the dramatic differences between intracellular and extracellular concentrations of calcium ion and the dramatically different functions of calcium and phosphate inside cells.
Figure 26-2 Parathyroid hormone (PTH)-calcium feedback loop that controls calcium homeostasis. Four organs—the parathyroid glands, intestine, kidney, and bone—together determine the parameters of calcium homeostasis. +, positive effect; -, negative effect.
Figure 26-3 Sequences of pre-parathyroid hormone from six species. Completely conserved residues are in boldface. Arrows indicate the sites of signal sequence ("pre") and "pro" sequence cleavage. Numbers start at residue +1 of mature parathyroid hormone (PTH); because of gaps, the numbers correspond only to the mammalian and not to the chicken sequence. Amino acids are indicated by the single letter code: A, Ala; R, Arg; N, Asn; D, Asp; C, Cys; Q, Gln; E, Glu; G, Gly; H, His; I, Ile; L, Leu; K, Lys; M, Met; F, Phe; P, Pro; S, Ser; T, Thr; W, Trp; Y, Tyr; V, Val.
Figure 26-4 Intracellular processing of pre-proparathyroid hormone (pre-pro-PTH). Diagonal arrows indicate sites of cleavage by enzymes that generate pro-PTH in the rough endoplasmic reticulum (ER), PTH in the Golgi, and carboxy-terminal fragments of PTH in the secretory granule.
Figure 26-5 Parathyroid hormone (PTH) secretion. A, Secretory response of bovine parathyroid glands to induced alterations of plasma calcium concentration. Calves were infused with calcium chloride or ethylenediaminetetraacetic acid (EDTA), and PTH secretion was assessed by measuring PTH levels in the parathyroid venous effluent. The symbols and vertical bars indicate the secretory rate (mean ±SE) in calcium concentration ranges of 1.0 or 0.5 mg/100 mL. The number of calves and samples are indicated, respectively, by numbers below and above the bars. (From Mayer GP, Hurst JG. Sigmoidal relationship between parathyroid hormone secretion rate and plasma calcium concentration in calves. Endocrinology 1978; 10:10371042.) B, Sigmoidal curve generated by the equation \( Y = \frac{[A D]}{[1 + (X/C)^B]} + D \). Such a curve can be defined by four parameters: the maximal secretory rate (A), the slope of the curve at its mid-point (B), the level of calcium at the mid-point (often called the set-point) (C), and the minimal secretory rate (D); the significance of A, B, C, and D is described in the text. (Modified from Brown EM. Four-parameter model of the sigmoidal relationship between parathyroid hormone release and extracellular calcium concentration in normal and abnormal parathyroid tissue. J Clin Endocrinol Metab 1983; 56:572581.) C, Relationships between calcium and PTH levels when each in turn is treated as an independent variable. The dashed line represents the sigmoidal relationship between calcium and PTH, when calcium is the independent variable. This curve is the same as that in A and B, but it is turned on its side, because the axes are reversed. The solid line represents the relationship between calcium and PTH when PTH is considered the independent variable; values for this curve result from measurements made during PTH infusion into parathyroidectomized animals. Actual data are limited; thus, the curves should be viewed as illustrative. (From Parfitt AM. Calcium homeostasis. In Mundy GR, Martin TJ [eds]. Physiology and Pharmacology of Bone. Berlin, Springer-Verlag, 1993.)
Figure 26-6 Structural model of parathyroid cell calcium-sensing receptor predicted from its amino acid sequence. The large amino-terminal domain is extracellular. Conserved residues among the metabotropic glutamate receptors and the bovine parathyroid calcium-sensing receptor are indicated by the symbols noted in the box. Also indicated are potential glycosylation and protein kinase C phosphorylation sites. SP, signal peptide; HS, hydrophobic segment. Missense and chain-terminating mutations identified in patients with either familial hypocalciuric hypercalcemia or familial hypoparathyroidism due to activating mutations of the calcium sensing receptor are indicated as well. (From Brown EM, Bai M, Pollak M. Familial benign hypocalciuric hypercalcemia and other syndromes of altered responsiveness to extracellular calcium. In Krane SM, Avioli LV [eds]. Metabolic Bone Diseases, 3rd ed. San Diego, Academic Press, 1998.)
Figure 26-7 Effects of parathyroid hormone (PTH) on distal tubular calcium transport. PTH acts to increase chloride efflux through channels in the basolateral membrane. As indicated, this increase leads to calcium influx through apical calcium channels. PTH also increases basolateral Ca\(^{2+}\)-Na\(^{+}\) exchange. The apical Na\(^{+}\)-Cl\(^{-}\) cotransporter allows chloride to enter the cell and is the target of thiazide diuretics. Cl\(^{-}\), intracellular chloride. (Adapted from Friedman PA, Gesek FA. Calcium transport in renal epithelial cells. Am J Physiol 1993; 264:F181-F198.)
Figure 26-8 Nomogram for determining renal threshold phosphate concentration ($Tm_{\text{PO}_4}/\text{GFR}$) from the plasma phosphate concentration and the fractional reabsorption of filtered phosphate (TRP) or fractional excretion of filtered phosphate (1TRP, or $C_{\text{PO}_4}/C_{\text{creat}}$). Because the blood level of phosphate influences the renal handling of phosphate, the renal threshold phosphate concentration best separates normal from abnormal renal phosphate handling. C, clearance; creat, creatinine; GFR, glomerular filtration rate; TRP, tubular resorption of phosphate. (From Walton RJ, Bijvoet QLM. Nomogram of derivation of renal threshold phosphate concentration. Lancet 1975; 2:309310.)
Figure 26-9 Osteoblast lineage. All precursors of osteoblasts can proliferate; osteoblasts are transformed to osteocytes and lining cells without further proliferation. Some data suggest that lining cells may revert to osteoblast function after parathyroid hormone stimulation. At each stage in the lineage, apoptotic cell death is probably an alternative fate.
Figure 26-10 Stromal cell control of osteoclastogenesis and osteoclast activity. Parathyroid hormone (PTH) acts on PTH/PTH-related protein (PTHrP) receptors on precursors of osteoblasts to increase the production of macrophage colony-stimulating factor (M-CSF) and RANK ligand and to decrease the production of osteoprotegerin (OPG). M-CSF and RANK ligand stimulate the production of osteoclasts and increase the activity of mature osteoclasts by binding to the receptor RANK. OPG blocks the interaction of RANK ligand and RANK.
Figure 26-11 Parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptors act as nucleotide exchangers. PTH binding to the receptor leads to exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to G subunits. G subunits bound to GTP are released from the receptor and from the subunits and then activate effectors. Gs activates adenylate cyclase, leading to the formation of cyclic AMP (cAMP), which then activates protein kinase A (PKA). Gq and related subunits activate phospholipase C (PLC). PLC hydrolyzes phosphatidylinositol (1,4,5)tris-phosphate to generate diacyl glycerol (DAG) and inositol (1,4,5)tris-phosphate (IP3). The DAG then activates protein kinase C (PKC), and the IP3 activates a receptor on microsomal vesicles that directs the movement of calcium from microsomal vesicles into the cytosol.
Figure 26-12  Network of parathyroid hormone (PTH) ligands and receptors (R). PTH and PTH-related protein (PTHrP) closely resemble each other at the amino-terminal region; TIP39 is more distantly related. Although only the PTH/PTHrP receptor and the PTH2 receptors have been cloned, biologic actions suggest receptors specific for the carboxy-terminal portion of PTH, as well as distinct receptors for the mid-region of PTHrP and for a more distal region of PTHrP. Not shown are possible nuclear sites of action of PTHrP.
Figure 26-13 Interactions between parathyroid hormone (PTH) and the PTH/PTH-related protein (PTHrP) receptor. Key residues involved in PTH/PTH receptor function are indicated (amino acid residues and position numbers correspond to the human PTH/PTHrP receptor sequence): circles, residues identified in crosslinking studies; octagon, a site involved in Blomstrand's chondrodysplasia; ovals, hydrophobic residues important for PTH(134) and PTH(114) binding; triangles, residues mutated in patients with Jansen's chondrodysplasia; hexagons, sites at which the corresponding residues in the PTH2 receptor play a role in discriminating between PTH and PTHrP; squares, residues that determine agonist versus antagonist action of Arg2-PTH(134); diamonds, sites at which mutations impair PTH(134) binding but not PTH(334) binding; rectangles, residues that when mutated alter G protein coupling; and dashed curves with arrows, interdomain interactions as determined by paired mutations affecting PTH(134) interaction (R233 and Q451) or by zinc chelation studies (H307 and R408). (From DeGroot LJ (ed). Endocrinology, 4th ed. Philadelphia, WB Saunders, 2001, p 986.)
Figure 26-14  Sequences of parathyroid hormone-related protein (PTHrP) from five species. Completely conserved residues are in **boldface**; note the high level of conservation through residue 111. Arrows indicate sites of internal cleavage after residues 37 and 95, which lead to generation of PTHrP(3894) amide and PTHrP(3895). Another site of cleavage, generating PTHrP(38101) and, perhaps, PTHrP(107139) is not shown. The three human sequences represent proteins synthesized from alternatively spliced mRNAs and differ only after residue 139. Amino acids are indicated by the single letter code; see legend to Figure 26-3 for code.
Figure 26-15 The amino acid sequences of calcitonin, calcitonin generelated peptide (CGRP), and amylin and adrenomedullin (ADM) from selected species. The bold Cs represent the cysteine residues that form the disulfide linkages critical for the secondary structure of these peptides. The other residues conserved among species are indicated by a dashed line. See the legend to Figure 26-3 for the single-letter amino acid codes.
Figure 26-16 Tissue-specific expression of the calcitonin gene. Splicing of alternative exons leads to two different messenger RNAs (mRNAs). The mRNA encoding calcitonin is found predominantly in the thyroid C cell; the mRNA encoding calcitonin gene related-peptide (CGRP) is found predominantly in the hypothalamus and other nervous tissue. (From Amara SG, Jonas V, Rosenfeld MG, et al. Alternative RNA processing in calcitonin gene expression generates mRNAs encoding different polypeptide products. Nature 1982; 298:240-244.)
Figure 26-17  Vitamin D precursors and alternative reaction products. The numbering system for vitamin D carbons and the distinct structures of vitamin D$_2$ (ergocalciferol) and D$_3$ (cholecalciferol) are noted, as is the structure of dihydrotachysterol, a synthetic product not produced in vivo. Note that the 3-hydroxyl group of dihydrotachysterol is in a pseudo 1-hydroxyl configuration. This may explain the relatively high potency of dihydrotachysterol in conditions associated with low 1-hydroxylase activity.
Figure 26-18 Relative potency of analogues of 1,25(OH)₂D₃ (1,25-dihydroxyvitamin D₃) in competitive binding to vitamin D receptors of chick intestinal mucosa. Slopes, are plotted for (left to right): 1,25(OH)₂-D₃, 1,25-dihydroxyvitamin D₃, 3 deoxy-1,25(OH)₂D₃, 3 deoxy-1,25-dihydroxyvitamin D₃, 25-OH-DHT, 25-hydroxydihydrotachysterol, 25-OH-5,6-trans-D₃, 25-hydroxy-5,6 transvitamin D₃, 25-OH-D₃, 25-hydroxyvitamin D₃, 1--OH-D₃, 1--hydroxyvitamin D₃; 24,25-OH₂-D₃, 24,25-dihydroxyvitamin D₃; 3-deoxy-1-OH-D₃, 3-deoxy-1-hydroxyvitamin D₃; D₃, vitamin D₃; DHT, dihydrotachysterol. (From Proscai DA, Okamura WH, Norman AW. Structural requirements for the interaction of 1,25-(OH)₂vitamin D₃ with its chick intestinal system. J Biol Chem 1975; 250:8382-8388.)
Figure 26-19 Transcriptional activation by 1,25-dihydroxyvitamin D₃ (1,25(OH)₂ D₃). A heterodimer of retinoid X receptor (RXR) and vitamin D receptor (VDR) binds to a pair of hexameric sequences separated by three intervening bases (ATG). Arrows indicate that the hexamers found in the up-regulated rat osteocalcin gene are variants of a consensus sequence, repeated here with identical orientations (direct repeats). Upon binding to DNA, the RXR-VDR heterodimer facilitates formation of a transcription initiation complex, which binds to DNA at and near the TATA sequence.
Figure 26-20 Homeostatic responses to variations in dietary calcium content. Major homeostatic responses to dietary calcium deprivation or loading are depicted. Arrow thickness indicates relative activity of transport or secretory mechanisms, whereas amounts of hormones or transported ions are related to the size of their notations. Parentheses indicate an inhibitory regulation. Note that the extracellular calcium concentration is well maintained, although different underlying mechanisms are involved in the two circumstances (see text for details).
Figure 26-21 Intact immunoreactive parathyroid hormone (PTH) determined using a two-site immunoradiometric assay in normal and three different patient groups. Note some overlap between normal people and patients with primary hyperparathyroidism, but no overlap between hypercalcemic patients with primary hyperparathyroidism and those with hypercalcemia of malignancy. (From Segre GV. Advances in techniques for measurement of parathyroid hormone: current applications in clinical medicine and directions for future research. Trends Endocrinol Metab 1990; 1:243-247.)
Figure 26-22 Plasma PTHrP(174) determined by two-site immunoradiometric assay in selected patient groups and normals. Also shown are concentrations of PTHrP in human milk (filled circles) and in bovine milk (open circles). Two normocalcemic patients with cancer (filled triangles) subsequently became hypercalcemic. Hatched area denotes levels too low to detect with this assay. PTHrP, parathyroid hormone-related protein. (Adapted from Burtis WJ, Brady TG, Orloff JJ, et al. Immunochemical characterization of circulating parathyroid hormone-related protein in patients with humoral hypercalcemia of cancer. N Engl J Med 1990; 322:11061112.)
Figure 26-23 Radiograph of hand from a patient with severe primary hyperparathyroidism. Note the dramatic remodeling associated with the intense region of high bone turnover in the third metacarpal in addition to widespread evidence of subperiosteal, endosteal, and trabecular resorption.  (Courtesy of Fuller Albright Collection, Massachusetts General Hospital.)
Figure 26-24 Iliac crest biopsy specimens from a patient with primary hyperparathyroidism (left) and a normal control (right), viewed by scanning electron microscopy. Note the thin cortices and contrasting maintenance of trabecular bone in the patient. (From Parisien M, Silverberg SJ, Shane E, et al. The histomorphometry of bone in primary hyperparathyroidism: preservation of cancellous bone structure. J Clin Endocrinol Metab 1990; 70:330938.)
Figure 26-25 Abnormal patterns of parathyroid hormone (PTH) secretion from cells prepared from adenomatous glands and stimulated with varying levels of calcium in tissue culture. The shaded area shows the pattern of PTH release (±1 SD) from normal human parathyroid cells. Panel A illustrates the pattern from four patients with little suppression of PTH secretion by calcium. Panel B illustrates the pattern from four patients with relatively intact mechanism of suppression of PTH secretion by calcium. Even in this group the set-point for calcium suppression is shifted to the right. (From Brown, EM. Calcium-regulated parathyroid hormone release in primary hyperparathyroidism, studies in vitro with dispersed parathyroid cells. Am J Med 1979; 66:923931.)
**Figure 26-26** Sites of ectopic location of 104 parathyroid glands found at reoperation for primary hyperparathyroidism.  *(From Wang C-A. A clinical and pathological study of 112 cases. Ann Surg 1977; 186:140145.)*
Figure 26-27  Technetium Tc 99m sestamibi $^{123}$I subtraction scanning of a patient with persistent hyperparathyroidism after two previous unsuccessful operations. Arrow points to parathyroid adenoma, shown as increased tracer uptake in the aortopulmonary window. (From Thule P, Thakore K, Vansant J, et al. Preoperative localization of parathyroid tissue with technetium-99m sestamibi $^{123}$I subtraction scanning. J Clin Endocrinol Metab 1994; 78:7782.)
Figure 26-28 Index of urinary excretion rate for calcium as a function of creatinine clearance. Each point represents the mean of multiple determinations for a hypercalcemic patient with familial hypocalcic hypercalcemia (filled circles) or with typical primary hyperparathyroidism (open circles). The data are based on average 24-hour urinary excretion values and average fasting serum samples. (From Marx SJ, Attie MF, Levine M, et al. The hypocalcic or benign variant of familial hypercalcemia: clinical and biochemical features in fifteen kindreds. Medicine 1981; 60:397-412.)
Figure 26-29 A patient with Jansen's metaphyseal chondrodysplasia at ages 5 years and 22 years. Note the short stature, characteristic facies, and misshapen metaphyseal region of long bones. (From Frame B, Poznanski AK. Conditions that may be confused with rickets. In DeLuca HF and Anastas CS (eds). Pediatric Diseases Related to Calcium. New York, Elsevier, 1980, pp 269289.)

Figure 26-33 Daughter (left) and mother (right) with pseudohypoparathyroidism and Albright's hereditary osteodystrophy.
**Figure 26-34** Radiograph of hand from a patient with pseudohypoparathyroidism and Albright's hereditary osteodystrophy. Note the shortened fourth metacarpal.
**Figure 27-2** Synthesis and assembly of collagen fibrils. A, Intracellular post-translational modifications of pro alpha chains, association of propeptide domains, and folding into triple-helical conformation. Gal, galactose; Glc, glucose; Glc Nac, N-acetylglucosamine; (Man)n, mannose. B, Enzymatic cleavage of procollagen to collagen, self-assembly of collagen monomers into fibrils, and cross-linking of fibrils. (Modified from Prockop DJ, Kivirikko K. Heritable diseases of collagen. N Engl J Med 1984; 311:376386.)
Figure 27-3 The staggered arrangement of individual molecules in collagen fibers results in hole zones between the head of one molecule and the tail of the next. Mineral deposition (bottom) begins within the hole zones. (From Glimcher MJ, Krane SM. Treatise on Collagen 2, part B. New York, Academic Press, 1968, pp 672-5.)
Figure 27-4 Electron micrograph of rat calvarial bone showing mature osteoblasts with their dense, rough endoplasmic reticulum and large Golgi apparatus (a); an osteocyte embedded in the bone (b); and a less differentiated cell that may represent a preosteoblast (c). (Courtesy of Dr. Marijke E. Holtrop.)
**Figure 27-5** A. Cross-section of an osteon. B. Cultured cells from avian bone, showing osteocytes and their cytoplasmic connections. (From Aarden EM, Burger EH, Nijweide PJ. Function of osteocytes and bone. J Cell Biochem 1994; 55:287299. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)
Figure 27-6 Osteoclast formation. Osteoclasts form from osteoclast precursor cells, which are derived from hematopoietic lineage cells. These express C-FMS (the receptor for M-CSF) and RANK and attach to stromal/osteoblastic cells, which express M-CSF (both membrane-bound and soluble), membrane-bound RANKL, and OPG under the influence of stimulators of resorption (PTH, 1,25-Vit D, IL-1, TNF, IL-6, IL-11, or prostaglandins [PG]). If stromal or osteoblastic cells produce more RANKL than OPG, osteoclasts are formed and activated, which increases bone resorption. If stromal or osteoblastic cells produce more OPG than RANKL, OPG binds the available RANKL and new osteoclast formation is prevented. During states of inflammation, T lymphocytes are activated and produce both membrane-bound and soluble RANKL, which can, in turn, stimulate osteoclast-mediated bone resorption. It has also been shown that IL-1 and TNF can augment the effects of RANKL and M-CSF on osteoclast formation and bone resorption by directly stimulating osteoclast precursor cells and mature osteoclasts. IL, interleukin; M-CSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; PTH, parathyroid hormone; RANK, receptor activator of nuclear factor B; RANKL, RANK ligand; TNF, tumor necrosis factor; 1,25 Vit D, 1,25-dihydroxyvitamin D.
Figure 27-7 Functional elements of the fully differentiated osteoclast. (From Suda T, Takahashi N, Martin T.J. Modulation of osteoclast differentiation. Endocr Rev 1992; 13:6680. Copyright © 1992, by The Endocrine Society.)
Figure 27-8 Stages of bone remodeling. The resorptive, reversal, and formative phases of bone remodeling and a completed bone structural unit (BSU) on a trabecular surface are illustrated. The morphologic features of the activation step have not been defined. (Courtesy of Dr. Robert E. Schenk, University of Berne, Switzerland.)
Figure 27-9 Three-dimensional reconstruction of the remodeling sequence in human trabecular bone. 1, Early bone resorption with osteoclasts (OCL); 2, late bone resorption with mononuclear cells (MON); 3, reversal phase with preosteoblasts (POB); 4, early matrix formation by osteoblasts (OB); 5, late bone formation with mineralization; 6, completed remodeling cycle with reversion to lining cells. (From Eriksen EF. Normal and pathological remodeling of human trabecular bone: three-dimensional reconstruction of the remodeling sequence in normals and in metabolic bone disease. Endocr Rev 1986; 7:379408. Copyright © 1986, by The Endocrine Society.)
Figure 27-10 Use of dual-energy x-ray absorptiometry for vertebral body morphometry. Posterior vertebral body heights and the ratio of anterior to posterior (A/P) height are presented in terms of standard deviation scores. Note that minor anterior wedging alone may not indicate an osteoporotic fracture. (Courtesy of Dr. Richard B. Mazess.)
Collagen cross-links. Cross-links are formed between the COOH-terminal and NH₂-terminal nonhelical portions of collagen and adjacent helical molecules. Immunoassays are available for the pyridinoline and deoxypyridinoline molecules themselves and for the adjacent nonhelical peptides. (Redrawn from Eyre DR. The specificity of collagen cross-links as markers of bone and connective tissue degradation. Acta Orthop Scand 1995; 66:16170.)
Figure 27-12  Tetracycline labels sites of active mineralization and is deposited at the calcification front (Cf) (top). A double-label technique can be used to measure the rate of mineralization; label A was administered about 10 days before label B (bottom). Undecalcified iliac crest, ultraviolet light, ×113. (From Aaron J. Histology and microanatomy of bone. In Nordin BEC [ed]. Calcium, Phosphate and Magnesium Metabolism. Edinburgh, Churchill Livingstone, 1976, pp 298356.)
Figure 27-13 Estimation of the current prevalence of osteoporosis in the United States. On the basis of World Health Organization criteria, more than 9 million women in the United States have osteoporosis; more than half of these women have established osteoporosis with fractures. In addition, 17 million postmenopausal women have osteopenia (low bone mass) and are at risk for development of osteoporosis. (From Melton LJ. How many women have osteoporosis now? J Bone Miner Res 1995; 10:175177.)

Figure 29-4 Relationship between body mass index (A) or intra-abdominal fat (B) and insulin sensitivity. (A, From Fujimoto WY, Bergstrom RW, Boyko EJ, et al. Obesity Res 1995; Suppl 2:17951863; B, from Kahn SE, Pigeon RL, McCulloch DK, et al. Quantification of the relationship between insulin sensitivity and beta-cell function in human subjects: evidence for a hyperbolic function. Diabetes 1993; 42:16631672.)
Figure 29-5  Tissue uptake of glucose in nondiabetic and insulin-resistant diabetic subjects during a hyperinsulinemic-euglycemic clamp. (From DeFronzo RA. Lilly lecture 1987. The triumvirate: beta-cell, muscle, liver. A collusion responsible for NIDDM. Diabetes 1988; 37:667-687.)
Figure 29-6  Simplified schematic diagram demonstrating fatty acid (FA) uptake, activation (formation of FAcoenzyme A [CoA]), and intracellular transport to different organelles within a muscle cell. IMTG, intramuscular triglyceride; PG, prostaglandin; PL, phospholipid; SL, sphingolipid.
Figure 29-7  Glucose effect on triglyceride metabolism. Increased uptake of glucose results in an increase in the production of acetyl coenzyme A (CoA) as a product of glycolysis. The increased tricarboxylic acid (TCA) cycle activity associated with oxidation of both triglycerides and glucose increases the production of citrate, which is shuttled to the cytoplasm, activates the enzyme acetyl-CoA carboxylase (ACC) by allosteric mechanisms, and increases the susceptibility of ACC to phosphatases. This leads to increased ACC activity converting acetyl CoA to malonyl CoA. Malonyl CoA is a potent inhibitor of carnitine palmitoyltransferase I (CPT-I) on the outer mitochondrial membrane, which leads to accumulation of fatty acyl CoAs in the cytoplasm. This can result in the production of signaling molecules that can increase the activity of kinases and other enzymes and lead to insulin resistance.
Figure 29-9 Insulin resistance and dyslipidemia. The suppression of lipoprotein lipase and very-low-density lipoprotein (VLDL) production by insulin is defective in insulin resistance, leading to increased free fatty acid (FFA) flux to the liver, and increased VLDL production, which results in increased circulating triglyceride concentrations. The triglycerides are transferred to low-density lipoprotein (LDL) and high-density lipoprotein (HDL) and the VLDL particle gains cholesterol esters by the action of the cholesterol ester transfer protein (CETP). This leads to increased catabolism of HDL particles by the liver and loss of apolipoprotein A (ApoA), resulting in low HDL concentrations. The triglyceride-rich LDL particle is stripped of the triglycerides, resulting in the accumulation of atherogenic small, dense LDL particles.
Figure 29-10 Insulin suppresses hepatic glucose production by direct and indirect mechanisms. In insulin resistance, insulin's ability to suppress lipolysis in adipose tissue and glucagon secretion by alpha cells in the islet results in increased gluconeogenesis. In addition, insulin inhibition of glycogenolysis is impaired. Thus, both hepatic and peripheral insulin resistance results in abnormal glucose production by the liver.
Figure 29-11 Relationship between fasting hepatic glucose output and fasting plasma glucose levels. Open squares represent nondiabetic control subjects; closed squares represent diabetic subjects. (From Maggs DG, Buchanan TA, Burant CF, et al. Metabolic effects of troglitazone monotherapy in type 2 diabetes mellitus: a randomized, double-blind, placebo-controlled trial. Ann Intern Med 1998; 128:176185.)
Figure 29-12 Mean 24-hour profiles of plasma concentrations of glucose, C peptide, and insulin in normal and obese subjects. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. J Clin Invest 1988; 81:442448.)
Figure 29-13 Mean 24-hour profiles of insulin secretion rates in normal and obese subjects (top). The hatched areas represent ± 1 standard error of the mean. The curves in the lower panel were derived by dividing the insulin secretion rate measured in each subject by the basal secretion rate derived in the same subject. Mean data for the normal (dashed line) and obese (solid line) subjects are shown. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. J Clin Invest 1988; 81:442448.)
Figure 29-14 Patterns of insulin secretion in normal and obese subjects. Four representative 24-hour profiles from two normal-weight subjects (left) and two obese subjects (right). Meals were consumed at 0900, 1300, and 1800 hours. Statistically significant pulses of secretion are shown by the arrows. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. J Clin Invest 1988; 81:442448.)
Figure 29-15 Plasma insulin concentrations (A) and insulin secretion rates (B) in response to molar increments in the plasma glucose concentration during the graded glucose infusion in the insulin-resistant (dotted line) and insulin-sensitive (solid line) groups. (From Jones CNO, Pei D, Staris P, et al: Alterations in the glucose-stimulated insulin secretory dose-response curve and in insulin clearance in nondiabetic insulin-resistant individuals. J Clin Endocrinol Metab 1997; 82:1834-1838.)
Figure 29-16 Dose-response relationship between glucose and insulin secretory rate (ISR) after an overnight fast in control subjects (CON), normoglycemic subjects with a family history of noninsulin dependent diabetes mellitus (FDR), subjects with a nondiagnostic OGTT (NDX), subjects with impaired glucose tolerance (IGT), and subjects with noninsulin-dependent diabetes mellitus (NIDDM). BME, body mass index. (From Byrne MM, Sturis J, Sobel RJ, Polonsky KS. Elevated plasma glucose 2 h postchallenge predicts defects in beta-cell function. Am J Physiol 1996; 270:E572-E579. The American Physiological Society, copyright 1996.)
Figure 29-17 Oscillatory glucose infusions were administered with a periodicity of 144 minutes in representative subjects with type 2 diabetes, impaired glucose tolerance (IGT), and normal glucose tolerance. In the control subject, the insulin secretion rate (ISR) adjusts and responds to the 144-minute oscillations in glucose, resulting in sharp spectral peak at 144 minutes. In the subjects with IGT and type 2 diabetes, the ISR does not respond to the oscillatory glucose stimulus and although oscillations in insulin secretion are evident, they are irregular, resulting in markedly reduced spectral peaks at 144 minutes and small-amplitude high-frequency spectral peaks. (Adapted from O’Meara NM, Sturis J, Van Cauter E, Polonsky KS. Lack of control by glucose of ultradian insulin secretory oscillations in impaired glucose tolerance and in noninsulin-dependent diabetes mellitus. J Clin Invest 1993; 92:262271.)
**Figure 29-18** Mean (± standard error of the mean [SEM]) rates of insulin secretion in type 2 diabetic patients compared with control subjects. The *shaded area* corresponds to 1 SEM above and below the mean in control subjects. The curves in the lower panel were derived by dividing, for each subject, the insulin secretion rate at each sampling time by the average fasting secretion rate measured between 6 AM and 9 AM in the same subject.
Figure 29-19 Temporal variations in postbreakfast, postlunch, and postdinner rates of insulin secretion in control and diabetic subjects. In each subject, the secretion rates during the 30 minutes before the meal and the 4 hours after breakfast or the 5 hours after lunch or dinner were expressed as a percentage of the mean rate of insulin secretion during that interval. The curves were obtained by concatenating the resulting postmeal profiles in eight representative subjects. The times at which the meals were served to successive subjects in the series are indicated by arrows. (From Polonsky KS, Given BD, Hirsch LJ, et al. Abnormal patterns of insulin secretion in noninsulin-dependent diabetes mellitus. N Engl J Med 1988; 318:1231-1239.)
**Figure 29-20** Treatment algorithm for type 2 diabetes. FPG, fasting plasma glucose; PPG, postprandial plasma glucose.
Figure 30-1 Progression to diabetes of initially discordant monozygotic twins of patients with type 1 diabetes subdivided by the age of diabetes onset of the first twin to develop diabetes (proband). Late progression to diabetes is evident, with some twins becoming diabetic more than 20 years after their twin mate. For discordant twins whose twin mate developed diabetes after age 25, the risk of diabetes is less than 10%. (From Redondo MJ, Yu L, Hawa M, et al. Heterogeneity of type 1 diabetes: analysis of monozygotic twins in Great Britain and the United States. Diabetologia 2001; 44:354-362.)
Figure 30-2 Genes within the human leukocyte antigen (HLA) region (major histocompatibility complex) with HLA class I, class II, and class III regions illustrated. Each class II molecule is made up of two chains. DRB alleles are polymorphic; DRA does not vary. DQA and DQB molecules are both polymorphic. DPA and DPB are both also polymorphic. The class III region contains important genes such as complement components as well as the tumor necrosis factor gene. The class I region includes MIC-A and MIC-B genes as well as the classical histocompatibility HLA genes, A, B, and C.
Figure 30-4 Progression to type 1 diabetes of first-degree relatives of patients with diabetes subdivided by the number of anti-islet autoantibodies of insulin, GAD65 (glutamic acid decarboxylase), and ICA512 (IA-2) expressed. (From Verge CF, Gianani R, Kawasaki E, et al. Prediction of type 1 diabetes in first-degree relatives using a combination of insulin, GAD, and ICA512 bdc/IA-2 autoantibodies. Diabetes 45:926933, 1996.)
**Figure 31-1** Relative risks for the development of diabetic complications at different levels of mean hemoglobin A₁c (HbA₁c, glycated hemoglobin), obtained from the Diabetes Control and Complications Trial. *(Adapted from Skyler J: Diabetic complications: the importance of glucose control. Endocrinoel Metab Clin North Am 1996; 25:243254.)*
Figure 31-2 Lack of down-regulation of glucose transport in cells affected by diabetic complications. **Upper**, 2-deoxyglucose (2DG) uptake in vascular smooth muscle cells preexposed to either 1.2, 5.5, or 22 mM glucose. **Lower**, 2DG uptake in bovine endothelial cells preexposed to either 1.2, 5.5, or 22 mM glucose. (From Kaiser N, Feener EP, Boukobza-Vardi N, et al. Differential regulation of glucose transport and transporters by glucose in vascular endothelial and smooth muscle cells. Diabetes 1993; 42:8089.)
Figure 31-3 Overexpression of GLUT1 in mesangial cells cultured in normal glucose mimics the diabetic phenotype. Mesangial cells transfected with either LacZ (MCLacZ)- or GLUT1 (MCGLT)-expressing constructs were cultured in 5-mM glucose, and the amount of the indicated matrix components secreted was determined. (From Heilig CW, Concepcion LA, Riser BL, et al. Overexpression of glucose transporters in rat mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype. J Clin Invest 1995; 96:1802-1814.)
Figure 31-4 Development of retinopathy during posthyperglycemic normoglycemia ("hyperglycemic memory"). Quantitation of retinal microaneurysms and acellular capillaries in normal dogs, dogs with poor glycemic control for 5 years, dogs with good glycemic control for 5 years, dogs with poor glycemic control for 2.5 years (PGa), and the same dogs after a subsequent 2.5 years of good glycemic control (PGb). (Adapted from Engerman RL, Kern TS. Progression of incipient diabetic retinopathy during good glycemic control. Diabetes 1987; 36:808-812.)
**Figure 31-5** Cumulative incidence of further progression of retinopathy 4 years after the end of the Diabetes Control and Complications Trial. Median glycosylated hemoglobin was 8.2% for the conventional therapy group and 7.9% for the intensive therapy group. EDIC, Epidemiology of Diabetes Interventions and Complications [Research Group]. (From Retinopathy and nephropathy in patients with type 1 diabetes four years after a trial of intensive therapy. The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group. N Engl J Med 2000; 342:381389.)
Figure 31-7 Adjusted death rates by number of cardiovascular disease (CVD) risk factors for diabetic and nondiabetic men. Subjects are participants from the Multiple Risk Factor Intervention Trial (MRFIT) study; risk factors are hypercho-esterolemia, hypertension, and cigarette smoking. (From Stamler J, Vaccaro O, Neaton JD, Wentworth D. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. Diabetes Care 1993; 2:434444.)
Figure 31-9 Schematic summary relating insulin resistance (IR) to the characteristic dyslipidemia of type 2 diabetes mellitus. IR at the adipocyte results in increased free fatty acid (FFA) release. Increased FFA flux stimulates very-low-density lipoprotein (VLDL) secretion, causing hypertriglyceridemia (TG). VLDL stimulates a reciprocal exchange of TG to cholesteryl ester (CE) from both high-density lipoprotein (HDL) and low-density lipoprotein (LDL), catalyzed by CE transfer protein (CETP). TG-enriched HDL dissociates from ApoA-I, leaving less HDL for reverse cholesterol transport. TG-enriched LDL serves as a substrate for lipases that convert it to atherogenic small, dense LDL particles (SD LDL). (From Ginsberg HN. Insulin resistance and cardiovascular disease. J Clin Invest 2000; 106:453458.)
Figure 31-10 Aldose reductase and the polyol pathway. Aldose reductase reduces reactive oxygen species (ROS)-generated toxic aldehydes to inactive alcohols, and glucose to sorbitol, using triphosphopyridine nucleotide, reduced form of NADP (NADPH) as a cofactor. In cells where aldose reductase activity is sufficient to deplete reduced glutathione (GSH), oxidative stress would be augmented. Sorbitol dehydrogenase (SDH) oxidizes sorbitol to fructose using nicotinamide-adenine dinucleotide (NAD⁺) as a cofactor. GSSG, oxidized glutathione.
Figure 31-11  Potential pathways leading to the formation of advanced glycation end product (AGE) from intracellular dicarbonyl precursors. Glyoxal arises from the auto-oxidation of glucose, 3-deoxyglucosone arises from decomposition of the Amadori product, and methylglyoxal arises from fragmentation of glyceraldehyde 3-phosphate. These reactive dicarbonyls react with amino groups of proteins to form AGEs. Methylglyoxal and glyoxal are detoxified by the glyoxalase system.

Figure 31-12 Potential mechanisms by which intracellular production of advanced glycation end-product (AGE) precursors damages vascular cells. First, intracellular protein modification alters protein function. Second, extracellular matrix modified by AGE precursors has abnormal functional properties. Third, plasma proteins modified by AGE precursors bind to AGE receptors on adjacent cells such as macrophages, thereby inducing receptor-mediated production of deleterious gene products such as cytokines. mRNA, messenger RNA; NFB, neurotropic factor-B; ROS, reactive oxygen species. (Adapted from Brownlee M. Lilly Lecture 1993: Glycation and Diabetic Complications. Diabetes 1994; 43:836841.)
Figure 31-14 Schematic representation of the hexosamine pathway. The glycolytic intermediate fructose-6-phosphate (Fru-6-P) is converted to glucosamine-6-phosphate (Glc-6-P) by the enzyme glutamine:fructose 6-phosphate amidotransferase (GFAT). Increased donation of N-Acetylglucosamine moieties to serine and threonine residues of transcription factors such as Sp1 increases production of such complication-promoting factors as PAI-1 and TGF-β. See text for additional abbreviations. (Adapted from Du XL, Edelstein D, Rossetti L, et al. Hyperglycemia-induced mitochondrial superoxide overproduction activates the hexosamine pathway and induces plasminogen activator inhibitor-1 expression by increasing Sp1 glycosylation. Proc Natl Acad Sci USA 2000; 97:12222-12226.)
Figure 31-15 Production of superoxide by the mitochondrial electron transport chain. Increased hyperglycemia-derived electron donors from the tricarboxylic acid cycle (NADH and FADH$_2$) generate a high mitochondrial membrane potential ($\mu$H$^+$) by pumping protons across the mitochondrial inner membrane. This inhibits electron transport at complex III and increases the half-life of free radical intermediates of coenzyme Q, which reduce O$_2$ to superoxide. See text for abbreviations. (From Boss O, Hagen T, Lowell BB. Uncoupling proteins 2 and 3: potential regulators of mitochondrial energy metabolism. Diabetes 2000; 49:143156.)
Figure 31-16  Effect of agents that alter mitochondrial electron transport chain function on the three main pathways of hyperglycemic damage.  A, Hyperglycemia-induced protein kinase C (PKC) activation.  B, Intracellular advanced glycation end-product (AGE) formation.  C, Sorbitol accumulation. Cells were incubated in 5-mM glucose, 30-mM glucose alone, and 30-mM glucose plus either agents that uncouple oxidative phosphorylation and reduce the high mitochondrial membrane potential (TTFA, CCCP, UCP-1), or dismutate superoxide (Mn-SOD). See text for additional abbreviations. (From Nishikawa T, Edelstein D, Du XL, et al. Normalizing mitochondrial superoxide production blocks three pathways of hyperglycaemic damage. Nature 2000; 404:787-790.)
Figure 31-17 Potential mechanism by which hyperglycemia-induced mitochondrial superoxide overproduction activates four pathways of hyperglycemic damage. Excess superoxide partially inhibits the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase, thereby diverting upstream metabolites from glycolysis into pathways of glucose overutilization. This results in increased flux of triose phosphate to diacylglycerol (DAG), an activator of protein kinase C (PKC), and to methylglyoxal, the major intracellular advanced glycation end-product (AGE) precursor. Increased flux of fructose-6-phosphate to UDP- N-acetylglucosamine increases modification of proteins by hexosamine, and increased glucose flux through the polyol pathway consumes NADPH and depletes GSH. See text for additional abbreviations.
Figure 31-18 Diabetic retinopathy pathogenesis flow chart. The schematic flow chart represents the major preclinical and clinical findings associated with the full spectrum of diabetic retinopathy and macular edema. VEGF, vascular endothelial growth factor.
Figure 31-20 Major multicenter clinical trials of diabetic retinopathy. Schematic representation of the major multicenter clinical trials of diabetic retinopathy and the levels of diabetic retinopathy that they primarily addressed. DCCT, Diabetes Control and Complications Trial; DRS, Diabetic Retinopathy Study; DRVS, Diabetic Retinopathy Vitrectomy Study; ETDRS, Early Treatment Diabetic Retinopathy Study; PDR, proliferative diabetic retinopathy.
Figure 31-21 Initial ophthalmic examination flow chart. Schematic flow chart of major principles involved in determining the timing of initial ophthalmic examination following diagnosis of diabetes mellitus. These are maximal recommended guidelines. Ocular symptoms, complaints, or other associated medical issues may necessitate earlier evaluation.
Figure 31-22 Diabetic retinopathy and macular edema examination and treatment flow chart: nonpregnant patients. The schematic flow chart is of major principles involved in determining routine ophthalmic follow-up and indications for treatment in nonpregnant patients with diabetes. These are only general, maximal recommended guidelines. Ocular symptoms, complaints, or other associated ophthalmic or medical issues may necessitate earlier evaluation and/or an altered approach. CSME, clinically significant macular edema; DR, diabetic retinopathy; HRC PDR, high-risk character proliferative diabetic retinopathy; ME, macular edema; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.
Figure 31-23 Diabetic retinopathy and macular edema examination and treatment flow chart: pregnant patients. The schematic flow chart is of major principles involved in determining routine ophthalmic follow-up and indications for treatment in pregnant patients with diabetes. These are only general, maximal recommended guidelines. Ocular symptoms, complaints, or other associated ophthalmic or medical issues may necessitate earlier evaluation and/or an altered approach. Because retinopathy may progress rapidly in patients with diabetes, careful and more frequent evaluation is often indicated. CSME, clinically significant macular edema; DR, diabetic retinopathy; HRC PDR, high-risk character proliferative diabetic retinopathy; ME, macular edema; NPDR, nonproliferative diabetic retinopathy.
**Figure 31-24** Photocoagulation flow chart. The schematic flow chart details general photocoagulation treatment approaches in patients with diabetic retinopathy and/or diabetic macular edema. These are only general guidelines, and actual treatment choices can be affected by numerous other factors, including findings in the same eye, contralateral eye, systemically, and others. DR, diabetic retinopathy; ME, macular edema; PRP, panretinal (scatter) photocoagulation.
**Figure 31-25** Fluorescein angiogram flow chart. The schematic flow chart details a general algorithm for appropriate use of fluorescein angiography in the ocular evaluation of patients with diabetes mellitus. In unusual cases, confounding factors may alter the appropriate approach.
Figure 31-26  End-stage renal disease (ESRD) among Medicare patients in 1998 with diagnosis specified. USRDS, United States Renal Data System.  *(From The absence of a glycemic threshold for the development of long-term complications: the perspective of the Diabetes Control and Complications Trial. Diabetes 1996; 45:1289-1298.)*
Figure 31-27  A, Periodic acid Schiff (PAS) stain of a normal glomerulus sectioned through the vascular pole. The mesangial cellularity and matrix are normal.  B, Glomerulus showing marked diffuse diabetic glomerulosclerosis. There is extreme expansion of the mesangium with both matrix and cellular material (PAS).  C, Example of nodular diabetic glomerulosclerosis (Kimmelstiel-Wilson lesions). Note the reduction of glomerular capillary luminal space (PAS).  D, Electron photomicrograph showing a normal glomerular basement membrane width (bottom panel) and diffuse thickening of the glomerular basement membrane secondary to diabetes (upper panel).
Figure 31-28 Schematic representation of the progression of diabetic nephropathy. Glomerular hyperfiltration and microalbuminuria are the earliest manifestations of glomerulopathy. Subsequently, urinary protein increases to nephrotic range (>3.5 g/day) and glomerular filtration rate (GFR) declines relentlessly.
Figure 31-29 Flow chart illustrating the management of patients with diabetic nephropathy before the onset of renal failure. ACE, angiotensin-converting enzyme; HIV, human immunodeficiency virus; LDL, low-density lipoprotein.
Figure 31-30 Flow chart illustrating the management of patients with diabetic nephropathy after the onset of clinical proteinuria. ACE, angiotensin-converting enzyme; HIV, human immunodeficiency virus; LDL, low-density lipoprotein.
Figure 31-31 Flow chart illustrating the management of patients after onset of renal failure. ACE, angiotensin-converting enzyme; HIV, human immunodeficiency virus; LDL, low-density lipoprotein.
Figure 31-32 A theoretical framework for the development of diabetic neuropathy. Ab, antibody; AGE, advanced glycation end product; C', complement; DAG, diacylglycerol; EDRF, endothelium-derived relaxing factor; ET, endothelin; GF, growth factor; IGF, insulin-like growth factor; NGF, nerve growth factor; NO, nitric oxide; PKC, protein kinase C; ROS, reactive oxygen species. (Adapted from Vinik AI, Newlon P, Lauterio TJ, et al. Diabetes Rev 1995; 3:139157.)
Figure 31-35 Impaired neurovascular blood flow. (From Stansberry KB, Hill MA, Shapiro SA et al. Impairment of peripheral blood flow responses in diabetes resembles an enhanced aging effect. Diabetes Care 1997; 20:1711-1716.)
**Figure 31-36** Mechanisms of neuropathic pain. **A**, Normal. **B**, C-fiber sensitization. Peripheral nociceptive fibers can be abnormally sensitized and then central nociceptive second-order neurons in the spinal cord dorsal horn can also be sensitized. Then they are hyperexcitable and start responding to non-noxious stimuli. **C**, C-fiber loss or degeneration may trigger anatomic sprouting of low-threshold mechanosensitive terminals to central nociceptive neurons and may subsequently induce synaptic reorganization in the dorsal horn. **D**, Central disinhibition and cold hyperalgesia. A selective damage of cold-sensitive A delta (A) fibers leads to a loss of central inhibition mediated by interneurons (disinhibition), resulting in cold hyperalgesia. DRG, dorsal root ganglion.
Figure 31-37 Diagnostic algorithm for assessment of neurologic deficit and classification of neuropathic syndrome. Ab, antibody; EMG, electromyography; Hx, history; NCV, nerve conduction velocity; NIS, neurologic impairment score; NSS, neurologic symptom score; QAFT, quantitative autonomic function test; QST, quantitative sensory test.
Figure 31-38 Management of painful diabetic neuropathy. (Modified from Vinik AI, Holland MT, LeBeau JM, et al. Diabetic neuropathies. Diabetes Care 1992; 15:19261975.)
Figure 31-39 Diagnosis and treatment algorithm of diabetic autonomic neuropathy. ACE, angiotensin-converting enzyme; ARI, aldose reductase inhibitor; BP, blood pressure; DM, diabetes mellitus; GI, gastrointestinal; HRV, heart rate variability; PGE$_1$, prostaglandin E$_1$; SSR, sympathetic skin response.
Figure 31-40 Marked increase in the risk of coronary artery disease in patients with type 2 diabetes mellitus compared to nondiabetic subjects, in a population-based study in Finland, over a 7-year follow-up period. Patients with diabetes without a history of previous myocardial infarction had an approximately equal risk for first myocardial infarction as nondiabetic subjects who had already sustained a myocardial infarction. These data support recent recommendations from the American Diabetes Association to treat diabetic subjects as if they already have established coronary artery disease. (From Haffner SM, Lehto S, Ronnemaa T, et al. Mortality from coronary heart disease in subjects with type 2 diabetes and in nondiabetic subjects with and without prior myocardial infarction. N Engl J Med 1998; 339:229234.)
Figure 31-41 Age-adjusted cardiovascular disease (CVD) death rates by presence of number of risk factors for men with and without diabetes at baseline screened for the Multiple Risk Factor Intervention Trial. In the presence of diabetes the cardiovascular death rate steeply rises at any level of concomitant risk factors. SBP, systolic blood pressure. (From Stamler J, Vaccaro O, Neaton JD, et al. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. Diabetes Care 1993; 16:434444.)
Figure 31-42 All-cause mortality, cardiovascular mortality, and ischemic heart disease mortality in patients with type 2 diabetes mellitus by quintiles of average fasting blood glucose (FBG). Cardiovascular mortality and all-cause mortality increase throughout the range of fasting plasma glucose in a graded fashion. (From Anderson DK, Svardsudd K. Long-term glycemic control relates to mortality in type II diabetes. Diabetes Care 1995; 18:15341543.)
Figure 31-43 A and B, The high-risk neuropathic foot. Two lateral views of a patient with typical signs of a high-risk neuropathic foot. Note the small muscle wasting, clawing of the toes, and marked prominence of the metatarsal heads. At presentation of type 2 diabetes mellitus, this patient had severe neuropathy with foot ulceration on both right (as noted in these figures) and left feet. (© Copyright University Department of Medical Illustration, Royal Infirmary, Manchester M13 9WJ, England. Reproduced with permission.)
Figure 31-44 Simple algorithm for risk screening in the diabetic foot.
Figure 32-1 Schematic representation of glucose metabolism. TCA, tricarboxylic acid.
Figure 32-4 Summary of studies of the mechanisms of glucose recovery from short-term hypoglycemia in healthy humans. Insulin was injected intravenously at time 0 minutes. Interventions were started at time 0 minutes and stopped at time 90 minutes (i.e., between the vertical lines in each panel). Plasma glucose curves during control studies (solid curves, same in all six panels) and as modified (dashed curves) by the following. A, Somatostatin infusion (glucagon plus growth hormone [GH] deficiency. B, somatostatin infusion plus growth hormone replacement (glucagon deficiency). C, Somatostatin infusion plus glucagon replacement (GH deficiency). D, Phentolamine and propranolol infusion (combined -adrenergic and -adrenergic blockade) or studies performed in bilaterally adrenalectomized individuals (epinephrine deficiency). E, Somatostatin, phentolamine, and propranolol infusion (glucagon deficiency + -adrenergic and -adrenergic blockade). F, Somatostatin infusion in bilaterally adrenalectomized individuals (glucagon + epinephrine deficiency). (Curves derived from data in Clarke WL et al. Am J Physiol 1979; 236:E147E152; Gerich JE et al. Am J Physiol 1979; 236:E370-E385; and Rizza RA et al. J Clin Invest 1979; 64:6271. From Cryer PE. Glucose counter-regulation in man. Diabetes 1981; 30:261264. Copyright 1981, American Diabetes Association, Alexandria, Va.)
Figure 32-6 Neurogenic (autonomic) and neuroglycopenic symptoms of hypoglycemia in normal humans. Among the neurogenic symptoms, "sweaty," "hungry," and "tingling" are cholinergic and "shaky/tremulous," "heart pounding," and "nervous/anxious" are adrenergic. See text for discussion. Mean (±SE) subject scores for awareness of hypoglycemia (blood sugar low) during clamped euglycemia (EU) and during hypoglycemia (Hypo) alone (closed column), with combined α-adrenergic and β-adrenergic blockade with infused phentolamine and propranolol (ADB, crosshatched column), and with combined α-adrenergic and β-adrenergic blockade plus muscarinic cholinergic blockade with atropine, panautonomic blockade (PAB, open column), are also shown. Data from Towler DA et al. Diabetes 1993; 42:1791-1798. (From Cryer PE. Hypoglycemia: the limiting factor in the management of IDDM. Diabetes 1994; 43:1378-1389. Copyright, 1994, American Diabetes Association, Alexandria, Va.)

Figure 32-12 Schematic representation of the pathophysiology of glucose counterregulation in people with type 1 diabetes mellitus (T1DM). See text for discussion.
Figure 32-14 Mean (±SE) neurogenic (autonomic) and neuroglycopenic symptom scores during hyperinsulinemic stepped hypoglycemic glucose clamps in nondiabetic subjects (rectangles) and people with type 1 diabetes (IDDM, insulin-dependent diabetes mellitus) selected for hypoglycemia unawareness studied at baseline before (0 days, open columns), and after 3 days (first set of cross-hatched columns), 3 to 4 weeks (closed columns), and 3 months (second set of cross-hatched columns) of scrupulous avoidance of iatrogenic hypoglycemia. (From Dagogo-Jack S, Rattarasam C, Cryer PE. Reversal of hypoglycemia unawareness, but not defective glucose counterregulation, in IDDM. Diabetes 1994; 43:14261434. Copyright, 1994, American Diabetes Association, Alexandria, Va.)
Figure 32-15 Mean (±SE) plasma glucose concentrations during hypoglycemia produced by subcutaneous insulin injection in people with type 1 diabetes in response to 10 g (circles) and 20 g (squares) of oral (p.o.) glucose and 1.0 mg of subcutaneous (S.C.) glucagon (triangles) compared with placebo (shaded area). (From Wiethop BV, Cryer PE. Alanine and terbutaline in the treatment of hypoglycemia in IDDM. Diabetes Care 1993; 16:1131-1136. Copyright, 1993, American Diabetes Association, Alexandria, Va.)
Figure 32-16 Diagnostic algorithm for suspected hypoglycemia. GI, gastrointestinal.
Figure 33-1 Relationship between body mass index and cardiovascular mortality in adult men and women in the United States who never smoked and had no preexisting illness. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). (Adapted from Calle EE, Thun MJ, Petrelli JM, et al. Body-mass index and mortality in a prospective cohort of U.S. adults. N Engl J Med 1999; 341:1097.)
Figure 33-2 Relationship between body mass index and type 2 diabetes in adult men and women in the United States. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). The data demonstrate that the risk of diabetes begins to increase at the upper end of the lean body mass index category. (Adapted from Colditz GA, Willett WC, Rotnitzky A, Manson JE. Weight gain as a risk factor for clinical diabetes mellitus in women. Ann Intern Med 1995; 122:481-486; Chan JM, Rimm EB, Colditz GA, et al. Obesity, fat distribution, and weight gain as risk factors for clinical diabetes in men. Diabetes Care 1994; 17:961969.)
Figure 33-3 Progression of 3T3-L1 preadipocyte differentiation with subsequent changes in cellular characteristics. The distinct stages of differentiation (very early, early, intermediate, and late) are shown. C/EBP, CCAAT/enhancer binding protein; DEX, dexamethasone; LPL, lipoprotein lipase; MIX, methylisobutylxanthine; PPAR, peroxisome proliferator-activated receptor. (Modified from Ntambi JM, Kim Y-C. Adipocyte differentiation and gene expression. J Nutr 2000; 130:3122S-3126S.)
Figure 33-4 Medical complications associated with obesity.
Figure 33-5 Weight loss in obese subjects treated with anorexiant medication (sibutramine) alone, medication plus group behavior modification therapy, or medication plus group behavior modification therapy and meal replacements. These data demonstrate that greater weight loss is achieved when antiobesity medications are used in conjunction with lifestyle modification than when they are used alone. (Adapted from Wadden TA, Berkowitz RI, Sarwer DB, et al. Benefits of lifestyle modification in the pharmacologic treatment of obesity. Arch Intern Med 2001; 161:218227.)
Figure 33-7 Percentage of excess weight (mean ± standard deviation) lost over 36 months after the gastric bypass procedure (GBP) and vertical banded gastroplasty (VBGP). (Adapted from Sugerman HJ, Starkey JV, Birkenhauer R. A randomized prospective trial of gastric bypass versus vertical banded gastroplasty for morbid obesity and their effects on sweets versus non-sweets eaters. Ann Surg 1987; 205:613624.)
Figure 34-1 Structures of the common lipids.
Figure 34-2  A, Cholesterol biosynthesis. 3-Hydroxy-3-methyl glutaryl coenzyme A (HMG-CoA) reductase is a rate-limiting enzyme regulating cholesterol biosynthesis. The enzyme is down-regulated by excess cholesterol in the cell.  B, Enterohepatic circulation of cholesterol and bile acids. About 50% of cholesterol and 97% of bile acids are reabsorbed from the intestine and recirculated to the liver.  (A, modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. Science 1986; 232:3447.)
Figure 34-3 Triglyceride synthesis and the DGAT reaction. 
A. Two major pathways of triglyceride synthesis have been described: the glycerol-phosphate pathway and the monoacylglycerol pathway, which is prominent in the small intestine. 
B. DGAT catalyzes a reaction in which 1,2-diacylglycerol and fatty acyl CoA react to form triacylglycerol at the surface of the endoplasmic reticulum. (From Farese RV Jr, Cases S, Smith SJ. Triglyceride synthesis: insights from the cloning of diacylglycerol acyltransferase. Curr Opin Lipidol 2000; 11:229234.)
Figure 34-4 Cascade of reactions involved in activation of hormone-sensitive lipase. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; DG, diglyceride; FFA, free fatty acid; MG, monoglyceride. (From Steinberg D, Huttunen JK. The role of cyclic AMP in activation of hormone-sensitive lipase of adipose tissue. Adv Cyclic Nucleotide Res 1972; 1:4762.)
Figure 34-5 General structure of lipoproteins (a schematic representation of very-low-density lipoprotein, VLDL).
Figure 34-6  Polyacrylamide gel showing the various apolipoproteins characteristic of each type of plasma lipoprotein particle. HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein. (Modified from Mahley RW, Innerarity TL. Lipoprotein receptors and cholesterol homeostasis. Biochim Biophys Acta 1983; 737:197-222. With permission from Elsevier Science-NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.)
Figure 34-7 Synthesis of apolipoprotein B100 (apo-B100) and apo-B48 by a unique messenger ribonucleic acid (mRNA) editing mechanism. In the human intestine, a specific cytosine (C) is changed to a uracil (U) in the apo-B mRNA. This change results in a stop codon and the formation of apo-B48, which contains only the first 2152 amino acids of the full-length apo-B100 (4536 amino acids).
Figure 34-8 Schematic representation of apolipoprotein B100 (apo-B100) on the surface of a low-density lipoprotein (LDL) particle. The receptor-binding domain may form a cluster of positively charged arginine and lysine residues (a basic patch) capable of interacting with critical negatively charged glutamic and aspartic acid residues in the ligand-binding domain of the LDL receptor. (Adapted from Yang C-Y; Gu Z-W; Weng S-A, et al. Structure of apolipoprotein B-100 of human low density lipoproteins. Arteriosclerosis 1989; 9:96108.)
Figure 34-9: Isoelectric focusing gels of very-low-density lipoprotein (VLDL) apolipoproteins from three individuals homozygous for the common apo-E phenotypes. The relative charge differences among the different apo-E isoforms are accounted for by the specific amino acid substitutions that are responsible for the three isoforms. The minor, more acidic apo-E isoforms represent sialylated forms of the protein. (From Mahley RW, Rall SC Jr. Type III hyperlipoproteinemia [dysbeta lipoproteinemia]: the role of apolipoprotein E in normal and abnormal lipoprotein metabolism. In Scriver CR, Beaudet AL, Sly WS, et al [eds]. The Metabolic and Molecular Bases of Inherited Disease, 7th ed. New York, McGraw-Hill, 1995, pp 1953-1980.)
**Figure 34-10** Predicted secondary structure of apolipoprotein E (apo-E). The majority of the structure is composed of alpha helices, beta-sheet structures, and beta turns. A region of random structure encompassing residues 165 to 200 appears to form a boundary or hinge region between the two functional domains. HDL, high-density lipoprotein; VLDL, very-low-density lipoprotein.
Figure 34-11 Schematic representation of the receptor-binding domain of apolipoprotein E, indicating the location and identity of naturally occurring amino acid substitutions that lead to type III hyperlipoproteinemia. In each substitution, the bottom amino acid represents the mutant.
Figure 34-12 Three-dimensional structure of the amino-terminal region (residues 1 to 191) of apolipoprotein E, which forms a four-helix bundle. The receptor-binding domain resides in helix 4. (Modified from Wilson C, Wardell MR, Weisgraber KH, et al. Three-dimensional structure of the LDL receptor-binding domain of human apolipoprotein E. Science 1991; 252:1817-1822.)
Figure 34-13 Low-density lipoprotein (LDL) receptor pathway. The LDLs interact with their receptors on the cell surface. The complex enters the coated pit and is internalized. The coated vesicle loses its clathrin coat and becomes an endosome, the site of lipoprotein and receptor dissociation. The receptors recycle to the cell surface, and the lipoproteins are degraded. Alternatively, new receptors are synthesized in the rough endoplasmic reticulum and transported to the cell surface. (Modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. Science 1986; 232:3447; and Myant NB. Cholesterol Metabolism, LDL, and the LDL Receptor. San Diego, Academic Press, 1990.)
Figure 34-14 Functional domains of the low-density lipoprotein receptor. See text for complete description. EGF, epidermal growth factor.
Figure 34-15 Low-density lipoprotein (LDL) receptor gene regulation. SREBP, sterol regulatory element binding protein.
**Figure 34-16** Lipoprotein lipase (LPL), attached by interaction with glycosaminoglycans on the endothelial cells, interacts with chylomicrons to catalyze the hydrolysis of the chylomicron triglycerides (Tg) to form free fatty acids (FFA). Apolipoprotein CII on the lipoprotein serves as a cofactor for LPL.
Figure 34-17 General scheme summarizing the major pathways involved in the metabolism of chylomicrons synthesized by the intestine and very-low-density lipoprotein (VLDL) synthesized by the liver. Apo-E, apolipoprotein E; FFA, free fatty acid; HL, hepatic lipase; IDL, intermediate-density lipoprotein. (Modified from Mahley RW. Biochemistry and physiology of lipid and lipoprotein metabolism. In Becker KL [ed]. Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, JB Lippincott, 1995, pp 13691378.)
Figure 34-18 Pathways involved in chylomicron remnant metabolism. In sequestration, chylomicron remnants are trapped in the space of Disse, possibly through apolipoprotein E-mediated proteoglycan binding. In processing, enzymes, including lipases, may continue processing the remnants to smaller particles. In uptake, receptors involved in the uptake of the remnants appear to include the low-density lipoprotein (LDL) receptor and the LDL receptor-related protein (LRP).
Figure 34-19 Heparan sulfate proteoglycan (HSPG)/low-density lipoprotein (LDL) receptorrelated protein (LRP) pathway. Apo-E, apolipoprotein E; HL, hepatic lipase; LPL, lipoprotein lipase.
Figure 34-20 Very-low-density lipoprotein (VLDL) biosynthesis by hepatocytes. The nascent apolipoprotein B (apo-B) containing apolipoproteins synthesized by the rough endoplasmic reticulum (RER) apparently combine with the lipids in the smooth endoplasmic reticulum (SER). The VLDLs are processed in the Golgi apparatus and accumulate in large secretory vesicles. They are then released into the space of Disse, from which they enter the plasma. (Modified from Alexander CA, Hamilton RL, Havel RJ. Subcellular localization of B apoprotein of plasma lipoproteins in rat liver. J Cell Biol 1976; 69:241263; by copyright permission of The Rockefeller University Press)
Figure 34.21 Origin of high-density lipoprotein (HDL) from liver, intestine, and surface material from chylomicrons and very-low-density lipoprotein (VLDL). Apo-AI, free cholesterol; HDL-E, HDL with apo-E; LCAT, lecithin:cholesterol acyltransferase; PL, phospholipid; Tg, triglyceride.
Figure 34-22 Role of high-density lipoprotein (HDL) in the redistribution of lipids from cells with excess cholesterol to cells requiring cholesterol or to the liver for excretion. The reverse cholesterol transport pathway is indicated by bold arrows (net transfer of cholesterol from cells HDL LDL liver). CETP, cholesteryl ester transfer protein; FC, free cholesterol; HDL-E, HDL with apolipoprotein E; IDL, intermediate-density lipoprotein; LCAT, lecithin:cholesterol acyltransferase; LDL, low-density lipoprotein; PL, phospholipid; Tg, triglyceride; VLDL, very-low-density lipoprotein.
Figure 34-23 Relation between plasma cholesterol levels and coronary heart disease (CHD) mortality in the Multiple Risk Factor Intervention Trial. (Modified from Stamler J, Wentworth D, Neaton JD. Is relationship between serum cholesterol and risk of premature death from coronary heart disease continuous and graded? Findings in 356,222 primary screenees of the Multiple Risk Factor Intervention Trial (MRFIT). JAMA 1986; 256:28232828; Copyright © 1986, by the American Medical Association.)
Figure 34-24 Coronary heart disease mortality (10-year death rates) versus median serum cholesterol (mg/dL). All men were free of heart disease at the beginning of the study. B = Belgrade, Serbia; C = Crevalcore, Italy; D = Dalmatia, Croatia; E = East Finland; G = Corfu, Greece; I = Italian railroad workers (Rome division); K = Crete, Greece; M = Montegiorgio, Italy; N = Zutphen, The Netherlands; R = American railroad workers (Green Bay, WI; San Francisco, CA; Seattle, WA); S = Slavonia, Croatia; T = Tanushimaru, Japan; U = Ushibuka, Japan; W = West Finland; Z = Zrenjanin, Serbia. (From Keys A. Seven Countries: A Multivariate Analysis of Death and Coronary Heart Disease. Cambridge, Mass, Harvard University Press, 1980.)
Figure 34-25 Schematic representation of the progression of atherogenesis.  
A. Normal artery wall showing the three major regions of the vessel wall: intima, media, and adventitia. The thickness of the intima beneath the endothelial cell layer is exaggerated relative to the media to allow illustration of the changes that occur within the subendothelial intima.  
B. Initial events in lesion formation include recruitment of monocyte-macrophages to the subendothelial space and the infiltration of plasma low-density lipoproteins (LDLs) (small circles), which are oxidized by unknown mechanisms that may include reactive oxygen species. Oxidized LDLs are taken up by macrophages, leading to the formation of foam cells. MCP-1, monocyte chemoattractant protein 1.  
C. Fatty streak lesion. Further recruitment of monocyte-macrophages from the plasma takes place along with smooth muscle cell proliferation and collagen synthesis (rows of vertical lines). Elastin fibers (thin curved lines) begin to accumulate.  
D. Proliferative or fibrous lesion. Atherogenesis continues as the lesion begins to extend into the vessel lumen. Necrosis of foam cells begins, and smooth muscle cells start to migrate from the media through the disrupted internal elastic lamina. Some smooth muscle cells accumulate lipid droplets.  
E. Complicated lesion. The endothelial cell layer covering the lesion is lost. As a result, the surface of the lesion becomes thrombogenic, inducing thrombus formation. Cellular debris increases. Calcification and appearance of cholesterol crystals can occur.
Figure 35-1  X chromosome inactivation analysis of tumor clonality with the use of the M27 polymorphism.  

A. Diagrammatic illustration of general principles. Left, Lightly shaded and dark rectangles represent the maternally and paternally inherited copies of the two X chromosomes of somatic cells early in the development of a female embryo. As embryogenesis proceeds, one of the X chromosomes in each somatic cell is randomly chosen for inactivation (lyonization); the inactivated chromosome is represented as a small oval with shading corresponding to its origin. Subsequently, daughter cells (third column) faithfully maintain the same selection of inactivated X chromosome as found in their parent cells. Accordingly, an adult tissue typically contains a mixture of approximately 50% cells with the maternally inherited X chromosome inactive and 50% with the paternally inherited X chromosome inactive. Lower right, A polyclonal tumor arising from a large number of cells in a tissue, maintains this relatively even mixture of cells with different X inactivation patterns. Upper right, A monoclonal tumor, derived from a single somatic cell, has a uniform pattern of X chromosome inactivation in all cells. B, Partial restriction endonuclease map of the M27 locus (DXS255) and an example of two distinguishable M27 alleles. The variable number of tandem repeat (VNTR, minisatellite) region, which is highly variable in its length from person to person, is shown in stripes. A 2.5-kb DNA fragment used as the hybridization probe is shown as a solid rectangle. Cleavage sites for restriction enzyme  PstI  flank the locus. The enzyme  MspI  cleaves the sequence CCGG whether or not the internal cytosine is methylated. In contrast, the enzyme  HpaII  cleaves this sequence only if the internal cytosine is unmethylated. The diagrammed  MspI-HpaII  site actually represents a 270-base-pair region containing three such sites, two of which vary in their methylation status in accord with location on the active versus the inactive X chromosome. In the example of two distinguishable alleles, variation in size of the minisatellite repeat region (VNTR) causes a difference in the size of the  PstI  restriction fragment detectable by hybridization to the labeled M27 probe. If an individual with these two alleles had a monoclonal tumor, in which the larger allele was uniformly associated with the active X chromosome, the  MspI-HpaII  site of this allele would be consistently methylated and, therefore, resistant to cleavage by  HpaII  (asterisks). The resulting Southern blot pattern would correspond to monoclonal pattern 1 in C. C, Schematic diagram of prototypical Southern blot hybridization patterns for X inactivation analysis using M27. A monoclonal tumor can exhibit only one of the two monoclonal patterns shown. The  PstI  +  MspI  control digestion is useful for marking the sizes of fully cleaved alleles. (A to C, From Arnold A, Brown MF, Urena P, et al. Monoclonality of parathyroid tumors in chronic renal failure and in primary parathyroid hyperplasia. J Clin Invest 1995; 95:2047-2053. Copyright, The American Society for Clinical Investigation.)
Figure 35-2 Diagram of the molecular structure of the parathyroid hormone-cyclin D1 DNA rearrangement in a subset of parathyroid adenomas and its functional consequences. The dark X represents the chromosome breakpoint between the PTH gene regulatory region, plus PTH noncoding exon 1 (solid light vertical bar) and part of its first intron, from 11p15 (left), and the intact promoter and five exons of the cyclin D1 gene from 11q13. Cyclin D1 gene transcription proceeds in a left-to-right direction, as drawn. (Modified from Arnold A. Genetic basis of endocrine disease: 5. Molecular genetics of parathyroid gland neoplasia. J Clin Endocrinol Metab 1993; 77:11081112. Copyright 1993, The Endocrine Society.)
Figure 35-3 Schematic representation of the normal RET protein (upper) and the oncoproteins created by selected RET-PTC oncogenes in papillary thyroid cancer (lower). For each indicated rearranged oncoprotein, the number of N-terminal amino acids contributed by the specified partner gene is shown, fused to the tyrosine kinase domain and C-terminus of RET. aa, amino acid; TMD, transmembrane domain. (From Pasini B, Ceccherini I, Romeo G. RET mutations in human disease. Trends Genet 1996; 12:138-144. Copyright 1996, Elsevier Science.)
**Figure 36-1** Age at onset for endocrine tumor expressions in multiple endocrine neoplasia type 1 (MEN1). Data from retrospective analysis of multiple tumor expressions in 130 inpatients with MEN1 during 15 years. Age of tumor onset was defined as the earlier of age at first symptom and age at first abnormal test result. (Modified from Marx S, Spiegel AM, Skarulis MC, et al. Multiple endocrine neoplasia type 1: clinical and genetic topics. Ann Intern Med 1998; 129:484494.)
Figure 36-2 Parathyroid gland sizes at initial parathyroidectomy for 18 cases with familial multiple endocrine neoplasia type 1. Volumes of all glands at one operation are connected by a vertical line. Dashed horizontal line is upper limit of normal gland volume) 0.075 cm$^3$, equivalent to 75 mg mass). (Modified from Marx SJ, Menczel J, Campbell G, et al. Heterogeneous size of the parathyroid glands in familial multiple endocrine neoplasia type 1. Clin Endocrinol (Oxf) 1991; 35:521526.)
Figure 36-3  Tumor multiplicity within a tissue in multiple endocrine neoplasia type 1 (MEN1). Top, Hypercellular parathyroid gland from patient with MEN1. The gland is totally replaced by diffuse sheets and two discreet nodules of chief cells. This image could reflect three or more second hits to the normal copy of the MEN1 gene in three different clone precursor cells and thus growth of three or more independent clones. An alternative pathogenesis could be stepwise evolution from one clone, that is, third hits to genes other than MEN1. Bottom, Duodenal mucosa from a second MEN1 patient, showing two large, submucosal microgastrinomas. Each tumor was positive for gastrin immunostain and negative for other peptide hormones. Possible development of these two adjacent tumors could have followed mechanisms suggested for the two parathyroid nodules at the top. (From I. Lubensky, National Institutes of Health, Bethesda, Md.)
Figure 36-4 Effect of parathyroidectomy in patients with multiple endocrine neoplasia type 1 and Zollinger-Ellison syndrome. Basal acid output and fasting serum gastrin are shown. All patients became normocalcemic except for one (case 4), who remained hypercalcemic. Dashed line is upper limit of normal for serum gastrin. Upper limit of normal for basal acid output is 15 mEq/hour. (From Jensen RT. Management of the Zollinger-Ellison syndrome in patients with multiple endocrine neoplasia type 1. J Intern Med 1998; 243:477488.)
Figure 36-5  Intact parathyroid hormone (PTH) by rapid assay during parathyroid surgery. Normal range is indicated by dashed lines. The patient had multiple endocrine neoplasia type 1 and primary hyperparathyroidism without prior parathyroidectomy. Three and one half similarly enlarged parathyroid glands (0.8 to 1.6 g; normal less than 0.08 g) and the accessible portions of the thymus were removed at the times indicated; the thymus contained no parathyroid tumor. A rapid fall of PTH below a cutoff criterion (such as 50% drop within 5 minutes) indicates that little or no hyperfunctioning parathyroid tumor remains. Note that removal of the first two parathyroid tumors was not followed by a fall in PTH. The PTH assay result for each time point was available within several minutes to help establish the time at which no hyperfunctioning parathyroid tumor remained and thereby contribute to serial decisions about extending or ending the operation.  (From S. K. Libutti, H. R. Alexander, and A. Remaley, National Institutes of Health, Bethesda, Md.)
Figure 36-6 Serum ionized calcium and peripheral midregion parathyroid hormone (PTH) levels after total parathyroidectomy and graft of parathyroid tissue in a patient with multiple endocrine neoplasia type 1. After total parathyroidectomy (PTX) and grafting of parathyroid tissue to the nondominant forearm, the ionized calcium and PTH levels fell to subnormal values. Subsequent measurements demonstrated a continuous rise of the ionized calcium and peripheral PTH levels (taken from the arm not containing the transplant) over a 60-month period, which necessitated removal of some of the grafted parathyroid tissue. The numbers in parentheses represent selected PTH values for blood taken from the brachial vein immediately downstream from the grafted parathyroid tissue. These results demonstrate continued secretion of PTH by the graft in the presence of hypercalcemia. The upper, lighter shaded area shows the normal range for ionized calcium; the lower, darker shaded area shows the normal range for serum midregion PTH. (Data from L. E. Mallette, Baylor College of Medicine.)
Figure 36-7 Facial angiofibroma in patients with multiple endocrine neoplasia type 1. A small, light pink lesion on the vermilion border of the lip (top) and a large, reddish angiofibroma on the nose (bottom) are shown. Typical lesions are smaller and may require biopsy for confirmation. (From T. Darling and M. Turner, National Institutes of Health, Bethesda, Md.)
Figure 36-8  Germ line and somatic mutations of the MEN1 gene. Unique germ line MEN1 mutations in families, sporadic cases, and nonhereditary tumors. Germ line mutations are shown as vertical check marks about the messenger ribonucleic acid (mRNA). Somatic MEN1 mutations in diverse tumors are shown separately as "flags" along the upper and lower border. MEN1 mRNA is diagrammed with exons numbered; untranslated regions are crosshatched. Truncating mutations (frameshift mutations, splice error, and nonsense [stop codon] mutations) are shown above the mRNA. Codon change mutations (missense mutations or small in-frame deletions) are shown below. Repeating mutations within the germ line or somatic category are shown only once, with a small number in parentheses to indicate total occurrences. Stippling about exon 3 represents the main zone of menin interaction with junD. One large deletion, probably of the entire MEN1 gene, is not shown.\[286\] NLS, nuclear localization sequence.
**Figure 36-9** Test categories and test methods in a hereditary tumor syndrome. Tests of the germ line carrier status (left) are largely distinguished from tests of tumor status (right). When DNA testing is not informative, carrier status can be tested by streamlined surveillance of tumors.
Figure 36-10 Bilateral medullary thyroid carcinoma in multiple endocrine neoplasia type 2A. Large bilateral foci of medullary thyroid carcinoma are located in each lobe of the thyroid gland.
**Figure 36-11** Progression of histologic changes from C-cell hyperplasia to medullary thyroid carcinoma. These sections were taken from a single thyroid lobe of a patient with hereditary medullary thyroid carcinoma and demonstrate the multicentric nature of this tumor. *A*, Nodular hyperplasia with containment of C cells within a thyroid follicle. Magnification ×250. *B*, Microscopic medullary thyroid carcinoma that is locally invasive. Magnification ×100.
Figure 36-12 A pheochromocytoma set on a background of diffuse adrenomedullary hyperplasia in multiple endocrine neoplasia type 2A. In the normal adrenal gland, the adrenal cortices are separated by a thin (less than 1 mm) band of adrenal medulla (not shown). In this pheochromocytoma there is diffuse expansion of the adrenal medulla.
**Figure 36-13a** Surveillance for pheochromocytoma in multiple endocrine neoplasia type 2 (MEN2) using catecholamines and their metabolites. Panel A, Results of 24-hour urinary norepinephrine excretion, epinephrine excretion, and ratio of epinephrine to norepinephrine in 11 prospectively surveyed patients with MEN2A proved to have pheochromocytoma. Each open square indicates a value or the mean of two or more values for a patient, and each filled square represents the mean for all the subjects in a particular year; the latter symbols are connected by a solid line. The dashed line shows the upper limit of normal. To convert epinephrine values to nanomoles, multiply by 5.5; to convert norepinephrine values to nanomoles, multiply by 5.9.
Figure 36-13b Panel B, Plasma concentrations of normetanephrine, norepinephrine, metanephrine, and epinephrine (top) and urinary excretion of norepinephrine, epinephrine, metanephrines, and vanillylmandelic acid (bottom). The values are expressed as percentages of the upper reference limit for each test. Data on individual patients are shown for three groups of patients with von Hippel-Lindau (VHL) disease and MEN2 as follows: patients with VHL disease or MEN2 in whom a pheochromocytoma was ruled out on the basis of normal computed tomography (CT-negative), patients with VHL disease who had histologically verified pheochromocytomas (VHL), and patients with MEN2 who had histologically verified pheochromocytomas (MEN2). The values for patients with pheochromocytoma were determined when the tumors were first identified by CT. The dotted horizontal line represents the upper reference limit for each test. The scales are logarithmic. (A, From Gagel RF, Tashjian AH Jr, Cummings T, et al. The clinical outcome of prospective calcitonin-based surveillance for multiple endocrine neoplasia type 2A: an 18-year experience. N Engl J Med 1988; 318:478484. B, Data from Eisenhofer G, Lenders JWM, Linehan WM, et al. Plasma normetanephrine and metanephrine for detecting pheochromocytoma in von Hippel-Lindau disease and multiple endocrine neoplasia type 2. N Engl J Med 1999; 340:18721879.)
Figure 36-14 Cutaneous and oral manifestations in multiple endocrine neoplasia type 2 (MEN2) variants. A. The characteristic clinical picture of cutaneous lichen amyloidosis associated with MEN2A. The pruritic skin lesion may cover a small area or the entire right or left upper back, as shown in this patient. B and C. Patient with MEN2B demonstrating thick bumpy lips and eversion of upper eyelids (B) and neuromas on anterior third of tongue (C). (A, From Gagel RF, Levy ML, Donovan DT, et al. Multiple endocrine neoplasia type 2A associated with cutaneous lichen amyloidosis. Ann Intern Med 1989; 111:802806; B and C, from Brown RS, Colle E, Tashjian AH Jr. The syndrome of multiple mucosal neuromas and medullary thyroid carcinoma in childhood. Importance of recognition of the phenotype for the early detection of malignancy. J Pediatr 1975; 86:7783.)
Molecular abnormalities of the RET proto-oncogene in multiple endocrine neoplasia type 2 (MEN2). Mutations of the RET proto-oncogene have been identified in MEN2A, familial medullary thyroid carcinoma (FMTC), MEN2A associated with Hirschsprung disease, MEN2A associated with cutaneous lichen amyloidosis (CLA), and as somatic mutations in sporadic MTC. Two regions of the RET tyrosine kinase are affected. The first is a cysteine-rich extracellular domain (Cys-Rich) important for dimerization of the ret receptor (codons 609, 611, 618, 620, 634). Mutations of individual cysteines at these codons cause RET dimerization, activation, autophosphorylation, and transformation. Mutations of the second region, the intracellular tyrosine kinase (TK) domain involving codons 768, 790, 791, 804, 883, 891, 918, and 922, cause activation, autophosphorylation, and transformation. A role for the cadherin-like region (Cadherin) has not been defined, although it may be involved in an interaction with the glial cell line-derived neurotrophic factor receptor. The most common germ line mutation is a codon 634 mutation that converts a cysteine to an arginine and accounts for 50% or more of all MEN2 mutations. Somatic mutations of codons 768, 804, and 918 have been identified as somatic mutations in sporadic MTC. Codon 768 and 804 mutations are rare; a somatic codon 918 mutation is identified in approximately 25% of sporadic MTCs. (TM, transmembrane domain.)
Figure 36-16 The RET tyrosine kinase and glial cell linederived neurotrophic factor receptor signaling system.  

A. The RET receptor is a tyrosine kinase receptor that couples with the glial cell linederived neurotrophic factor receptor (GFR-1) to form a receptor for glial cell linederived neurotrophic factor (GDNF). In the absence of GDNF, RET and GFR-1 exist in an undimerized form. Addition of ligand results in activation of the receptor system, autophosphorylation (P), and activation of downstream signaling pathways (phospholipase C [PLC], p38MAPK, and JNK pathways).  

B. Mutations of the extracellular cysteine-rich domain (codon 634) cause dimerization, autophosphorylation of the RET receptor complex, and activation of downstream signaling pathways.  

C. Mutations of the intracellular tyrosine kinase (codon 918) cause autophosphorylation and activation of the kinase domain in the absence of dimerization. (MAPK, mitogen-activated protein kinase; JNK, c-Jun N-terminal terminal.)
Figure 36-17 Trisomy 10 with nonrandom duplication of the mutant RET allele in pheochromocytoma associated with multiple endocrine neoplasia type 2 (MEN2). A. Representative interphase fluorescence in situ hybridization analysis of tumor touch preparation from patient 2 (tumor 2A). Three copies of chromosome 10 are shown using a centromeric satellite probe (fluorescein isothiocyanate, green signal) specific for chromosome 10. B. Combined pedigree and tumor allelic analysis of patient 2 (Pt2). Arrow, patient 2. Filled symbols, individuals with MEN2. Genotypes are shown for the chromosome 10 microsatellite marker D10S1239 linked to the RET locus. Allele 2 of D10S1239 is co-inherited with the disease in this patient's family. In patient 2, allele 2 shows greater intensity in lanes 2A and 2B (tumors) than allele 1, representing the wild-type allele, as compared with lane N2 (blood DNA). Lane N1 (blood DNA) shows equal intensities of mutant and wild-type allele in the patient's affected cousin (C). C. Representative results of microsatellite and phosphorimage analyses. After polymerase chain reaction amplification using marker D10S1239, quantitative measurement of allelic intensity was performed using phosphorimage analysis. In tumor tissue (T), allele 2 is more intense than allele 1. Phosphorimage densitometry shows a 2:1 imbalance between the two alleles in the tumor (T) compared with the normal tissue (N). D. Representative results of sequencing analysis of RET in tumor 3A. Blood DNA from an unaffected healthy individual (C, left) shows the wild-type RET sequence (codon 631 GAC). Blood DNA from patient 3 (N, middle) shows the germ line mutation (G/T). Tumor DNA (T, right) shows a higher intensity of the mutant nucleotide (T) compared with the wild type. (From Huang SC, Koch CA, Vortmeyer AO, et al. Duplication of the mutant RET allele in trisomy 10 or loss of the wild-type allele in multiple endocrine neoplasia type 2 associated pheochromocytomas. Cancer Res 2000; 60:6226-26.)
Figure 37-1 Reproduction of a plate from Addison's initial description of primary adrenal insufficiency (Addison's disease) (A) and hand of a patient with vitiligo and hyperpigmentation of Addison's disease (B). (A, From Addison T. On the Constitutional and Local Effects of Disease of the Supra-renal Capsules. London, Samuel Highley, 1855, plate XI; B, courtesy of F. Neelon.)
Figure 37-2 Autoimmune polyendocrine syndrome type II family with Addison's disease and type 1 diabetes.
**Figure 37-3** 21-Hydroxylase autoantibodies of patients with known Addison's disease, normal control subjects, and patients with type 1 diabetes mellitus. Data for the 15 patients with type 1 diabetes discovered to be 21-hydroxylase positive on screening are plotted on the right, where multiple different serum samples are available for an individual, values for each individual are connected by lines. (From Yu L, Brewer KW, Gates S, et al. DRB1*04 and DQ alleles: expression of 21-hydroxylase autoantibodies and risk of progression to Addison's disease. J Clin Endocrinol Metab 1999; 84:328335.)
Figure 37-4 Adrenal antibody (AA) titers and levels of adrenocorticotropin hormone (ACTH), cortisol, plasma renin activity (PRA), and aldosterone in three antiadrenal autoantibody-positive patients treated for 6 months with glucocorticoids for concomitant Graves' ophthalmopathy. (From De Bellis A, Bizzaro A, Rosai R, et al. Remission of subclinical adrenocortical failure in subjects with adrenal autoantibodies. J Clin Endocrinol Metab 1993; 76:10021007.)
Figure 37-5 Age at onset of mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency in patients with autoimmune polyendocrine syndrome type I. (From Neufeld M, Maclaren NK, Blizzard RM. Two types of autoimmune Addison's disease associated with different polyglandular autoimmune [PGA] syndromes. Medicine [Baltimore] 1981; 60:355362.)
**Figure 38-1** Essential requirement for Pax6 for glucagon-positive enteroendocrine cell formation in the murine intestine. Pax6 SEY<sup>+/−</sup> mutant mice (I) exhibit markedly reduced numbers of glucagon-immunopositive cells in the small and large intestine.
Figure 38-2 Glucagon-like peptide II receptor (GLP-2R) expression in subsets of endocrine cells in the human stomach (ST) and large bowel (LB). Most cells exhibiting positivity with antisera against the human GLP-2R also exhibited immunopositivity for an endocrine marker such as chromogranin (CHROM). In contrast, most endocrine cells in the stomach and both small and large intestine did not express the GLP-2R. Arrows denote cells positive for both the GLP-2R and chromogranin, and arrowheads denote cells positive for the GLP-2R or chromogranin. (From Yusta B, Huang L, Munroe D, et al. Endocrine localization of GLP-2 expression in humans and rodents. Gastroenterology 2000; 119:744755.)
Figure 38-3. Clinically "nonfunctioning" tumors are often found to express one or more peptide hormones after immunocytochemical analyses. The photomicrographs represent histologic sections from the identical nonfunctioning human pancreatic endocrine tumor that exhibit immunopositivity for glucagon (A) and pancreatic polypeptide (B). (Courtesy of Dr. G. Rindi, Brescia, Italy.)
Figure 38-4 Treatment algorithm for the management of a patient with gastrinoma. The dotted line indicates that in some circumstances, patients with familial gastrinoma may also be candidates for surgical resection if disease is highly limited. MEN 1, multiple endocrine neoplasia type 1; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.
Figure 38-5  Somatostatin immunoreactivity in a human duodenal D cell tumor. The low-power micrograph illustrates the diffuse somatostatin immunoreactivity. Brunner's glands and the partly eroded mucosa are seen in the lower and upper right areas, respectively, in relation to the immunopositive endocrine tumor.
Figure 39-1 Diagrammatic representation of mechanisms by which estradiol causes breast cancer. By binding to its receptor and stimulating genes involved in cell proliferation, estradiol \( (E_2) \) increases the rate of cell division. The chances of error during deoxyribonucleic acid (DNA) replication increase as the number of dividing cells is enhanced. The number of mutations increases, and cancer ultimately develops. This mechanism can be called the cell proliferation mechanism of cancer (see Preston-Martin et al, 1993\[24\]). Increasing data suggest that metabolites of estradiol are directly genotoxic and result in deletions of DNA segments and point mutations (see Jefcoate et al, 2000\[28\]; Yager and Liehr, 1996\[29\]; and Cavalleri et al, 2000\[468\]). These two mechanisms may act in an additive or synergistic fashion to cause breast cancer. (From Santen RJ. Symposium overview. J Natl Cancer Inst Monogr 2000; 27:1516.)
Figure 39-2 Relative risk of breast cancer as a function of several factors related to long-term exposure to estradiol (see Zhang et al, 1997; Boyd et al, 1995; Cauley et al, 1996; Hulka, 1997; Huang et al, 1997; and Mouridsen, 2001). E, estrogen; E₂, estradiol; HRT, hormone replacement therapy; OOX, oophorectomy; P, progesterone.
**Figure 39-4 A**, Increase in relative risk of breast cancer in women taking estrogen alone as hormone replacement therapy (HRT). *Solid line* represents the mean increase in relative risk over time. *Shaded area* represents the 95% confidence limits of that risk. **B**, Increase in relative risk of breast cancer in women taking estrogen plus a progestin as HRT. *Solid line* represents the mean increase in relative risk over time. *Shaded area* represents the 95% confidence limits of that risk. (From Santen RJ, Pinkerton J, McCartney C, et al. Risk of breast cancer with progestins in combination with estrogen as hormone replacement therapy. J Clin Endocrinol Metab 2001; 86:1623.)
Figure 39-5 Relative risk of invasive breast cancer related to several benign breast lesions in women with long-term follow-up.
Figure 39-6. A, Reduction in risk of breast cancer in response to administration of tamoxifen (TAM) or raloxifene for a mean duration of 4 years (see Fisher et al, 1998; and Cummings et al, 1999). RR, relative risk; SERM, selective estrogen receptor modulator. B, Absolute benefit from tamoxifen expressed as percentage of women whose breast cancer was prevented as a function of the underlying risk factor present. ADH, atypical ductal hyperplasia; ER, estrogen receptor; LCIS, lobular carcinoma in situ; NSABP, National Surgical Adjuvant Breast Project.
Figure 39-7 Prognostic value of several parameters related to patients with an initial diagnosis of breast cancer. All values are presented as the percent difference in survival at the 5-year interval. This method of presentation allows one to determine the increased number of women per 100 who will be alive at 5 years if they have a favorable prognostic factor compared with those with an unfavorable factor. LI, labeling index.
Figure 39-8 Aromatase activity remaining during the administration of first-generation, second-generation, and third-generation aromatase inhibitors and inactivators. Data are expressed on a logarithmic scale to emphasize the expected log dose-response characteristics of hormone actions. With the most potent inhibitor, only 1% of aromatase activity persists during therapy. Degree of aromatase suppression determined by an isotopic kinetic method using $^3$H-labeled androstenedione and $^{14}$C-labeled estrone to assess the rho value before and during therapy. The rho value represents the percent conversion of androgens to estrogens under equilibrium conditions. ANA, anastrozole; EXE, exemestane; FAD, fadrozole; For, formestane; LET, letrozole. The numbers under bars represent daily dose in milligrams. (Data from Dowsett et al, 1995; Geisler et al, 1996; Geisler et al, 1996; Jones et al, 1992; MacNeill et al, 1992; and Geisler and Hayes.)
Figure 39-9  Cumulative frequency analysis of development of amenorrhea in women with breast cancer as a function of age in response to chemotherapy, hormonal therapy, or both in comparison with no treatment. The effect of chemotherapy on ovarian function reduces the age of menopause by an average of nearly 20 years. (Data from Goodwin PJ, Ennis M, Pritchard KI, et al. Risk of menopause during the first year after breast cancer diagnosis. J Clin Oncol 1999; 17:2365-2370.)
Figure 39-10 Absolute benefit from tamoxifen in the treatment and prevention setting. Absolute benefit is defined as the number of women per 100 who benefit from the use of tamoxifen. In the adjuvant or treatment setting, tamoxifen was used for a period of 5 years. Adj, adjuvant; DCIS, ductal carcinoma in situ; ER, estrogen receptor; Rx, treatment. (Data from Early Breast Cancer Trialists’ Collaborative Group, 1998; Abe, 1994; Carstensen et al, 2000; Cufer, 2000; Delozier et al, 2000; and Ferno et al, 2000.)
Figure 39-11 Disease-specific survival in percent in women receiving tamoxifen or a placebo as adjuvant therapy for breast cancer. Data taken from a meta-analysis of adjuvant trials for breast cancer. SD, standard deviation; -ve, node negative; +ve, node positive. (From Ovarian ablation in early breast cancer: overview of the randomized trials. Early Breast Cancer Trialists’ Collaborative Group. Lancet 1996; 348:1189-1196. Published with permission of the Lancet.)
**Figure 39-12** Results from three trials directly comparing tamoxifen with an aromatase inhibitor in postmenopausal women. CR represents complete objective tumor response, PR represents partial objective response, and clinical benefit is defined as complete and partial objective responses plus stable disease for greater than or equal to 6 months. ANA, anastrozole; LET, letrozole; SD, stable disease for greater than or equal to 6 months; TAM, tamoxifen. The numbers below each column represent the number of women in the arm of the study considered. (Data from Bonneterre et al, 2000[217]; Nabholtz et al, 2000[218]; Smith et al, 2001[220]; and Mouridsen et al, 2001[473].)
Figure 39-13 Survival data for patients undergoing a prophylactic oophorectomy in comparison with a group of women not receiving this therapy. (From Ovarian ablation in early breast cancer: overview of the randomized trials. Early Breast Cancer Trialists’ Collaborative Group. Lancet 1996; 348:11891196. Reprinted with permission of the Lancet.)
Figure 39-14 Percent reduction in tumor volume in response to either letrozole, anastrozole, or tamoxifen given for 3 months prior to the time of excisional surgery and used as neoadjuvant therapy. (From Dixon JM. Neoadjuvant endocrine therapy. In Miller WR, Santen RJ (eds). Aromatase Inhibition and Breast Cancer. New York, Marcel Dekker, 2001, p 109.)
Figure 39-16  Two analogous systems for classification of prostate cancer. The Tumor-Node-Metastasis (TNM) system is generally used for a wide range of neoplasms; it involves an estimate of tumor size and presence of distant metastases or lymph nodes that contain tumor. The Jewett classification integrates these factors into stages A to D, which indicate progressively more severe disease. Both are used by various authors, and the parallels between the two systems are demonstrated here. PSA, prostate-specific antigen; TRUS, transrectal ultrasonography.
Figure 39-17 Diagrammatic representation of the endocrinology of prostate cancer growth. Androgens are directly secreted by the testis into the circulation, are synthesized in peripheral tissues from steroidal precursors, and are formed directly in the prostate gland. AR, androgen receptor; DHA, dehydroepiandrosterone; DHT, dihydrotestosterone; HRE, hormone response element. (From Denis LJ, Griffiths K. Endocrine treatment in prostate cancer. Semin Surg Oncol 2000; 18:5254. Published with permission of Seminars in Surgical Oncology.)
Figure 39-18  Illustration of death rates in men of various ages with prostate cancer. Heavily shaded areas represent death from all causes. Lightly shaded areas indicate prostate cancer related death rates. (From Albertsen PC, Hanley JA, Gleason DF, Barry MJ. Competing risk analysis of men aged 55 to 74 years at diagnosis managed conservatively for clinically localized prostate cancer. JAMA 1998; 280:975. Reprinted with permission of the American Medical Association.)

Figure 41-2. Histopathology of classic well-differentiated midgut carcinoid tumor.
Figure 41-3 Biosynthesis and metabolism of 5-hydroxytryptamine (5-HT) (serotonin).
Figure 41-4 The tachykinin family of peptides shares the same carboxyl terminus. Neuropeptide-K is a prohormone containing neurokinin-A, which can be spliced off.
Figure 41-5 Chromatography samples of plasma from a patient with carcinoid before flush (upper panel) and during flush (lower panel). Note the significant increase in eledoisin-like peptide as well as in neuropeptide-K.
Figure 41-6 The glycoprotein chromogranin-A and related peptides.
**Figure 41-7** Schematic drawing of an enterochromaffin cell. The initial step in 5-hydroxytryptamine (5-HT) synthesis is carrier transport of the amino acid tryptophan from blood into the cell across the cell membrane. Intracellular tryptophan is first converted to 5-hydroxytryptophan (5-HTP), in turn converted to 5-HT and stored in secretory granules. The transport of 5-HT into granules requires vesicular membrane transporters (VMATs). Via the basal lateral membrane, 5-HT can be released into the circulation. There is also a membrane pump mechanism in the cell membrane responsible for amine reuptake. A minor part of 5-HT can also be released into the gut lumen. Monoamine oxidase (MAO) degrades 5-HT to 5-hydroxyindoleacetic acid (5-HIAA). Peptide prohormones are synthesized in the rough endoplasmic reticulum (RER) together with chromogranin-A (CgA) and other granula proteins. The products are transported to the Golgi apparatus (GA) for packaging into prosecretory granules. On stimulation, the secretory products are released from the granules by exocytosis.
Figure 41-8 Carcinoid syndrome before and after provocation. A, Before flush provocation. B, Same patient after pentagastrin-stimulated flush.
Figure 41-9  Long-lasting chronic flushing in a patient with long-standing carcinoid disease. Note the telangiectases.
Figure 41-10 The patient has lung carcinoid and carcinoid syndrome with severe, long-standing flushing, lacrimation, and a swollen face.
Figure 41-11  Tachykinin levels (TKLI) after stimulation with pentagastrin in patients with classic midgut carcinoids. Pretreatment for 15 minutes with somatostatin causes inhibition of tachykinin release and inhibition of the flush reaction (00). P, placebo.
Figure 41-12 Plasma levels of chromogranin-A (CgA), CgB, and CgC in patients with various neuroendocrine tumors. EPTs, endocrine pancreatic tumors; MEN-1, multiple endocrine neoplasia type 1.
Figure 41-13 Bronchial carcinoid.  
A, Somatostatin-receptor scintigraphy in a patient with a bronchial carcinoid.  
B, CT scan in the same patient.
Figure 41-14  Positron emission tomography (PET) with \(^{11}C\)-5-hydroxytryptophan. Note the metastasis in the liver.
Figure 41-15 Diagnostic algorithm for patients with carcinoid tumor. CgA, chromogranin-A; $^{11}$C-5-HTP, $^{11}$C-5-hydroxytryptophan; 5-HIAA, 5-hydroxyindoleacetic acid; 5-HT, 5-hydroxytryptamine; NPK, neuropeptide-K; PET, positron emission tomography; SRS, somatostatin-receptor scintigraphy; sst 15, somatostatin-receptor subtypes 15.
Figure 41-16 Molecular structure of human somatostatin-14, octreotide acetate, and lanreotide.
