Foreword

Robert H. Williams

The publication of the tenth edition comes 52 years after the first edition of Williams' Textbook of Endocrinology. There had been other large textbooks of endocrinology, such as Biedl's *Innere Sekretion* in 1916 and Rolleston's *The Endocrine Organs in Health and Disease* in 1936, but only a handful of physicians could be identified as endocrinologists by the middle of the twentieth century. Consequently, Robert H. Williams exercised "powerful persuasion" to overcome the reluctance of the sales staff of the W. B. Saunders Company to publish a book that had no visible audience. In fact, however, Williams was correct in predicting a large readership, because its publication coincided with an explosive increase in basic endocrine science and in the application of this basic information to patients, and with the evolution of endocrinology into a recognized subspecialty of several branches of medicine. Indeed, the book has had a profound impact on endocrine science and on the development of the clinical discipline, and it is appropriate at this time to remember Robert Williams and his contributions to the field and to Textbook of Endocrinology.

Williams described in a memoir the training and the background that led to his development of the textbook. After his graduation from Washington and Lee University, he obtained the M.D. degree at Johns Hopkins University Medical School in 1934. His house staff training was spread between the Mallory Institute of Pathology at the Boston City Hospital, the Department of Medicine at Vanderbilt (where he did research with Tinsley R. Harrison), and the Department of Medicine at Johns Hopkins (where he worked with Warren Longcope). He finished his training at the Massachusetts General Hospital as an endocrine fellow at a time when there were "many quacks in this area throughout the world." He and his mentor, Fuller Albright, became good friends and maintained close contact over the years.

In 1940, Williams was appointed to the staff of the Endocrine Unit of the Thorndike Laboratory in the Harvard Medical Unit at the Boston City Hospital. In 1942, he became head of the Unit, where his research focused principally on the biochemistry and physiology of thyroid disease, including pioneering work on the treatment of thyrotoxicosis with thionamide drugs and with radioactive iodine. In addition, he described the syndrome of biotin deficiency and published papers on adrenal physiology, obesity, and nephrogenic diabetes insipidus.

To attract students and fellows into the field, he developed the concept that "endocrinology is the backbone of metabolism and metabolism is the interstitium of medicine." His students and trainees included at least three future contributors to his textbook, Sidney Ingbar, Peter Forsham, and William H. Daughaday. Daughaday describes Williams as a man of extraordinary exuberance and enthusiasm who took great pleasure in lecturing and in bedside teaching and whose motto was "B(bright) and E(early) and on the B(basis)."

Williams considered himself first and foremost an educator, and in 1948 he moved to the University of Washington as Chairman of the Department of Medicine, where his extraverted and outgoing personality made him a superb teacher, recruiter, administrator, and institution builder. The Endocrine Division in Seattle was very broad and encompassed diabetes mellitus, clinical nutrition, and metabolism, as well as endocrinology. Williams served as President of the Endocrine Society, the American Society for Clinical Investigation, and the Association of American Physicians, and he was the founder of the Association of the Professors of Medicine. In brief, he was an academic giant of twentieth century medicine.

The founding of the Textbook of Endocrinology evolved from his interest in education: "In view of the rapid progress in endocrinology and metabolism, and the fact that our unit at Boston City Hospital had registered very high in undergraduate, graduate, and postgraduate teaching, I decided that there was a great need for a new textbook in endocrinology." The arrangements for the textbook were completed before Williams left Boston, and the aims were clearly described in the preface to the first edition:

The rapidity and extent of advances in endocrinology have made it increasingly difficult for the student and physician to take full advantage of information available for understanding, diagnosis and treatment of clinical disorders. It is the realization of these difficulties that prompted the writing of this book. The main

objective is to provide a condensed and authoritative discussion of the management of clinical endocrinopathies, based upon the application of fundamental information obtained from chemical and physiologic investigations.

The product was a book that over the years has served as an effective bridge between clinical medicine and the science of endocrinology. There may be no other arena of medicine in which the basic and clinical sciences are so tightly interwoven into one discipline. On the one hand, the clinical discipline profits immensely from scientific advances; on the other hand, clinical observations often raise important questions for investigation and on occasion provide answers that have an impact on basic science. By reflecting advances in both areas, the Williams Textbook was designed to convey the intellectual excitement of a rapidly changing scientific base and, at the same time, to promote the integration of a spectrum of disciplines ranging from molecular genetics to patient care into a unified discipline. The achievement of this aim was possible because, from the initial edition, Williams chose contributors who were at the forefront of the field, thereby ensuring the freshness of each edition.

Now, of course, there are several textbooks of endocrinology, but Williams' pioneering book continues to enjoy a growing readership of both the English and the foreign language editions. Williams edited the first five editions, and Edwin L. Bierman completed the editing of the sixth edition after Williams' death in 1979. Jean D. Wilson and Daniel W. Foster edited the seventh and eighth editions and were joined by Henry M. Kronenberg and P. Reed Larsen as editors for the ninth edition. For the tenth edition, Larsen and Kronenberg are joined by editors Kenneth S. Polonsky and Shlomo Melmed, and continuing the tradition set by Williams, the editors of the tenth edition have enlisted an outstanding group of new and former contributors. Saunders continues as publisher.
Endocrinology has changed in many ways during the past 50 years, and the editorial challenges likewise change with each edition. On one level, these challenges reflect scientific advances, such as the explosion of knowledge about hormone action, the development of new and improved diagnostic techniques and imaging modalities, and the application of molecular genetics to biology. On another level, the concept that the discipline of endocrinology was defined by the concept of humoral control mechanisms has become blurred by recognition that the endocrine, immune, and neurologic signaling systems constitute a single integrated system rather than separate control mechanisms. The most significant challenge now, however, is the same as that faced by all textbooks at a time when the volume of published information is rapidly increasing, namely the dilemma of how to take full advantage of developments in electronic publishing and the evolving revolution in information retrieval systems to devise effective learning systems for the near and remote futures. The fundamental educational issues are the same that Williams faced in 1948, namely the need to integrate rapidly evolving basic and clinical science in a cohesive format appropriate for undergraduate, graduate, and continuing medical education. Now, however, the prose text can be enhanced by multimedia additions, and updating can be done in a continuum. How these tools will be utilized to create new types of teaching materials by academicians faced with multiple demands on their time is not entirely clear, but the response to this challenge will determine whether Williams Textbook of Endocrinology will continue to have the same impact over the next 50 years.

Jean D. Wilson

References

5. Daughaday WH. Personal communication.
This tenth edition of Williams Textbook of Endocrinology is a milestone in many respects. A tenth edition per se is testimony to the enduring accomplishments of our predecessors, who have consistently created a product that remains the most popular textbook in this field. It is also now a half century since the publication of the first edition of Williams, a landmark suitably celebrated in a foreword by our coauthor and former editor, Dr. Jean Wilson. Two internationally renowned endocrinologists, Drs. Shlomo Melmed and Kenneth Polonsky, have joined Drs. Reed Larsen and Henry Kronenberg to formulate, co-edit, and assemble this volume. We will strive to meet the high standards maintained by Drs. Wilson and Daniel Foster during their editorial leadership.

Our goal for this first edition of the new millennium was to emulate the achievements of our predecessors by producing a definitive and fresh approach to the presentation of the essentials of clinical endocrinology. Accordingly, we invited a number of new authors, including several European colleagues, to prepare 23 of the 41 chapters. Our challenge to them and to those updating their material was to distill the burgeoning molecular and physiological knowledge into a complete, but relevant, scholarly presentation. Where appropriate, this would include a practical experienced guide as to how the author uses this information in the diagnosis and management of his or her own patients. Achieving such relevance, thoroughness, and practicality requires a unique combination of scientific knowledge and total clinical familiarity best encapsulated in the term “physician-scientist.” We believe that our physician-scientist authors have again met Robert Williams’ stipulation that this text should provide “a condensed and authoritative discussion of the management of clinical endocrinopathies based upon the application of fundamental information obtained from chemical and physiologic investigation.” We hope our readers will agree.

Both new and revised chapters are replete with tables and figures. Highlights of this edition include a new and expanded diabetes section, new chapters on many old and new topics including endocrinology and aging, female reproduction and fertility control, sexual function and dysfunction, kidney stones, the adrenal cortex, endocrine hypertension, endocrine-responsive tumors, and non-insulin-secreting tumors of the gastrointestinal system. A largely new, concise introductory section includes several new chapters discussing mechanisms of hormone action and the clinical approach to the endocrine patient, as well as a thorough guide to the intricacies of the rapidly changing laboratory techniques. The entire section containing chapters on the hypothalamus and both anterior and posterior pituitary disorders is original, and the thyroid section has been thoroughly revised and divided into expanded disorder-based presentations.

Stylistic innovations include page numbers in the introductory outlines for each chapter, which we hope will permit the reader ready access to specific topics. We have also introduced algorithms and clinical guidelines for diagnostic and treatment strategies to crystallize recommendations for each disease. Readers will also note that this edition is published only five years following its predecessor, reflecting the all-too-familiar rapidity with which new knowledge is accumulating in the biomedical disciplines. Its timely appearance despite so much new material reflects the diligent efforts of our editorial staff and especially the new authors.

We would like to express our deep gratitude to the coworkers in our offices, Anita Nichols, Debra Hession, Lynn Moulton, Grace Labrado, Linda Walker, Louise Ishibashi, and Sherri Turner, without whose dedication this project could not have been completed. We also wish to thank our colleagues at Elsevier, Richard Zorab and Cathy Carroll, and our tireless and effective developmental editors, Faith Voit and Joanne Husovsky. Their painstaking attention to every detail is a major contribution to this new edition.

Kenneth S. Polonsky
INTRODUCTION

Roughly a hundred years ago, Starling coined the term *hormone* to describe secretin, a substance secreted by the small intestine into the blood stream to stimulate pancreatic secretion. In his Croonian Lectures, Starling considered the endocrine and nervous systems as two distinct mechanisms for coordination and control of organ function. Thus, endocrinology found its first home in the discipline of mammalian physiology.

Work over the next several decades by biochemists, physiologists, and clinical investigators led to the characterization of many hormones secreted into the blood stream from discrete glands or other organs. These investigators showed for the first time that diseases such as hypothyroidism and diabetes could be treated successfully by replacing specific hormones. These initial triumphs formed the foundation of the clinical specialty of endocrinology.

Advances in cell biology, molecular biology, and genetics over the ensuing years began to help explain the mechanisms of endocrine diseases and of hormone secretion and action. Although these advances have embedded endocrinology into the framework of molecular cell biology, they have not changed the essential subject of endocrinology—the signaling that coordinates and controls the functions of multiple organs and processes. Here we would like to survey the general themes and principles that underpin the diverse approaches used by clinicians, physiologists, biochemists, cell biologists, and geneticists to understand the endocrine system.
Hormones can be defined as chemical signals secreted into the blood stream that act on distant tissues, usually in a regulatory fashion. Hormonal signaling represents a special case of the more general process of signaling between cells. Even unicellular organisms such as baker's yeast, Saccharomyces cerevisiae, secrete short peptide mating factors that act on receptors of other yeast cells to trigger mating between the two cells. These receptors resemble the ubiquitous family of mammalian 7-transmembrane spanning receptors that respond to ligands as diverse as photons and glycoprotein hormones. Because these yeast receptors trigger activation of heterotrimeric G proteins just as mammalian receptors do, this conserved signaling pathway must have been present in the common ancestor of yeast and humans.

Signals from one cell to adjacent cells, so-called paracrine signals, often trigger cellular responses that use the same molecular pathways used by hormonal signals. For example, the sevenless receptor controls the differentiation of retinal cells in the Drosophila eye by responding to a membrane-anchored signal from an adjacent cell. Sevenless is a membrane-spanning receptor with an intracellular tyrosine kinase domain that signals in a way that closely resembles the signaling by hormone receptors such as the insulin receptor tyrosine kinase. Since paracrine factors and hormones can share signaling mechanisms it is not surprising that hormones can, in some settings, act as paracrine factors. Testosterone, for example, is secreted into the blood stream but also acts locally in the testes to control spermatogenesis. Insulin-like growth factor I (IGF-I) is a hormone secreted into the blood stream from the liver and other tissues, but it is also a paracrine factor made locally in most tissues to control cell proliferation. Further, one receptor can mediate the actions of a hormone, such as parathyroid hormone, and of a paracrine factor, such as parathyroid hormone-related protein.

Target cells respond similarly to signals that reach them from the blood stream (hormones) or from the cell next door (paracrine factors); the cellular response machinery does not distinguish the sites of origin of signals. The shared final common pathways used by hormonal and paracrine signals should not, however, obscure important differences between hormonal and paracrine signaling system (Fig. 1-1). Paracrine signals do not travel very far; consequently, the specific site of origin of a paracrine factor determines where it will act and provides specificity to that action. When the paracrine factor BMP4 is secreted by cells in the developing kidney, it regulates the differentiation of renal cells; when BMP4 is secreted by cells in bone, it regulates bone formation. Thus, the site of origin of BMP4 determines its physiologic role. In contrast, since hormones are secreted into the blood stream, their sites of origin are often divorced from their functions. We know nothing about thyroid hormone function, for example, that requires that the thyroid gland be in the neck.

Because the specificity of action of paracrine factors is so dependent on their precise site of origin, elaborate mechanisms have evolved to regulate and constrain the diffusion of paracrine factors. Paracrine factors of the hedgehog family, for example, are covalently bound to cholesterol to constrain the diffusion of these molecules in the extracellular milieu. Most paracrine factors interact with binding proteins that block their action and control their diffusion. Chordin, noggin, and many other distinct proteins all bind to various members of the BMP family to regulate their action, for example. Proteases such as tolloid then destroy the binding proteins at specific sites to liberate BMPs so that the BMPs can act on appropriate target cells.

Hormones have rather different constraints. Because they diffuse throughout the body, they must be synthesized in enormous amounts relative to the amounts of paracrine factors needed at specific locations. This synthesis usually occurs in specialized cells designed for that specific purpose. Hormones must then be able to travel in the blood stream and diffuse in effective concentrations into tissues. Therefore, for example, lipophilic hormones bind to soluble proteins that allow them to travel in the aqueous media of blood at relatively high concentrations. The ability of hormones to diffuse through the extracellular space means that the local concentration of hormone at target sites will rapidly decrease when glandular secretion of the hormone stops. Because hormones diffuse throughout extracellular fluid quickly, hormonal metabolism can occur in specialized organs such as the liver and kidney in a way that determines the effective concentration of the hormones in other tissues.

Paracrine factors and hormones thus use several distinct strategies to control their biosynthesis, sites of action, transport, and metabolism. These differing strategies may partly explain why a hormone such as IGF-I, unlike its close relative insulin, has multiple binding proteins that control its action in tissues. As noted earlier, IGF-I has a double life as both a hormone and a paracrine factor. Presumably, the local actions of IGF-I mandate an elaborate binding protein apparatus.

All the major hormonal signaling programs are G protein-coupled receptors, tyrosine kinase receptors, serine/threonine kinase receptors, ion channels, cytokine receptors, nuclear receptors are also used by paracrine factors. In contrast, several paracrine signaling programs are used only by paracrine factors and are probably not used by hormones. For example, Notch receptors respond to membrane-based ligands to control cell fate, but no bloodborne ligands use Notch-type signaling (at least none is currently known). Perhaps the intracellular strategy used by Notch, which involves cleavage of the receptor and subsequent nuclear actions of the receptor's cytoplasmic portion, is too inflexible to serve the purposes of hormones.

The analyses of the complete genomes of multiple bacterial species, the yeast Saccharomyces cerevisiae, the fruit fly Drosophila melanogaster, the worm Caenorhabditis elegans, the plant Arabidopsis thaliana, and humans have allowed a comprehensive view of the signaling machinery used by various forms of life. As noted already, S. cerevisiae uses G protein-linked receptors; this organism, however, lacks tyrosine kinase receptors and nuclear receptors that resemble the estrogen/thyroid receptor family. In contrast, the worm and fly share with humans the use of each of these signaling pathways, although with substantial variation in number of genes committed to each pathway. For example, the Drosophila genome encodes 20 nuclear receptors, the C. elegans genome encodes 270, and the human genome encodes (tentatively) more than 50. These patterns suggest that ancient multicellular animals must have already established the signaling systems that are the foundation of the endocrine system as we know it in mammals.

Even before the sequencing of the human genome, sequence analyses had made clear that many receptor genes are found in mammalian genomes for which no clear ligand or function was known. The analyses of these "orphan" receptors has succeeded in broadening the current understanding of hormonal signaling. For example, the liver X receptor (LXR) was one such orphan receptor found when searching for unknown nuclear receptors. Subsequent experiments showed that oxygenated derivatives of cholesterol are the ligands for LXR, which regulates genes involved in cholesterol and fatty acid metabolism. The example of LXR and many others raise the question of what constitutes a hormone. The classical view of hormones is that they are synthesized in discrete glands and have no function other than activating receptors on cell membranes or in the nucleus. In contrast, cholesterol, which is converted in cells to oxygenated derivatives that activate the LXRs, uses a hormonal strategy to regulate its own metabolism. Other orphan nuclear receptors respond similarly to ligands, such as bile acids and fatty acids. These "hormones" have important metabolic roles quite separate from their signaling properties, although the hormone-like signaling serves to allow regulation of the
metabolic function. The calcium-sensing receptor is an example from the G protein-linked receptor family of receptors that responds to a nonclassical ligand, ionic calcium. Calcium is released into the blood stream from bone, kidney, and intestine and acts on the calcium-sensing receptor in parathyroid cells, renal tubular cells, and other cells to coordinate cellular responses to calcium. Thus, many important metabolic factors have taken on hormonal properties as part of a regulatory strategy.
ENDOCRINE GLANDS

Hormone formation may occur either in localized collections of specific cells, in the endocrine glands, or in cells that have additional roles. Many protein hormones, such as growth hormone, parathyroid hormone, prolactin, insulin, and glucagon, are produced in dedicated cells by standard protein synthetic mechanisms common to all cells. These secretory cells usually contain specialized secretory granules designed to store large amounts of hormone and to release the hormone in response to specific signals. Formation of small hormone molecules initiates with commonly found precursors, usually in specific glands such as the adrenals, gonads, or thyroid. In the case of the steroid hormones, the precursor is cholesterol, which is modified by various hydroxylations, methylations, and demethylations to form the glucocorticoids, androgens, and estrogens, and their biologically active derivatives. In contrast, the precursor of vitamin D, 7-dehydrocholesterol, is produced in skin keratinocytes, again from cholesterol, by a photochemical reaction. Leptin, which regulates appetite and energy expenditure, is formed in adipocytes, thus providing a specific signal reflecting the organism’s nutritional state to the central nervous system.

Thyroid hormone synthesis occurs via a unique pathway. The thyroid cell synthesizes a 660,000-kd homodimer, thyroglobulin, which is then iodinated at specific iodotyrosines. Certain of these “couple” to form the iodothyronine molecule within thyroglobulin, which is then stored in the lumen of the thyroid follicle. In order for this to occur, the thyroid cell must concentrate the trace quantities of iodide from the blood and oxidize it via a specific peroxidase. Release of thyroxine (T₄) from the thyroglobulin requires its phagoctyosis and cathepsin-catalyzed digestion by the same cells.

Hormones are synthesized in response to biochemical signals generated by various modulating systems. Many of these systems are specific to the effects of the hormone product; for example, parathyroid hormone synthesis is regulated by the concentration of ionized calcium, whereas gonadal, adrenal, and thyroid hormone synthesis is achieved by the hormonostatic function of the hypothalamic-pituitary axis. Cells in the hypothalamus and pituitary monitor the circulating hormone concentration and secrete trophic hormones that activate specific pathways for hormone synthesis and release. Typical examples are luteinizing (LH) follicle-stimulating (FSH), thyroid-stimulating (TSH), and adrenocorticotropic (ACTH) hormones.

These trophic hormones increase rates of hormone synthesis and secretion and also may induce target cell division, thus causing enlargement of the various target glands. For example, in hypothroid individuals living in iodine-deficient areas of the world, TSH secretion causes a marked hyperplasia of thyroid cells. In such regions, the thyroid gland may be 20- to 50-fold its normal size. Adrenal hyperplasia occurs in patients with genetic deficiencies in cortisol formation. Hypertrophy and hyperplasia of parathyroid cells, in this case initiated by an intrinsic response to the stress of hypocalcemia, occur in patients with renal insufficiency or calcium malabsorption.

Hormones may be fully active when released into the blood stream (e.g., growth hormone or insulin) or may require activation in specific cells to produce their biological effects. These activation steps are often highly regulated. For example, the T₄ released from the thyroid cell is a prohormone that must undergo a specific deiodination to form the active 3,5,3’ triiodothyronine (T₃). This deiodination reaction can occur in target tissues, such as in the central nervous system; in the thyrotrhophs, where T₄ provides feedback regulation of TSH production; or in hepatic and renal cells, from which T₃ is released into the circulation for uptake by all tissues. A similar post secretory activation step catalyzed by a 5-reductase causes tissue-specific activation of testosterone to dihydrotestosterone in target tissues, including the male urogenital tract and genital skin, as well as in the liver. Vitamin D undergoes hydroxylation at the 25 position in the liver and in the 1 position in the kidney. Both hydroxylations must occur to produce the active hormone 1,25(OH)₂ vitamin D. The activity of the 1-hydroxylase, but not that of the 25-hydroxylase, is stimulated by parathyroid hormone and reduced plasma phosphate but is inhibited by calcium and 1,25(OH)₂ vitamin D.

Hormones are synthesized as required on a daily, hourly, or minute-to-minute basis with minimal storage, but there are significant exceptions. One such exception is the thyroid gland, which contains enough stored hormone to last for about two months. This permits a constant supply of this hormone despite significant variations in the availability of iodine. If iodine deficiency is prolonged, however, the normal reservoirs of thyroxine can be depleted.

The various feedback signaling systems exemplified above provide the hormonal homeostasis characteristic of virtually all endocrine systems. Regulation may include the central nervous system or local signal recognition mechanisms in the glandular cells, such as the calcium-sensing receptor of the parathyroid cell. Superimposed, centrally programmed increases and decreases in hormone secretion or activation through neuroendocrine pathways also occur. Examples include the circadian variation in the secretion of ACTH directing the synthesis and release of cortisol. The monthly menstrual cycle exemplifies a system with much longer periodicity that requires a complex synergism between central and peripheral axes of the endocrine glands. Disruption of hormonal homeostasis due to glandular or central regulatory system dysfunction has both clinical and laboratory consequences. Recognition and correction of these are the essence of clinical endocrinology.
TRANSPORT OF HORMONES IN BLOOD

Protein hormones and some small molecules such as the catecholamines are water-soluble and readily transported by the circulatory system. Others are nearly insoluble in water (e.g., the steroid and thyroid hormones), and their distribution presents special problems. Such molecules are bound to 50 to 60-kd carrier plasma glycoproteins such as thyroxine-binding globulin (TBG), sex hormone-binding globulin (SHBG), and corticosteroid-binding globulin (CBG), as well as to albumin. These ligand-protein complexes serve as reservoirs of these hormones, ensure ubiquitous distribution of their water-insoluble ligands, and protect the small molecules from rapid inactivation or excretion in the urine or bile. Without these proteins, it is unlikely that hydrophobic molecules would be transported much beyond the veins draining the glands in which they are formed. The protein-bound hormones exist in rapid equilibrium with the often minute quantities of hormone in the aqueous plasma. It is this "free" fraction of the circulating hormone that is taken up by the cell. It has been shown, for example, that if tracer thyroid hormone is injected into the portal vein in a protein-free solution, it is bound to hepatocytes at the periphery of the hepatic sinusoid. When the same experiment is repeated with a protein-containing solution, there is a uniform distribution of the tracer hormone throughout the hepatic lobule. Despite the very high affinity of some of the binding proteins for their ligands, one specific protein may not be essential for hormone distribution. For example, in humans with a congenital deficiency of TBG, other proteins, transthyretin and albumin, subsume its role. Because the affinity of these secondary thyroid hormone transport proteins is several orders of magnitude lower than that of TBG, it is possible for the hypothalamic-pituitary feedback system to maintain free thyroid hormone in the normal range at a much lower total hormone concentration. The fact that the "free" hormone concentration is normal in subjects with TBG deficiency indicates that it is this free moiety that is defended by the hypothalamic-pituitary axis and is the active hormone.

The availability of gene-targeting techniques has allowed specific tests of the physiologic role of several hormone-binding proteins. For example, mice with targeted inactivation of the vitamin D-binding protein (DBP) have been generated. Although the absence of DBP markedly reduces the circulating concentration of vitamin D, the mice are otherwise normal. However, they show enhanced susceptibility to a vitamin D-deficient diet because of the reduced reservoir of this sterol. In addition, the absence of DBP markedly reduces the half-life of 25(OH)D$_2$ by accelerating its hepatic uptake, making the mice less susceptible to vitamin D intoxication.

In rodents, transthyretin (TTR) carries retinol-binding protein and is also the principal thyroid hormone-binding protein. This protein is synthesized in the liver and in the choroid plexus. It is the major thyroid hormone-binding protein in the cerebrospinal fluid of both rodents and humans and was thought to perhaps serve an important role in thyroid hormone transport into the central nervous system. This hypothesis has been disproven by the fact that mice without TTR have normal concentrations of T$_4$ in the brain as well as of free T$_4$ in the plasma. To be sure, the serum concentrations of vitamin A and total T$_4$ are decreased, but the knockout mice have no signs of vitamin A deficiency or hypothyroidism. Such studies suggest that these proteins primarily serve distributive/reservoir functions.

Protein hormones and some small ligands (e.g., catecholamines) produce their effects by interacting with cell surface receptors. Others, such as the steroid and thyroid hormones, must enter the cell to bind to cytosolic or nuclear receptors. In the past, it has been thought that much of the transmembrane transport of hormones was passive. Evidence is now in hand that there are specific organic anion transporters involved in cellular uptake of thyroid hormone (see reference ). This may be found to be the case for other small ligands as well, revealing yet another mechanism for ensuring the distribution of a hormone to its site of action.
TARGET CELLS AS ACTIVE PARTICIPANTS

Hormones determine cellular target actions by binding with high specificity to receptor proteins. Whether a peripheral cell is hormonally responsive depends to a large extent on the presence and function of specific and selective hormone receptors. Receptor expression thus determines which cells will respond, as well as the nature of the intracellular effector pathways activated by the hormone signal. Receptor proteins may be localized to the cell membrane, cytoplasm, and nucleus. Broadly, polypeptide hormone receptors are cell-membrane associated, whereas soluble intracellular proteins selectively bind to steroid hormones (Fig. 1-2) (Figure Not Available). This idea of selective localization has recently been challenged, however, because related sequences can be found in multiple cellular compartments.

Membrane-associated receptor proteins usually consist of extracellular sequences that recognize and bind ligand, transmembrane anchoring hydrophobic sequences, and intracellular sequences, which initiate intracellular signaling. Intracellular signaling is mediated by soluble second messengers (e.g., cyclic AMP) or by activation of intracellular signaling molecules (e.g., signal transduces and activates of transcription [STAT] proteins). Receptor-dependent activation of heterotrimeric G-proteins, comprising , , and subunits, may either induce or suppress effector enzymes or ion channels.

Figure 1-2 (Figure Not Available) Hormonal signaling by cell-surface and intracellular receptors. The receptors for the watersoluble polypeptide hormones, LH, and IGF-I; are integral membrane proteins located at the cell surface. They bind the hormone-utilizing extracellular sequences and transduce a signal by the generation of second messengers, cAMP for the LH receptor, and tyrosine-phosphorylated substrates for the IGF-I receptor. Although effects on gene expression are indicated, direct effects on cellular proteins, for example, ion channels, are also observed. In contrast, the receptor for the lipophilic steroid hormone progesterone resides in the cell nucleus. It binds the hormone and becomes activated and capable of directly modulating target gene transcription. (TF = transcription factor; R = receptor molecule.) (Reproduced from Mayo K. In Conn PM, Melmed S (eds). Endocrinology: Basic and Clinical Principles. Totowa, NJ, Humana Press, 1997, p. 11.)

Several growth factors and hormone receptors (e.g., for insulin) behave as intrinsic tyrosine kinases or activate intracellular protein tyrosine kinases. Ligand activation may cause receptor dimerization (e.g., growth hormone [GH]) or heterodimerization (e.g., interleukin-6 [IL-6]), followed by activation of intracellular phosphorylation cascades. These activated proteins ultimately determine specific nuclear gene expression.

Both the number of receptors expressed per cell and their responses are also regulated, thus providing a further level of control for hormone action. Several mechanisms account for altered receptor function. Receptor endocytosis causes internalization of cell surface receptors; the hormonereceptor complex is subsequently dissociated, resulting in abrogation of the hormone signal. Receptor trafficking may then result in recycling back to the cell surface (e.g., as for insulin), or the internalized receptor may undergo lysosomal degradation. Both these mechanisms triggered by activation of receptors effectively lead to impaired hormone signaling by down-regulation of these receptors. The hormone signaling pathway may also be down-regulated by receptor desensitization (e.g., as for epinephrine); ligand-mediated receptor phosphorylation leads to a reversible deactivation of the receptor. Desensitization mechanisms can be activated by a receptor’s ligand (homologous desensitization) or by another signal (heterologous desensitization), thereby attenuating receptor signaling in the continued presence of ligand. Receptor function may also be limited by the action of specific phosphatases (e.g., Src homology 2 domain-containing protein tyrosine phosphatase [SHP]) or by intracellular negative regulation of the signaling cascade (e.g., suppressor of cytokine signaling [SOCS] proteins inhibiting Janus kinase [JAK]-STAT signaling).

Mutational changes in receptor structure can also determine hormone action. Constitutive receptor activation may be induced by activating mutations (e.g., TSH receptor), leading to endocrine organ hyperfunction, even in the absence of hormone. Conversely, inactivating receptor mutations may lead to endocrine hypofunction (e.g., testosterone or vasopressin receptors). These syndromes are now well characterized and are well described in this volume (Fig. 1-3).

The functional diversity of receptor signaling also results in overlapping or redundant intracellular pathways. For example, both GH as well as cytokines activate JAK-STAT signaling, whereas the distal effects of these stimuli clearly differ. Thus, despite common signaling pathways, hormones elicit highly specific cellular effects. Tissue or cell-type genetic programs or receptorreceptor interactions at the cell surface (e.g., dopamine D2 with somatostatin receptor hetero-oligization) may also confer specific cellular response to a hormone and provide an additive cellular effect.
CONTROL OF HORMONE SECRETION

Anatomically distinct endocrine glands are composed of highly differentiated cells that synthesize, store, and secrete hormones. Circulating hormone concentrations are a function of glanular secretory patterns and hormone clearance rates. Hormone secretion is tightly regulated to attain circulating levels that are most conducive to elicit the appropriate target tissue response. For example, longitudinal bone growth is initiated and maintained by exquisitely regulated levels of circulating hormones, whereas mild GH hyperssecretion results in gigantism and GH deficiency causes growth retardation. Ambient circulating hormone concentrations are not uniform, and secretion patterns determine appropriate physiologic function. Thus, insulin secretion occurs in short pulses elicited by nutrient and other signals and gonadotrophin secretion is episodic, determined by a hypothalamic pulse generator, whereas prolactin secretion appears to be relatively continuous, with secretory peaks elicited during suckling.

Hormone secretion also adheres to rhythmic patterns. Circadian rhythms serve as adaptive responses to environmental signals and are controlled by a circadian timing mechanism. Light is the major environmental cue adjusting the endogenous clock. The retinohypothalamic tract entrains circadian pulse generators situated within hypothalamic suprachiasmatic nuclei. These signals subserve timing mechanisms for the sleep-wake cycle and determine patterns of hormone secretion and action. Disturbed circadian timing results in hormonal dysfunction and may also be reflective of entrainment or pulse generator lesions. For example, adult GH deficiency due to a damaged hypothalamus or pituitary is associated with elevations in integrated 24-hour leptin concentrations, decreased leptin pulsatility, and yet preserved circadian rhythm of leptin. GH replacement restores leptin pulsatility, followed by loss of body fat mass. Sleep is also an important cue regulating hormone pulsatility. About 70% of overall GH secretion occurs during sleep, and increasing age is associated with declining slow-wave sleep and concomitant decline in GH and elevation of cortisol secretion. Most pituitary hormones are secreted in a circadian (day-night) rhythm, best exemplified by ACTH peaks before 9 AM, whereas ovarian steroids follow a 28-day menstrual rhythm. Disrupted episodic rhythms are often a hallmark of endocrine dysfunction. Thus, loss of circadian ACTH secretion with high midnight cortisol levels is a feature of Cushing's disease.

Hormone secretion is induced by multiple specific biochemical and neural signals. Integration of these stimuli results in the net temporal and quantitative secretion of the hormone (Fig. 1-4). Thus, signals elicited by hypothalamic hormones (GHRH, somatostatin), peripheral hormones (iGF-I, sex steroids, thyroid hormone), nutrients, adrenergic pathways, stress, and other neuropeptides, all converge on the somatotroph cell, resulting in the ultimate pattern and quantity of GH secretion. Networks of reciprocal interactions allow for dynamic adaptation and shifts in environmental signals. These regulatory systems embrace the hypothalamic, pituitary, and target endocrine glands, as well as the adipocyte and lymphocyte. Peripheral inflammation and stress elicit cytokine signals, which interface with the neuroendocrine system, resulting in hypothalamic-pituitary axis activation. The parathyroid and pancreatic secreting cells are less tightly controlled by the hypothalamus, but their functions are tightly regulated by the effects they elicit. Thus, parathyroid hormone (PTH) secretion is induced when serum calcium levels fall, and the signal for sustained PTH secretion is abrogated by rising calcium levels.

Several tiers of control subserve the ultimate net glandular secretion. First, central nervous system signals including stress, afferent stimuli, and neuropeptides signal the synthesis and secretion of hypothalamic hormones and neuropeptide (Fig. 1-5). Four hypothalamic releasing hormones (GHRH, corticotropin-releasing hormone [CRH], TRH, and gonadotrophin releasing hormone [GnRH]) traverse the hypothalamic portal vessels and impinge on their respective transmembrane tropic hormone-secreting cell receptors. These distinct cells express GH, ACTH, TSH, and gonadotrophins. In contrast, hypothalamic somatostatin and dopamine suppress GH, prolactin (PRL), or TSH secretion. Trophic hormones also maintain the structural-functional integrity of endocrine organs, including the thyroid and adrenal glands, and the gonads. Target hormones, in turn, serve as powerful negative feedback regulators of their respective tropic hormone and often also suppress secretion of hypothalamic releasing hormones. In certain circumstances, for example during puberty, peripheral sex steroids may positively induce the hypothalamic-pituitary-gland axis. Thus, luteinizing hormone (LH) induces ovarian estrogen.
A further level of secretion control occurs within the gland itself. Thus, intraglandular paracrine or autocrine growth peptides serve to autoregulate pituitary hormone secretion, as exemplified by epidermal growth factor (EGF) control of prolactin or IGF-I control of GH secretion. Molecules within the endocrine cell may also subserves an intracellular feedback loop. Thus, corticotrope SOCS-3 induction by gp 130-linked cytokines serves to abrogate the ligand-induced JAK-STAT cascade and to block pro-opiomelanocortin gene transcription and ACTH secretion. This rapid on-off regulation of ACTH secretion provides a plastic endocrine response to changes in environmental signaling and serves to maintain homeostatic integrity.\(^1\)

In addition to the central-neuroendocrine interface mediated by hypothalamic chemical signal transduction, the CNS directly controls several hormonal secretory processes. Posterior pituitary hormone secretion occurs as direct efferent neural extensions. Postganglionic sympathetic nerves also regulate rapid changes in renin, insulin, and glucagon secretion, and preganglionic sympathetic nerves signal to adrenal medullary cells, eliciting adrenaline release.
HORMONE MEASUREMENT

Endocrine function can be assessed by measuring levels of basal circulating hormone, evoked or suppressed hormone, or hormone-binding proteins. Alternatively, peripheral hormone receptor function can be assessed. Meaningful strategies for timing hormonal measurements vary from system to system. In some cases, circulating hormone concentrations can be measured in randomly collected serum samples. This measurement, when standardized for fasting, environmental stress, age, and gender, is reflective of true hormone concentrations only when levels do not fluctuate appreciably. For example, thyroid hormone, prolactin, and IGF-I levels can be accurately assessed in fasting morning serum samples. On the other hand, when hormone secretion is clearly episodic, timed samples may be required over a defined time course to reflect hormone bioavailability. Thus, early morning and late evening cortisol measurements are most appropriate. Although 24-hour sampling for GH measurements, with samples collected every 2, 10, or 20 minutes, are expensive and cumbersome, they may yield valuable diagnostic information. Random sampling may also reflect secretion peaks or nadirs, thus confounding adequate interpretation of results.

In general, confirmation of failed glandular function is made by attempting to evoke hormone secretion by recognized stimuli. Thus, testing of pituitary hormone reserve may be accomplished by injecting appropriate hypothalamic releasing hormones. Injection of tropic hormones, including TSH and ACTH, evokes specific target gland hormone secretion. Pharmacologic stimuli, for example metoclopramide for induction of prolactin secretion, may also be useful tests of hormone reserve. In contrast, hormone hypersecretion can be diagnosed by suppressing glandular function. Thus, failure to appropriately suppress GH levels after a standardized glucose load implies inappropriate GH hypersecretion.

Radioimmunoassays utilize highly specific antibodies unique to the hormone, or a hormone fragment, to quantify hormone levels. Enzyme-linked immunoabsorbent assays (ELISA) employ enzymes instead of radioactive hormone markers, and enzyme activity is reflective of hormone concentration. This sensitive technique has allowed ultrasensitive measurements of physiologic hormone concentrations. Hormone-specific receptors may be employed in place of the antibody in a radioreceptor assay.
ENOCRINE DISEASES

Endocrine diseases fall into four broad categories: (1) hormone overproduction; (2) hormone underproduction; (3) altered tissue responses to hormones; and (4) tumors of endocrine glands.

Hormone Overproduction

Occasionally, hormones are secreted in increased amounts because of genetic abnormalities that cause abnormal regulation of hormone synthesis or release. In glucocorticoid-remediable hyperaldosteronism, for example, an abnormal chromosomal crossing-over event puts the aldosterone synthetase gene under the control of the ACTH-regulated 11α-hydroxylase gene. More often, diseases of hormone overproduction are associated with an increase in the total number of hormone-producing cells. For example, the hyperthyroidism of Graves' disease, in which antibodies mimic TSH and activate the TSH receptors on thyroid cells, is associated with dramatic increase in thyroid cell proliferation, as well as with increased synthesis and release of thyroid hormone from each thyroid cell. In this example, the increase in thyroid cell number represents a polyclonal expansion of thyroid cells, in which large numbers of thyroid cells proliferate in response to an abnormal stimulus. Most endocrine tumors are not polyclonal expansions, however, but instead represent monoclonal expansions of one mutated cell. Pituitary and parathyroid tumors, for example, are usually monoclonal expansions in which somatic mutations occur in multiple tumor suppressor genes and proto-oncogenes. These mutations lead to an increase in proliferation and/or survival of the mutant cells. Sometimes this proliferation is associated with abnormal secretion of hormone from each tumor cell as well. For example, mutant G proteins in somatotrophs can lead to both increased cellular proliferation and increased secretion of growth hormone from each tumor cell.
Hormone Underproduction

Underproduction of hormone can result from a wide variety of processes, ranging from surgical removal of parathyroid glands during neck surgery, to tuberculous destruction of adrenal glands, or to iron deposition in β-cells in hemochromatosis. A frequent cause of destruction of hormone-producing cells is autoimmunity. Autoimmune destruction of beta cells in type 1 diabetes mellitus and autoimmune destruction of thyroid cells in Hashimoto’s thyroiditis are two of the most common disorders treated by endocrinologists. More uncommonly, a host of genetic abnormalities can also lead to decreased hormone production. These disorders can result from abnormal development of hormone-producing cells (e.g., hypogonadotrophic hypogonadism caused by KAL gene mutations), from abnormal synthesis of hormones (e.g., deletion of the growth hormone gene), or from abnormal regulation of hormone secretion (e.g., the hypoparathyroidism associated with activating mutations of the parathyroid cell’s calcium-sensing receptor).
Altered Tissue Responses

Resistance to hormones can be caused by a variety of genetic disorders. Examples include mutations in the growth hormone receptor in Laron dwarfism and mutations in the G gene in the hypoparathyroidism of pseudohypoparathyroidism, type 1a. The insulin resistance in muscle and liver central to the etiology of type 2 diabetes mellitus appears to be polygenic in origin. Type 2 diabetes is also an example of a disease in which end organ insensitivity is worsened by signals from other organs, in this case by signals originating in fat cells. In other cases, the target organ of hormone action is more directly abnormal, as in the parathyroid hormone (PTH) resistance of renal failure.

Increased end organ function can be caused by mutations in signal reception and propagation. For example, activating mutations in TSH, LH, and PTH receptors can cause increased activity of thyroid cells, Leydig cells, and osteoblasts, even in the absence of ligand. Similarly, activating mutations in the $G_s$ protein can cause precocious puberty, hyperthyroidism, and acromegaly in McCune-Albright syndrome.
Tumors of Endocrine Glands

Tumors of endocrine glands, as noted above, often result in hormone overproduction. Some tumors of endocrine glands produce little if any hormone but cause disease by their local compressive symptoms or by metastatic spread. Examples include so-called nonfunctioning pituitary tumors, which are usually benign but can cause a variety of symptoms due to compression on adjacent structures, and thyroid cancer, which can spread throughout the body without causing hyperthyroidism.
THERAPEUTIC STRATEGIES

In general, hormones are employed pharmacologically for both their replacement and their suppressive effects. Hormones may also be used for diagnostic stimulatory effects (e.g., hypothalamic hormones) to evoke target organ responses or to diagnose endocrine hyperfunction by suppressing hormone hypersecretion (e.g., T_{3}). Ablation of endocrine gland function due to genetic or acquired causes can be restored by hormone replacement therapy. In general, steroid and thyroid hormones are replaced orally, whereas peptide hormones (e.g., insulin, DH) require injection. Gastrointestinal absorption and first-pass kinetics determine oral hormone dosage and availability. Physiologic replacement can achieve both appropriate hormone levels (e.g., thyroid), as well as approximate hormone secretory patterns (e.g., GnRH delivered intermittently via a pump). Hormones can also be used to treat diseases associated with glandular hyperfunction. Long-acting depot preparations of somatostatin analogs suppress GH hypersecretion in acromegaly or 5-HIAA hypersecretion in carcinoid syndrome. Estrogen receptor antagonists (e.g., tarmoxifen) are useful for some patients with breast cancer, and GnRH analogs may downregulate the gonadotrophin axis and benefit patients with prostate cancer.

Novel formulations of receptor-specific hormone ligands are now being clinically developed (e.g., estrogen agonists/antagonists, somatostatin receptor subtype ligands), resulting in more selective therapeutic targeting. Modes of hormone injection (e.g., for PTH) may also determine therapeutic specificity and efficacy. Improved hormone delivery systems, including computerized minipumps, intranasal sprays (e.g., for 1-desamino-8-D-arginine vasopression [DDAVP]), pulmonary inhalations, and depot intramuscular injections, will also allow added patient compliance and ease of administration.

Despite this tremendous progress, some therapies, such as insulin delivery to rigorously control blood sugar, still require tremendous patient involvement and await innovative approaches.

Chapter 2 - The Endocrine Patient

Daniel D. Federman

A textbook of medicine is inevitably about disease, but the practice of medicine deals with illness, that is, a person experiencing a disease. It is for that reason that the present chapter has been entitled "The Endocrine Patient." It is my intention to lay out the general issues and approaches applicable to caring for patients with endocrine disorders. The topics to be discussed include initial evaluation and the nature of referral, the fact finding required in clinical evaluation, the use of the laboratory and imaging, the formulation of a differential diagnosis, decision making, and management. In each case, the steps are portrayed from the patient's point of view.

It is worth noting that, except for acute adrenal insufficiency, endocrine disorders are seldom life-threatening. They have enormous effect on the quality of life, however, and successful intervention can be extremely important to both patient and family.
GENERAL CONSIDERATIONS

Many features of being an endocrine patient are common to all experiences of illness. Most often, a perceived change in bodily function, a symptom, gets one to the doctor. Although generations of medical students have described new patients as being “in no acute distress,” most patients are, in fact, worried and anxious when they see a physician, the more so when the physician is not known to them. A few minutes spent in getting to know the patient can pay enormous dividends in the accuracy of the history obtained and in setting the stage for further cooperation with testing and treatment.

Inasmuch as most endocrine consultation is elective rather than emergent, I favor asking a few simple questions, such as “Where are you from?” “What do you do?” “How did you come to us?” “Were you referred?” and so on. Almost always, some common experience or acquaintance is discovered that provides the basis for a rapport that does not emerge from formal medical questioning. This step also immediately conveys that you are interested in the patient as a person and not just as a disease.
SPECIAL FEATURES OF ENDOCRINE ILLNESS

Discovery through Screening

Numerous special features of endocrine disease make patient presentation quite different from that seen in general medicine. One is the discovery of abnormality through screening of asymptomatic individuals, for example, a high serum calcium level discovered through multiphasic screening or a high blood glucose level discovered in a shopping mall kiosk. The very absence of symptoms lends an unreality to the moment and should become an explicit topic of the patient-doctor interaction. In this circumstance, it is worth emphasizing the value of early discovery and prevention of greater morbidity.
Quantitative Rather Than Qualitative Abnormalities

A second special feature of endocrine disorders is that they are all quantitative, rather than qualitative, departures from normal. No endocrine disorder is due to a novel hormone. Everyone has cortisol circulating as a determining feature of his or her life. Hypercorticism and adrenal insufficiency represent just more or less of the hormone. Similarly, all hormones found in excess or in deficiency in disease are physiologic determinants of stature, weight, complexion, hairiness, temperament, and behavior. In contrast, no one has a little pneumonia or a little inflammatory bowel disease as a constitutive status. In addition, most endocrine glands have both a basal and a stimulable or reserve function. It is common to have partial diminution of capacity in which the basal function is adequate but a reserve called upon during part of each day or, more dramatically, in emergencies is not available.
Overlap with Other Diseases

The symptoms of endocrine disorders overlap a great range of normal characteristics, including body contour, facial configurations, weight distributions, skin and hair coloring, and muscular capacity. They also overlap with other conditions that are far more common, including depression and normal aging. The added adipose tissue of hyperadrenocorticism is more difficult to recognize in a person who is already obese. The nervousness associated with hyperthyroidism is less apparent in a thin, hyperkinetic man than in a person of moderate body weight. The effects of an androgen-producing adrenal tumor are less likely to be noticed in a family of swarthy, hirsute individuals.

Finally, most endocrine disorders evolve gradually over months to years instead of appearing suddenly, such as a heart attack or an acute infection. This combination of varied host background and slow evolution of disease leads to considerable delay in diagnosis: both the patient and primary care physician adapt to the changes as part of the person, and definitive evaluation, now relatively easy for most disorders, is not undertaken. Hypothyroidism and acromegaly are good examples of this phenomenon. All series show a remarkable delay in diagnosis despite sometimes disabling symptoms.

Hormones have more distant effects than local effects. This, of course, reflects their messenger status. Unlike an abscess, a myocardial infarction, or an esophageal cancer, endocrine disorders seldom produce symptoms near the gland of origin. (Subacute thyroiditis and large pituitary tumors, of course, are exceptions.) But because in most endocrinopathies the excess or missing hormone works on several or many systems, the resulting syndrome can be enigmatic.

Several endocrine disorders are important not because of their incidence but because of their curability: Cushing's disease, acromegaly, and pheochromocytoma are cases in point. Although these disorders enter the differential diagnosis of common problems such as diabetes, their occurrence is so rare that the primary care physician does not easily think of them.
Unique Features of Reproductive Disorders

Reproductive disorders have symptoms and signs that have no parallel in other areas. This is the one system in which sexual dimorphism is inherent rather than epiphenomenal; it is also the one with the greatest span of developmental change. Once the heart starts beating in the embryo, it goes on doing so until the last moment of life; but puberty, adult sexual functioning, and menopause establish time lines against which all symptoms are to be assessed. Thus, vaginal bleeding has entirely different meanings whether it occurs on the first day of life, as a natural appearance at age 12, between menstrual periods at age 25 years, as a harbinger of menopause at age 46 years, or as a highly probable symptom of cancer at age 66 years.

Physical appearance and function are important features of self-image. Thus, hirsutism, thinness, obesity, sexual arousal, and erectile capacity bear considerable psychological import to the endocrine patient. The clinician should be constantly aware of both spoken and unspoken thoughts that may be troubling the patient.

The Couple as a Clinical Unit

The ultimate goal of reproductive capacity is, of course, a fertile union. This means that the couple, rather than the individual, is the unit of clinical concern. It is thus the principal area in medicine whereby two people and their interaction, rather than a single person and her capacities, are studied and treated. In addition, there are dimensions of successful sexual function that are important at other times than when fertility is sought. Sex drive, erotic responsiveness, affection, and tenderness are all important aspects of life whether or not fertility is an issue. These areas are notoriously difficult to evaluate in a society that treats sexual function as such a special topic, particularly enshrouded in personal issues of such importance.
EVALUATION OF PATIENTS WITH ENDOCRINE DISORDERS

I have emphasized previously the belief that establishing an interested and warm relationship is the beginning of excellence in any elective medical interaction. In addition to its affective power, the relationship elicits a more informative history, establishes better cooperation in both testing and treatment, and provides a platform for informed decision making by the patient.

History

As in most areas of medicine, precision of diagnosis and economy of investigation begin with a carefully wrought history. An open-ended question, combined with an attentive silence, allows the patient to provide the background for the clinical moment. After the patient has spoken spontaneously, the physician provides a guided expansion of the information. Details of timing, sequence, changes of diet or activity, relationship to the menstrual cycle, changes in weight or size, and alterations in mood or sleep pattern all of these may provide clues to underlying endocrine abnormality.

A good example of the power of the history is the interpretation of irregular periods in a woman of reproductive age. The simple statement, “I’ve never been regular,” points to a presumptive diagnosis of polycystic ovary syndrome in a way that a very convoluted sequence of questions might actually fail to do. That statement is to be contrasted with this one: “I used to be regular, but in the last year or so, I never know when my period is going to come.” If the presenting symptom is irregular periods, the simple invitation, “Tell me about your periods,” is likely to be the key to the diagnosis.

Careful questioning about use of complementary and alternative medicines is an important and, occasionally, a very revealing step.

A thorough family history has become increasingly important as the genetic basis for more and more endocrine diseases becomes established. For practical purposes, I favor diagramming a pedigree of the first-order relatives—parents, siblings, children—of all patients, not just those for whom a genetic disorder is already suspected. Known disorders are readily revealed this way, and unknown conjunctions of clinical and genetic factors may also be disclosed.
Physical Examination

General Examination

It is said that the history is 80% or more of clinical diagnosis, and that is no less true in endocrine disorders than in general medicine. Yet the physical examination is a critical element in the process of arriving at a diagnosis, and here I want to call particular attention to the first impression.

The possibility of Cushing’s syndrome, Addison’s disease, hyperthyroidism and hypothyroidism, acromegaly, polycystic ovary syndrome, hypogonadism, and Turner’s syndrome and other endocrine disorders should be considered from the first moment one encounters a new patient. Otherwise, one risks accepting that the appearance of the patient is just that and no more. In other words, as soon as one accepts that the initial impression is what the person looks like naturally, the quantitative departure from normal that is the essence of endocrine disease fails to impress one. This, incidentally, is why both families and primary care physicians often miss a diagnosis that seems obvious to the consultant endocrinologist.

A quantification of this last point may be helpful. If the signs of hypothyroidism or acromegaly, for example, take 3 years to become striking, the person living with the patient is exposed to 1/1095th of fractional change per day, well below the threshold of just noticeable difference. Similarly, a primary care physician seeing the patient perhaps four times a year for a general checkup and management of hypertension is exposed to 91/1095 fractional change. This can sometimes lead to a diagnosis but often does not. When one sees the patient for the first time, however, the imprint of the disease catches attention and the constitutional appearance is in the background.

Although a consultant participates because of a special area of interest and expertise, he or she is a general physician first and should be alert to all dimensions of the physical examination:

- What is the height/weight ratio?
- What is the basic degree of muscularity?
- Is there evidence of heart disease to explain the chest pain and dyspnea one has heard about in the history?
- What is the degree of hirsutism?
- Are there signs of liver disease, malnutrition, or poor or excellent physical training?
- What is the blood pressure with the patient standing as well as lying or sitting?

These and many other points of a general examination begin to modify the thinking one has undertaken on the basis of history.

Targeted Examination

The targeted physical examination of any consultant is an interesting interplay of general and specific goals. Theoretically, any experienced clinician should undertake a general examination and come to all the findings pertinent to an underlying endocrine disorder. In fact, however, the physical examination is greatly influenced by the hypotheses generated in the history. Let us look at a few examples.

If a patient reports weight loss despite a good appetite, there is only a very restricted differential diagnosis, principally malabsorption or hypermetabolism. In doing a physical examination, therefore, I would pay particular attention to signs of malabsorption (muscular wasting, vitamin deficiencies, purpura) and to signs of thyroid disease with its generalized hypermetabolism and localized autoimmune phenomena, including ophthalmopathy.

Similarly, if a patient complains of hirsutism or other signs of androgen excess, one is immediately thrust into a consideration of ethnic hair distribution and quality. Is there temporal recession of the forehead? Does the hair on the abdomen come up over the umbilicus? Is hair present on the back (rare without marked hyperandrogenism)? How much acne is there? At the extreme, is there evidence of clitoral enlargement?

Finally, and most important, does the patient look like or unlike the other women in her family?

Direct Assessment of Endocrine Glands

Three endocrine glands are palpable: the thyroid, the testis, and the ovary. Specific attention should be given to each of these.

The thyroid gland should be approached first by inspection while the patient swallows for size, symmetry, or localized enlargement. Many thyroid nodules are visible, and inspection often calls attention to lesions that would be missed on palpation. The thyroid should then be felt while the patient swallows, from the front with your thumbs or from behind the patient with the index and third fingers. It is crucial to keep your own fingers from moving while the patient is swallowing. The principal observation is whether there is diffuse enlargement of the thyroid gland (most often Graves’ diffuse hyperplasia or Hashimoto’s thyroiditis) or one or more nodules. Although the consistency of the gland is to be noted, in fact it is often not concordant with the pathology.

Functioning tumors of the testis may be too small to be felt with the fingers, and most internists and general physicians are not skilled in palpation of the ovaries. For this reason, ultrasound and other forms of imaging have become key features of gonadal evaluation and are discussed later.

The size of one other endocrine gland, the pituitary, can be inferred from physical examination for what Cushing called “neighborhood signs.” As a pituitary tumor or adenoma increases in size, it pushes up on the optic apparatus, producing visual field changes and often to a degree to be easily detected. Many consequences of hormone action can be detected on physical examination; the results combine with the history to produce a highly reliable differential diagnosis and thus an informed basis for laboratory evaluation and imaging. Among the things to be looked for are the eye signs and dermopathy of Graves’ disease, acanthosis nigricans as a clue to insulin resistance, muscular wasting and tremor, changes in the voice due to hypothyroidism or acromegaly, and a general impression of nutrition and its adequacy or excess. Each of these findings is described in more detail with the specific disorder in subsequent chapters.

Indirect Assessment of Endocrine Status

Many consequences of hormone action can be detected on physical examination; the results combine with the history to produce a highly reliable differential diagnosis and thus an informed basis for laboratory evaluation and imaging. Among the things to be looked for are the eye signs and dermopathy of Graves’ disease, acanthosis nigricans as a clue to insulin resistance, muscular wasting and tremor, changes in the voice due to hypothyroidism or acromegaly, and a general impression of nutrition and its adequacy or excess. Each of these findings is described in more detail with the specific disorder in subsequent chapters.
LABORATORY TESTING OF ENDOCRINE FUNCTION

Modern endocrine laboratory evaluation began with the introduction of radioimmunoassay by Berson and Yalow. The precise measurement of hormone concentrations, determined by competitive displacement of specific antibodies, was soon succeeded by competitive binding assays and, more recently, by immunofluorescent and radioluminescent determinations of even greater sensitivity and specificity. It should therefore be possible to enter the name of a hormone on a laboratory slip and expect to get back a definitive reflection of the status of the patient for that gland.

For practical purposes, that has become true of thyroid-stimulating hormone (TSH). Reliable determinations of elevated, normal, and suppressed levels of this hormone by radioor chemiluminescent determination have made it the standard of care for thyroid disease and a model for all endocrine laboratory tests. However, it is an exception rather than the rule, and it is worthwhile reviewing why other testing is not as easy and why considerable judgment is required. The following examples illustrate this point.

Pulsatile Hormone Secretion

Many hormones are secreted in pulses rather than steadily. The peaks or valleys of hormones secreted in pulsatile fashion, such as luteinizing hormone or growth hormone, may fall above or below the ostensibly normal range. If such a value is obtained by chance, it can erroneously suggest hypofunction or hyperfunction. Repeating the test with three samples drawn at 30-minute intervals and pooled can clarify this type of problem.
Diurnal Variation

The hypothalamic-pituitary-adrenal axis of cortisol secretion is typically maximal during the day and lower in the evening and night. A plasma cortisol level of 12 µg/dL is normal at 8 AM, but the same value at 8 PM reflects a loss of diurnal rhythm resulting from either stress or hypercorticism. A plasma cortisol sample drawn at midnight is an excellent test for evaluation of overactive adrenal function.
Cyclic Variation

The menstrual cycle provides the most extreme "normal variation" of any hormone level. From the first day of a menstrual period, when estrogen levels may be indistinguishable from those of a normal man, the level rises extraordinarily rapidly and at the 14th day can be as high as in early pregnancy. As a consequence, an estrogen level must be evaluated in the light of the stage of the cycle at which it is drawn.
Age

All clinicians are aware that gonadal hormones show marked differences reflective of the individual's stage of life. It is not as widely known that the adrenal hormone dehydroepiandrosterone (DHEA) is barely secreted during childhood, is actively put out by the adrenal glands from age 8 or so to age 55, and then disappears as mysteriously as it came. At present, there is no clear understanding of the physiologic role of its presence or absence.
Sleep Entrainment

Both prolactin and growth hormone have a sleep-entrained secretory pulse shortly after sleep begins. In people who work at night and sleep during the day, this secretion is clearly related to sleep and not to clock time.
Hormone Antagonism

Certain hormones antagonize the effects of other hormones; it is thus necessary to know the value of each hormone to interpret the clinical phenomenon. The opposite effects of estrogen and androgen on the male breast are a good example. A normal testosterone level combined with an elevated estrogen level, or a normal estrogen level but a decreased androgen level, easily accounts for gynecomastia.
Dynamic Testing

Many endocrine glands have a basal secretory level and a reserve secretion elicited by either a tropic hormone or a change in metabolic or physiologic state. Cortisol secretion can increase fivefold to 10-fold in response to stress or adrenocorticotropic hormone (ACTH). Insulin release is stimulated by both glucose and amino acids and by distinct pathways.

Baseline hormone levels can be misleading. The test results in Table 2-1 were obtained on a 30-year-old woman who complained of fatigue and amenorrhea 6 months after a pregnancy during which she had been markedly anemic (hemoglobin, 9 g/dL); she had never been in shock and had received no transfusions.
Hormone and Metabolite Interaction

Insulin is a good example of a hormone whose absolute level is less meaningful than its relationship to the blood glucose level. A plasma insulin of 70 is a normal response to a meal, when the blood glucose level is rising. In contrast, an insulin value of 10 or 12 is abnormal (is not appropriately suppressed) if the glucose level is 40 mg/dL. Indeed, the lower insulin level in a hypoglycemic patient is distinct evidence of spontaneous hyperinsulinism, such as in an islet cell tumor.

Growth hormone represents another instance in which a single random sample cannot be given much meaning. During a day, plasma growth hormone levels vary from values that, if sustained, would be diagnostic of acromegaly to values that, again if sustained, would point to hypopituitarism. In normal people, growth hormone secretion is suppressed by glucose intake. A plasma growth hormone of 8 within an hour of a standard meal containing glucose would be pathologically elevated; it should be less than 2. Similarly, however, a growth hormone value of 2 in a fasting person who had run up a flight of stairs suggests deficient pituitary function.

Most hormones are part of a feedback loop in which an artificial increase, especially by ingestion of the hormone in a medication, decreases endogenous secretion. If a normal person takes 0.1 to 0.3 mg of thyroxine (T₄), hypothalamic secretion of thyrotropin-releasing hormone (TRH) and pituitary secretion of thyrotropin (TSH, or thyroid-stimulating hormone) are suppressed. Plasma levels of T₄ and triiodothyronine (T₃) may not change, but TSH levels would be decreased and reflections of TSH effect, such as radioactive iodine uptake, would similarly be suppressed. Although ultrasensitive TSH testing has replaced tests of suppressibility for the diagnosis of thyroid disease, tests of suppressibility are the standard approach to evaluating growth hormone and ACTH/cortisol regulation, respectively.
Protein Binding

Hormones such as T₄ and cortisol are compartmentalized into a fraction attached to a transport protein (and thus physiologically unavailable) and a free portion able to diffuse into cells and initiate a hormone effect. It is the free or unbound portion that is physiologically regulated; the level of the binding protein may be increased or decreased without physiologic consequence if the free portion is unchanged. The measurement of free T₄ or a free T₄ index (FT₄ I) (see Chapter 10) has become the standard second step if a screening TSH value is abnormally high or low.

Testosterone is even more complicated because it is trebly partitioned among sex hormone-binding globulin, albumin, and a free portion. Measurement of the free hormone level is often necessary, particularly when the binding protein level has been artifactually raised or lowered (see Chapter 6).

*In this study, all basal values are within normal limits. Note, however, that intravenous insulin lowers the blood glucose levels but does not elicit an adequate release of cortisol. Thyrotropin-releasing hormone (TRH) does not induce a normal rise in thyrotropin (TSH) or prolactin. Gonadotropin-releasing hormone (GnRH) evokes a submaximal increase in follicle-stimulating hormone (FSH) and luteinizing hormone (LH).*
Laboratory Error

Laboratory error may seem too obvious a source of confusion to mention, but it provides a reminder for an important caution about laboratory testing. It is easy to be seduced by numbers and to consider the laboratory report the final arbiter. In fact, it is the history and physical examination, plus the clinician’s judgment, that establish the prior probability of a given diagnosis. Both in choosing and in interpreting laboratory tests, the endocrinologist should establish his or her own expectations before testing. If the physician feels strongly that a particular condition is present, discordant initial laboratory results should not be dissuasive. More detailed testing, as discussed in subsequent chapters, is then appropriate. The clinician’s judgment is still a key component of the process.
IMAGING

The extraordinary power of modern imaging, particularly ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI), has enriched endocrinology as it has all of medicine. However, the role of imaging in endocrinology is, to my mind, different from its contribution elsewhere.

For one thing, several endocrine glands (the thyroid, the pituitary, and the adrenals in particular) frequently contain clinically insignificant, nonfunctioning adenomas and cysts. Second, functioning and nonfunctioning lesions other than in the thyroid gland can be very difficult to distinguish from each other. Thus, except in an emergency (e.g., suspected pituitary apoplexy), the clinician should define the functional state of the gland before requesting imaging. In other words, one should be clear from hormone measurements, including dynamic testing, whether the gland is overactive, underactive, or normal.

In addition, one should have a clear idea of how the radiologist can be expected to help. Such clarity reduces costs by targeting the selection of imaging and making the radiologic findings a truly complementary element of evaluation. The best imaging modalities for the various glands are discussed in their respective chapters. The approach suggested here, however, is broadly applicable.
CONVEYING RESULTS

Both sophisticated imaging and thorough laboratory testing produce results after the actual office visit. Patients are understandably anxious about the findings and deserve a prompt response. The best approach depends on the circumstance. A new patient with Cushing's syndrome or acromegaly should be given an early in-person visit. A patient with hypothyroidism who understands the disease well and just needs a slight change in $T_4$ dose can easily be informed with a telephone call. Someone with negative results can be left a message of reassurance and can be encouraged to call back, both to confirm receipt of the information and to get questions answered.
SOME NEW FEATURES OF CLINICAL ENDOCRINOLOGY

Genetics

The decoding of the human genome promises to change the face of medical practice. Ironically, the first human disease in which cancer was prevented by application of genetic testing in susceptible families was the screening for medullary thyroid carcinoma in pedigrees of multiple endocrine neoplasia type 2 (MEN-2). The screening at that time was done by pentagastrin or calcium provocation of calcitonin release. Now the screening for endocrine manifestations of MEN-2 is secondary to screening families for the \textit{RET} proto-oncogene defect that is the basis of the disease.

Endocrine testing, such as measurement of calcitonin or plasma catecholamines, is restricted to patients who have the genetic abnormality. In the dangerous variant of the MEN-2 syndrome in which medullary thyroid carcinomas appear in the first year of life, aggressive genetic screening is done during that year, and endocrine testing in patients at risk can justify surgical thyroidectomy before the first birthday. Hereditary predispositions will certainly emerge for other endocrine disorders and will make it crucial for the clinician to take a revealing family history and follow up even minor clues.
The Internet

Never in history has so much medical information been available to patients. I therefore now routinely ask patients what they already know about their condition or their symptoms. A bit sheepishly in some cases, many patients admit to looking up topics on the World Wide Web and are about to compare what I tell them with what they have already read. Much of that information is accurate, but some is nonsense, and it requires patience and clear explanation before such patients go away satisfied.
Electronic Mail

Although opinions differ widely, I find e-mail an extremely useful advance in communicating with patients who have computers. They have access to you between appointments and on a time frame of mutual convenience. The computer thus reduces anxiety on the patient's part, particularly regarding questions or findings for which they might otherwise hesitate to make an appointment. Reporting laboratory test results is expedited, and accompanying the report with a few sentences of interpretation can be as useful as a telephone call.

It is wise to keep copies of e-mails so that a clear record of the exchange is available. There are, however, several important caveats. Never let an e-mail exchange substitute for a true evaluation, including history and physical examination. I believe that one should not prescribe for a patient whom one has not seen, and one should not provide much interpretation of history or laboratory tests without very fundamental disclaimers. On the whole, however, e-mail can be used to initiate a new relationship and can certainly support an ongoing one.
Managed Care

The effort to control health care costs by limiting reimbursement for physician services, laboratory testing, and imaging has had a profound impact throughout medicine. Without taking on the whole issue, I want to comment on several practical consequences.

"Curbsiding" the request by a physician for patient guidance without being asked to see the patient has increased strikingly. Consultants can provide some general help to primary care physicians without seeing the patient; however, much hinges on the history and physical examination done by the primary care physician. The failure to realize that hyperthyroidism is due to a hot nodule, for example, totally distorts the picture and will lead to an erroneous recommendation for treatment. The failure to distinguish a recent onset of amenorrhea and virilization from a polycystic ovary-like syndrome may hide the presence of a readily curable virilizing tumor. The failure to recognize hypoglycemic unresponsiveness may perpetuate a dangerous degree of overinsulinization and elicit inappropriate advice from the consultant. Thus, the consultant must set bounds and at some point indicate that it is important for a formal consultation to take place.
Costs

Some endocrine work-ups can be expensive and invite challenge from third-party insurers. The best approach to this concern is a careful history and physical examination, clear establishment of the prior probabilities of certain diagnoses, and then effective use of screening tests before embarking on an unnecessarily extensive evaluation.

For example, in a patient with suspected Cushing's syndrome, it is mandatory to establish the presence of hypercorticism before embarking on a search for its cause. Once this lethal but curable disorder has been properly diagnosed, however, no cost should deter one from finding the cause and correcting it. One argument I make is that expensive tests and imaging should be amortized rather than considered an extravagant or unnecessary expense. If a young woman age 30, with a life expectancy of 80 years or more, has a husband and two children to whom her life matters, the $3000 evaluation breaks down to $20 per loved one per year of life expectancy. Any plan manager has to see that this is an appropriate cost.
MANAGEMENT

There are few more gratifying experiences in medicine than recognizing and correcting an endocrine disorder. Patients feel that they have been rescued from a mysterious overtaking of their identity. Body contour, facial appearance, temperament, and well-being are restored to the patient's constitutive status. Deterioration attributed to aging or depression or chronic disease is reversed. In brief, something almost miraculous takes place. Even when these goals cannot be achieved, as in diabetes, a major impact on mortality and morbidity can be.

Of course, these optimal outcomes require accuracy of diagnosis but that is only the beginning. A true sharing by patient and physician, based on a sound knowledge of normal physiology, provides the best foundation for choice of therapy and maintenance of a continuing program. The result can be, simply put, wonderful.
Chapter 3 - Genetic Control of Peptide Hormone Formation

Joel F. Habener

Advances in the fields of molecular and cellular biology have provided new insights into the mechanistic workings of cells. Recombinant deoxyribonucleic acid (DNA) technology and the sequencing (decoding) of the entire human and mouse genomes now make it possible to analyze the precise structure and function of DNA, the genetic substance that is the basis for life. The discovery of the unique biochemical and structural properties of DNA provided the conceptual framework with which to begin a systematic investigation of the origins, development, and organization of life forms.

The near completion of the entire sequences of the human and mouse genomes was accomplished in the years 2000 and 2001, 5 years ahead of the originally anticipated schedule. The availability of a complete blueprint of the structure and organization of all expressed genes now provides profound insights into the basis of genetically determined diseases. Within the next decades, genotyping of individuals shortly after birth will be possible. Therapeutic approaches for the correction of genetic defects by techniques of gene replacement are likely to become a reality.

The polypeptide hormones constitute a critically important and diverse set of regulatory molecules encoded by the genome whose functions are to convey specific information among cells and organs. This type of molecular communication arose early in the development of life and evolved into a complex system for the control of growth, development, and reproduction and for the maintenance of metabolic homeostasis. These hormones consist of approximately 400 or more small proteins ranging from as few as three amino acids (thyrotropin-releasing hormone, TRH) to 192 amino acids (growth hormone). In a broader sense, these polypeptides function both as hormones, whose actions on distant organs are mediated by way of their transport through the blood stream, and as local cell-to-cell communicators (Fig. 3-1). The latter function of the polypeptide hormones is exemplified by their elaboration and secretion within neurons of the central, autonomic, and peripheral nervous systems, where they act as neurotransmitters. These multiple modes of expression of the polypeptide hormone genes have aroused great interest in the specific functions of these peptides and the mechanisms of their synthesis and release.

This chapter reviews the diverse structures of genes encoding peptide hormones and the multiple mechanisms that govern their expression. The synthesis of nonpeptide hormones (e.g., catecholamines, thyroid hormones, steroid hormones) involves the action of multiple enzymes and hence the expression of multiple genes and is discussed in the individual chapters devoted to such hormones.
Peptide hormones arose early in the evolution of life. Indeed, polypeptides that are structurally similar to mammalian peptides are present in lower vertebrates, insects, yeasts, and bacteria. An example of the early evolution of regulatory peptides is the factor (matting pheromone) of yeast, which is similar in structure to mammalian luteinizing hormone-releasing hormone (also called gonadotropin-releasing hormone [GnRH]). The oldest member of the cholecystokinin-gastrin family of peptides appeared at least 500 million years ago in the protostome Ciona intestinalis.

Thus, the genes encoding polypeptide hormones, and particularly regulatory peptides, evolved early in the development of life and initially fulfilled the function of cell-to-cell communication to cope with problems concerning nourishment, growth, development, and reproduction. As specialized organs connected by a circulatory system developed during evolution, similar, if not identical, gene products became hormones for purposes of organ-to-organ communication.
STEPS IN EXPRESSION OF A PROTEIN-ENCODING GENE

The steps involved in transfer of information encoded in the polynucleotide language of DNA to the poly-amino acid language of biologically active proteins involve gene transcription, post-transcriptional processing of ribonucleic acids (RNAs), translation, and post-translational processing of the proteins. The expression of genes and protein synthesis can be considered in terms of several major processes, any one or more of which may serve as specific control points in the regulation of gene expression (Fig. 3-2):

1. **Rearrangements and transpositions of DNA segments.** These processes occur over many years (eons) in evolution, with the exception of uncommon mechanisms of somatic gene rearrangements such as the rearrangements in the immunoglobulin genes during the lifetime of an individual.

2. **Transcription.** Synthesis of RNA results in the formation of RNA copies of the two gene alleles and is catalyzed by the basal RNA polymerase II-associated transcription factors.

3. **Post-transcriptional processing.** Specific modifications of the RNA include the formation of messenger RNA (mRNA) from the precursor RNA by way of excision and rejoinder of RNA segments (introns and exons) and modifications of the 3’ end of the RNA by polyadenylation and of the 5’ end by addition of 7-methylguanine “cap.”

4. **Translation.** Amino acids are assembled by base pairing of the nucleotide triplets (anticodons) of the specific “carrier” aminoacylated transfer RNAs to the corresponding codons of the mRNA bound to polyribosomes and are polymerized into the polypeptide chains.

5. **Post-translational processing and modification.** Final steps in protein synthesis may involve one or more cleavages of peptide bonds, which result in the conversion of biosynthetic precursors (prohormones), to intermediate or final forms of the protein: derivation of amino acids (e.g., glycosylation, phosphorylation, acetylation, myristoylation); and the folding of the processed polypeptide chain into its native conformation.

Each of the specific steps of gene expression requires the integration of precise enzymatic and other biochemical reactions. These processes have developed to provide high fidelity in the reproduction of the encoded information and to provide control points for the expression of the specific phenotype of cells.

The post-translational processing of proteins creates diversity in gene expression through modifications of the protein. Although the functional information contained in a protein is ultimately encoded in the primary amino acid sequence, the specific biologic activities are a consequence of the higher order secondary, tertiary, and quaternary structures of the polypeptide. Given the wide range of possible specific modifications of the amino acids, such as glycosylation, phosphorylation, acetylation, and sulfation, any one of which may affect the conformation or function of the protein, a single gene may ultimately encode a wide variety of specific proteins as a result of post-translational processes.

Polypeptide hormones are synthesized in the form of larger precursors that appear to fulfill several functions in biologic systems (Fig. 3-3), including (1) intracellular trafficking, by which the cell distinguishes among specific classes of proteins and directs them to their sites of action, and (2) the generation of multiple biologic activities from a common genetically encoded protein by regulated or cell-specific variations in the post-translational modifications (Fig. 3-4).

All the peptide hormones and regulatory peptides studied thus far contain signal or leader sequences at the amino termini; these hydrophobic sequences recognize specific sites on the membranes of the rough endoplasmic reticulum, which results in the transport of nascent polypeptides into the secretory pathway of the cell (see Fig. 3-2 and Fig. 3-3). The consequence of the specialized signal sequences of the precursor proteins is that proteins destined for secretion are selected from a great many other cellular proteins for sequestration and subsequent packaging into secretory granules and export from the cell. In addition, most, if not all, of the smaller hormones and regulatory peptides are produced as a consequence of post-translational cleavages of the precursors within the Golgi complex of secretory cells.
SUBCELLULAR STRUCTURE OF CELLS THAT SECRETE PROTEIN HORMONES

Cells whose principal functions are the synthesis and export of proteins contain highly developed, specialized subcellular organelles for the translocation of secreted proteins and their packaging into secretory granules. The subcellular pathways utilized in protein secretion have been elucidated largely through the early efforts of Palade and colleagues (reviewed by Jamieson and colleagues (reviewed by Jamieson)). Secretory cells contain an abundance of endoplasmic reticulum, Golgi complexes, and secretory granules (Fig. 3-5). The proteins that are to be secreted from the cells are transferred during their synthesis into these subcellular organelles, which transport the proteins to the plasma membrane.

Protein secretion begins with translation of the mRNA encoding the precursor of the protein on the rough endoplasmic reticulum, which consists of polyribosomes attached to elaborate membranous saccules that contain cavities (cisternae). The newly synthesized, nascent proteins are discharged into the cisternae by transport across the lipid bilayer of the membrane. Within the cisternae of the endoplasmic reticulum, proteins are carried to the Golgi complex by mechanisms that are incompletely understood. The proteins gain access to the Golgi complex either by direct transfer from the cisternae, which are in continuity with the membranous channels of the Golgi complex, or by way of shuttling vesicles known as transition elements (see Fig. 3-5).

Within the Golgi complex, the proteins are packaged into secretory vesicles or secretory granules by their budding from the Golgi stacks in the form of immature granules. Immature granules undergo maturation through condensation of the proteinaceous material and application of a specific coat around the initial Golgi membrane. On receiving the appropriate extracellular stimuli (regulated pathway of secretion), the granules migrate to the cell surface and fuse to become continuous with the plasma membrane, which results in the release of proteins into the extracellular space, a process known as exocytosis.

The second pathway of intracellular transport and secretion involves the transport of proteins contained within secretory vesicles and immature secretory granules (see Fig. 3-5). Although the use of this alternative vesicle-mediated transport pathway remains to be demonstrated conclusively (it is generally considered to be a constitutive, or unregulated, pathway), different extracellular stimuli may modulate hormone secretion differently, depending on the pathway of secretion. For example, in the parathyroid gland and in the pituitary cell line derived from corticotropic cells (AIT-20), newly synthesized hormone is released more rapidly than hormone synthesized earlier. These findings suggest that the newly synthesized hormone may be transported by way of a vesicle-mediated pathway without incorporation into mature storage granules.
INTRACELLULAR SEGREGATION AND TRANSPORT OF POLYPEPTIDE HORMONES

Specific amino acid sequences encoded in the proteins serve as directional signals in the sorting of proteins within subcellular organelles. A typical eukaryotic cell synthesizes an estimated 5000 different proteins during its life span. These different proteins are synthesized by a common pool of polyribosomes. However, each of the different proteins is directed to a specific location within the cell, where its biologic function is expressed. For example, specific groups of proteins are transported into mitochondria, into membranes, into the nucleus, or into other subcellular organelles, where they serve as regulatory proteins, enzymes, or structural proteins. A subset of proteins is specifically designed for export from the cell (e.g., immunoglobulins, serum albumin, blood coagulation factors, and protein and polypeptide hormones).

This process of directional transport of proteins involves sophisticated informational signals. Because the information for these translocation processes must reside either wholly or in part within the primary structure or in the conformational properties of the protein, sequential post-translational modifications may be crucial for determining the specificity of protein function.

Signal Sequences in Peptide Prohormone Processing and Secretion

The early processes of protein secretion that result in the specific transport of exported proteins into the secretory pathway are now becoming better understood. Initial clues to this process came from determinations of the amino acid sequences of the proteins programmed by the cell-free translation of mRNAs encoding secreted polypeptides. Secreted proteins are synthesized as precursors that are extended at their NH₂ termini by sequences of 15 to 30 amino acids, called signal or leader sequences. Signal sequence extensions, or their functional equivalents, are required for targeting the ribosomal or nascent protein to specific membranes and for the vectorial transport of the protein across the membrane of the endoplasmic reticulum. On emergence of the signal sequence from the large ribosomal subunit, the ribosomal complex specifically makes contact with the membrane, which results in translocation of the nascent polypeptide across the endoplasmic reticulum membrane into the cisterna as the first step in the transport of the polypeptide within the secretory pathway. These observations initially left unanswered the question of how specific polyribosomes that translate mRNAs encoding secretory proteins recognize and attach to the endoplasmic reticulum (Fig. 3-6).

Figure 3-5 Schematic representation of subcellular organelles involved in transport and secretion of polypeptide hormones or other secreted proteins within a protein-secreting cell. (1) Synthesis of proteins on polyribosomes attached to endoplasmic reticulum (RER) and vectorial discharge of proteins through the membrane into the cisterna. (2) Formation of shutting vesicles (transition elements) from endoplasmic reticulum followed by their transport to and incorporation by the Golgi complex. (3) Formation of secretory granules in the Golgi complex. (4) Transport of secretory granules to the plasma membrane, fusion with the plasma membrane, and exocytosis resulting in the release of granule contents into the extracellular space. Note that secretion may occur by transport of secretory vesicles and immature granules as well as mature granules. Some granules are taken up and hydrolyzed by lysosomes (catabolism). Golgi, Golgi complex; RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum. (From Habener JF. Hormone biosynthesis and secretion. In Felig P, Baxter JD, Broadus AE, et al. [eds]. Endocrinology and Metabolism. New York, McGraw-Hill, 1981, pp 2959. Copyright © 1981 by McGraw-Hill, Inc. Used by permission of McGraw-Hill Book Company.)

from the large ribosomal subunit, the ribosomal complex specifically makes contact with the membrane, which results in translocation of the nascent polypeptide across the endoplasmic reticulum membrane into the cisterna as the first step in the transport of the polypeptide within the secretory pathway. These observations initially left unanswered the question of how specific polyribosomes that translate mRNAs encoding secretory proteins recognize and attach to the endoplasmic reticulum (Fig. 3-6).

Because microsomal membranes in vitro reproduce the processing activity of intact cells, it was possible to identify macromolecules responsible for processing of the RNA precursor. Initial clues to this process came from determinations of the amino acid sequences of the proteins programmed by the cell-free translation of mRNAs encoding secreted polypeptides. Secreted proteins are synthesized as precursors that are extended at their NH₂ termini by sequences of 15 to 30 amino acids, called signal or leader sequences. Signal sequence extensions, or their functional equivalents, are required for targeting the ribosomal or nascent protein to specific membranes and for the vectorial transport of the protein across the membrane of the endoplasmic reticulum. On emergence of the signal sequence from the large ribosomal subunit, the ribosomal complex specifically makes contact with the membrane, which results in translocation of the nascent polypeptide across the endoplasmic reticulum membrane into the cisterna as the first step in the transport of the polypeptide within the secretory pathway. These observations initially left unanswered the question of how specific polyribosomes that translate mRNAs encoding secretory proteins recognize and attach to the endoplasmic reticulum (Fig. 3-6).

The specific interaction of the signal recognition particle with the nascent signal sequence and the polypeptide bears further translation of the mRNA. The nascent protein remains in a state of arrested translation until it finds a high-affinity binding protein on the endoplasmic reticulum membrane, the signal recognition particle receptor, or docking protein. On interaction with the specific docking protein, the translational block is released and protein synthesis resumes. The protein is then transferred across the membrane of the endoplasmic reticulum through a proteinaceous tunnel.

At some point, near the termination of synthesis of the polypeptide chain, the NH₂-terminal signal sequence is cleaved from the polypeptide by a specific signal peptidase located on the cisternal surface of the endoplasmic reticulum membrane. The removal of the hydrophobic signal sequence frees the protein (prohormone or hormone) so that it may assume its characteristic secondary structure during transport through the endoplasmic reticulum and the Golgi apparatus. Interestingly, after its cleavage from the protein by signal peptidase, the signal peptide may sometimes be further cleaved in the endoplasmic reticulum membrane to produce a biologically active peptide. The signal sequence of preprolactin of 30 amino acids, for example, is cleaved by a signal peptide peptidase to give a charged peptide of 20 amino acids that is released into the cytosol, where it binds to calmodulin and inhibits Ca²⁺-calmodulin-dependent phosphodiesterase.

This sequence in the directional transport of specific polypeptides ensures optimal conditional processing of secretory proteins, even when synthesis commences on free ribosomes. The presence of a proteinaceous form of the signal recognition particle complex that blocks translation guarantees that the synthesis of the presecretory proteins is not completed in the cytoplasm; the efficient transfer of proteins occurs only after contact has been made with the specific receptor or docking protein on the membrane. Although the identification of the signal recognition particle and the docking protein explains the specificity of the binding of ribosomes containing mRNAs encoding the secretory proteins, it does not explain the mode of translocation of the nascent polypeptide chain across the membrane bilayer. Further dissection and analysis of the membrane have identified other macromolecules that are responsible for the transport process.
Figure 3-6 Diagram depicting cellular events in initial stages of synthesis of a polypeptide hormone according to the signal hypothesis. In this schema, a signal recognition particle, consisting of a complex of six proteins and an RNA (7S RNA), interacts with the NH$_2$-terminal signal peptide of the nascent polypeptide chain after approximately 70 amino acids are polymerized, which results in the arrest of further growth of the polypeptide chain. The complex of the signal recognition particle and the polyribosome nascent chain remains in a state of translational arrest until it recognizes and binds to a docking protein, which is a receptor protein located on the cytoplasmic face of the endoplasmic reticular membrane. This interaction of the signal recognition particle complex with docking protein releases the translational block, and protein synthesis resumes. The nascent polypeptide chain is discharged across the membrane bilayer into the cisterna of the endoplasmic reticulum and is released from the signal peptide by cleavage with a signal peptidase located in the cisternal face of the membrane. In this model, the signal peptide is cleaved from the polypeptide chain by signal peptidase before the chain is completed (cotranslational cleavage). The configuration of the polypeptide during transport across the membrane and the forces and mechanisms responsible for its translocation are unknown. The loop, or hairpin, configuration of the chain that is shown is an arbitrary model; other models are equally possible.
Cellular Processing of Prohormones

The signal sequences of prehormones and pre-prohormones are involved in the transport of these molecules, but the function of the intermediate hormone precursors (prohormones) is not fully understood. The conversion of prohormones to their final products begins in the Golgi apparatus. For example, the time that elapses between the synthesis of pre-proparathyroid hormone and the first appearance of parathyroid hormone correlates closely with the time required for radioautographic grains to reach the Golgi apparatus. Similarly, the conversion of proinsulin to insulin takes place about an hour after the synthesis of proinsulin is complete, and processing of proinsulin to insulin and C peptide takes place during the transport within the secretory granule. The conversion of prohormones to hormones can also be blocked by inhibitors of cellular energy production such as antimycin A and dinitrophenol and by drugs that interfere with the functions of microtubules (vinblastine, colchicine). Thus, the translocation of the prohormone from the rough endoplasmic reticulum to the Golgi complex depends on metabolic energy and probably involves microtubules.

There is no evidence that sequences that are specific to the prohormone contribute to or are chemically involved in transport of the newly synthesized protein from the rough endoplasmic reticulum to the Golgi apparatus or that they are involved in the packaging of the hormone in the vesicles or granules. Analyses of the structures of the primary products of translation of mRNAs encoding secretory proteins indicate that many of these are not synthesized in the form of prohormone intermediates (see Fig. 3-3). It remains puzzling that some secretory proteins (e.g., parathyroid hormone, insulin, serum albumin) are formed by way of intermediate precursors, whereas others (e.g., growth hormone, prolactin, albumin) are not.

Size constraints may be placed on the length of a secretory polypeptide. When the bioactivity of peptides resides at the COOH termini of the precursors (e.g., somatostatin, calcitonin, gastrin), NH₂-terminal extensions may be required to provide a sufficient "spacer" sequence to allow the signal sequence on the growing nascent polypeptide chain to emerge from the large ribosome subunit for interaction with the signal recognition particle and to provide adequate polypeptide length to span the large ribosomal subunit and the membrane of the endoplasmic reticulum during vectorial transport of the nascent polypeptide across the membrane (see Fig. 3-6). When the final hormonal product is 100 amino acids long or longer (e.g., growth hormone, prolactin, or the α and β subunits of the glycoprotein hormones), there may be no requirement for a prohormone intermediate.

Although the exact functions of prohormones remain unknown, certain details of their cleavages have been established. Unlike

![Figure 3-7](image)

Figure 3-7 Regulatory feedback loops of the hypothalamic-pituitary-target organ axis. Being a combination of both stimulatory and inhibitory factors, hormones often act in concert to maintain homeostatic balance in the presence of physiologic or pathophysiologic perturbations. The concerted actions of hormones typically establish closed feedback loops by stimulatory and inhibitory effects coupled to maintain homeostasis.

Specific prohormone-converting enzymes (PCs) consist of a family of at least eight such enzymes. The most studied of the isozymes are PC2 and PC1/3, which are responsible for the cleavages of proinsulin between the A chain/C peptide and B chain/C peptide, respectively. A rare patient missing PC1 presented with childhood obesity, hypogonadotropic hypogonadism, and hypercortisolism and was found to have elevated proinsulin levels and presumably widespread abnormalities in neuropeptide modification. Targeted disruption of the PC2 gene in mice resulted in incomplete processing of proinsulin, leaving the A chain and C peptide intact. Notably, proglucagon in the pancreas remains completely unprocessed, indicating that PC2 is required for the formation of glucagon. As a consequence of defective PC2 activity and low levels of glucagon, the mice have severe chronic hypoglycemia.

After endopeptidase cleavage, the remaining basic residues are selectively removed by exopeptidases with activity resembling that of carboxypeptidase B. In the instances in which the COOH-terminal residue of the peptide hormone is amidated, a process that appears to enhance the stability of a peptide by conferring resistance to carboxypeptidase, specific amidation enzymes in the Golgi complex work in concert with the cleavage enzymes for modification of the COOH terminal of the bioactive peptides.

All proproteins and prohormones are cleaved by PC enzymatic processes within the Golgi complex of cells of diverse origins. The significance of specific cleavages of specific prohormones remains incompletely understood, as does the reason for the existence of prohormone intermediates in some but not all secretory proteins. As indicated earlier, precursor peptides removed from the prohormones may have intrinsic biologic activities that are as yet unrecognized.
 PROCESSES OF HORMONE SECRETION

Specific extracellular stimuli control the secretion of polypeptide hormones. The stimuli consist of changes in homeostatic balance; the hormonal products released in response to the stimuli act on the respective target organs to reestablish homeostasis [Fig. 3-7]. Endocrine systems typically consist of closed-loop feedback mechanisms such that, if hormones from organ A stimulate organ B, organ B in turn secretes hormones that inhibit the secretion of hormones from organ A. The concerted actions of both positive and negative hormonal influences thereby maintain homeostasis. For example, an increase in the concentration of plasma electrolytes as a consequence of dehydration stimulates the release of arginine vasopressin (also called antidiuretic hormone [ADH]) in the neural lobe of the pituitary gland, and vasopressin in turn acts on the kidney to increase the reabsorption of water from the renal tubule, thereby readjusting serum electrolyte concentrations toward normal levels.

These regulatory processes commonly include inhibitory feedback loops in which the products elaborated by the target organs in response to the actions of a hormone inhibit further endocrine secretion. An example of such negative feedback regulation is the control of the secretion of adrenocorticotropic hormone (ACTH) by the anterior pituitary gland. Increased ACTH stimulates the adrenal cortex to produce and secrete cortisol, which in turn feeds back to suppress further pituitary secretion of ACTH.

In many instances, endocrine regulation is complex and involves the responses of several endocrine glands and their respective target organs. After a meal, the release of a dozen or more hormones is triggered as a result of gastric distention, variations in the pH of the contents of the stomach and duodenum, and increased concentrations of glucose, fatty acids, and amino acids in the blood. The rise in plasma glucose and amino acid levels stimulates the release of insulin and the incretin hormones glucagon-like peptide 1 and glucose-dependent insulinotropic peptide and suppresses the release of glucagon from the pancreas. Both effects promote the net uptake of glucose by the liver; insulin increases cellular transport and uptake of glucose, and the lower blood levels of glucagon decrease the outflow of glucose because of diminished rates of glycogenolysis and gluconeogenesis.
STRUCTURE OF A GENE ENCODING A POLYPEPTIDE HORMONE

Structural analyses of gene sequences have resulted in at least three major discoveries that are important for understanding the expression of peptide-encoding genes. First, sequences of almost all the known biologically active hormonal peptides are contained within larger precursors that often encode other peptides, many of which are of unknown biologic activity. Second, the transcribed regions of genes (exons) are interrupted by sequences (introns) that are transcribed but subsequently cleaved from the initial RNA transcripts during their nuclear processing and assembly into specific mRNAs. Third, specific regulatory sequences reside in the regions of DNA flanking the 5' ends of structural genes, and these DNA sequences constitute specific targets for the interactions of DNA-binding proteins that determine the level of expression of the gene.

The DNA of higher organisms is wound into a tightly and regularly packed chromosomal structure in association with a number of different proteins organized into elements called nucleosomes. Nucleosomes are composed of four or five different histone subunits that form a core structure about which approximately 140 base pairs of genomic DNA are wound. The nucleosomes are arranged similarly to beads on a string, and coils of nucleosomes form the fundamental organizational units of the eucaryotic chromosome.

The nucleosomal structure serves several purposes. For example, nucleosomes enable the large amount of DNA (2 × 10^6 pairs) of the genome to be compacted into a small volume. Nucleosomes are involved in the replication of DNA and gene transcription. In addition to histones, other proteins are associated with DNA, and the complex nucleoprotein structure provides specific recognition sites for regulatory proteins and enzymes involved in DNA replication, rearrangements of DNA segments, and gene expression. The acetylation and deacetylation of histone-rich chromatin is involved in the regulation of gene transcription.

The topography of a typical protein-encoding gene consists of two functional units (Fig. 3-8):

- A transcriptional region
- A promoter or regulatory region

Transcriptional Regions

The transcriptional unit is the segment of the gene that is transcribed into an mRNA precursor. The sequences corresponding to the mature mRNA consist of the exon sequences that are spliced from the primary transcript during the posttranscriptional processing of the precursor RNA; these exons contain the code for the mRNA sequence that is translated into protein and for untranslated sequences at the 5' and 3'-flanking regions. The 5' sequence typically begins with a methylated guanine residue known as the cap site. The 3'-untranslated region contains within it a short sequence, AATAAA, that signals the site of cleavage of the 3' end of the RNA and the addition of a poly(A) tract of 100 to 200 nucleotides located approximately 20 bases from the AATAAA sequence. Although the functions of these modifications of the ends of mRNAs are not completely understood, they appear to provide signals for leaving the nucleus; enhance stability, perhaps through providing resistance to degradation by exonucleases; and stimulate initiation of mRNA translation. The protein-coding sequence of the mRNA begins with the codon AUG for methionine and ends with the codon immediately preceding one of the three nonsense, or stop, codons (UGA, UAA, and UAG).

The nature of the enzymatic splicing mechanisms that result in the excision of intron-coded sequences and the rejoining of exon-coded sequences is incompletely understood. Short "consensus" sequences of nucleotides reside at the splice junctions; for example, the bases GT and AG at the 5' and 3' ends of the introns, respectively, are invariant and a polypyrimidine stretch is found near the AG. Splicing involves a series of cleavage and ligation steps that remove the introns as a lariat structure with its 5' end ligated near the 3' end of the introns and ligate the two adjacent exons together. An elaborate machinery (the spliceosome) consisting of five small nuclear RNAs (snRNAs) and roughly 50 proteins direct these steps, guided by base pairing between three of the snRNAs and the mRNA precursor.
Regulatory Regions

The regulation of the expression of genes that encode polypeptides is beginning to be understood in some detail. As a result of experiments involving the deletion of 5' sequences upstream from structural genes, followed by analyses of the expression of the genes after introduction into cell lines, several insights have been obtained. These regulatory sequences, termed promoters and enhancers, consist of short polynucleotide sequences (see Fig. 3-8). They can be divided into at least four groups with respect to their functions and distances from the transcriptional initiation site.

First, the sequence TATAA (TATA, or Goldberg-Hogness, box) is usually present in the more proximal promoter within 25 to 30 nucleotides upstream from the point of transcriptional initiation. The TATA sequence is required to ensure the accuracy of initiation of transcription at a particular site. The TATA box directs the binding of a complex of several proteins, including RNA polymerase II. The proteins, referred to as TATA box transcription factors (TFs), number six or more basal factors (IIA, IIB, IID, IIE, IIF, IIH) and, along with RNA polymerase II, form the general or basal transcriptional machinery required for the initiation of RNA synthesis.

The other three groups of regulatory sequences consist of tissue-specific silencers (TSSs), which function by binding repressor proteins; tissue-specific enhancers (TSEs), which are activated by the binding of transcriptional activator proteins; and metabolic response elements (MREs), which are regulated by the binding of specialized proteins whose transcriptional activities (repressor or activator) are regulated by metabolic signaling, often involving changes in their phosphorylation.
Introns and Exons

Genes encoding proteins and ribosomal RNAs in eukaryotes are interrupted by intervening DNA sequences (introns) that separate them into coding blocks (exons). In bacterial genes the nucleotide sequences of the chromosomal genes match precisely the corresponding sequences in the mRNAs. Interruption of the continuity of genetic information appears to be unique to nucleated cells. The reasons for such interruption are not completely understood, but introns appear to separate exons into functional domains with respect to the proteins that they encode. An example is the gene for proglucagon, a precursor of glucagon in which five introns separate six exons, three of which encode glucagon and the two glucagon-related peptides contained within the precursor. A second example is the growth hormone gene, which is divided into five exons by four introns that separate the promoter region of the gene from the protein-coding region and the latter into three partly homologous repeated segments, two coding for the growth-promoting activity of the hormone and the third for its carbohydrate metabolic functions. As a rule, the genes for the precursors of hormones and regulatory peptides contain introns at or about the region where the signal peptides join the apoproteins or prohormones, thus separating the signal sequences from the components of the precursor that are exported from the cell as hormones or peptides.

There are exceptions to the one exon, one function theory in mammalian cells. The genes of several precursors of peptide hormones are not interrupted by introns in a manner that corresponds to the separation of the functional components of the precursor. Notable in this regard is the precursor proopiomelanocortin, from which the peptides ACTH, -melanocyte-stimulating hormone, and -endorphin are cleaved during the post-translational processing of the precursor. The protein-coding region of the pro-opiomelanocortin gene is devoid of introns. Likewise, no introns interrupt the protein-coding region of the gene for the proenkephalin precursor, which contains seven copies of the enkephalin sequences. It is possible that, in the past, introns separated each of these coding domains and were lost during the course of evolution.

A precedent for the selective loss of introns appears to be exemplified by the rat insulin genes. The rat genome harbors two nonallelic insulin genes: one containing two introns and the other containing a single intron. The most likely explanation is that an ancestral gene containing two introns was transcribed into RNA and spliced; then that RNA was copied back into DNA by a cellular reverse transcriptase and inserted back into the genome at a new site.
REGULATION OF GENE EXPRESSION

The regulation of expression of genes encoding polypeptide hormones can take place at one or more levels in the pathway of hormone biosynthesis (Fig. 3-10):

- DNA synthesis (cell growth and division)
- Transcription
- Post-transcriptional processing of mRNA
- Translation
- Post-translational processing

In different endocrine cells, one or more levels may serve as specific control points for regulation of production of a hormone (see also Generation of Biologic Diversification later).

Figure 3-10 Diagram of an endocrine cell showing potential control points for regulation of gene expression in hormone production. Specific effector substances bind either to plasma membrane receptors (peptide effectors) or to cytosolic or nuclear receptors (steroids), which leads to initiation of a series of events that couple the effector signal with gene expression. In the illustration shown, peptide effector-receptor complex interactions act initially through activation of adenylate cyclase (AC) coupled with a guanosine triphosphate-binding protein (G). Coupling factors and substances such as glucose, cyclic adenosine monophosphate, and cations activate protein kinases, resulting in a series of phosphorylations of macromolecules. As discussed in the text, specific effectors for various endocrine cells appear to act at one or more of the indicated five levels of gene expression, with the possible exception of post-translational processing of prohormones, for which no definite examples of metabolic regulation have yet been found.

Levels of Gene Control

Newly synthesized prolactin transcripts are formed within minutes after exposure of a prolactin-secreting cell line to TRH. Cortisol stimulates growth hormone synthesis in both somatotropic cell lines and pituitary slices through increases in rates of gene transcription and enhancement of the stability of mRNA. The time required for cortisol to enhance transcription of the growth hormone gene is 1 to 2 hours, which is considerably longer than the time required for the action of TRH on prolactin gene transcription. Regulation of proinsulin biosynthesis appears to take place primarily at the level of translation. Within minutes after raising the plasma glucose level, the rate of proinsulin biosynthesis increases fivefold to 10-fold. Glucose acts either directly or indirectly to enhance the efficiency of initiation of translation of proinsulin mRNA.

Rapid metabolic regulation at the level of post-transcriptional processing of mRNA precursors is not yet clearly established. However, alternative exon splicing plays a major role in the regulation of the formation of mRNAs during development (see next section in chapter on Generation of Biologic Diversification). For example, the primary RNA transcripts derived from the calcitonin gene are alternatively spliced to provide two or more tissue-specific mRNAs that encode chimeric protein precursors with both common and different amino acid sequences, suggesting that regulation might take place at the level of processing of the calcitonin gene transcripts.

In many instances, the level of gene expression under regulatory control is optimal for meeting the secretory and biosynthetic demands of the endocrine organ. For example, after a meal there is an immediate requirement for the release of large amounts of insulin. This release depletes insulin stores of the pancreatic beta cells within a few minutes, and increasing the translational efficiency of preformed proinsulin mRNA provides additional hormone rapidly.
Differentiated cells have a remarkable capacity for selective expression of specific genes. In one cell type, a single gene may account for a large fraction of the total gene expression, and in another cell type the same gene may be expressed at undetectable levels.

When a gene can be expressed in a particular cell type, the associated chromatin is loosely arranged; when the same gene is never expressed in a particular cell type, the chromatin organization is more compact. Thus, the DNA within the chromatin of expressed genes is more susceptible to cleavage by deoxyribonuclease than is the DNA in tissues in which the genes are quiescent. This looseness may facilitate access of RNA polymerase to the gene for purposes of transcription. In addition, inactive genes appear to have a higher content of methylated cytosine residues than the same genes in tissues in which they are expressed.

Determinants for the tissue-specific transcriptional expression of genes exist in control sequences usually residing within 1000 base pairs of the 5'-flanking region of the transcriptional sequence. Enhancer sequences in animal cell genes were first described for immunoglobulin genes, a finding that extended the earlier observations of enhancer control elements in viral genomes. However, the first clear demonstrations of these elements directing transcription to cells of distinct phenotypes came from studies of the comparative expression of two model genes, insulin and chymotrypsin, in the endocrine and exocrine pancreas, respectively. The restricted expression of genes in a cell-specific manner is determined by the assembly of specific combinations of DNA-binding proteins on a predetermined array of control elements of the promoter regions of genes to create a transcriptionally active complex of proteins that includes the components of the general or basal transcriptional apparatus.
Transcription Factors in Developmental Organogenesis of Endocrine Systems

Certain families of transcription factors are critical for organogenesis and the development of the body plan. Among these factors are the homeodomain proteins and the nuclear receptor proteins. The family of homeodomain selector, or homeodomain, proteins are highly conserved throughout the animal kingdom from flies to humans. The orchestrated spatial and temporal expression of these proteins and the target genes that they activate determine the orderly development of the body plan of specific tissues, limbs, and organs. Similarly, the actions of families of nuclear receptors (steroid and thyroid hormones, retinoic acid, and others) are critical for normal development to occur. Inactivating mutations in the genes encoding these essential transcription factors predictably result in loss or impairment of the development of the specific organ whose development they direct.

Three examples are described of impaired organogenesis attributable to mutations in essential transcription factors:

- Partial anterior pituitary agenesis (Pit-1)
- Adrenal and gonadal agenesis (SF-1, DAX-1)
- Pancreatic agenesis (IDX-1)

Partial Pituitary Agenesis

The transcription factor Pit-1 is a member of a family of pou-homeodomain proteins, which is a specialized subfamily of the larger family of homeodomain proteins. Pit-1 is a key transcriptional activator of the promoters of the growth hormone, prolactin, and thyroid-stimulating hormone genes, produced in the anterior pituitary somatotrophs, lactotrophs, and thyrotrophs, respectively. Pit-1 is also the major enhancer activating factor for the promoter of the growth hormone-releasing factor receptor gene. Mutations in Pit-1 that impair its DNA-binding and transcriptional activation functions are responsible for the phenotype of the Jackson and Snell dwarf mice.

Mutations in the gene encoding Pit-1 have been found in patients with combined pituitary hormone deficiency in which there is no production of growth hormone, prolactin, or thyroid-stimulating hormone, resulting in growth impairment and mental deficiency. Notably, the production of the other two of the five hormones secreted by the anterior pituitary gland, adrenocorticotropin and the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), is unaffected.

In these human Pit-1 mutations, Pit-1 can bind to its cognate DNA control elements but is defective in trans-activating gene transcription. Furthermore, the mutated Pit-1 acts as a dominant negative inhibitor of Pit-1 actions on the unaffected allele.

Pancreatic Agenesis

The homeodomain protein islet duodenum homeobox 1 or IDX-1 (somatostatin transcription factor 1 [STF-1], insulin promoter factor 1 [IPF-1]) appears to be responsible for the development and growth of the pancreas. Targeted disruption of the IDX-1 gene in mice resulted in a phenotype of pancreatic agenesis. A child born without a pancreas was shown to be homozygous for inactivating mutations in the IDX-1 gene. Notably, the parents and their ancestors who are heterozygous for the affected allele have a high incidence of maturity-onset (type 2) diabetes mellitus, suggesting that a decrease in gene dosage of IDX-1 may predispose to the development of diabetes. The possibility that a mutated IDX-1 allele may be one of several "diabetes genes" is supported by the observation that IDX-1 and the helix-loop-helix transcription factors E47 and beta-2 appear to be key up-regulators of the transcription of the insulin gene.

Agensis of the Adrenal Gland and Gonads

Two nuclear receptor transcription factors have been identified as critical for the development of the adrenal gland, gonads, pituitary gonadotrophs, and the ventral medial hypothalamus. These nuclear receptors are SF-1 (steroidogenic factor 1) and DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome). SF-1 binds to half-sites of estrogen response elements that bind estrogen receptors in the promoters of genes. DAX-1 binds to retinoic acid receptor (RAR) binding sites in promoters and inhibits RAR actions. Targeted disruption of SF-1 in mice results in a phenotype of adrenal and gonadal agenesis. In addition, pituitary gonadotrophs are absent and the ventral medial hypothalamus is severely underdeveloped.

X-linked adrenal hypoplasia congenita is an X-linked, developmental disorder of the human adrenal gland that is lethal if untreated. The gene responsible for adrenal hypoplasia congenita has been identified by positional cloning and encodes DAX-1, a member of the nuclear receptor proteins related to RAR. Several inactivating mutations identified in the DAX-1 gene result in the syndrome of adrenal hypoplasia congenita and hypogonadotropic hypogonadism. Thus, genetically defined and transmitted defects in the genes encoding the transcription factors SF-1 and DAX-1 result in profound arrest in the development of the target organs regulated by the hypothalamic-pituitary-adrenal axis involved in steroidogenesis (the adrenal gland (glucocorticoids, mineral corticoids) and the gonads (estrogens and androgens)).
Coupling of Effector Action to Cellular Response

Another mode of gene control consists of the induction and suppression of genes that are normally expressed in a specific tissue. These processes are at work in the minute-to-minute and day-to-day regulation of rates of production of the specific proteins produced by the cells (e.g., production of polypeptide hormones in response to extracellular stimuli).

At least two classes of signaling pathways protein phosphorylation and activation of steroid hormone receptors by hormone bindings appear to be involved in the physiologic regulation of hormone gene expression. These two pathways mediate the actions of peptide and steroid hormones, respectively. Peptide ligands bind to receptor complexes on the plasma membrane, which results in enzyme activation, mobilization of calcium, formation of phosphorylated nucleotide intermediates, activation of protein kinases, and phosphorylation of specific regulatory proteins such as transcription factors (see Chapter 5).

Steroidal compounds, because of their hydrophobic composition, readily diffuse through the plasma membrane, bind to specific receptor proteins, and interact with other macromolecules in the nucleus, including specific domains on the chromatin located in and around the gene that is activated (see Chapter 4). Phosphorylated nucleotides such as cyclic adenosine monophosphate (cAMP), adenosine triphosphate, and guanosine triphosphate, as well as calcium, appear to have important functions in secretory processes. In particular, fluxes of calcium from the extracellular fluid into the cell and from intracellular organelles (e.g., endoplasmic reticulum) into the cytosol are closely coupled to secretion.

The cellular signaling pathways that involve protein phosphorylations are multiple and complex. They typically consist of sequential phosphorylations and dephosphorylations of molecules referred to as protein kinase or phosphatase cascades. These cascades are initiated by hormones, sensor molecules known as ligands, that bind to and activate receptors located on the surface of cells, resulting in the generation of small second messenger molecules such as cAMP, diacylglycerol, or calcium ions. These second messengers then activate protein kinases that phosphorylate and thereby activate key target proteins. The final step in the signaling pathways is the phosphorylation and activation of important transcription factors, resulting in gene expression (or repression).

Insight has been gained into the identities of some of the phosphoproteins. As discussed earlier, a specific group of transcription factors, DNA-binding proteins, interacts with cAMP-responsive and phorbol ester-responsive DNA elements to stimulate gene transcription mediated by the cAMP-protein kinase A, diacylglycerol-protein kinase C, and calcium-calmodulin signal transduction pathways (see Fig. 3-11). These proteins are encoded by a complex family of genes and bind to the DNA elements in the form of heterodimers or homodimers through a coiled coil helical structure known as a leucine zipper motif. There is evidence that phosphorylation of these proteins modulates dimerization, DNA recognition and binding, and transcriptional trans-activation activities. Phosphorylation of the protein substrates might change their conformations and activate the proteins, which, in turn, interact with coactivator proteins such as the cAMP response element-binding protein (CREB) and the protein components of the basal transcriptional machinery, thereby allowing RNA polymerase to initiate gene transcription.

Generally, the second messengers activate serine/threonine kinases, which phosphorylate serine or threonine residues, or both, on proteins, whereas the receptor kinases are tyrosine-specific kinases that phosphorylate tyrosine residues. Examples of receptor tyrosine kinases are growth factor receptors such as those for insulin, insulin-like growth factor (IGF), and platelet-derived growth factor. Receptors in the cytokine receptor family, which include leptin, growth hormone, and prolactin, activate associated tyrosine kinases in a variation on the theme.

The different types of signal transduction pathways are described as more or less distinct pathways for semantic purposes. In reality, there is considerable cross-talk among the different pathways that occur developmentally and in cell typespecific settings. An active area of research in endocrine systems is attempting to understand these complex interactions among different signal transduction pathways. Although the growth factor and cytokine receptors are similar in some respects, they differ in other respects. For example, growth factor receptor tyrosine kinases activate transcription factors through cascades that involve both tyrosine phosphorylation and serine/threonine kinases such as mitogen-activated protein kinases, whereas the Janus kinases (JAKs) activated by cytokine receptors directly tyrosine phosphorylate the signal transducer and activator of transcription (STAT) factors.
GENERATION OF BIOLOGIC DIVERSIFICATION

In addition to providing control points for the regulation of gene expression, the various steps involved in transfer of information encoded in the DNA of the gene to the final bioactive protein are a means for diversification of information stored in the gene (Fig. 3-12). Five steps in gene expression can be arbitrarily described: (1) gene duplication and copy number, (2) transcription, (3) post-transcriptional RNA processing, (4) translation, and (5) post-translational processing.

Gene Duplications

At the level of DNA, diversification of genetic information comes about by way of gene duplication and amplification. Many of the polypeptide hormones are derived from families of multiple, structurally related genes. Examples include the growth hormone family, consisting of growth hormone, prolactin, and placental lactogen; the glucagon family, consisting of glucagon, vasoactive intestinal peptide, secretin, gastric inhibitory peptide, and growth hormonereleasing hormone; and the glycoprotein hormone family, thyrotropin, luteinizing hormone, follicle-stimulating hormone, and chorionic gonadotropin.

A remarkable example of diversification at the level of gene amplifications is the extraordinarily large number of genes encoding the pheromone and odorant receptors. It is estimated that as many as 1000 such receptor genes may exist in mouse and rat genomes, each receptive to a particular odorant ligand. Over the course of evolution, an ancestral gene encoding a prototypic polypeptide representative of each of these families was duplicated one or more times and, through mutation and selection, the progeny proteins of the ancestral gene assumed different biologic functions. The exonic-intronic structural organization of the genomes of higher animals lends itself to gene recombination and RNA copying of genetic sequences with subsequent reintegration of DNA reverse-transcribed sequences back into the genome, resulting in rearrangement of transcriptional units and regulatory sequences.
Transcription

In addition to duplication of genes and their promoters, another way to create diversity in expression is at the level of gene transcription by providing genes with alternative promoters and by utilizing a large array of cis-regulatory elements in the promoters regulated by complex combinations of transcription factors.

Alternative Promoters

Many of the genes encoding hormones and their receptors utilize more than one promoter during development or when expressed in different tissue types. The employment of alternative promoters results in the formation of multiple transcripts that differ at their 5' ends. It is presumed that some genes have multiple promoters because they provide flexibility in the control of expression of the genes. For example, in some cases, expression of genes in more than one tissue or developmental stage may require distinct combinations of tissue-specific transcription factors. This flexibility enables genes in different cell types to respond to the same signal transduction pathways or genes in the same cell type to respond to different signal transduction pathways. A single promoter may not be adequate to respond to a complex array of transcription factors and a changing environment of cellular signals.

The organization of alternative promoters in genes is manifested in several patterns within exons or introns in the 5' noncoding sequence or the coding sequence. The most common occurrence of alternative promoters is within the 5' noncoding or leader exons. The utilization of different promoters in the 5' untranslated region of a gene, often accompanied by alternative exon splicing, results in the formation of mRNAs with different 5' sequences. The alternative usage of promoters in 5' leader exons can affect gene expression and generate diversity in several different ways. These include the developmental stagespecific and temporal expression of genes, the tissue-type specificity of expression, the levels of expression, the responsivity of gene expression to specific metabolic signals conveyed through signal transduction pathways, the stability of the mRNAs, the efficiencies of translation, and the structures of the amino termini of proteins encoded by the genes.

Examples of genes that use alternative 5' leader promoters during development are those encoding IGF-I, IGF-II, the retinoic acid receptors, and glucokinase, all of which are regulated by multiple promoters that are active in a variety of embryonic and adult tissues and are subject to developmental and tissue-specific regulation. During fetal development, promoters P2, P3, and P4 of the IGF-II gene are active in the liver. These promoters are shut off after birth, at which time the P1 promoter is activated. The P1 and P2 promoters of the IGF-I gene are differentially responsive to growth hormone: P2 expressed in liver is responsive to growth hormone, whereas P1 expressed in muscle is not.

The retinoic acid receptor exists in three isoforms (RAR, RAR, and RAR) encoded by separate genes that give rise to at least 17 different mRNAs generated by a combination of multiple promoters and alternative splicing. The RAR isoforms appear to differ in their specificity for retinoic acid receptors, in their affinities for ligand isoforms, and in trans-activating capabilities. The different RAR isoforms are expressed at different times in different tissues during development. It has been proposed that the different RAR isoforms provide a means of achieving a diverse set of cellular responses to a single, simple ligand, retinoic acid.

Glucokinase is an example of the alternative use of 5' leader promoters that have different metabolic responsiveness. Expression of glucokinase in pancreatic beta cells and some other neuroendocrine cells utilizes an upstream promoter (1), whereas in liver a promoter (IL) 26 kb downstream of the 1 promoter is used exclusively. In beta cells, expression of the glucokinase gene is apparently not responsive to hormones. In contrast, in liver expression mediated by the IL promoter is intensely up-regulated by insulin and down-regulated by glucagon.

The amylase gene provides an example in which two alternative promoters in the 5' noncoding exons expressed in two different tissues have dramatically different strengths of expression. A strong upstream promoter directs expression within the parotid gland, contrasting with weak expression directed by an alternative downstream promoter in liver.

Examples of the alternative usage of promoters in the coding regions of genes are the progesterone receptor (PR) and the transcription factor CAMP response element modulator (CREM). In both of these examples, different protein isoforms are produced that have markedly different functional activities. The genes encoding the chicken and human progesterone receptors express two isoforms of the receptor (isoforms A and B). Isoform A initiates translation at a methionine residue located 164 amino acids downstream from the methionine that initiates the translation of the longer form B. Analyses of the mechanisms responsible for the synthesis of two different isoforms revealed that two promoters exist in the human PR gene: one upstream of the 5' leader exon and the other in the first protein coding exon. The two isoforms of the human PR differ markedly in their capabilities to trans-activate transcription from different progesterone responsive elements (PRE). Both human PR isoforms equivalently activate a canonical PRE. Isoform B is much more efficient than A at activating the PRE in the mouse mammary tumor virus promoter, whereas isoform A, but not B, activates transcription from the ovalbumin promoter.

The utilization of an alternative intronic promoter within the protein coding sequence of a gene is exemplified by the CREM gene. The CREM gene employs a constitutively active, unregulated promoter (P1) that encodes predominantly activator forms of CREM and an internal promoter (P2) located in the fourth intron that is regulated by cAMP signaling and encodes a repressor isoform, ICER (inducible cAMP early response). The remarkable complexity of the alternative mechanisms of expression of the CREM and CREB genes is discussed subsequently.

Diversity of Transcription Factors

Another mechanism to create diversity at the level of gene transcription is that of the interplay of multiple transcription factors on multiple cis-regulatory sequences. The promoters of typical genes may contain 20 or 30 or more cis-acting control elements, either enhancers or silencers. These control elements may respond to ubiquitous transcription factors found in all cell types and to cell type-specific factors.

Unique patterns of control of gene expression can be affected by several different mechanisms acting in concert. The spacing, relative locations, and juxtapositioning of control elements with respect to each other and to the basal transcriptional machinery can influence levels of expression. Transcription factors often act in the form of dimers or higher oligomers among factors of the same or different classes. A given transcription factor may act as either an activator or a repressor as a consequence of the existing circumstances. The ambient concentrations of transcription factors within the nucleus in conjunction with their relative DNA-binding affinities and trans-activation potencies may determine the levels of expression of genes.
Post-transcriptional Processing (Alternative Exon Splicing)

Identification of the mosaic structure of transcriptional units encoding polypeptide hormones and other proteins that consist of exons and introns raised the possibility that the use of alternative pathways in RNA splicing could provide informationally distinct molecules. Different proteins could arise either by inclusion or exclusion of specific exonic segments or by utilization of parts of introns in one mRNA as exons in another mRNA. In addition, differences in the splice sites would result in expression of new translational reading frames. Alternative splicing utilizes two distinct mechanisms (Fig. 3-14). One is that of exon skipping or switching in or out of exons. The other mechanism, known as intron slippage, is to include part of an intron in an exon, to splice out part of an exon along with the intron, or to include a "coding" intron.

There are many examples of both mechanisms used to generate diversity in endocrine systems. Included among the genes encoding prohormones in which the pre-mRNAs are alternatively spliced by exon skipping or switching are those for procalcitonin/calcitonin gene-related peptide, prosubstance P/K, and the prokininogens. Alternative processing of the RNA transcribed from the calcitonin gene results in production of an mRNA in neural tissues that is distinct from that formed in the C cells of the thyroid gland. The thyroid mRNA encodes a precursor to calcitonin, whereas the mRNA in the neural tissues generates a neuropeptide known as calcitonin gene-related peptide. Immunocytochemical analyses of the distribution of the peptide in brain and other tissues suggest functions for the peptide in perception of pain, ingestive behavior, and modulation of the autonomic and endocrine systems.

The splicing of the RNA precursor that encodes substance P can take place in at least two ways. One splicing pattern results in the mRNA that encodes substance P and another peptide, called substance K, in a common protein precursor. Other mRNAs are apparently spliced so as to exclude the coding sequence for substance K. An alternative RNA splicing pattern also occurs in the processing of transcripts arising from the gene encoding bradykinin.

Other examples of genetic diversification arise from the programmed flexibility in the choice of splice acceptor sites within coding regions (intron slippage), which allows an array of coding sequences (exons) to be put together in a number of useful combinations. For example, the coding sequences of the growth hormone, lutropin-choriogonadotropin, and leptin receptors can be brought together in two different ways, one to include, the other to exclude, an exonic coding sequence specifying the transmembrane spanning domains of the polypeptide chains that anchor the receptors to the surface of cells. If mRNA splicing excludes the anchor's peptide sequence, a secreted rather than a surface protein is produced.
Translation

The process of translation provides a fourth level for the creation of diversity of gene expression. As discussed earlier in the section on Regulation of Gene Expression, the rate of translational initiation can be regulated as typified by the proinsulin and prohormone convertase mRNAs, in which translation is augmented by glucose and cAMP. Molecular diversity of translation, however, is generated by the developmentally regulated utilization of alternative translation initiation (start) codons (methionine codons, AUGs). The mechanism of translation initiation involves the assembly of the 40S ribosome subunit on the 5' methyl guanosine cap of the mRNA. The ribosome subunit then scans 5' to 3' along the mRNA until it encounters an AUG sequence in a context of surrounding nucleotides favorable for the initiation of protein synthesis. Upon encountering such a favorable AUG, the subunit pauses and recruits the 60S subunit plus a number of other essential translation initiation factors, allowing the polymerization of amino acids.

The use of an alternative downstream start codon for translation can occur by mechanisms of loose scanning and reinitiation (Fig. 3-15). Loose scanning is believed to occur when the most 5' AUG codon is not in a strongly favorable context and allows the 40S ribosomal subunit to continue scanning until it encounters a more favorable AUG downstream. Thus, in the loose scanning mechanism, both translational start codons are used. In contrast, the mechanism of translational reinitiation involves the termination of translation followed by the reinitiation of translation at a downstream start codon. Thus, two proteins are encoded from the same mRNA by a start and stop mechanism.

This process of translational reinitiation can occur either by continued scanning of the 40S ribosomal subunit after termination of translation followed by reinitiation, or by complete dissociation of the ribosomal subunits at the time of termination followed by complete reassembly at a downstream start codon, referred to as an internal ribosomal entry site (IRES). Such utilization of alternative translation start codons occurs in mRNAs encoding certain classes of transcription factors illustrated by the basic leucine zipper (bZIP) proteins CREB, CREM, and certain of the CCAAT/enhancer binding proteins (C/EBPs), the C/EBP and C/EBP isoforms. In all four of these DNA-binding proteins, the alternative use of internal start codons results in a switch from activators to repressors.

The CREB gene uses translational reinitiation by the somewhat novel mechanism of alternative exon switching that occurs during spermatogenesis. At developmental stages IV and V of the seminiferous tubule of the rat, an exon (exon W) is spliced into the CREB mRNA. Exon W introduces an inframe stop codon, thereby terminating translation approximately 40 amino acids upstream of the DNA-binding domain. The termination of translation then permits reinitiation of translation at each of two downstream start codons, resulting in the synthesis of two repressor or inhibitor isoforms of CREB known as I-CREBs that are powerful dominant negative inhibitors of activator forms of CREB and CREM because they consist of the DNA-binding domain devoid of any trans-activation domains. The function, if any, of the amino-terminal truncated protein consisting of the activation domains devoid of the DNA-binding domain is unknown. It has been postulated that the role of the alternative splicing of exon W in the CREB pre-mRNA is to interrupt a forward positive feedback loop during spermatogenesis.

CREM, C/EBP, and C/EBP mRNAs utilize alternative downstream start codons to synthesize repressors during development. Like the I-CREBs, these repressors consist of the DNA-binding domains and lack trans-activation domains. The CREM repressor (S-CREM) is expressed during brain development. The C/EBP-30 and C/EBP-20 isoforms are expressed during the differentiation of adipoblasts to adipocytes, and the C/EBP repressor liver inhibitory protein (LIP) is expressed during the development of the liver.
Post-translational Processing

A fifth level of gene expression at which diversification of biologic information can take place is that of post-translational processing. Many precursors of polypeptide hormones, particularly those encoding small peptides, contain multiple peptides that are cleaved during post-translational processing of the prohormones. Certain polyprotein precursors, however, contain several copies of the peptide. Examples of prohormones that contain multiple identical peptides are the precursors encoding TRH and the mating factor of yeast, each of which contains four copies of the respective peptide. Polypeptides that contain several distinct peptides include proenkephalins, pro-opiomelanocortin, and proglucagon.

In many instances, biologic diversification at the level of post-translational processing occurs in a tissue-specific manner. The processing of pro-opiomelanocortin differs markedly in the anterior compared with the intermediate lobe of the pituitary gland. In the anterior pituitary the primary peptide products are ACTH and -endorphin, whereas in the intermediate lobe of the pituitary one of the primary products is -melanocyte-stimulating hormone. The smaller peptides produced are extensively modified by acetylation and phosphorylation of amino acid residues.

The processing of proglucagon in the pancreatic A cells and that in the intestinal L cells are also different. In the pancreatic A cells, the predominant bioactive product of the processing of proglucagon is glucagon itself; the two glucagon-like peptides are not processed efficiently from proglucagon in the A cells and are biologically inactive by virtue of having NH$_2$-terminal and COOH-terminal extensions. On the other hand, in the intestinal L cell the glucagon immunoreactive product is a molecule, called glicentin, that consists of the NH$_2$-terminal extension of the proglucagon plus glucagon and the small COOH-terminal peptide known as intervening peptide I.

Glicentin has no glucagon-like biologic activity, and therefore the bioactive peptide (or peptides) in the intestinal L cells must be one or both of the glucagon-like peptides. In fact, glucagon-like peptide I in its shortened form of 31 amino acids, GLP-I (737), is a potent insulinotropic hormone in its actions of stimulating insulin release from pancreatic beta cells. This peptide is released from the intestines into the blood stream in response to oral nutrients and appears to be a potent intestinal incretin factor implicated in the augmented release of insulin in response to oral compared with systemic (intravenous) nutrients. This potential for diversification of biologic information provided by the alternative pathways of gene expression is impressive when one considers that these pathways can occur in multiple combinations.
Unexpectedly Low Numbers of Expressed Genes in Genomes of Mammals (Humans and Mice)

A somewhat surprising initial conclusion, heralded in the lay press when the results of the sequencing of the human and mouse genomes were revealed, was that the number of genes in the human and mouse was approximately 30,000. This number was viewed as remarkably low because the number of genes in yeast (Saccharomyces cerevisiae), worm (Caenorhabditis elegans), and fly (Drosophila melanogaster) is about 20,000. However, it seems quite clear from the complexities of the mRNAs expressed in humans and mice, as exemplified by the growing database of expressed sequence tags, that tissue-specific alternative exon splicing and alternative promoter usage occur much more frequently in humans and mice than in yeast, worms, and flies. Considering the as yet incomplete database of expressed genes at the mRNA level, it seems reasonable to extrapolate that the human genome may actually express as many as 100,000 to 200,000 mRNAs that encode proteins with distinct, specific functions. This extrapolation is based on the observation that alternative exon splicing and promoter usage appear to be on the order of 5 to 10 times more frequent in higher vertebrate mammals than in yeasts and flies.

Chapter 4 - Mechanism of Action of Hormones That Act on Nuclear Receptors

Mitchell A. Lazar

Hormones can be divided into two groups on the basis of where they function in a target cell. The first group includes hormones that do not enter cells; instead, they signal via second messengers generated by interacting with receptors at the cell surface. All polypeptide hormones, as well as monoamines and prostaglandins, utilize cell surface receptors (see Chapter 5, “Mechanism of Action of Hormones That Act at the Cell Surface”). The second group, the focus of this chapter, includes hormones that can enter cells. These hormones bind to intracellular receptors that function in the nucleus of the target cell to regulate gene expression. Classical hormones that utilize intracellular receptors include thyroid and steroid hormones.

Hormones serve as a major form of communication between different organs and tissues that allows specialized cells in complex organisms to respond in a coordinated manner to changes in the internal and external environments. Classical endocrine hormones, such as thyroid and steroid hormones, are secreted by ductless glands and are distributed throughout the body via the blood stream. These hormones were discovered by purifying the biologically active substances from clearly definable glands.

It is now recognized that numerous other signaling molecules share with thyroid and steroid hormones the ability to function in the nucleus to convey intercellular and environmental signals. Not all of these molecules are produced in glandular tissues. Further, whereas some of these signaling molecules arrive at target tissues via the blood stream like classical endocrine hormones, others have paracrine functions (i.e., they act on adjacent cells) or autocrine functions (i.e., they act on the cell of origin).

Lipophilic signaling molecules that utilize nuclear receptors include the following:

- Derivatives of vitamins A and D
- Endogenous metabolites such as oxysterols and bile acids
- Non-natural chemicals encountered in the environment (xenobiotics)

These molecules are referred to generically as ligands for nuclear receptors. The nuclear receptors for all of these signaling molecules are structurally related and collectively referred to as the nuclear receptor superfamily.
LIGANDS THAT ACT VIA NUCLEAR RECEPTORS

General Features of Nuclear Receptor Ligands

Unlike polypeptide hormones that function via cell surface receptors, no ligands for nuclear receptors are directly encoded in the genome. To the contrary, all nuclear receptor ligands are small (molecular weight < 1000 daltons [d]) and lipophilic, enabling them to enter cells. Cellular uptake of nuclear receptor ligands may be a passive process, but in some cases a membrane transport protein is involved. For example, the oatp3 organic anion transporter mediates thyroid hormone entry into cells. The lipophilicity of nuclear receptor ligands also allows them to be absorbed from the gastrointestinal tract, thus facilitating their use in replacement or pharmacologic therapies of disease states.

Another common feature of nuclear receptor ligands is that all are derived from dietary, environmental, and metabolic precursors. In this sense, the function of these ligands and their receptors is to translate cues from the external and internal environments into changes in gene expression. Their critical role in maintaining homeostasis in multicellular organisms is highlighted by the fact that nuclear receptors are found in all vertebrates as well as insects but not in single-cell organisms such as yeast.
Subclasses of Nuclear Receptor Ligands

One classification of nuclear receptor ligands is outlined in Table 4-1 and is described next.

Classical Hormones

The classical hormones that utilize nuclear receptors for signaling are thyroid hormone and steroid hormones. Steroid hormones include receptors for cortisol, aldosterone, estrogen, progesterone, and testosterone. In some cases (e.g., thyroid hormone receptor [TR] and genes, estrogen receptor [ER] and ), there are multiple receptor genes, encoding multiple receptors. Multiple receptors for the same hormone can also derive from a single gene either by alternative promoter usage or alternative splicing (e.g., TR 1 and 2).

Finally, some receptors can mediate the signal of multiple hormones. For example, the mineralocorticoid (aldosterone) receptor (MR) has equal affinity for cortisol and probably functions as a glucocorticoid receptor in some tissues, such as the brain. The androgen receptor (AR) binds and responds to both testosterone and dihydrotestosterone (DHT).

Vitamins

Vitamins were discovered as essential constituents of a healthful diet. Two fat-soluble vitamins, A and D, are precursors of important signaling molecules that function as ligands for nuclear receptors.

<table>
<thead>
<tr>
<th>TABLE 4-1 – Nuclear Receptor Ligands and Their Receptors</th>
</tr>
</thead>
</table>

### Classical Hormones

- Thyroid hormone: thyroid hormone receptor (TR), subtypes
- Estrogen: estrogen receptor (ER), subtypes
- Testosterone: androgen receptor (AR)
- Progesterone: progesterone receptor (PR)
- Aldosterone: mineralocorticoid receptor (MR)
- Cortisol: glucocorticoid receptor (GR)

### Vitamins

- 1,25-(OH)2-vitamin D3: vitamin D receptor (VDR)
- All-trans-retinoic acid: retinoic acid receptor, subtypes
- 9-cis-retinoic acid: retinoid X receptor (RXR), subtypes

### Metabolic Intermediates and Products

- Oxysterols: liver X receptor (LXR), subtypes
- Bile acids: bile acid receptor (BAR)
- Fatty acids: peroxisome proliferator-activated receptor (PPAR), subtypes

### Xenobiotics

- Pregnancy X receptor (PXRx), constitutive androstane receptor (CAR)

Precursors of vitamin D are synthesized and stored in skin and activated by ultraviolet light; vitamin D can also be derived from dietary sources. Vitamin D is then converted in the liver to 25(OH) vitamin D and in the kidney to 1,25-(OH)2-vitamin D2, the most potent natural ligand of the vitamin D receptor (VDR). 1,25-(OH)2-vitamin D2 acts as a circulating endocrine hormone.

Vitamin A is stored in the liver and is activated by metabolism to all-trans-retinoic acid, which is a high affinity ligand for retinoic acid receptors (RARs). Retinoic acid is likely to function as a signaling molecule in paracrine as well as endocrine pathways. Retinoic acid is also converted to its 9-cis-isomer, which is a ligand for another nuclear receptor called the retinoid X receptor (RXR). These retinoids and their receptors are essential for normal life and development of multiple organs and tissues. They also have pharmaceutical utility for conditions ranging from skin diseases to leukemia.

Another "orphan receptor," bile acid receptor (BAR) also known as FXR, or "Farnesyl X receptor", is thus likely to play a role in regulation of bile synthesis and circulation in normal as well as disease states.

The peroxisome proliferator-activated receptors (PPARs) constitute another subfamily of nuclear receptors. There are three subtypes, and all are activated by polyunsaturated fatty acids. No single fatty acid has particularly high affinity for any PPAR, and it is possible that these receptors may function as integrators of the concentration of a number of fatty acids.

PPAR is expressed primarily in liver; to date, the natural ligand with highest affinity for PPAR is an eicosanoid, 8(S)-hydroxyeicosatetraenoic acid. The most potent PPAR ligands are the fibrate class of lipid-lowering pharmaceuticals. The name PPAR derives from the fact that compounds such as fibrates induce proliferation of hepatic peroxisomes, organelles involved in -oxidation of fatty acids.

The other PPARs ( and ) are structurally related but are not activated by peroxisome proliferators. PPAR- is ubiquitous, and its ligandother than fatty acidss are not well characterized. PPAR is expressed primarily in fat cells (adipocytes) and is necessary for differentiation along the adipocyte lineage. PPAR is also expressed in other cell types, including colonocytes, macrophages, and vascular endothelial cells, where it may play physiologic as well as pathologic roles. The natural ligand for PPAR is not known, although prostaglandin J derivatives have the highest affinity (in the micromolar range). It is exciting news that PPAR appears to be the target of thiazolidinedione antidiabetic drugs that improve insulin sensitivity. These pharmaceutical agents bind to PPAR with nanomolar affinities, and
non-thiazolidinedione PPAR ligands are also insulin sensitizers, further implicating PPAR in this physiologic role.

**Xenobiotics**

Other nuclear receptors appear to function as integrators of exogenous environmental signals, including natural **endobiotics** (e.g., medicinals and toxins found in plants) and xenobiotics (compounds that are not naturally occurring). In these cases, the role of the activated nuclear receptor is to induce cytochrome P450 enzymes that facilitate detoxification of potentially dangerous compounds in the liver. Receptors in this class include:

- SXR, or sterol and xenobiotic receptor
- CAR, or constitutive androstane receptor
- PPAR, which is also activated by certain environmental chemicals

Unlike other nuclear receptors that have high affinity for very specific ligands, xenobiotic receptors have low affinity for a large number of ligands, reflecting their function in defense from a varied and challenging environment. Although these xenobiotic compounds are clearly not "hormones" in the classical sense, the function of these nuclear receptors is consistent with the general theme of helping the organism to cope with environmental challenges.

**Orphan Receptors**

The nuclear receptor superfamily is one of the largest families of transcription factors. The hormones and vitamins just described account for the functions of only a fraction of the total number of nuclear receptors. The remainder have been designated as **orphan receptors** because their putative ligands are not known.

From analyses of mice and humans with mutations in various orphan receptors, it is clear that many of these receptors are required for life or development of specific organs ranging from brain nuclei to endocrine glands. Some orphan receptors appear to be active in the absence of any ligand ("constitutively active") and may not respond to a natural ligand. Nevertheless, all of the receptors now known to respond to metabolites and environmental compounds were originally discovered as orphans. Thus, it is likely that future research will find that additional orphan receptors function as receptors for physiologic, pharmacologic, or environmental ligands.

**Variant Receptors**

As to be discussed later, the carboxyl (C-) terminus of the nuclear receptors is responsible for hormone binding. In the case of a few nuclear receptors, including TR and the glucocorticoid receptor, alternative splicing leads to the production of variant receptors with unique C-termini that do not bind ligand. These variant receptors are normally expressed, but their biologic relevance is uncertain. It has been speculated that they modulate the action of the classical receptor to which they are related by inhibiting its function.

Another type of normally occurring variant nuclear receptors

Lacks a classical deoxyribonucleic acid (DNA) binding domain (see later). These include DAX-1, which is mutated in human disease, and SHP-1. Their ligands, if any, are not known, and it is likely that DAX-1 and SHP-1 bind to and repress the actions of other receptors.

Rare, naturally occurring mutations of hormone receptors can cause hormone resistance in affected patients, for instance:

1. Inheritance of the hormone resistance phenotype can be dominant if the mutant receptor inhibits the action of the normal receptor, as with generalized resistance to thyroid hormone.
2. Inheritance is recessive if the mutation results in a complete loss of receptor function, as with the syndrome of hereditary 1,25-dihydroxyvitamin D-resistant rickets.
3. Inheritance can be X-linked, as with the mutated androgen receptor in androgen insensitivity syndromes, including testicular feminization.
Regulation of Ligand Levels

Ligand levels can be regulated in a number of ways. A dietary precursor may not be available in required amounts, as occurs in hypothyroidism due to iodine deficiency. Pituitary hormones (e.g., thyroid-stimulating hormone) regulate the synthesis and secretion of classical thyroid and steroid hormones. When the glands that synthesize these hormones fail, hormone deficiency can occur.

Many of the nuclear receptor ligands are enzymatically converted from inactive prohormones to the biologically active hormone (e.g., 5' deiodination of thyroxine \( T_4 \) to triiodothyronine \( T_3 \)). In other cases, one hormone is precursor for another (e.g., aromatization of testosterone to estradiol). Biotransformation may occur in a specific tissue that is not the main target of the hormone (e.g., renal 1-hydroxylation of vitamin D) or may occur primarily in target tissues (e.g., 5-reduction of testosterone to DHT). Deficiency or pharmacologic inhibition of such an enzyme can also reduce hormone levels.

Hormones can be inactivated by standard hepatic or renal clearance mechanisms or by more specific enzymatic processes. In the latter case, reduction in enzyme activity due to gene mutations or pharmacologic agents can result in hormone excess syndromes, for example, the renal deactivation of cortisol by 11-hydroxysteroid dehydrogenase (11-OHSD). Since, as noted earlier, cortisol can activate the mineralocorticoid receptor, insufficient 11-OHSD activity due to licorice ingestion, gene mutation, or extremely high cortisol levels causes syndromes of apparent mineralocorticoid excess.
NUCLEAR RECEPTOR SIGNALING MECHANISMS

Nuclear receptors are multifunctional proteins that transduce the signals of their cognate ligands. General features of nuclear receptor signaling are illustrated in Figure 4-1.

First and foremost, the ligand and the nuclear receptor must get to the nucleus. The nuclear receptor must also bind its ligand with high affinity. Because a major function of the receptor is to selectively regulate target gene transcription, it must recognize and bind to promoter elements in appropriate target genes. One discriminatory mechanism is dimerization of a receptor with a second copy of itself or with another nuclear receptor. The DNA-bound receptor must also work in the context of chromatin to signal the basal transcription machinery to increase or decrease transcription of the target gene.

Throughout the following discussion on the mechanisms and regulation of signaling by nuclear receptors, it should be kept in mind that some basic mechanisms are generally used by many or all members of the nuclear receptor superfamily, whereas other mechanisms impart the specificity that is crucial to the vastly different biologic effects of the many hormones and ligands that utilize these related receptors.

Domain Structure of Nuclear Receptors

The nuclear receptors are proteins whose molecular weights are generally between 50,000 and 100,000 d. They all share a common series of domains, referred to as A to F (Fig. 4-2). This linear depiction of the receptors is useful for describing and comparing the receptors, but it does not capture the role of protein folding and tertiary structure in mediating the various receptor functions. As of this writing, no full-length nuclear hormone receptor has been crystallized, but structures of individual domains have been extremely revealing, as will be clear from the discussions of specific receptor functions that follow.
Nuclear Localization

The nuclear receptors, like all cellular proteins, are synthesized on ribosomes that reside outside the nucleus. Import of the nuclear receptors into the nucleus requires the nuclear localization signal (NLS), located near the border of the C and D domains (see Fig. 4-2). As a result of their nuclear localization signals, most of the nuclear receptors reside in the nucleus in the absence, as well as in presence, of ligand. A major exception is the glucocorticoid receptor (GR), which, in the absence of hormone, is tethered in the cytoplasm to a complex of chaperone molecules, including heat shock proteins (hsp90). Hormone binding to GR induces a conformational change that results in dissociation of the chaperone complex, thereby allowing the hormone-activated GR to translocate to the nucleus via its nuclear localization signal.
Hormone Binding

High-affinity binding of a lipophilic ligand is a shared characteristic of many nuclear receptors. This defining function of the receptor is mediated by the C-terminal ligand-binding domain (LBD), domains D and E in Figure 4-2. This region of the receptor also has many other functions, including dimerization and transcriptional regulation (see "Receptor Dimerization" and "Receptor Regulation of Gene Transcription" below).

The structure of the LBD has been solved for a number of receptors. All share a similar overall structure consisting of 12-helical segments in a highly folded tertiary structure (Fig. 4-3). The ligand binds within a hydrophobic pocket composed of amino acids in helix 3 (H3), H4, and H5. The major structural change induced by ligand binding is an internal folding of the most C-terminal helix (H12), which forms a cap on the ligand-binding pocket. Although the overall mechanism of ligand binding is similar for all receptors, the details are crucial in determining ligand specificity. Although the molecular details of ligand binding are beyond the scope of this chapter, this is the most critical determinant of receptor specificity.
Target Gene Recognition by Receptors

Another crucial specificity factor for nuclear receptors is their ability to recognize and bind to the subset of genes that are to be regulated by their cognate ligand. Target genes contain specific DNA sequences that are called hormone response elements (HREs). Binding to the HRE is mediated by the central C domain of the nuclear receptors (see Fig. 4-2). This region is typically composed of 66 to 68 amino acids, including two subdomains called zinc fingers because the structure of each subdomain is maintained by four cysteine residues that coordinate with a zinc atom.

The first of these zinc-ordered modules contains basic amino acids that contact DNA; as with the LBD, the overall structure of the DNA-binding domain (DBD) is very similar for all members of the nuclear receptor superfamily. The specificity of DNA binding is determined by multiple factors (Table 4-3). All steroid hormone receptors, except for the estrogen receptor (ER), bind to the double-stranded DNA sequence AGAACA (Fig. 4-4).

By convention, the double-stranded sequence is described by the sequence of one of the complementary strands, with the bases ordered from the 5’ to the 3’ end. Other nuclear receptors recognize the sequence AGGTCA. The primary determinant of this specificity is a group of amino acids residues in the so-called P-box of the DBD (see Fig. 4-4). These hexamer DNA sequences are referred to as half-sites. The only two differences between these hexameric half-sites are the central two base pairs (underlined). For some nuclear receptors, the C-terminal extension of the DBD contributes specificity for extended half-sites containing additional, highly specific DNA sequences 5’ to the hexamer (see Fig. 4-2).

Another source of specificity for target genes is the spacing and orientation of these half-sites, which in most cases are bound by receptor dimers.
Receptor Dimerization

As noted earlier, the nuclear receptor DBD has affinity for the hexameric half-site, or extended half-sites; many HREs, however, are composed of repeats of the half-site sequence, and most nuclear receptors bind such HREs as dimers. Steroid receptors, including ER, function primarily as homodimers, which preferentially bind to two half-sites oriented toward each other (inverted repeats) with three base pairs in between (IR3) (Fig. 4-4A). The major dimerization domain in steroid receptors is within the C-domain, although the LBD contributes. Ligand-binding facilitates dimerization and DNA binding of steroid hormone receptors. Most other receptors, including

\[ \text{Figure 4-3 Structural basis of nuclear receptor ligand binding and cofactor recruitment.} \]

TR, RAR, VDR, PPAR, LXR, and VDR, bind to DNA as heterodimers with RXR (Fig. 4-4B). Heterodimerization is mediated by two distinct interactions. The receptor LBD mediates the strongest interaction, which occurs even in the absence of DNA. These receptor heterodimers bind to two half-sites arranged as direct repeats (DRs) with variable numbers of base pairs in between.

The spacing of the half-sites is a major determinant of target gene specificity. This is due to the second receptor-receptor interaction, which involves the DBDs and is highly sensitive to the spacing of the half-sites. For example, VDR/RXR heterodimers bind preferentially to direct repeats separated by three bases (DR3 sites), TR/RXR binds DR4, and RAR/RXR binds DR5 with highest affinity. \[ \text{[30]} \]

The structural basis of this restriction on DNA binding is related to the fact that the RXR binds to the upstream half-site (farthest from the start of transcription). As a result of the periodicity of the DNA helix, each base pair separating the half-sites leads to a rotation of about 36° of one half-site relative to the other. Subtle differences in the structure of the receptor LBDs make the DBD interactions more or less favorable at the different degrees of rotation. \[ \text{[31]} \]
Nuclear receptors mediate a variety of effects on gene transcription. The most common modes of regulation (Table 4-4) are:

- Ligand-dependent gene activation
- Ligand-independent repression of transcription
- Ligand-dependent negative regulation of transcription

The remainder of this chapter describes these mechanisms.

**Ligand-Dependent Activation**

Ligand-dependent activation is the most well-understood function of nuclear receptors and their ligands. In this case, the ligand-bound receptor increases transcription of a target gene to which it is bound. The DBD serves to bring the receptor domains that mediate transcriptional activation to a specific gene. Transcriptional activation itself is mediated primarily by the LBD, which can function in the same way even when it is transferred to a DNA-binding protein that is not related to nuclear receptors. The *activation function* (AF) of the LBD is referred to as AF-2 (see Fig. 4-2).

Gene transcription is mediated by a large complex of factors that ultimately regulate the activity of ribonucleic acid (RNA) polymerase, the enzyme that uses the chromosomal DNA template to direct the synthesis of messenger RNA. Most mammalian genes are transcribed by RNA polymerase II, utilizing a large set of cofactor proteins, including *basal transcription factors*, and associated factors collectively referred to here as *general transcription factors* (GTFs). Details about GTFs are of fundamental importance and are available elsewhere. These GTFs bind to the nuclear receptor on DNA only when hormone or ligand is bound. Thus, these coactivators specifically recognize the ligand-bound conformation of the LBD.

The most important determinant of coactivator binding is the position of H12, which changes dramatically when ligands bind receptors (see Fig. 4-3). Along with H3, H4, and H5, H12 forms a hydrophobic cleft that is bound by short polypeptide regions of the coactivator molecules. These polypeptides, called *NR boxes*, have characteristic sequences of LxxLL, where L is leucine and xx can be any two amino acids. A number of coactivator proteins containing LxxLL

negative response elements

The activity of the positively acting factors results in the observed negative regulation.

Interaction leads to removal of coactivators such as p300 and CBP from the other transcription factors that positively regulate the gene.

This leads to suppression of transcription.

Element of the gene for the subunit of thyroid-stimulating hormone (TSH), transcription is activated. Ligand binding recruits corepressors and HDAC to the TR and

Ligand-bound receptors recruit corepressors and HDAC activity to such binding sites.

This mechanism involves nuclear receptor binding to DNA binding sites that reverse the paradigm of ligand-dependent activation (negative response elements).

Ligand-bound receptors recruit corepressors and HDAC activity to such binding sites.

For example, when the unliganded TR binds to the negative response element of the gene for the subunit of thyroid-stimulating hormone (TSH), transcription is activated. Ligand binding recruits corepressors and HDAC to the TR and leads to suppression of transcription.

In other cases, it has been postulated that negative regulation may result from ligand binding to nuclear receptors that bind to other transcription factors without binding DNA. This

The receptor utilizes helices 3 to 5 to form the hydrophobic pocket, as in coactivator binding, but H12 does not promote and even hinders corepressor binding. This negative role of H12 highlights the role of the ligand-dependent change in the position of H12 as the switch that determines repression and activation by nuclear receptors. (see Fig. 4-5).

The transcriptional functions of N-CoR and SMRT are the opposite of those of the coactivators. The corepressors themselves do not possess enzyme activity but do interact directly with GTFs and further enhance their activities. An important complex that also links nuclear receptors to GTFs is the TRAP (TR-associated proteins) or DRIP (D receptor-associated proteins) complex.

It is possible that the recruitment of multiple HATs reflects different specificities for core histones and potentially other, nonhistone proteins. Some HATs also interact directly with GTFs and further enhance their activities. An important complex that also links nuclear receptors to GTFs is the TRAP (TR-associated proteins) or DRIP (D receptor-associated proteins) complex.

Repression of Gene Expression by Unliganded Receptor

Although DNA binding is ligand-dependent for steroid hormone receptors, other nuclear receptors are bound to DNA even in the absence of their cognate ligand. The unliganded DNA-bound receptor is not passively waiting for hormone; instead, it actively represses transcription of the target gene. This repression both "turns off" the target gene and amplifies the magnitude of the subsequent activation by hormone. For instance, if the level of gene transcription in the repressed state is 10% of the basal level in the absence of receptor, a hormone-activation to 10-fold above that basal level represents a 100-fold difference of transcription rate between hormone-deficient (repressed) genes and hormone-activated genes (Fig. 4-4).

In many ways, the molecular mechanism of repression is the mirror image of ligand-dependent activation. The unliganded nuclear receptor recruits negatively acting factors (corepressors) to the target gene. The two major corepressors are large (270 kd) proteins:

Nuclear receptor corepressor (N-CoR)
Silencing mediator for retinoid and thyroid receptors (SMRT)

N-CoR and SMRT specifically recognize the unliganded conformation of nuclear receptors and use an amphipathic helical sequence similar to the NR box of coactivators to bind to a hydrophobic pocket in the receptor.

For corepressors, the peptide responsible for receptor binding is called the CoRNR box and contains the sequence (I or L) xx (I or V)I (where I is isoleucine, L is leucine, V is valine, and xx represents any two amino acids). The receptor utilizes helices 3 to 5 to form the hydrophobic pocket, as in coactivator binding, but H12 does not promote and even hinders corepressor binding. This negative role of H12 highlights the role of the ligand-dependent change in the position of H12 as the switch that determines repression and activation by nuclear receptors.

The transcriptional functions of N-CoR and SMRT are the opposite of those of the coactivators. The corepressors themselves do not possess enzyme activity but do interact directly with GTFs to inhibit their transcriptional activities.

Repression and activation functions augmenting the dynamic range of transcriptional regulation by nuclear receptors. HRE, hormone response element.

The ligand-dependent switch between the repressed and activated receptor conformations explains how hormones activate gene expression. However, many of the most important gene targets of hormones are turned off in the presence of the ligand. This is referred to as ligand-dependent negative regulation of transcription, or transrepression, to distinguish it from the repression of basal transcription by unliganded receptors.

The mechanism of negative regulation is less well understood than ligand-dependent activation, and, indeed, there may be more than one mechanism. One mechanism involves nuclear receptor binding to DNA binding sites that reverse the paradigm of ligand-dependent activation (negative response elements).

Ligand-bound receptors recruit coactivators and HDAC activity to such binding sites.

For example, when the unliganded TR binds to the negative response element of the gene for the subunit of thyroid-stimulating hormone (TSH), transcription is activated. Ligand binding recruits corepressors and HDAC to the TR and leads to suppression of transcription.

In other cases, it has been postulated that negative regulation may result from ligand binding to nuclear receptors that bind to other transcription factors without binding DNA. This

interaction leads to removal of coactivators such as p300 and CBP from the other transcription factors that positively regulate the gene. In this model, inhibition of the activity of the positively acting factors results in the observed negative regulation.
Role of Other Nuclear Receptor Domains

The N-terminal A/B domain of the nuclear receptors is the most variable region among all members of the superfamily in terms of length and amino acid sequence. Even subtypes of the same receptor often have completely different A/B domains. The function of this domain is least well defined. It is not required for unliganded repression or ligand-dependent activation. In many receptors, the A/B domain contains a positive transcriptional activity, often referred to as AF-1 [see Fig. 4-2], that is ligand-independent but probably interacts with coactivators [56] and may influence the magnitude of activation by agonists or partial agonists (see later). This activation function is tissue-specific and tends to be more important for steroid hormone receptors, whose A/B domains are notably longer than those of other members of the superfamily. The F domain of the nuclear receptors is hypervariable in length and sequence, and its function is not known.

Cross-talk with Other Signaling Pathways

Hormones and cytokines that signal via cell surface receptors also regulate gene transcription, often by activating protein kinases that phosphorylate transcription factors such as cAMP-response element-binding protein (CREB). Such signals can also lead to phosphorylation of nuclear receptors. Multiple signal-dependent kinases can phosphorylate nuclear receptors, leading to conformational changes that regulate function. Phosphorylation can lead to changes in DNA binding, ligand binding, or coactivator binding; these variable consequences depend on the specific kinase, receptor, and domain of the receptor that is phosphorylated. The properties of coactivators and corepressor molecules are also regulated by phosphorylation.

Receptor Antagonists

Certain ligands function as receptor antagonists by competing with agonists for the ligand-binding site. In the case of steroid hormone receptors, the position of H12 in antagonist-bound conformation is not identical to that in the unliganded receptor or the agonist-bound receptor. H12, which itself has a sequence that resembles the NR box, binds to the coactivator-binding pocket and thereby prevents coactivator binding. This antagonist-bound conformation also favors corepressor binding to steroid hormone receptors.

Tissue-Selective Ligands

Some ligands function as antagonists in some tissues but as full or partial agonists in others. These selective receptor modulators include compounds such as tamoxifen, a selective estrogen receptor modulator (SERM). SERMs are estrogen receptor antagonists with respect to the functions of AF-2, including coactivator binding, and require the AF-1 function for their agonist activity. Such agonism, like AF-1 activity, tends to be tissue-specific and therefore has great therapeutic utility.

In addition to drugs, certain endogenous ligands (e.g., testosterone, DHT) also mediate tissue-specific effects. The molecular basis of tissue-specific activity is not well understood but is probably due to the expression or activity of transcriptional cofactors that differentiate between receptors bound to different ligands. Table 4-6 summarizes factors contributing to tissue-specificity of receptor activity.

Structure and Function of Nuclear Receptors

Chapter 5 - Mechanism of Action of Hormones That Act at the Cell Surface

Allen Spiegel
Christin Carter-Su
Simeon Taylor

Hormones are secreted into the blood and act upon target cells at a distance from the secretory gland. In order to respond to a hormone, a target cell must contain the essential components of a signaling pathway. First, there must be a receptor to bind the hormone. Second, there must be an effector for example, an enzymatic activity that is regulated when the hormone binds to its receptor. Finally, there must be appropriate downstream signaling pathways to mediate the physiologic responses to the hormone. In fact, this type of mechanism involving receptors, effectors, and downstream signaling pathways is quite general and also functions in nonendocrine systems such as neurotransmitters, cytokines, and paracrine and autocrine factors. This chapter reviews several examples of endocrine signaling pathways, with particular attention to the molecular mechanisms that function in normal physiology and to the molecular pathology causing disease.
RECEPTORS

Definition and Classification

There are two essential functions that define hormone receptors: (1) the ability to bind the hormone and (2) the ability to couple hormone binding to hormone action. Both components of the definition are essential; for example, many hormones bind to binding proteins, which are distinct from receptors because the binding proteins do not trigger the signaling pathways that mediate hormone action.

Many classes of receptors are of interest in endocrinology. Some receptors are located within the cell and function as transcription factors (e.g., receptors for steroid and thyroid hormones). Other receptors are located on the cell surface and function primarily to transport their ligands into the cell by a process referred to as receptor-mediated endocytosis (e.g., low-density lipoprotein receptors). In this chapter, we focus upon cell-surface receptors that trigger intracellular signaling pathways. These cell-surface receptors can be classified according to the molecular mechanisms by which they accomplish their signaling function:

1. Ligand-gated ion channels (e.g., nicotinic acetylcholine receptor).
2. Receptor tyrosine kinases (e.g., receptors for insulin and insulin-like growth factor I).
3. Receptor serine/threonine kinases (e.g., receptors for activins and inhibins).
4. Receptor guanylate cyclase (e.g., atrial natriuretic factor receptor).
5. G protein-coupled receptors (e.g., receptors for adrenergic agents, muscarinic cholinergic agents, glycoprotein hormones, glucagon, and parathyroid hormone).
6. Cytokine receptors (e.g., receptors for growth hormone, prolactin, and leptin).

The receptors belonging to classes 1 to 4 are bifunctional molecules that can bind hormone and also serve as effectors by functioning either as ion channels or as enzymes. In contrast, the receptors belonging to classes 5 and 6 have the ability to bind the hormone but must recruit a separate molecule to catalyze the effector function. For example, as the name implies, G protein-coupled receptors utilize G proteins to regulate downstream effector molecules. Similarly, cytokine receptors recruit cytosolic tyrosine kinases (e.g., Janus family tyrosine kinases, JAKs) as effectors to trigger downstream signaling pathways.
Hormone Binding

As predicted by the fact that hormones circulate in relatively low concentrations in the plasma, the binding interaction between a hormone and its receptor is characterized by high binding affinity. Furthermore, hormone binding has a high degree of specificity. Generally, the receptor binds its cognate hormone more tightly than it binds other hormones. However, some receptors may bind structurally related hormones with lower affinity. For example, the insulin receptor binds insulin-like growth factors (IGFs) with approximately 100-fold lower affinity than it binds insulin. Similarly, the thyrotropin receptor binds human chorionic gonadotropin with lower affinity than it binds thyrotropin. This phenomenon has been referred to as specificity spillover and provides an explanation of several pathologic conditions, such as hypoglycemia caused by tumors secreting IGF-II and hyperthyroidism associated with choriocarcinoma.

Binding of a hormone (H) to its receptor (R) can be described mathematically as an equilibrium reaction:

\[ H + R \rightleftharpoons HR \]

At equilibrium, \( K_a = \frac{[HR]}{[H][R]} \), where \( K_a \) is the association constant for the formation of the hormone receptor complex (HR). As originally shown by Scatchard, it is possible to rearrange this equation in terms of the total concentration of receptor binding sites, \( R_0 = [R] + [RH] \), as follows:

\[ K_a = \frac{[RH]}{[R_0][RH][H]} \]

\[ \frac{[RH]}{[H]} = K_a \frac{R_0}{K_a} \]

A straight line is obtained when \( \frac{[RH]}{[H]} \) (i.e., the ratio of bound to free hormone) is plotted as a function of \( [RH] \) (the concentration of bound hormone). The slope of the line is \(-K_a\), and the line intercepts the horizontal axis at the point where \( [HR] = R_0 \), the total number of binding sites. This type of plot is referred to as a Scatchard plot and has been used as a graphic method to estimate the affinity with which a receptor binds its hormone. Although the binding properties of some receptors are described more or less accurately by these simple equations, other receptors exhibit more complex properties. This simple algebraic derivation of the Scatchard equation implicitly assumes that there is only one class of receptors and that the binding sites on the receptors do not interact with one another. If these assumptions do not apply to the interaction of a particular hormone with its receptor, the Scatchard plot may not be linear.

Several molecular mechanisms may contribute to nonlinearity of the Scatchard plot. For example, there may be more than one type of receptor that binds the hormone (e.g., a high-affinity, low-capacity site and a low-affinity, high-capacity site). Alternatively, some receptors have more than one binding site, and there may be cooperative interactions among the binding sites (e.g., the insulin receptor). In addition, the interaction between a G protein and a G protein-coupled receptor may affect the affinity with which the receptor binds its ligand; moreover, the effect on binding affinity depends on whether guanosine diphosphate (GDP) or guanosine triphosphate (GTP) is bound to the G protein. However, a detailed discussion of these complexities is beyond the scope of this chapter.
REGULATION OF HORMONE SENSITIVITY

Early in the history of endocrinology, attention was focused on the regulation of hormone secretion as the most important mechanism for regulating physiology. However, it has become apparent that the target cell is not passive. Rather, there are many influences that can alter the sensitivity of the target cell's response to a given concentration of hormone. For example, the number of receptors can be regulated. All things being equal, hormone sensitivity is directly related to the number of hormone receptors expressed on the cell surface. In addition, post-translational modifications of the receptor can modify either the affinity of hormone binding or the efficiency of coupling to downstream signaling pathways. Moreover, all of the downstream components in the hormone action pathway are subject to similar types of regulatory influences, which can have a significant impact on the ability of the target cell to respond to hormone.

Just as hormone sensitivity is subject to normal physiologic regulation, pathologic influences can cause disease by targeting components of the hormone action pathway. Multiple etiologic factors can impair the hormone action pathway, such as genetic, autoimmune, and exogenous toxins. For example, disease mechanisms can alter the functions of cell-surface receptors, effectors such as G proteins, and other components of the downstream signaling pathways. This chapter describes several examples illustrating these principles.
RECEPTOR TYROSINE KINASES

Receptor tyrosine kinases have several structural features in common: an extracellular domain containing the ligand-binding site, a single transmembrane domain, and an intracellular portion that includes the tyrosine kinase catalytic domain. Analysis of the sequence of the human genome suggests that there are approximately 100 receptor tyrosine kinases. The tyrosine kinase domain is the most highly conserved sequence among all the receptors in this family. In contrast, there is considerable variation among the sequences of the extracellular domains. Indeed, the family of receptor tyrosine kinases can be classified into 16 subfamilies, primarily on the basis of the differences in the structure of the extracellular domain. Furthermore, receptor tyrosine kinases mediate the biologic actions of a wide variety of ligands, including insulin, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and vascular endothelial cell-derived growth factor. The variation in the sequences of the extracellular domains enables the receptors to bind this structurally diverse collection of ligands.

The EGF receptor was the first cell-surface receptor demonstrated to possess tyrosine kinase activity and also the first receptor tyrosine kinase to be cloned. Like most receptor tyrosine kinases, the EGF receptor exists primarily as a monomer in the absence of ligand. However, binding of ligand induces receptor dimerization. As discussed later in this chapter, ligand-induced dimerization is central to the mechanism whereby the receptor mediates the biologic activity of EGF. In addition to the ability to form homodimers, the EGF receptor can form heterodimers with other members of the same subfamily of receptor tyrosine kinases. Because a small number of receptors can combine in a large number of pairings, heterodimers formation has the potential to fine-tune the specificity of receptors with respect to both ligand binding and downstream signaling.

The insulin receptor is of special interest to endocrinologists because diabetes is among the most common diseases of the endocrine system. Furthermore, the insulin receptor closely resembles the type 1 receptor for IGF1 and therefore also plays an important role in the physiology of growth hormone (GH) in vivo. Although the kinase domains of receptors for insulin and IGF-I closely resemble other receptor tyrosine kinases, at least two distinctive features set them apart. First, the receptors are synthesized as proreceptors that undergo proteolytic cleavage into two subunits and . The subunit contains the ligand-binding site; the subunit includes the transmembrane and tyrosine kinase domains. Second, both receptors exist as heterotetramers that are stabilized by intersubunit disulfide bonds. In contrast to other receptor tyrosine kinases, which are thought to dimerize in response to ligand binding, the insulin receptor exists as a dimer of monomers even in the absence of ligand. The remainder of this section reviews the molecular mechanisms whereby receptor tyrosine kinases mediate biologic action, with special emphasis on the insulin receptor as an illustrative example.

Receptor Activation: Role of Receptor Dimerization

Dimerization plays a central role in the mechanism whereby most receptor tyrosine kinases are activated by their cognate ligands. Although receptor dimerization is a common theme, the detailed molecular mechanisms differ from receptor to receptor. The following are three examples of the mechanisms of receptor dimerization.

### Dimeric Ligand

PDGF and vascular endothelial cell-derived growth factor are examples of dimeric ligands. Because each subunit of ligand can bind one receptor molecule, simultaneous binding of two receptor molecules drives receptor dimerization. Direct support for this type of mechanism is provided by the crystal structure of vascular endothelial cell-derived growth factor bound to its receptor (Fig. 5-1). As illustrated by the crystal structure of GH bound to its receptor, one molecule of ligand can bind two molecules of receptor. In fact, there are two distinct receptor-binding sites on each GH molecule, and this enables the ligand to promote receptor dimerization. This observation has an important implication for pharmacology. By abolishing one of the two receptor-binding sites, it is possible to design mutant ligands that lack the ability to promote receptor dimerization and therefore lack the ability to trigger hormone action. Nevertheless, by binding to receptors, the mutant ligand acquires the ability to inhibit the
action of the endogenous hormone. Such mutant GH molecules are being evaluated as potential therapeutic agents, for example, in conditions such as acromegaly.

Preexisting Receptor Dimers

The insulin receptor represents a paradox. The insulin receptor exists as a dimer even in the absence of ligand. (Actually, it is an \( \beta_2 \) heterotetramer, which is a dimer of monomers.) If the receptor is already dimerized, why is it not active? Although the molecular details remain to be elucidated, it seems likely that the two halves of the insulin receptor are not oriented in an optimal way to permit receptor activation in the absence of ligand. Perhaps, insulin binding triggers a conformational change that somehow mimics the effects of dimerization in other receptor tyrosine kinases. In any case, several studies have demonstrated that receptor dimerization is necessary for the ability of insulin to activate its receptor. For example, monomers retain the ability to bind insulin but are not activated in response to insulin binding.\(^{13}\)\(^{14}\) Furthermore, indirect evidence suggests that a single insulin molecule binds simultaneously to both subunits of the insulin receptor \(^{15}\)\(^{16}\); the ability to bind simultaneously to both halves of the dimeric receptor appears to be essential to the ability of insulin to activate its receptor.
Receptor Activation: Conformational Changes in the Kinase Domain

When ligand binds to the extracellular domain, it stimulates the tyrosine kinase activity of the intracellular domain. Although the detailed mechanisms of transmembrane signaling are not completely understood, considerable progress has been made in elucidating the molecular mechanisms of receptor activation. Investigations of the three-dimensional structure of the insulin receptor tyrosine kinase domain help to explain why the receptor is maintained in a low-activity state in the absence of insulin. In the inactive form of the insulin receptor kinase, Tyr1162 is located in a position so that it blocks protein substrates from binding to the active site. Furthermore, in the inactive state of the tyrosine kinase domain, the active site assumes a conformation that does not accommodate magnesium adenosine triphosphate (ATP). Thus, the tyrosine kinase is inactive because the active site cannot bind either of its substrates. How does insulin activate the receptor? Insulin binding triggers autophosphorylation of three tyrosine residues (Tyr1158, Tyr1162, and Tyr1163) in the "activation loop." When the three tyrosine residues in the activation loop become phosphorylated, an important conformational change occurs. As a result of the movement of the activation loop, the active site acquires the ability to bind both ATP and protein substrates. Thus, the conformational change induced by autophosphorylation activates the receptor to phosphorylate other substrates.

It remains unclear how this process is initiated. Because the inactive state of the tyrosine kinase cannot bind ATP, it seems unlikely that phosphorylation of Tyr1162 proceeds by a true autophosphorylation mechanism. Rather, it is likely that Tyr1162 in one subunit is transphosphorylated by the second subunit in the heterotetrameric molecule. However, this proposed mechanism poses a "chicken and egg" problem. It requires that at least one of the subunits is active before the Tyr residues in the activation loop become phosphorylated. Perhaps the activation loop is somewhat mobile so that some molecules of unphosphorylated tyrosine kinase can assume an active conformation and initiate a chain reaction of transphosphorylation and receptor activation.
Receptor Tyrosine Kinases Phosphorylate Other Intracellular Proteins

Once activated, tyrosine kinases are capable of phosphorylating other protein substrates. Several factors determine which proteins are phosphorylated under physiologic conditions within the cell.

Amino Acid Sequence Context of Tyr Residue

Tyrosine kinases do not exhibit strict specificity with respect to the amino acid sequence of the phosphorylation site. Nevertheless, most tyrosine phosphorylation sites are located in the vicinity of acidic amino acid residues (i.e., Glu or Asp). \[2\]

Binding to the Tyrosine Kinase

Some protein substrates bind directly to the intracellular domain of the receptor. The binding interaction brings the substrate into close proximity to the kinase, thereby promoting phosphorylation of the substrate. For example, the insulin receptor substrate (IRS) proteins are characterized by a highly conserved phosphotyrosine-binding (PTB) domain that binds to a conserved motif (Asn-Pro-Xaa-pTyr) in the juxtamembrane domain of the insulin receptor. \[23\] \[24\] \[25\] Binding of the PTB domain to the insulin receptor requires phosphorylation of the Tyr residue in the Asn-Pro-Xaa-pTyr motif. This provides another mechanism (in addition to activation of the intrinsic receptor tyrosine kinase) whereby autophosphorylation of the receptor enhances phosphorylation of IRS proteins. Similarly, substrates for some tyrosine kinases contain Src homology 2 (SH2) domains, highly conserved domains that bind phosphotyrosine residues (see later). For example, the activated PDGF receptor contains a phosphotyrosine residue near its C-terminus that binds the SH2 domain of phospholipase C. This enables the PDGF receptor to phosphorylate and activate phospholipase C. \[2\] \[26\]

Subcellular Localization

Because receptor tyrosine kinases are located in the plasma membrane, they are in close proximity to other plasma membrane proteins. This colocalization has the potential to promote phosphorylation. For example, the insulin receptor has been reported to phosphorylate pp120/hepatocyte antigen-4 (HA4). \[27\] \[28\] Like the insulin receptor, pp120/HA4 is an integral membrane glycoprotein associated with the plasma membrane of hepatocytes. Similarly, FGF receptor substrate-2 (FRS2), a substrate of the fibroblast-derived growth factor receptor, is targeted to the plasma membrane by an N-terminal myristoylation site. \[29\]
There are at least two distinct mechanisms whereby tyrosine phosphorylation regulates protein function. First, tyrosine phosphorylation can induce a conformational change in a protein, thereby altering its function. For example, as discussed earlier, phosphorylation of the three Tyr residues in the activation loop of the insulin receptor changes the conformation of the active site, thereby facilitating binding of substrates and activating the receptor tyrosine kinase. However, most of the effects of tyrosine phosphorylation on protein function are mediated indirectly by regulating protein-protein interactions. In order to understand how tyrosine phosphorylation regulates protein-protein interactions, it is useful to review the biochemistry of c-src, the prototype of a nonreceptor tyrosine kinase. When the amino acid sequence of c-src is analyzed, it is apparent that there are three highly conserved domains in the molecule: the kinase catalytic domain and two noncatalytic domains that are referred to as src homology domains 2 and 3 (SH2 and SH3, respectively).

**SH2 Domains**

SH2 domains consist of conserved sequences (approximately 100 amino acid residues) that are present in many proteins that function in signaling pathways. From a functional point of view, SH2 domains share the ability to bind pTyr residues. However, individual SH2 domains vary with respect to their binding specificity. The binding affinity of an SH2 is determined by the three amino acid residues downstream from the pTyr residue. For example, the SH2 domains of phosphatidylinositol (PI) 3-kinase exhibit a preference for pTyr-(Met/Xaa)-Xaa-Met, whereas the SH2 domain of growth factor receptor binding protein 2 (Grb-2) prefers to bind pTyr-Xaa-Asn-Xaa. Thus, a given SH2 domain binds to a tyrosine-phosphorylated protein if and only if the pTyr residue is located in a context that corresponds to the binding specificity of the SH2 domain.

**SH3 Domains**

SH3 domains consist of conserved sequences (approximately 50 amino acid residues) that bind to proline-rich sequences. Like SH2 domains, SH3 domains are found in many proteins that function in signaling pathways.
Downstream Signaling Pathways

Receptor tyrosine kinases mediate the action of a wide variety of ligands in a wide variety of cell types. The bewildering complexity of the downstream signaling pathways corresponds to the huge number of physiologic processes that are regulated by receptor tyrosine kinases. Although it is beyond the scope of this chapter to attempt an encyclopedic review of all the downstream signaling pathways, we have selected examples to illustrate general principles.

As discussed earlier, the activated insulin receptor phosphorylates multiple substrates including IRS-1, IRS-2, IRS-3, and IRS-4. Each of these substrates contains multiple tyrosine phosphorylation sites, many of which correspond to consensus sequences for SH2 domains in important signaling molecules. Thus, IRS proteins serve as docking proteins that bind SH2 domain-containing proteins. Among these, two of the most important are PI 3-kinase and Grb-2. As discussed subsequently, binding of SH2 domains triggers multiple downstream signaling pathways.

Phosphatidylinositol 3-Kinase

The catalytic subunit of PI 3-kinase (p110; molecular mass approximately 110,000) is bound to a regulatory subunit. The classical isoforms of the regulatory subunit (p85; molecular mass approximately 85,000) contain two SH2 domains, both of which bind to pTyr in the context of pTyr-(Met/Xaa)-Xaa-Met motifs. Binding of pTyr residues to both SH2 domains of p85 leads to maximal activation of PI 3-kinase catalytic activity. (Submaximal activation can be achieved with occupancy of a single SH2 domain in p85.) Because all four IRS molecules (IRS-1, IRS-2, IRS-3, and IRS-4) contain multiple tyrosine phosphorylation sites that conform to the Tyr-(Met/Xaa)-Xaa-Met consensus sequence, insulin-stimulated phosphorylation promotes binding of IRS proteins to the SH2 domains in the regulatory subunit PI 3-kinase, thereby increasing the enzymatic activity of the catalytic subunit. Activation of PI 3-kinase triggers activation of a cascade of downstream kinases, beginning with phosphoinositide-dependent kinases 1 and 2. These phosphoinositide-dependent kinases phosphorylate and activate multiple downstream protein kinases including protein kinase B and atypical isoforms of protein kinase C.

A large body of evidence demonstrates that the pathways downstream from PI 3-kinase mediate the metabolic activities of insulin (e.g., activation of glucose transport into skeletal muscle, activation of glycogen synthesis, and inhibition of transcription of the phosphoenolpyruvate carboxykinase gene). Among other lines of evidence, PI 3-kinase inhibitors (e.g., LY294002 and wortmannin) block the metabolic actions of insulin. Similarly, overexpression of dominant negative mutants of the p85 regulatory subunit of PI 3-kinase also inhibits the metabolic actions of insulin. Although it is generally agreed that activation of PI 3-kinase is necessary, it is controversial whether it is sufficient to trigger the metabolic actions of insulin. For example, a second parallel pathway may also be required. The latter pathway involves tyrosine phosphorylation of Cbl, another protein that can be phosphorylated by the insulin receptor in some cell types.

Grb-2 and the Activation of Ras

Grb-2 is a short adaptor molecule that contains an SH2 domain capable of binding to pTyr residues in several signaling molecules, for example, IRS-1 and Shc, another PTB domain-containing protein that is phosphorylated by several receptor tyrosine kinases including the insulin receptor. The SH2 domain of Grb-2 is flanked by two SH3 domains which bind to proline-containing sequences in mSos (the mammalian homologue of Drosophila son-of-sevenless). mSos is capable of activating Ras, a small G protein that plays an important role in intracellular signaling pathways. mSos activates Ras by catalyzing the exchange of GTP for GDP in the guanine nucleotide-binding site of Ras. This, in turn, triggers the activation of a cascade of serine/threonine-specific protein kinases including Raf, mitogen-activated protein/extracellular signal-regulated kinase (MEK), and mitogen-activated protein (MAP) kinase. These pathways downstream from Ras contribute to the ability of tyrosine kinases to promote cell growth and regulate the expression of various genes.

We have focused on the signaling pathways downstream from the insulin receptor because of the importance of insulin and IGF-I in endocrinology. In many ways, the molecular mechanisms closely resemble those downstream from other receptor tyrosine kinases. However, the insulin signaling pathway is atypical in at least one respect. The insulin receptor phosphorylates docking proteins (e.g., IRS-1), which bind SH2 domain-containing proteins (e.g., PI 3-kinase and Grb-2). In contrast, the intracellular domains of most receptor tyrosine kinases contain binding sites for SH2 domains. For example, the SH2 domain of Grb-2 binds to pTyr716 in the activated PDGF receptor. Similarly, the PDGF receptor contains two Tyr-(Met/Xaa)-Xaa-Met motifs in the kinase insert domain that bind to the two SH2 domains in the p85 subunit of PI 3-kinase. It is not clear why some tyrosine kinases (e.g., the PDGF receptor) activate PI 3-kinase through a direct binding interaction, whereas others (e.g., the insulin receptor) utilize an indirect mechanism involving docking proteins. However, in contrast to PDGF receptors, which are associated with the plasma membrane, IRS proteins appear to be associated with the cytoskeleton. Perhaps this differential subcellular localization contributes to signaling specificity. In other words, if insulin and PDGF receptors trigger translocation of PI 3-kinase to different locations within the cell, this compartmentation may permit two different receptors to elicit different biologic responses even though both responses are mediated by the same signaling molecule (i.e., PI 3-kinase).
Off Signals: Termination of Hormone Action

Just as there are complex biochemical pathways that mediate hormone action, there are also mechanisms to terminate the biologic response. The necessity for these mechanisms is illustrated by the following example. After we eat a meal, the concentration of plasma glucose increases. This elicits an increase in insulin secretion, which in turn leads to a decrease in plasma glucose levels. If these processes went on unchecked, the level of glucose in the plasma would eventually fall so low that it would lead to symptomatic hypoglycemia. How is insulin action terminated? The answers to this question are not yet entirely clear, but several mechanisms contribute to turning off the insulin signaling pathway.

Receptor-Mediated Endocytosis

Insulin binding to its receptor triggers endocytosis of the receptor. Although most of the internalized receptors are recycled to the plasma membrane, some receptors are transported to lysosomes, where they are degraded. As a result, insulin binding accelerates the rate of receptor degradation, thereby down-regulating the number of receptors on the cell surface. Furthermore, endosomes contain proton pumps, which acidify the lumen; the acidic pH within the endosome promotes dissociation of insulin from its receptor. Ultimately, insulin is transported to the lysosome for degradation. In fact, receptor-mediated endocytosis is the principal mechanism whereby insulin is cleared from the plasma. Binding of ligands to other receptor tyrosine kinases also triggers receptor-mediated endocytosis by similar mechanisms.

Protein Tyrosine Phosphatases

Protein phosphorylation is a dynamic process. Tyrosine kinases catalyze the phosphorylation of tyrosine residues, but there are also protein tyrosine phosphatases (PTPases) to remove the phosphates. Thus, PTPases antagonize the action of tyrosine kinases. Studies with knockout mice have demonstrated that the absence of PTPase-1B is associated with increased insulin sensitivity and also protects against weight gain. Nevertheless, the human genome encodes a large number of PTPases, and it is an important goal of research to elucidate their physiologic functions. If one could develop selective inhibitors of the PTPases that oppose the effects of the insulin receptor tyrosine kinase, it is possible that these inhibitors would provide novel therapies for diabetes.

![Figure 5-4](image-url) Simplified model of signaling pathways downstream from the insulin receptor. Insulin binds to the insulin receptor, thereby activating the receptor tyrosine kinase to phosphorylate tyrosine residues on insulin receptor substrates (IRSs) including IRS-1 and IRS-2. Consequently, phosphotyrosine residues in IRS molecules bind to Src homology 2 (SH2) domains in molecules such as growth factor receptor-binding protein 2 (Grb-2) and the p85 regulatory subunit of phosphatidylinositol (PI) 3-kinase. These SH2 domain-containing proteins initiate two distinct branches of the signaling pathway. Activation of PI 3-kinase leads to activation of phosphoinositide-dependent kinases (PDKs) 1 and 2, which activates multiple protein kinases including Akt/protein kinase B, atypical protein kinase C (PKC) isoforms, and serum/glucocorticoid-activated protein kinases (Sgk). Grb-2 interacts with m-SOS, a guanine nucleotide exchange factor that activates Ras. Activation of Ras triggers a cascade of protein kinases leading to the activation of mitogen-activated protein (MAP) kinase.

Serine/Threonine Kinases

Most receptor tyrosine kinases, including the insulin receptor, are substrates for phosphorylation by Ser/Thr-specific protein kinases. Interestingly, the Ser/Thr phosphorylation appears to inhibit the action of the tyrosine kinase. Similarly, other phosphorytyrosine-containing proteins are subject to inhibitory influences of Ser/Thr phosphorylation resistance. For example, it has been reported that Ser/Thr phosphorylation of IRS-1 may inhibit insulin action, thereby causing insulin resistance.
Mechanisms of Disease

The simplest forms of endocrine disease are caused by either a deficiency or an excess of a hormone. However, hormone resistance syndromes resulting from defects in the signaling pathways can masquerade as hormone deficiency states. Similarly, diseases associated with constitutively activated receptors can mimic a state of hormone excess. In some cases, the abnormality in hormone action is genetic in origin, resulting from a mutation in a gene encoding one of the proteins in the signaling pathway. Similar syndromes can also be caused by other mechanisms; for example, there are autoimmune syndromes caused by autoantibodies directed against cell-surface receptors. These clinical syndromes illustrate the principle that understanding the biochemical pathways of hormone action can provide important insights into the pathophysiology of human disease.

Genetic Defects in Receptor Function

At least two distinct major types of genetic defects can cause hormone resistance. First, mutations can lead to a decrease in the number of receptors. For example, in the case of the insulin receptor, mutations have been identified that decrease receptor number by at least three mechanisms: (1) impairing receptor biosynthesis, (2) inhibiting the transport of receptors to their normal location in the plasma membrane, and (3) accelerating the rate of receptor degradation. Second, mutations can impair the intrinsic activities of the receptor. In the case of the insulin receptor, mutations have been reported that decrease the affinity of insulin binding or inhibit receptor tyrosine kinase activity.

Receptor dimerization is known to play a central role in the mechanisms whereby ligands activate many cell-surface receptors. This role has been shown most convincingly in the case of the GH receptor (a member of the family of cytokine receptors) but has also been postulated for receptor tyrosine kinases. The syndromes of multiple endocrine neoplasia types 2A and 2B and familial medullary carcinoma of the thyroid are caused by mutations in the gene encoding the ret tyrosine kinase (a subunit of the receptor for glial cell-derived growth factor). Ordinarily, there are cysteine residues in the extracellular domain of Ret that participate in the formation of intramolecular disulfide bonds. Mutation of one of the cysteine residues leaves an unpaired cysteine residue that domain of Ret that participate in the formation of intramolecular disulfide bonds. Mutation of one of the cysteine residues leaves an unpaired cysteine residue that promotes dimerization of Ret molecules, thereby activating the Ret receptor tyrosine kinase. Activation of the Ret tyrosine kinase through this germ line mutation converts Ret into an oncogene.

Autoantibodies Directed against Cell-Surface Receptors

Inhibitory antireceptor autoantibodies were first identified in myasthenia gravis. In this neuromuscular disease, antibodies to the nicotinic acetylcholine receptor impair neuromuscular transmission, apparently by accelerating receptor degradation. Subsequently, autoantibodies to the insulin receptor were demonstrated to block insulin action in the syndrome of type B extreme insulin resistance. Insulin resistance is caused by at least two mechanisms: (1) the antireceptor antibodies inhibit insulin binding to the receptor, and (2) the antibodies accelerate receptor degradation.

Graves’ disease provided the first example of stimulatory antireceptor autoantibodies. In Graves’ disease, there are autoantibodies directed against the thyroid-stimulating hormone (TSH) receptor. These antireceptor antibodies activate the TSH receptor, thereby stimulating growth of the thyroid gland as well as hypersecretion of thyroid hormone. This “experiment of nature” demonstrates that the receptor can be activated by ligands other than the physiologic ligand and that the normal spectrum of biologic actions can be triggered by this unphysiologic ligand (i.e., the antireceptor antibody). Similarly, antibodies to the insulin receptor have been demonstrated to activate the insulin receptor by mimicking insulin action. Although it is more common for a patient with anti-insulin receptor autoantibodies to present with insulin resistance, patients with anti-insulin receptor autoantibodies have also been reported to experience fasting hypoglycemia.
RECEPTORS THAT SIGNAL THROUGH ASSOCIATED TYROSINE KINASES

Overview

Members of the cytokine family of receptors resemble receptor tyrosine kinases in their mechanism of action, with one important difference. Instead of the tyrosine kinase being intrinsic to the receptor, enzymatic activity resides in a protein that associates with the cytokine receptor. As with receptor tyrosine kinases, ligand binding to the cytokine receptor activates the associated kinase. The more than 25 known ligands that bind to members of the cytokine receptor family have diverse functions. Three of the ligands are hormones: GH, which is vital for normal body height; prolactin (PRL), which is required for reproduction and lactation; and leptin, which is a potent appetite suppressant and a regulator of rates of metabolism. Other ligands of cytokine receptors, for example, erythropoietin, most interleukins, and interferons, and, regulate hematopoiesis or the immune response. A number of genetic diseases can be traced to defects in cytokine receptors. For example, Laron dwarfism is caused by autosomal recessive mutations of the GH receptor and autosomal recessive mutations of the leptin receptor can cause morbid obesity.
Cytokine Receptors Are Composed of Multiple Subunits

Members of the cytokine family of receptors share homology in both the extracellular and cytoplasmic domains. Some cytokine receptors, including the receptors for GH, PRL, and leptin, are thought to be composed of dimers of a single receptor subunit (Fig. 5-6). One ligand is thought to bind to both receptor subunits, as discussed earlier for the GH receptor. However, most cytokine receptors are composed of two or more different subunits, with as many as six subunits constituting a single receptor. Some of these receptors are thought to bind ligand dimers. One or more of these receptor subunits is shared by receptors for other cytokines. This phenomenon of "mixing and matching" receptor subunits is an efficient way for the cell to fine-tune its cellular responses and increase the number of ligands a group of receptor subunits can bind. For example, a receptor composed of gp130 and leukemia inhibitory factor receptor subunit binds leukemia inhibitory factor, a pleiotropic cytokine with multiple functions that appears to serve as a molecular interface between the neuroimmune and endocrine systems. The same receptor subunits, when combined with a ciliary neurotrophic factor receptor subunit, show a preference for ciliary neurotrophic factor, a trophic factor for motor neurons in the ciliary ganglion and spinal cord and a potent appetite suppressor. Combine two gp130 subunits with an interleukin-6 (IL-6) receptor subunit, and the new receptor shows a preference for IL-6, an inducer of the acute phase response with additional anti-inflammatory properties.
Cytokine Receptors Activate Members of the Janus Family of Tyrosine Kinases

Members of the cytokine family of receptors do not themselves exhibit enzymatic activity. Rather, they bind members of the Janus family of tyrosine kinases (JAKs) through a proline-rich region (see Fig. 5-6). There are four known JAKs, designated JAK1, JAK2, JAK3, and TYK2. As do the cytokine receptors, the JAKs mix and match in that some receptors show a strong preference for a single JAK, some require two different JAKs, and others appear to activate multiple JAK family members. For example, GH, PRL, and leptin preferentially activate JAK2. Interferon- activates JAK1 and JAK2, and IL-2 activates JAK1 and JAK3.

Binding of ligand to a cytokine receptor activates the appropriate JAK family member or members. In some cases (e.g., PRL), the JAKs appear to be constitutively associated with the cytokine receptor and ligand binding increases their activity. In other cases (e.g., the GH receptor), ligand binding increases both the affinity of JAKs for the cytokine receptor and the activity of the associated JAKs. Activation of JAKs requires receptor oligomerization, presumably to bring two or more JAKs into sufficiently close proximity to transphosphorylate each other on the activating tyrosine in the kinase domain, as described previously in the chapter for the receptor tyrosine kinases. Although receptor dimerization appears to be required for receptor activation, a conformational change in receptor may also be required.

Transphosphorylation is believed to cause a conformational change that exposes the ATP- or substrate-binding site, or both. Once the JAKs are activated, they phosphorylate themselves and their associated receptor subunits on multiple tyrosines. JAKs appear to be vital for normal human function. Mutations in the JAK3 gene have been linked to an autosomal recessive form of severe combined immunodeficiency disease. Targeted disruption of the JAK2 gene in mice is embryonic lethal.
Signaling Pathways Initiated by Cytokine Receptor-JAK Complexes

Phosphorylated tyrosines within the cytokine receptor subunits and their associated JAKs form binding sites for various signaling proteins containing phosphotyrosine binding domains, such as SH2 and PTB domains. Each cytokine receptor-JAK complex would be expected to have some tyrosine-containing motifs shared with many other cytokine receptor-JAK complexes (e.g., tyrosines within JAKs) and some specific tyrosine-containing motifs (e.g., tyrosines within a specific combination of receptor subunits). Thus, ligand binding to cytokine receptors would be expected to initiate some signaling pathways that are shared by many cytokines and some that are more specialized to a particular cytokine receptor. The signaling proteins known to be recruited to subsets of cytokine receptor-JAK complexes are generally the same as those recruited to receptor tyrosine kinases. Examples include the IRS proteins, the adapter proteins Shc and Grb-2 that lead to activation of the Ras-MAP kinase pathway, phospholipase C, and PI 3-kinase. However, there is one family of signaling proteins that appears to be particularly important for the function of cytokine signal transducers and activators of transcription (STATs) (Fig. 5-7).

STAT proteins are latent cytoplasmic transcription factors. STATs bind, through their SH2 domains, to one or more phosphorylated tyrosines in activated receptor-JAK complexes. Once bound, they themselves are tyrosyl phosphorylated, presumably by the receptor-associated JAKs. STATs then dissociate from the receptor-JAK complexes, homodimerize or heterodimerize with other STAT proteins, move to the nucleus, and bind to gamma-activated sequence-like elements in the promoters of cytokine-responsive genes. The transcriptional response depends on how many STAT binding sites exist in the receptor-JAK complex, with which of the seven known STATs a particular STAT heterodimerizes, to what other proteins a particular STAT binds, the degree of serine or threonine phosphorylation of the STAT, and what other transcription factors are also activated. For example, leukemia inhibitory factor, whose receptor contains seven STAT3 binding motifs (YXXQ, where Y = tyrosine, X = any amino acid, and Q = glutamine) is a particularly potent activator of STAT3. The transcriptional activity of STAT5 is enhanced by its forming a complex with the glucocorticoid receptor.
Precise Regulation of the Cytokine Receptors Is Required for Normal Function

Ligand binding to cytokine receptors normally activates JAKs rapidly and transiently. Conversely, constitutively activated JAKs and STATs are associated with cellular transformation. For example, in cells transformed by the Abl oncoprotein v-Abl, JAK1 is constitutively activated and inhibition of JAK1 blocks the ability of v-Abl to transform bone marrow cells. Constitutively active JAKs and STATs are a common characteristic of leukemias, and both JAK2 and STAT5b have been identified as fusion partners in translocations in leukemias. The Tel-JAK2 fusion protein is constitutively active, leading to constitutively active STAT proteins. Thus, an understanding of what turns off cytokine receptor signaling is of utmost importance in understanding normal signaling through cytokine receptors.

As with the receptor tyrosine kinases, several steps have been hypothesized to serve as points of signal termination for cytokine signaling. These include receptor degradation (e.g., through a ubiquitination-proteosome pathway) and dephosphorylation of tyrosines within JAK or receptor (e.g., by an SH2 domain containing tyrosine phosphatase recruited to receptor-JAK complexes). The suppressors of cytokine-signaling (SOCSs) are thought to be particularly important players in the termination or suppression of cytokine-signaling pathways. SOCS proteins are an excellent example of an effective negative feedback loop. They are generally synthesized in response to cytokines. The newly synthesized SOCS proteins in turn bind, through their SH2 domain, to phosphorylated tyrosines within the cytokine receptor-JAK complex and inhibit further cytokine signaling. In some cases (i.e., SOCS1), SOCS proteins are thought to bind to phosphotyrosines in the kinase domain of JAK and inhibit kinase activity. In other cases (i.e., SOCS 3), SOCS proteins bind to phosphorylated tyrosines in the receptor and block STAT binding and activation. SOCS proteins can also be synthesized in response to noncytokine receptors, suggesting a mechanism whereby prior exposure to one ligand suppresses subsequent responses to another. For example, SOCS proteins have been implicated in the well-known ability of endotoxin to cause resistance to GH.

![Figure 5-6](image-url) Cytokine receptors are composed of multiple subunits and bind to one or more members of the Janus kinase (JAK) family of tyrosine kinases. A, Growth hormone (GH), like prolactin and leptin, binds to receptor homodimers and activates JAK2. B, Interferon (IFN) homodimers bind to their ligand-binding R1 subunits. The R2 subunits are then recruited, leading to activation of JAK1, which binds to R1 subunit, and JAK2, which binds to R2 subunit. Both subunits and both JAKs are necessary for responses to IFN. C, Interleukin-2 (IL-2) binds to receptors composed of three subunits: a common subunit shared with receptors for ILs 4, 7, 9, and 15; an IL-2R subunit shared with the IL-15 receptor; and a noncytokine receptor subunit, IL-2R. Extracellular regions of homology are indicated by the black lines and patterns. Intracellular regions of homology are indicated by the white boxed.
Hormones, growth factors, and cytokines that bind to members of the cytokine family of receptors activate JAK family tyrosine kinases. The activated kinases in turn phosphorylate tyrosines in themselves and associated receptors. The phosphorylated tyrosines form binding sites for other signaling proteins, including STAT proteins and a variety of other phosphotyrosine-binding proteins. STAT proteins promote the regulation of cytokine-sensitive genes, including SOCS proteins that serve a negative feedback function of terminating ligand activation of JAKs or STATs, or both.

Although this gives the general picture, it should be recognized that the picture is becoming much more complex every day. For example, there are reports that members of the Src family of tyrosine kinases can also be activated by some cytokine receptors (e.g., PRL receptor), that some JAK-binding proteins (e.g., SH2-B) are potent activators of JAK2, and that other proteins contribute to the down-regulation of cytokine-signaling pathways, including protein inhibitors of activated STAT (PIAS), that bind and inhibit specific STATs.
G PROTEIN-COUPLED RECEPTORS

Overview

G protein-coupled receptors (GPCRs) are an evolutionarily conserved gene superfamily with members in all eucaryotes from yeast to mammals. They transduce a wide variety of extracellular signals including photons of light; chemical odorants; divalent cations; monoamine, amino acid, and nucleoside neurotransmitters; lipids; and peptide and protein hormones. All members of the GPCR superfamily share a common structural feature, seven membrane-spanning helices, but various subfamilies diverge in primary amino acid sequence and in the domains that serve in ligand binding, G protein coupling, and interaction with other effector proteins (Fig. 5-8).

All GPCRs act as guanine nucleotide exchange factors. In their activated (agonist-bound) conformation, they catalyze exchange of GDP tightly bound to the subunit of heterotrimeric G proteins for GTP (Fig. 5-9). This in turn leads to activation of the subunit and its dissociation from the G protein dimer. Both G protein subunits are capable of regulating effector activity.

Effectors include enzymes of second messenger metabolism such as adenyl cyclase and phospholipase C- and a variety of ion channels. Agonist binding to GPCRs thus alters intracellular second messenger and ion concentrations with resultant rapid effects on hormone secretion, muscle contraction, and a variety of other physiologic functions. Long-term changes in gene expression are also seen as a result of second messenger-stimulated phosphorylation of transcription factors.

The G protein subunits are encoded by three distinct genes. The subunit binds guanine nucleotides with high affinity and specificity and has intrinsic guanosine triphosphatase (GTPase) activity. The and polypeptides are tightly but noncovalently associated in a functional dimer subunit. The three-dimensional structures of the individual and associated subunits have been determined.

There is considerable diversity in G protein subunits, with multiple genes encoding all three subunits and alternative gene splicing resulting in additional polypeptide products. There are at least 16 distinct subunit genes in mammals. These vary widely in range of expression. Some such as Gs- which couples many GPCRs to stimulation of adenyl cyclase, are ubiquitous; others such as Gt-, which couples the GPCR rhodopsin to cyclic guanosine monophosphate phosphodiesterase in retinal rod photoreceptor cells, are highly localized.

Because multiple distinct GPCRs, G proteins, and effectors are expressed within any given cell, the degree and basis for specificity in G protein coupling to GPCRs and to effectors are major subjects of investigation with implications for drug action and disease mechanisms. Since the pioneering work of Rodbell in discovering G proteins and showing that G protein-mediated signal transduction involves three separable components (receptor, G protein, and effector), additional complexity has emerged.

A large new gene family termed RGS (for regulators of G protein signaling) has been identified. RGS proteins bind to a transition state of the GTP-activated G protein subunit and accelerate its GTPase activity, thus helping deactivate the subunit. RGS domains have also been found in modular proteins with additional functions, in certain cases linking heterotrimeric G protein signaling with the function of low-molecular-weight GTP-binding proteins in the ras superfamily.

Lefkowitz has shown that a family of GPCR kinases and of arrestin proteins is involved in GPCR desensitization after agonist binding. In addition, it is now clear that GPCRs interact directly with a number of other proteins in addition to G proteins. Not only are GPCRs important targets for treatment of many diseases, but also mutations in genes encoding GPCRs have been identified as the cause of a number of endocrine as well as nonendocrine disorders.
G Protein-Coupled Receptor Structure and Function

Structure

Hydropathy analysis of the primary sequence of all GPCRs predicts seven membrane-spanning helices connected by three intracellular loops and three extracellular loops with an extracellular amino terminus and an intracellular carboxyl terminus (see Fig. 5-8). This basic structure has now been verified by x-ray crystallography for rhodopsin. Although there was already evidence that visual transduction in the retina and hormone activation of adenylyl cyclase share common features, the discovery that the adrenergic receptor has the same topographic structure as rhodopsin came as a surprise. Cloning of the complementary deoxyribonucleic acids (cDNAs) for a vast number of GPCRs followed elucidation of the primary sequence of the adrenergic receptor, and in every case the same core structure was predicted by hydropathy analysis. In addition to the predicted core structure, certain other common features (with exceptions in some subsets of the GPCR superfamily) were noted.

than for ligand binding. The disulfide bridge may help in proper arrangement of the transmembrane helices.

Superimposed on the basic structure of GPCRs are a number of variations relevant to differences in ligand binding, G protein coupling, and interaction with other proteins. First, there are major differences in amino acid sequence among members of the GPCR superfamily. Sequence alignment, especially of the transmembrane helices, allows one to divide the superfamily into subfamilies. Of these, family 1 is the largest and itself can be subdivided. The largest subset includes opsin, odorant receptors, and monoamine, purinergic, and opiate receptors. These are characterized by a short amino terminus. The next subset includes chemokines, protease-activated, and certain peptide hormone receptors characterized by a slightly longer amino terminus. The last subset comprises receptors for the large glycoprotein hormones, TSH, luteinizing hormone, and follicle-stimulating hormone. These have an approximately 400-residue extracellular amino terminus.

Family 2 shows essentially no sequence homology to family 1 even within the transmembrane helices and is characterized by an approximately 100-residue amino terminus. Members include receptors for peptide hormones such as parathyroid hormone (PTH) and secretin. Agonists (arrow) may bind to residues in the extracellular amino terminus and loops as well as transmembrane helices (arrow). Family 3 includes the extracellular Ca²⁺ sensing receptor and metaboletic glutamate receptors. Agonists (sphere) bind in a cleft of the Venus flytrap-like domain in the large extracellular amino terminus, thereby activating the receptor through as yet undefined interactions with the extracellular loops or transmembrane helices (arrow).

The G protein-coupled receptor (GPCR) superfamily: diversity in ligand binding and structure. Each panel depicts various members of the GPCR superfamily in cartoon form. The seven membrane-spanning helices are shown as cylinders with the extracellular amino terminus and three extracellular loops above and the intracellular carboxyl terminus and three intracellular loops below. The superfamily can be divided into three subfamilies on the basis of amino acid sequence conservation within the transmembrane helices. Family 1 includes (A) the opsins, in which light (jagged arrow) causes isomerization of retinal covalently bound within the pocket created by the transmembrane helices (bar); (B) monoamine receptors, in which agonists (arrow) bind noncovalently within the pocket created by the transmembrane helices (bar); (C) receptors for peptides such as vasopressin, in which agonist binding (arrow) may involve parts of the extracellular amino terminus and loops as well as the transmembrane helices (bar); and (D) glycoprotein hormone receptors, in which agonists (oval) bind to the large extracellular amino terminus, thereby activating the receptor through as yet undefined interactions with the extracellular loops or transmembrane helices (arrow). Family 2 includes receptors for peptide hormones such as parathyroid hormone (PTH) and secretin. Agonists (arrow) may bind to residues in the extracellular amino terminus and loops as well as transmembrane helices (bar). Family 3 includes the extracellular Ca²⁺ sensing receptor and metabotropic glutamate receptors. Agonists (sphere) bind in a cleft of the Venus flytrap-like domain in the large extracellular amino terminus, thereby activating the receptor through as yet undefined interactions with the extracellular loops or transmembrane helices (arrow)....
Because the number of potential G proteins to which GPCRs couple is much more limited than the number of ligands that bind GPCRs, more conservation of the domains involved in G protein coupling would be expected. Although GPCRs can be broadly divided into those that couple to Gs, those that couple to the Gq subfamily, and those that couple to the Gi-Go subfamily, the situation is probably more complicated. Specificity of coupling to the most recently identified G proteins, G12 and G13, is still uncertain. Also, some GPCRs evidently can couple to both Gs and Gq.

A vast number of studies have been performed to define the sites of ligand binding and G protein coupling of GPCRs. Considerable evidence points to the third intracellular loop (particularly its membrane-proximal portions) and to the membrane-proximal portion of the carboxyl terminus as key determinants of G protein coupling specificity. For example, exchanging only the third intracellular loop between different GPCRs confers the G protein coupling specificity of the exchanged loop upon the recipient GPCR. In contrast, the second intracellular loop, although important for G protein coupling, appears to play a role in the activation mechanism rather than in determining specificity of coupling. A tripeptide motif (D/E, R, Y/W) at the start of the second intracellular loop that is highly conserved in family 1 GPCRs is critical for G protein activation.

Mechanism of Activation

The precise mechanism of activation after agonist binding remains to be defined for most GPCRs, but studies of rhodopsin provide the clearest picture available. In the ground state, retinal covalently bound to the seventh transmembrane helix in rhodopsin holds the transmembrane helices in an inactive conformation. Isomerization of retinal upon absorption of light of the appropriate wavelength converts an antagonist ligand into an agonist. The rhodopsin crystal structure identifies the residues in the transmembrane helices that interact with retinal and suggests a mechanism for movement of the helices upon photoactivation of retinal. Movement of the transmembrane helices in turn leads to changes in conformation of cytoplasmic loops that promote G protein activation.

For family 1 receptors related to rhodopsin, the determination of its three-dimensional structure validates the idea that a change in conformation of transmembrane helices is the direct result of agonist versus antagonist binding to residues within the helices. Further refinements in understanding the mechanism of activation for opsin-related GPCRs should come as additional three-dimensional structures are determined. Until then, molecular modeling by computer on the basis of the rhodopsin structure and then experimental testing offer a useful approach. For other GPCRs whose presumptive site of agonist binding does not involve direct contact with transmembrane helices (families 2 and 3 and the glycoprotein hormone receptors in family 1), much remains to be learned about the mechanism of activation. Specifically, determining how agonist binding to the extracellular domains of such GPCRs leads to presumptive changes in conformation of transmembrane helices requires further studies of structure and function.

A general hypothesis of GPCR activation postulates that GPCRs are in equilibrium between an activated state and an inactive state. These states presumably differ in the disposition of the transmembrane helices and, in turn, the cytoplasmic domains that determine G protein coupling. Agonists, according to this model, are viewed as stabilizing the activated state. Antagonists may be neutral, that is, they simply compete with agonist for receptor binding but their binding does not influence this equilibrium. Alternatively, they may be "inverse" agonists; that is, their binding stabilizes the inactive state of the receptor. Naturally occurring, activating mutations of the residues in the transmembrane helices that interact with retinal and suggests a mechanism for movement of the helices upon photoactivation of retinal.

Dimerization

Members of the tyrosine kinase receptor family have long been known to require dimerization as part of their activation mechanism. It is now apparent that many GPCRs likewise form homodimers and heterodimers. Residues within transmembrane helix 6 may foster dimerization of small family 1 GPCRs and intermolecular disulfide bonds in the extracellular amino-terminal domain are involved in homodimerization of most family 3 GPCRs. A coiled-coil interaction in the carboxyl terminus of -aminobutyric acid B receptor subtypes is responsible for heterodimerization, and this is critical for proper receptor function. Modifications of ligand binding, signaling, and receptor sequestration have been demonstrated upon heterodimerization of angiotensin with bradykinin receptors, of opioid receptors, and of opioid with -adrenergic receptors. Further studies are needed to elucidate the role of homodimerization and heterodimerization in GPCR function.

G Protein Coupling

Mechanism of Activation

The precise mechanism of activation after agonist binding remains to be defined for most GPCRs, but studies of rhodopsin provide the clearest picture available. In the ground state, retinal covalently bound to the seventh transmembrane helix in rhodopsin holds the transmembrane helices in an inactive conformation. Isomerization of retinal upon absorption of light of the appropriate wavelength converts an antagonist ligand into an agonist. The rhodopsin crystal structure identifies the residues in the transmembrane helices that interact with retinal and suggests a mechanism for movement of the helices upon photoactivation of retinal. Movement of the transmembrane helices in turn leads to changes in conformation of cytoplasmic loops that promote G protein activation.

For family 1 receptors related to rhodopsin, the determination of its three-dimensional structure validates the idea that a change in conformation of transmembrane helices is the direct result of agonist versus antagonist binding to residues within the helices. Further refinements in understanding the mechanism of activation for opsin-related GPCRs should come as additional three-dimensional structures are determined. Until then, molecular modeling by computer on the basis of the rhodopsin structure and then experimental testing offer a useful approach. For other GPCRs whose presumptive site of agonist binding does not involve direct contact with transmembrane helices (families 2 and 3 and the glycoprotein hormone receptors in family 1), much remains to be learned about the mechanism of activation. Specifically, determining how agonist binding to the extracellular domains of such GPCRs leads to presumptive changes in conformation of transmembrane helices requires further studies of structure and function.

A general hypothesis of GPCR activation postulates that GPCRs are in equilibrium between an activated state and an inactive state. These states presumably differ in the disposition of the transmembrane helices and, in turn, the cytoplasmic domains that determine G protein coupling. Agonists, according to this model, are viewed as stabilizing the activated state. Antagonists may be neutral, that is, they simply compete with agonist for receptor binding but their binding does not influence this equilibrium. Alternatively, they may be "inverse" agonists; that is, their binding stabilizes the inactive state of the receptor. Naturally occurring, activating mutations of the residues in the transmembrane helices that interact with retinal and suggests a mechanism for movement of the helices upon photoactivation of retinal.

Dimerization

Members of the tyrosine kinase receptor family have long been known to require dimerization as part of their activation mechanism. It is now apparent that many GPCRs likewise form homodimers and heterodimers. Residues within transmembrane helix 6 may foster dimerization of small family 1 GPCRs and intermolecular disulfide bonds in the extracellular amino-terminal domain are involved in homodimerization of most family 3 GPCRs. A coiled-coil interaction in the carboxyl terminus of -aminobutyric acid B receptor subtypes is responsible for heterodimerization, and this is critical for proper receptor function. Modifications of ligand binding, signaling, and receptor sequestration have been demonstrated upon heterodimerization of angiotensin with bradykinin receptors, of opioid receptors, and of opioid with -adrenergic receptors. Further studies are needed to elucidate the role of homodimerization and heterodimerization in GPCR function.
Pharmacologists long ago appreciated that continued exposure to agonist leads to a diminished response, so-called desensitization. This phenomenon has been extensively studied in GPCRs. Two forms are defined: heterologous, in which binding of agonist to one GPCR leads to a diminished response of a different GPCR to its agonist, and homologous, in which desensitization occurs only for the GPCR to which agonist is bound. Both forms of desensitization involve GPCR phosphorylation but by different kinases and at different sites. Stimulation of cyclic adenosine monophosphate formation by agonist binding to a Gs-coupled GPCR leads to activation of protein kinase A, which in turn can phosphorylate and desensitize the GPCR. Such phosphorylation may also alter G protein coupling specificity. Similarly, protein kinase C activation resulting from GPCR coupling to Gq family members may cause protein kinase C catalyzed phosphorylation of GPCRs with desensitization.

In retinal photoreceptors, a specific rhodopsin kinase and a protein termed arrestin were implicated in attenuation of the light response. Just as parallels were identified between rhodopsin and GPCR structure, so were parallels identified in this desensitization mechanism. Rhodopsin kinase is but one member of a family of GPCR kinases and arrestin only one of a family of related proteins that function in desensitization of many members of the GPCR superfamily. GPCR kinases preferentially phosphorylate the agonist-bound form of a GPCR, thus ensuring homologous desensitization. Upon GPCR phosphorylation by GPCR kinase, arrestins bind to the third intracellular loop and carboxyl-terminal tail of the GPCR, thereby blocking G protein binding. There is evidence that GPCR kinases and arrestins not only act to desensitize GPCRs but also mediate other functions including receptor internalization and interaction with other effectors (see next section).
G Protein-Coupled Receptor Interactions with Other Proteins

The initial paradigm of GPCR function postulated that G protein activation is the sole outcome of agonist binding to GPCRs. With the identification of GPCR interactions with GPCR kinases and arrestins, this concept was modified to include these proteins involved in GPCR desensitization. Later evidence, however, suggests that GPCR interaction with arrestins may also permit recruitment of other proteins to the GPCR. For example, the src tyrosine kinase may interact with the -adrenergic receptor with -arrestin serving as an adaptor. A arrestins may also recruit proteins involved in endocytosis. GPCR kinases may also serve to recruit additional signaling proteins to the GPCR.

Other classes of proteins may interact with specific GPCRs without recruitment by GPCR kinases and arrestins. These include SH2 domain-containing proteins, small GTP-binding proteins, and PDZ (for postsynaptic density protein-95/discs large/zona occluden-1) domain-containing proteins. Examples of the latter include binding of the Na+/H+ exchanger regulatory factor to the carboxyl terminus of the -adrenergic receptor. The long carboxyl terminus of family 3 GPCRs such as metabotropic glutamate receptors contains polyproline motifs involved in binding members of the Homer family. The latter can facilitate functional interactions with yet other proteins such as the inositol trisphosphate receptor. Receptor activity-modifying proteins (RAMPs), a new family of single-transmembrane-domain proteins, appear to heterodimerize with certain GPCRs, assisting them in proper folding and membrane trafficking. Interestingly, when the calcitonin receptorlike GPCR associates with RAMP1, it forms a calcitonin generelated peptide receptor, whereas when it associates with RAMP2, it becomes an adrenomedullin receptor. Clearly, this rapidly evolving aspect of GPCR function holds many further interesting developments in store.
Because of their diverse and critical roles in normal physiology, their accessibility on the cell surface, and the ability to synthesize selective agonists and antagonists, GPCRs have long been a major target for drug development. One estimate is that about 65% of prescription drugs are targeted against GPCRs. With the cloning of GPCR cDNAs, much greater diversity of receptor subclasses became evident than had been anticipated on the basis of pharmacologic studies. For example, five muscarinic receptor subtypes and an even greater number of serotonergic GPCRs were identified. This has allowed the development of highly specific, subtype-selective drugs that have fewer side effects than those produced by previously available agents.

Another result of the cloning of GPCR cDNAs by homology screening and polymerase chain reaction-based approaches is the identification of orphan GPCRs, that is, receptors with the canonical, predicted seven-transmembrane-domain structure of GPCRs but without knowledge of their physiologic agonist. There have been substantial efforts to identify the relevant ligands for such orphan receptors. An example of the success of such efforts is the identification of an orphan GPCR as the neuropeptide U receptor involved in regulation of feeding.

Beyond drug development, defects in GPCRs are an important cause of a wide variety of human diseases. GPCR mutations can cause loss of function by impairing any of several steps in the normal GPCR-GTPase cycle. These include failure to synthesize GPCR protein altogether, failure of synthesized GPCR to reach the plasma membrane, failure of GPCR to bind or be activated by agonist, and failure of GPCR to couple to or activate G protein. Because in most cases clinically significant impairment of signal transduction requires loss of both alleles of the GPCR gene, most such diseases are inherited in autosomal recessive fashion. Most of these diseases are manifested as resistance to the action of the normal agonist and thus mimic deficiency of the agonist. For example, TSH receptor loss-of-function mutations cause a form of hypothyroidism mimicking TSH deficiency, but serum TSH is actually elevated in such cases, reflecting resistance to the hormone's action caused by defective receptor function. Nephrogenic diabetes insipidus (renal vasopressin resistance) is caused by loss-of-function mutations in the V2 vasopressin receptor gene located on the X chromosome. Thus, males with a single copy of the gene experience the disease when they inherit a mutant gene, whereas most females do not show overt disease because random X inactivation leaves them with on average 50% of normal gene function. Most V2 vasopressin receptor mutations associated with nephrogenic diabetes insipidus cause loss of function by impairing normal synthesis or folding of the receptor, or both. A novel mechanism for receptor loss of function elucidated for a V2 vasopressin receptor missense mutation associated with nephrogenic diabetes insipidus involves constitutive arrestin-mediated desensitization.

The extracellular Ca²⁺-sensing receptor appears to be an interesting exception to the association between GPCR loss-of-function mutations and hormone resistance. Loss-of-function mutations of the Ca²⁺-sensing receptor mimic a hormone hypersecretion state, primary hyperparathyroidism. In fact, Ca²⁺-sensing receptor loss-of-function mutations do cause hormone resistance, but in this case extracellular Ca²⁺ is the hormonal agonist that acts through this receptor to inhibit PTH secretion. A loss-of-function mutation of one copy of the receptor gene typically causes mild resistance to extracellular Ca²⁺ manifested as familial hypocalciuric hypercalcemia. If two defective copies are inherited, extreme Ca²⁺-sensing causing neonatal severe primary hyperparathyroidism results. In some cases, a heterozygous receptor loss-of-function mutation may be associated with neonatal severe primary hyperparathyroidism, perhaps reflecting a dominant negative effect caused by dimerization of wild-type and mutant receptors.

GPCR gain-of-function mutations (Table 5-2) are also an important cause of disease. Given the dominant nature of activating mutations, most such diseases are inherited in an autosomal dominant manner. Activating TSH receptor mutations may be inherited in autosomal dominant fashion and cause diffuse thyroid enlargement in familial nonautoimmune hyperthyroidism, or they may occur as somatic mutations causing focal, sporadic hyperfunctional thyroid nodules. Unlike loss-of-function mutations, which may be missense as well as nonsense or frameshift mutations that truncate the normal receptor protein, GPCR gain-of-function mutations are almost always missense mutations. The location and nature of naturally occurring, disease-causing mutations offer important insights into GPCR structure and function. The basis for defective receptor function is clear with mutations that truncate receptor synthesis prematurely. More subtle missense mutations may impair function if they involve highly conserved residues in transmembrane helices critical for normal protein folding. Activating missense mutations often involve residues within or bordering transmembrane helices and are thought to disrupt normal inhibitory constraints that maintain the receptor in its inactive conformation. Mutations disrupting these constraints mimic the effects of agonist binding and shift the equilibrium toward the activated state of the receptor.
Clinically, diseases caused by activating GPCR mutations therefore mimic states of agonist excess, but direct measurement shows that agonist concentrations are actually low, reflecting normal negative feedback mechanisms. Again, the Ca\textsuperscript{2+}-sensing receptor is an apparent exception, with activating mutations causing functional hypoparathyroidism. For most GPCRs, disease-associated gain-of-function mutations cause constitutive, agonist-independent, activation but with rare exceptions, the Ca\textsuperscript{2+}-sensing receptor gain-of-function mutations cause increased sensitivity to extracellular Ca\textsuperscript{2+} rather than to Ca\textsuperscript{2+}-independent activation.

Naturally occurring animal models of human disease have revealed additional examples of etiologic GPCR mutations. For example, a loss-of-function mutation in the hypocretin (orexin) type 2 receptor gene was identified in canine narcolepsy. Dozens of mouse GPCR gene knockout models have been created, many revealing interesting and in some cases unexpected phenotypes. Characterization of the phenotype resulting from disruption of a mouse GPCR gene may accurately predict the clinical picture resulting from the corresponding mutation in humans, such as with disruption of the melanocortin-4 receptor gene resulting in obesity in mouse and human and disruption of the PTH/PTH-related protein receptor gene impairing normal bone growth and development in mouse and in the human disease Blomstrand chondrodysplasia. Further knockout models and further detailed studies of these models can be expected to increase substantially our understanding of GPCR function and to address questions such as the unique roles of multiple subtypes of various GPCR subclasses, for example, the 3-adrenergic receptor subtype. Availability of mouse knockout models of human diseases such as nephrogenic diabetes insipidus should also facilitate testing of novel therapies including gene transfer.

Screening of GPCR genes for mutations as the potential cause of additional human disorders may continue to turn up new examples, but it is also becoming clear that variations in GPCR gene sequence can have profound consequences beyond mutations causing diseases. One of the most striking examples is the discovery that homozygous loss-of-function mutations of the type 5 chemokine receptor (CCRS) confer resistance to human immunodeficiency virus (HIV) infection in individuals with this genotype. The reason is that CCR5 serves as a coreceptor for HIV entry into cells. In the roundworm, two isoforms of a neuropeptide receptor are associated with profound differences in feeding behavior. As more polymorphisms are discovered in the human genome, many examples of variations in GPCR gene sequence will be found and the challenge will be to elucidate their possible functional significance. In vitro studies may reveal functional differences, such as differences in G protein coupling seen with a four-amino-acid polymorphism in the third intracellular loop of the \( \beta_2 \)-adrenergic receptor, but further studies are required to determine whether such differences are important in individual variation in response to various drugs (pharmacogenomics) or in other subtle physiologic differences that could confer susceptibility to disease (complex disease genes). Given the high proportion of the human genome devoted to GPCR genes, it is clear that studies of this gene superfamily will play a prominent role in the postgenomic era.

Chapter 6 - Laboratory Techniques for Recognition of Endocrine Disorders

George Klee

Endocrinology is a practice of medicine that is highly dependent on accurate laboratory measurements because small changes in hormone levels often may be more specific and more sensitive for early disease than the classic physical signs and symptoms. Because most endocrinologists currently do not have facilities to develop and validate laboratory assays, they rely on commercial analytic assays or send a patient’s specimen to specialized laboratories. Even most hospital and commercial laboratories have minimal expertise for developing analytic assays. This critical dependence on quality laboratory measurements, combined with minimal information about the performance of these tests, places endocrinologists in a potentially vulnerable position.

This chapter attempts to provide an overview of the strengths and weaknesses of the analytic techniques typically used for endocrine measurements in blood and urine. Concentrations of most hormones are much lower than those of general chemistry analytes, and specialized techniques are necessary to measure these low concentrations.

Three major types of assays for measuring hormones are described:
- Immunoassays (both competitive and sandwich)
- Chromatography
- Mass spectrometry

Nucleic acid measurements for evaluation of genetic alterations also are reviewed.

The minimal analytic performance validation required by the federal government for laboratories testing specimens of Medicare patients, along with explanations of these performance parameters, is outlined. This information should help endocrinologists better assess the performance of the analytic systems that they are using.

Techniques to investigate discordant laboratory test values also are presented to help clinicians work with their laboratories to reconcile test values that do not match clinical presentations.

Hormone concentrations are reported in molar units, mass units, or standardized units, such as World Health Organization (WHO) International Units (IU). When these measurements are expressed in molar units, most hormones in blood and urine are present in concentrations of 10^{-6} to 10^{-12} M/L (Fig. 6-1). The terms used to describe these concentrations are micromolar (10^{-6} M/L), nanomolar (10^{-9} M/L), and picomolar (10^{-12} M/L). The range from the lowest to highest concentrations is more than a million-fold difference. Therefore, laboratory techniques must be targeted to the levels of each given hormone.

The major techniques for measuring picomolar concentrations are immunoassay and mass spectrometry, whereas nanomolar and micromolar concentrations can be measured by these methods as well as chromatography and chemical detection systems. Some hormones, such as thyrotropin (TSH), have very low concentrations in the femtomolar (10^{-15} M/L) range in patients with diseases such as thyrotoxicosis. Exquisitely sensitive immunometric assays are usually needed to measure these very low concentrations.
TYPES OF ASSAYS

The four major techniques used for endocrine measurements are as follows:

Antibody-based immunologic assays, of which there are two subcategories: competitive immunoassays and immunometric (sandwich) assays

Chromatographic assays
Mass spectroscopy
Nucleic acid-based assays

Competitive Immunoassays

The term competitive radioimmunoassay refers to a measurement method in which an antigen (e.g., a hormone) in a specimen competes with radiolabeled reagent antigen for a limited number of binding sites on a reagent antibody. The three basic components of a competitive immunoassay are [14]:

1. Antiserum specific for a unique epitope on a hormone or antigen.
2. Labeled antigen that binds to this antiserum.
3. Unlabeled antigen in the specimen or standard that is to be measured.

The antisera is diluted to a concentration in which the number of binding sites available on the antibodies is fewer than the number of antigen molecules (labeled and unlabeled) in the reaction mixture. The labeled and unlabeled antigens compete for these limited number of binding sites on the antiserum. The competition is not always equal because the labeled antigen (tracer) may react differently with the antibody compared with the native antigen. This disparity in reactivity may be caused by alteration of the antigen due to the chemical attachment of the label or by differences in the endogenous antigen versus the form of the antigen used in the reagents. As long as the reactions are reproducible, these differences in reactivity are not important because the reaction can be calibrated with standard reference materials having known concentrations.

The precision of competitive immunoassays is related to the rate of change of the signal compared with the rate of change of concentration (i.e., the slope of the dose-response curve) [6]. In Figure 6-2, the slope is much lower at higher concentrations, causing the assay precision to be less at higher concentrations. Most competitive immunoassays also have a relatively flat dose-response curve at very low concentrations, causing poor precision at the low end of the assay. Consequently, the precision profile for most immunoassays is U-shaped, having the best coefficients of variation in the center of the dose-response curve.

As shown in Figure 6-2, the higher the concentration of the unlabeled antigen, the lower the amount of radiolabeled antigen that binds to the limited amount of antiserum. The signal decreases exponentially from the approximately half-maximum at zero concentration to a minimum value at high concentrations. This minimal binding, or nonspecific binding (NSB), is a valuable control parameter. Elevations in NSB usually signify impurities in the label that bind to the sides of the tubes and are not competitively displaced. Most assays add surfactants and proteins to minimize the NSB. Monitoring of changes in the NSB provides an early warning of potential assay problems.

Statistical data-processing techniques are needed to translate the assay signals into concentrations. As illustrated, because these reactions are not linear, numerous curve-fitting algorithms have been developed. Before the introduction of micro-processors, tedious error-prone, manual calculations were required to mathematically transform the data into linear models. A commonly used model was to cross-plot the logit of the normalized signal versus the logarithm of the concentration and to use linear regression lines to establish the dose-response curve. Fortunately, today this procedure of curve fitting usually is accomplished electronically by using programs that automatically test the robustness of fit of multivariable curves after statistically eliminating discordant data points. However, users of these systems must understand the limitations and should pay attention to any warnings presented by the programs during processing of the data.

In radioimmunoassays, radioactive iodine (¹²⁵I) is usually used to label the antigen. The immune complexes are separated from the unbound molecules by precipitation with centrifugation after reaction with secondary antisera and precipitating reagents (e.g., polyethylene glycol). These radioimmunoassays may require special handling and licensure to ensure safety of the radioisotopes and are labor-intensive. The statistical counting errors associated with the relatively low radioactive counts and the poor reproducibility associated with the multiple manual steps generally necessitate that most laboratories perform the measurements in
Immunoassays measure concentrations rather than biologic activity. For most hormones, there is a strong correlation between the concentration of the protein or measurement may provide more reliable information. Results and some disease states may require more analytic sensitivity to ensure sound clinical decisions. In these cases, extraction of specimens prior to commercial assays generally use reagents having adequate sensitivity and specificity to measure clinical laboratories. Although purification before immunoassay are seldom used in clinical assays. These techniques are difficult to automate and require skills and equipment not available in many solid-phase extraction with absorption and selective elution from resins such as silica gels, and (3) immunoaffinity chromatography.

Numerous extraction systems have been developed, including (1) organic-aqueous partitioning to remove water-soluble interferences seen with steroids, (2) extraction of hormones from serum and urine specimens prior to measurement is a technique that can enhance both sensitivity and specificity of immunoassays. The process of generating these antisera is a combination of art, science, and luck. Generally, a relatively pure form of the antigen is conjugated to a carrier protein (especially if the antigen is less than 10,000 d), mixed with adjuvant (e.g., Freund's complete adjuvant), and injected intradermally into the host animal. After several boosts with conjugated protein plus Freund's incomplete adjuvant, the host animal recognizes the material as foreign and develops immune responses. The antigen is then harvested from the animal's blood. Under optimal conditions, moderate quantities of high-affinity antisera, which react only with the specific target antigen, are developed. The analytic sensitivity of a competitive immunoassay is approximately inversely related to the affinity of the antigen, such that an antisera with an affinity constant of

10^9 L/M can be used to measure analytes in the nanomolar concentration range.

The polyclonal antisera developed by immunizing animals represents a composite of many immunologic clones, with each clone having a different affinity and different immunologic specificity. Most clones have affinities in the 10^-2 to 10^-4 L/M range, with only rarely having affinities above 10^-1 L/M. Various techniques are used to develop a specific antisera, including (1) altering the form of the antigen by blocking cross-reacting epitopes and (2) purifying the antisera using affinity chromatography to select antibodies directed toward the epitope of interest. Affinity-column purification can also be used for immunoextraction of higher-affinity antisera by selectively eluting antisera from the column by means of a series of buffers with increasing acidity. The major disadvantage of a polyclonal antisera is the limited quantity. The large quantities needed by commercial suppliers of immunoassay reagents often require them to use multiple sources of antisera. These changes in antisera can cause significant changes in assay performance. In many instances, laboratories and clinicians are not informed about these changes, which may cause problems in medical decisions.

Monoclonal antisera are used in many current immunoassays. These antisera are made by immunizing animals (usually mice) using techniques similar to those used for polyclonal antisera; instead of harvesting the antisera from the blood, however, the animal is killed and the spleen is removed. The lymphocytes in the spleen are fused with myeloma cells to make cells that will grow in culture and produce antisera. These fused cells are separated into clones by means of serial plating techniques similar to those used in subculturing bacteria. The supernantant of these monoclonal cell lines (or ascites fluid if the cells are transplanted into carrier mice) contains monoclonal antisera. The selection processes used to separate the initial clones can be targeted to identify specific clones producing antisera with high affinities and low cross-reactivity to related compounds.

The high specificity of monoclonal antisera can cause problems for some endocrine assays. Many hormones circulate in the blood as heterogeneous mixtures of multiple forms. Some of these forms are caused by genetic differences in patients, whereas other forms are related to metabolic precursors and degradation products of the hormone. Genetic differences cause some patients to produce variant forms of a hormone such as luteinizing hormone (LH). These genetic differences can cause marked variations in measurements made using assays with specific monoclonal antisera. Well-characterized monoclonal antisera can be mixed together to make an "engineered polyclonal antisem" with improved sensitivity and specificity. Cross-reactivity with precursor forms of the analytes and with metabolic degradation products can cause major differences in assays. For example, cross-reactivity with precursor forms causes differences in insulin assays, and cross-reactivity with metabolic fragments causes major differences in carbohydrate-terminal parathyroid hormone (PTH) assays. Extraction of hormones from serum and urine specimens prior to measurement is a technique that can enhance both sensitivity and specificity of immunoassays. Numerous extraction systems have been developed, including (1) organic-aqueous partitioning to remove water-soluble interferences seen with steroids, (2) solid-phase extraction with absorption and selective elution from resins such as silica gels, and (3) immunoaffinity chromatography. Unfortunately, extraction and purification before immunoassay are seldom used in clinical assays. These techniques are difficult to automate and require skills and equipment not available in many clinical laboratories. Although commercial assays generally use reagents having adequate sensitivity and specificity to measure most patient specimens, some patient specimens may give spurious results and some disease states may require more analytic sensitivity to ensure sound clinical decisions. In these cases, extraction of specimens prior to measurement may provide more reliable information.

Immunnoassays measure concentrations rather than biologic activity. For most hormones, there is a strong correlation between the protein or steroid being measured and the biologic activity, but this is not universally true. The reactive site for most antibodies is relatively small, about 5 to 10 amino acids for linear peptides. Some antisera reactions are specific for the tertiary structure that corresponds to unique molecular configurations, but immunoassays seldom react...
with the exact antigenic structure that confers biologic activity.

Figure 6-3 presents a schematic illustration of the difference between immunologic binding site and biologic receptor binding site on a hormone. Indirect immunoassays have been developed using cultured cells that synthesize second messengers such as cyclic adenosine monophosphate (cAMP) at rates proportional to the concentration of hormone in the specimen. An example of this technique is the immunoassay measurement of cAMP produced by osteosarcoma cells to quantitate PTH bioactivity in serum. Unfortunately, these assays are tedious and generally are not reproducible. More recent techniques using recombinant receptors as immunoassay binders may provide improved specificity with good reliability.
Immunometric (Sandwich) Assays

A second immunologic technique used to measure hormones is the immunometric (sandwich) assay. The three basic components of a sandwich assay are:

1. An antigen large enough to allow two antibodies to bind concurrently on different binding sites.
2. A capture antiserum directed to one of the antigenic sites on the antigen. This antiserum is attached to a solid phase to permit immunologic extraction of the immune complex.
3. A signal antiserum directed to a second antigenic site on the antigen. This antiserum is attached to an assay signal system.

In contrast to competitive immunoassays, these assays use a large excess of antiserum binding sites compared with the concentration of antigen. The capture antibody immunoextracts the antigen from the sample and the signal antibody binds to the capture antibody-antigen complex to form a tertiary complex. As the antigen concentration increases, the signal increases progressively.

Figure 6-4 schematically illustrates these concepts. The capture antiserum (ATB1) is attached to biotin (see solid circles). The signal antiserum (ATB2) is labeled with a detection system (see asterisks). The ATB1-antigen-ATB2 complexes are immunologically extracted using a streptavidin solid phase (see horizontal cups). After the complex is bound to the solid phase, most of the unbound signal antibody is washed away.

As shown in Figure 6-4, the signal increases progressively with the concentration. For lower concentrations, the signal generally increases proportional to the assay concentrations (after the offset caused by the NSB). At higher concentrations, the signal generally is less than proportional, so that nonlinear curve-fitting techniques are used to generate the dose-response curves. Again, the relative imprecision, expressed as a coefficient of variation, depends on the slope of the dose-response curve; consequently, the relative precision is less at higher concentrations.

In immunometric assays, the background level of signal is associated with very low concentrations. This background signal is caused by the NSB. The analytic sensitivity of immunometric assays is related to the ratio of the true signal to the NSB signal. Therefore, assays can be made more sensitive either by increasing the response signal or by decreasing NSB. Inadvertent increases in NSB caused by specimen interference or reagent deterioration can significantly alter the assay performance.

In immunometric assays, it is also important that a large excess of capture antibody be used. When the antigen concentration approaches the effective binding capacity of the capture antibody system, the signal no longer increases. If the antigen concentration exceeds the binding capacity of the capture antibody, the signal may actually decrease.

Figure 6-5 illustrates this high-dose hook effect for immunometric assays caused by insufficient amounts of capture or signal antiserum. The signal increases progressively until the hormone concentration exceeds the binding capacity; the signal then decreases, apparently as a result of the removal of some of the weaker binding antigen-antibody complexes during the wash cycle on the assay. This is a potentially dangerous phenomenon because very high concentrations can give the same “answer” as lower concentrations. If this artifact is suspected, the specimen can be diluted and reanalyzed. If the answer for the diluted specimen is higher than the original answer, a high-dose hook effect probably is present.

Most manufacturers are aware of this potential problem and configure assays with relatively large amounts of capture or signal antiserum; however, some patients produce high concentrations of hormones or antigens that may exceed assay limits. Laboratories are able to detect this phenomenon by analyzing specimens at two dilutions, but this practice generally is not cost-effective. Therefore, feedback to the laboratory about results that are inconsistent with clinical findings is essential.

Another potential problem for immunometric assays consists of endogenous heterophile antibodies that cross-react with reagent antiserum. Normally, the signal antibody does not form a “sandwich” with the capture antibody unless the specific antigen is present; however, divalent heterophile antibodies may mimic the antigen by simultaneously binding to the signal and capture reagent antibodies.

Figure 6-6 schematically illustrates this situation. The problem is most common with monoclonal antibodies but may also occur with polyclonal antibodies. Immunoglobulins contain both a constant (Fc) region and a variable (Fab) region. As implied in the name, the Fc region is constant, or similar, for all immunoglobulins from that species. Therefore, if a patient receives immunotherapy or imaging reagents containing mouse immunoglobulin, they are likely to develop human antimouse antibodies (HAMAs) directed to the Fc fragment. Some patients may develop heterophile antibodies after exposure to foreign proteins from domestic pets or food contaminants. When these endogenous antibodies are present in a patient’s specimen, they may bridge across the reagent antibodies used for immunometric assays.
in immunometric assays and may cause falsely high values. These antibodies also may bind to sites on the reagent antibodies, which sterically block the binding of the specific antigen and give falsely low test values. Most manufacturers include nonimmune immunoglobulin in the assays to help block these interferences; as with the high-dose hook effect, however, the amounts added are not always adequate and some patients with high titer antibodies thus may still show in vitro assay interference.

The combined specificity of the two antibodies used in an immunometric assay can produce exquisitely sensitive and specific immunoassays. In the past, a common problem with early competitive immunoassays was cross-reactivity among the structurally similar gonadotropins: LH, follicle-stimulating hormone (FSH), TSH, and human chorionic gonadotropin (hCG). The subunits of each of these hormones are almost identical, and the subunits have considerable structural homology. Many individual antisera (especially polyclonal antisera) used for measuring one of these hormones may have cross-reactivity for the other gonadotropins. The cross-reactivity of a pair of antibodies is less than the cross-reactivity of each of the individual antibodies because any cross-reacting substance must contain both of the binding epitopes in order to simultaneously bind to both antibodies.

For example, consider two antibodies for LH, each having 1% cross-reactivity with hCG. The cross-reactivity of the pair is less than the product of the two cross-reactivities or, in this case, less than 0.01%. Most current immunoassays for LH have cross-reactivity less than 0.01% because even this relatively low percentage of cross-reactivity would still cause significant assay interference in pregnant patients and patients with choriocarcinoma who have high hCG concentrations.

Multiple forms of most hormones circulate in the blood. Some hormones (e.g., prolactin, growth hormone) circulate with macro forms, which can cause difficulty in their analysis if specimens are not pretreated. For hormones composed of subunits (e.g., the gonadotropins), both the intact and the free subunits circulate in blood. Immunometric assays can be made specific for intact molecules by pairing an antibody specific for the - bridge site of the subunits with a second antibody specific for the subunit. Assays using these antibody pairs retain the two-antibody, low cross-reactivity needed for measuring gonadotropins and do not react with the free subunit forms of the hormones.

The heterogeneous specificity characteristics of immunoassays make calibration and harmonization difficult. Two immunoassays calibrated with the same reference preparation can give widely varying measurements on patient specimens. Consider the example of hCG in Table 6-1. The three assays are calibrated with a pure preparation of intact hCG, such as the WHO Third International Reference Preparation. The three assays differ in their cross-reactivity with free hCG (0, 100%, and 200%, respectively). These assays give identical measurements for a specimen containing only intact hCG but progressively disparate values as the percentage of free hCG in the specimen increases. In reality, the standardization issue is much more complex because multiple forms of hormones (i.e., intact, free subunits, nicked forms, glycosylated forms, degradation products) circulate in patients and each assay has different cross-reactivities for these forms.

Free (Unbound) Hormone Assays

Many hormones are tightly bound to specific plasma-binding proteins and loosely bound to albumin. The unbound (free) forms as well as some of the loosely bound forms are biologically active.

Multiple methods are available to measure these free or biologically active forms of a hormone. Theoretically, the best procedure is direct measurement of the free hormone concentration after physical separation of free-form bound hormone by equilibrium dialysis, ultrafiltration, or gel filtration. Unfortunately, this method is difficult to perform and is thus not readily available and is subject to technical errors.

The two major clinical applications for free hormone measurements are for thyroid hormones (thyroxine [FT₄] and triiodothyronine [FT₃]) and steroids (testosterone and estradiol). Four techniques are commonly used to estimate free thyroid hormone concentrations:

1. **Indirect index methods.** The indirect indices involve two measurements: one for total hormone concentration and another for the thyroxine-binding globulin (TBG), followed by calculation of the ratio or a normalized index (FT₄I or FT₃I). These methods correct for routine changes in TBG associated with estrogen levels, but they may produce inappropriately abnormal values in patients with extreme variations in TBG levels found in patients with congenital disorders of the TBG gene, familial dysalbuminemic hyperthyroxinemia, thyroid hormone autoantibodies, and nonthyroidal illnesses.

2. **Two-step labeled hormone methods.** These methods immunologically bind the free and loosely bound thyroid hormone to a solid phase. The other serum components are washed away, and the residual binding sites are back-titrated with labeled hormone. When calibrated with appropriate serum standards, these methods are thought to pose fewer problems with binding protein abnormalities.

3. **One-step labeled hormone analogue methods.** These methods use synthetic analogues of T₄ and T₃ that bind to the measurement antibody but do not bind to normal TBG. These methods are seldom used because performance has been poor in patients with abnormal albumin concentrations, abnormal free fatty-acid concentrations, and all conditions that interfere with the indirect indices.

4. **Labeled antibody methods.** These methods use kinetic reactions of antibodies with selected affinities that bind preferentially with the free form of the hormone. These methods work best for automated testing instruments and have become popular.

Each of these methods works well for correcting for minor changes in TBG levels, but each has problems with some patient sera, especially those containing interfering substances such as inhibitors and heterophilic antibodies. Unfortunately, most manufacturers have not fully validated their methods in patients with these abnormalities.

Multiple methods are also available for measuring both the free and the biologically active forms of steroid hormones. The preferred method for measurement of free hormones consists of direct physical separation and high-sensitivity assays similar to those recommended for the thyroid hormones. One-step labeled hormone-analogue methods also have been developed, but these are associated with interference problems similar to the problems with free thyroid hormone assays.

Another complexity in regard to steroid hormones is that in addition to the free hormones, testosterone and estrogen bound to albumin also are biologically active. The concentration of the biologically active forms can be estimated using indirect indices calculated from measurements of the total hormones and sex hormone-binding globulin (SHBG) or by measurement of the residual free and albumin-bound steroids after separation of the SHBG-bound forms after differential precipitation with ammonium sulfate.
Chromatographic Assays

Another major method of measuring hormone concentrations involves chromatographically separating the various biochemical forms and quantitating specific characteristics of the molecules. High-performance liquid chromatography (HPLC) systems utilize multiple forms of detection, including light absorption, fluorescence, electrochemical properties, and mass spectrometry.\[^{37,38}\]

There are two major advantages of these techniques: (1) they can be used to simultaneously measure multiple forms of an analyte, and (2) they are not dependent on unique immunologic reagents. Therefore, harmonization of measurements made with different assays is more feasible. The major disadvantages of these methods are their complexity and their limited availability.

Many chemical separation techniques are based on chromatography, but the two most commonly used for liquid chromatography are (1) normal-phase HPLC and (2) reverse-phase HPLC.\[^{25}\] In both systems, a bonded solid-phase column is made that interacts with the analytes as they flow past in a liquid solvent. In normal-phase HPLC, the functional groups of the stationary phase are polar (e.g., amino or nitrile ions) relative to the nonpolar stationary phase (e.g., hexane); in reverse-phase HPLC, a nonpolar stationary phase (e.g., C-18 octadecylsilane molecules bonded to silica) is used.

More recently, polymeric packings made of mixed copolymers have been made with C4, C8, and C18 functional groups directly incorporated so that they are more stable over a wide pH range. The mobile and stationary phases are selected to optimize adherence of the analytes to the stationary phase. The adhered molecules can be eluted differentially from the solid phase after washing to separate specific forms of the analyte from interfering substances as follows:

1. When the composition of the mobile phase remains constant throughout the run, the process is called an **isocratic elution**.
2. If the mobile-phase composition is abruptly changed, a **step elution** occurs.
3. If the composition is gradually changed throughout the run, a **gradient elution** occurs.

The efficiency of separation in a chromatography system is a function of the flow rates of the different substances.\[^{39}\] The resolution of the system is a measure of the separation of the two solute bands in terms of their relative retention volumes ($V_r$) and their bandwidths ($W$). Resolution ($R_s$) of solutes A and B is shown as:

$$ R_s = \frac{2(V_r(B) - V_r(A))}{W(A) + W(B)} $$

Values of $R_s$ less than 0.8 result in inadequate separation, and values greater than 1.25 correspond to baseline separation. The resolution of a chromatography column is a function of flow rates and thermodynamic factors.

The simultaneous measurement of the three catecholamines (epinephrine, norepinephrine, and dopamine) can be performed with reverse-phase HPLC with a C-18 column and electrochemical detection system or fluorometric detection. Prior extraction by absorption on activated alumina and acid elution helps to improve specificity. Dihydroxybenzylamine, a molecule similar to endogenous catecholamines, can be used as an internal standard.
Mass Spectrometry

The technique of mass spectrometry involves fragmentation of target molecules, followed by separation and measurement of the mass to charge ratio of the components. When coupled with liquid chromatography, a mass spectrometer can function as a unique detector to provide structural information about the composition of individual solutes. Inclusion of internal standards in the specimens, which are molecularly similar to the measured compounds, allows precise quantitation of the concentration of the eluting analytes. The measurement of specific mass fragments makes possible the quantitation of multiple specific analytes in complex mixtures.

A fundamental step in mass spectrometry is the fragmentation of the target compound into charged ions. Multiple techniques are used to generate these charged ions, including chemical ionization and electron-impact ionization.

Chemical ionization uses reagent gas molecules, such as methane, ammonia, water, and isobutane, to transfer protons. This process produces less fragmentation than other techniques because the process is not highly excited.

The electron impact bombards gas molecules from the sample, with electrons emitted from a heated filament. The process occurs in a vacuum to prevent the filament from burning out. Electron-spray ionization is a process in which a solution containing the analyte is introduced into a gas phase and is sprayed across an ionizing potential. The charged droplets are desolvated and analyzed in a mass spectrometer.

A mass spectrum is a bar graph in which the heights of the bars correspond to the relative abundance of a particular ion plotted as a function of the mass/charge ratio. Modern mass spectrometers can measure molecular masses so accurately and precisely that the elemental composition of a compound can be predicted by comparison with stored spectral libraries. When these systems are used to measure only a few select compounds having known spectrums, the mass spectrometer can be programmed to focus only on these selected ions.

Stable isotopes of the compounds of interest can be used as internal standards through a technique called isotope dilution mass spectrometry. Stable isotopes generally perform the same as the native compounds in terms of extraction, chromatography, and mass spectrometry and are thus ideal internal standards. However, they must have a sufficient number of isotopic atoms to ensure that their mass is different from naturally occurring substances that may be in the specimen.

Tandem mass spectrometry (MS/MS) is a powerful new tool consisting of two mass analyzers separated by an ion-activation device. The first analyzer is used to isolate and dissociate the ion of interest by activation, and the second mass analyzer is used to analyze its dissociation products. This technique can be used to provide rapid, definitive measurements of multiple endocrine analytes. For example, liquid chromatography and tandem mass-spectrometry can be used to simultaneously quantitate multiple glucocorticoid-related compounds. In Figure 6-7, the chromatograph shows peaks for ten steroids that were first separated on reverse-phase liquid chromatography using a Supelcosil LC-18 column (Supelco, Bellefonte, Calif.) and a gradient elution of a 53% to 75% methanol/water mixture. The column eluate was fed directly into an electrospray ionization device in a triple-quadrupole mass spectrometer (API 3000, Perkin-Elmer Sciex, Foster City, Calif.). The stable isotopes were from Cambridge Isotope Laboratories (Andover, Mass.). A 10-minute analysis provides quantitation of the 10 compounds: cortisone, cortisol, 21-deoxycortisol, corticosterone, 11-deoxycortisol, androstenedione, deoxycorticosterone (DOC), 17-hydroxyprogesterone, progesterone, and pregnenolone. The sensitivity for cortisol using d4 cortisol calibration is 0.1 µg/dL.
Nucleic Acid-Based Assays

The decoding of the human genome has set the stage for an enormous increase in nucleic acid-based gene assays. The basic principles of nucleic acid-based assays have been known for several decades, but the identification of specific genes and the mapping of gene defects to clinical disease states have now made these measurements clinically useful.\textsuperscript{48,49} Four concepts important for nucleic acid measurements are (1) hybridization, (2) amplification, (3) restriction fragment length polymorphisms (RFLPs), and (4) electrophoretic separation.\textsuperscript{50}

Hybridization

Nucleic acid molecules have a unique ability to fuse with complementary base-pair sequences. When a fragment of a known sequence (probe) is mixed under specific conditions with a specimen containing a complementary sequence, hybridization occurs. This feature is analogous to the antibody-antigen binding used in immunoassays. Many of the formats used for immunoassay have been adopted to nucleic acid assays, including some of the same signal systems (e.g., radioactivity, fluorescence, chemiluminescence) and the same solid-phase capture systems (e.g., magnetic beads, biotin-streptavidin binding). In situ hybridization, which involves the binding of probes to intact tissue and cells, provides information about morphologic localization analogous to immunohistochemistry.

Amplification

Nucleic acid assays have an advantage that low concentrations can be amplified in vitro prior to quantitation. The best known amplification procedure is the polymerase chain reaction (PCR), first reported by Mullis and Faloona.\textsuperscript{51} The three steps in the process (denaturation, annealing, and elongation) occur rapidly at different temperatures. Each "cycle" of amplification can occur in less than 90 seconds by cycling the temperature. The target double-stranded DNA is denatured at high temperature to make two single-stranded DNA fragments. Oligonucleotide primers, which are specific for target region, are annealed to the DNA when the temperature is lowered. Addition of DNA polymerase allows the primer DNA to extend across the amplification region, thus doubling the number of DNA copies.

At 85% to 90% efficiency, this process can amplify the DNA by about 250,000-fold in 20 cycles. This huge amplification is subject to major problems with contamination if special precautions are not taken. In one control technique, a psoralen derivative is used to prevent subsequent copying by polymerase during exposure to ultraviolet light.

Restriction Fragment Length Polymorphisms

Some diseases (e.g., sickle cell anemia) are associated with a specific gene mutation; generally, however, a series of deletions and additions of DNA are involved with the disease. A number of restriction enzymes that cleave DNA at specific locations have been identified. Changes in the sequence of DNA result in different fragment lengths. This technique, or RFLP, is particularly helpful in family studies for disorders that have a unique genetic fingerprint.

Electrophoretic Separation

E. M. Southern invented an electrophoretic separation technique known as Southern blotting.\textsuperscript{52} Restriction enzymes are used to digest a sample of DNA into fragments, and the product is subjected to electrophoresis. The separated bands of DNA are then transferred to a solid support and hybridized. Northern blotting is a similar technique, in which RNA is used as the starting material. Western blotting refers to electrophoresis and transfer of proteins.
ANALYTIC VALIDATION

Clinicians generally assume that laboratory methods have been validated and that they function correctly. Although this assumption is generally true, it is helpful to understand the level of assay validation performed and the appropriateness of the validation criteria for each clinical application of a test. These regulations, published in the Federal Register, outline the validation requirements for both Food and Drug Administration (FDA)-approved instruments, kits, and test systems as well as methods developed in-house. Laboratories must document analytic accuracy, precision, reportable ranges, and reference ranges for all procedures. The regulations for in-house procedures and modifications of approved commercial procedures are more extensive and require laboratories to further document (1) analytic sensitivity; (2) analytic specificity, including interfering substances; and (3) other performance characteristics required for testing patient specimens.

Although the details of method validation may be unique to a specific procedure, the following analytic validation studies have proved valuable for most procedures: (1) method comparison, (2) precision, (3) linearity, (4) recovery, (5) detection limit, (6) reportable range, (7) analytic interference, (8) carry-over, (9) reference interval, (10) specimen stability, and (11) specimen type. Laboratories should have documentation for each of these performance characteristics, either from the diagnostics manufacturer or from direct studies.

Method Comparison

Ideally, the system should be compared with an established reference method; however, many endocrine tests do not have reference methods and many laboratories do not have the facilities to perform reference methods when they exist. As a minimum, the assay should be compared with an analytic system that has been clinically validated with specimens from healthy subjects and specimens from patients with the diseases being investigated. The system should be traceable to established reference standards, such as those from the WHO and the National Institute of Standards and Technology (NIST). Between 100 and 200 different specimens distributed over the assay range are recommended for method comparisons.

A cross-plot displaying the new method on the vertical axis versus the established method on the horizontal axis, along with the identity line, reference value lines, and regression statistics, is a useful way of displaying these comparisons. An alternative display method is the Bland-Altman difference plot, in which the difference between the test method and the reference method is plotted against the reference method values.

Although acceptable performance criteria for method comparisons are not well established, some important characteristics to examine are as follows:

1. Any grossly discordant test values.
2. The degree of scatter about the regression curve.
3. The size of the regression off-set on the vertical axis.
4. The number of points crossing between the low, normal, and high reference intervals for the two methods.

The European Union (EU) has enacted the In Vitro Diagnostics Directive, which requires manufacturers marketing in the EU after the year 2003 to establish that their products are "traceable to reference standards and reference procedures of a higher order" when these references exist. This directive should serve to harmonize many test methods worldwide because most diagnostic companies market internationally.
Precision

Precision is a measure of the replication of repeated measurements of the same specimen; it is a function of the time between repeats and the concentration of the analyte. Both short-term precision (within a run or within a day) and long-term precision (across calibrations and across batches of reagents) should be documented at clinically appropriate concentration levels.

In general, normal range, abnormally low range, and abnormally high range targets are chosen for precision studies; however, targets focused on critical medical decision limits may be more appropriate for some analytes. Twenty measurements are recommended at each level for both short-term and long-term precision validations. Precision generally is expressed as the coefficient of variation, calculated as 100 times the standard deviation divided by the average of the replicate measurements.

There is no universal agreement on the performance criteria for analytic precision, although numerous recommendations have been put forth. Two major approaches to defining these criteria have been (1) comparison with biologic variation and (2) expert opinion of clinicians based on their perceived impact of laboratory variation on clinical decisions.

The total variation clinically observed in test measurements is a combination of the analytic and biologic variations, for instance:

1. If the analytic standard deviation (SD) is less than one-fourth of the biologic SD, the analytic component increases the SD of the total error by less than 3%.
2. If the analytic precision is less than one-half of the biologic SD, the total error increases by only 12%.

These observations have led to recommendations for maintaining precision less than one quarter or one-half of the biologic variation. The expert opinion precision recommendations are based on estimates of the magnitude of change of a test value that would cause clinicians to alter their clinical decisions. Table 6-2 lists some precision recommendations for selected endocrine tests.
Linearity

Patient specimens commonly contain several different forms of the hormones to be measured compared with the pure form contained in the reference standards and calibrators used to establish the assay dose-response curve. When a patient specimen is diluted, the measured value for these dilutions should parallel the dose-response curve and give results proportional to the dilution. Linearity can be evaluated by measuring serial dilutions of patient specimens with high concentrations diluted in the appropriate assay diluent. The product of the measured value multiplied by the dilution factor should be approximately constant. There are no performance standards for linearity, but a reasonable expectation for most hormones is that dilutions are comparable within 10% of the undiluted value.
Recovery

Two methods of assessing the recovery of assays are (1) measuring the increase in test values after the reference analyte is added and (2) measuring the proportional changes caused by mixing high-concentration and low-concentration specimens. Some analytes circulate in the blood in multiple forms, and some of these forms may be bound to carrier proteins. The recovery rate of pure substances added to a specimen may be low if the assay does not measure some of the bound forms. Mixtures of patient specimens may not be measured correctly if one of the specimens contains cross-reacting substances such as autoantibodies. A thorough understanding of the chemical forms of the analyte and their cross-reactivities in the assay is important during assessment of recovery data.
Detection Limit

The minimal analytic detection limit is the smallest concentration that can be statistically differentiated from zero. This concentration is mathematically determined as the upper 95% limit of replicate measurements of the zero standard, calculated from the average signal plus 2.0 SD. This minimal detection limit is valid only for the average of multiple replicate measurements. When individual determinations are performed on a specimen having a true concentration exactly at the minimal detection limit, the probability that the measurement is above the noise level of the assay is only about 50%.

A second term for the lowest level of reliable measurement for an assay is the functional detection limit, or the limit of quantitation. For this parameter to be measured, multiple pools with low concentrations are made and analyzed in the replicate. A cross-plot of the coefficient of variation of the measurements versus the concentration allows one to generate a precision profile. The concentration corresponding to a coefficient of variation of 20% is the functional detection limit. This term generally applies to across-assay variation, but it also can be calculated using within-assay variation if one uses the tests to evaluate results measured within one run (e.g., provocative and suppression tests).
Reportable Range

The reportable range of an assay generally spans from the functional detection limit to the concentration of the highest standard. Values above the highest standard may be reported if they are diluted and the measured value is multiplied by the dilution factor. The validity of the analytic range is documented by the linearity and recovery studies. Some laboratories erroneously report the exact values displayed by the test systems even if they are outside of the analytic range. Therefore, it is important for clinicians to understand the limitations of valid measurements and not inappropriately use meaningless numbers that may be reported.

Another potential source of error is failure of the technologist to multiply the measured value of diluted specimens by the dilution factor to correct for the dilution. In addition, care should be taken to define the number of significant figures used for reporting test values and to establish an appropriate algorithm for rounding test values to the significant number of digits.
Analytic Interference

The cross-reactivity and potential interference of other analytes that may react in a test system should be documented. The choice of potential interfering substances that must be evaluated requires an understanding of both the analytic system and the pathophysiology of the analyte being evaluated. In immunoassays, for example, compounds with similar structures as well as precursor forms and degradation products should be tested. Drugs commonly prescribed for the diseases under evaluation should be assessed for interference both by addition of the drug to a specimen and by analysis of specimens from patients before and after receiving the drug. Most assays also are evaluated for the effects of hemolysis, lipemia, and icterus.
Carry-over Studies

Many diagnostic systems use automated sample-handling devices. If a specimen to be tested is preceded by a specimen with a very high concentration, a trace amount of the first specimen may significantly increase the reported concentration of the second specimen. The choice of the concentration that should be tested for carry-over depends on the pathophysiology of the disease, but high values may need to be tested because some endocrine disorders may produce these high values. A prudent procedure would be to retest all specimens following a specimen with an extraordinarily high value. One also should document that carry-over from the sampling probe has not inadvertently contaminated subsequent specimen vials, thereby invalidating subsequently repeated measurements.
Reference Intervals

The development and validation of reference intervals for endocrine tests can be a very complex task. The normal reference interval for most laboratory tests is based on estimates of the central 95 percentile limits of measurements in healthy subjects. A minimum of 120 subjects is needed to reliably define the 2.5 and 97.5 percentiles. The reference intervals for many endocrine tests depend on gender, age, developmental status, and other test values. Formal statistical consultation is recommended to determine the appropriate number of subjects to test and to develop statistical models for defining multivariate reference ranges.

Full evaluation of the adrenal, gonadal, and thyroid axes requires simultaneous measurement of the trophic and target hormones. Bivariate displays of these hormone concentrations along with their multivariate reference intervals facilitate the interpretation. Preanalytic conditions should be well defined and controlled during evaluation of both healthy reference subjects and patients.

Figure 6-8 shows a recommended protocol to control preanalytic conditions for collection of plasma catecholamine specimens.
Specimen Stability

Analyte stability is a function of storage conditions and specimen type. Although most hormones are relatively stable in serum or urine if they are rapidly frozen and stored in hermetically sealed vials at -70°C, multiple freeze/thaw cycles may damage analytes, and storage in frost-free freezers that repeatedly cycle through thawing temperatures can adversely affect stability. Blood specimens collected in edetate (EDTA) often are more stable than serum or heparinized specimens because edetate chelates calcium and magnesium ions, which function as coenzymes for some proteases. The addition of protease inhibitors (e.g., aprotinin) to blood specimens may also improve specimen stability.
Types of Specimens

Most hormones are measured in blood or urine, but alternate testing sources, such as saliva and transdermal membrane monitors, are also used.

Urine Specimens

The 24-hour urine specimen is used for many endocrine tests. Urine specimens represent a time average that integrates over the multiple pulsatile spikes of hormone secretion occurring throughout the day. The 24-hour urine specimen also has the advantage of better analytic sensitivity for some hormones. Urine often contains not only the original hormone but also key metabolites that may or may not have biologic activity.

Drawbacks include the inconvenience of and delays in collecting the 24-hour specimen. Another limitation of urine specimens is the uncertainty of the completeness of the collection. Measurement of urinary creatinine concentrations helps in monitoring collection completeness, especially when it is compared with the patient’s muscle mass. Many urinary hormones are conjugated to carrier proteins before excretion. Therefore, both hepatic function and, to a lesser degree, renal function may alter urinary hormone values.

Blood Specimens

Blood specimens have both the advantage and the limitation of time dependency. The ability to direct rapid changes to a provocative stimulus is a strong advantage, whereas the unsuspected changes due to pulsatile secretions may be a major limitation. Most hormones undergo significant biologic variations, including ultradian, diurnal, menstrual, and seasonal changes. Many urinary hormones have short half-lives and are thus rapidly cleared from the blood. The half-life is particularly important when one is attempting to measure the response to a provocative drug, such as the effect of gonadotropin-releasing hormone (GnRH). The development of rapid intraoperative methods for measuring PTH and growth hormone has highlighted the importance of plasma specimens, which do not require extra waiting time for the blood to clot to make serum.

Saliva Specimens

Saliva has been used to measure some hormones. Methods of stimulation, collection, and storage of saliva should be standardized in order to ensure that the measurements are reproducible and meaningful. Saliva measurements correlate with blood measurements in some hormones like cortisol, progesterone, estradiol and testosterone but do not correlate well for others. Unconjugated steroid hormones enter saliva by diffusion, and their concentrations are relatively independent of the rate of saliva production. The saliva concentration of conjugated steroids, thyroxine, chorionic gonadotropin, and many protein hormones generally do no correlate well with plasma concentrations.

Blood Drops

Blood drops collected on filter paper from punctures of a finger or heel are a convenient system for collecting, transporting, and measuring hormones. If standardized collection conditions and extraction techniques are used, these measurements correlate well with serum measurements. Integration of immunochemistry with computer chip technology has also led to immunochips that can measure multiple analytes using a single drop of blood.

Noninvasive Measurements

Noninvasive transcutaneous measurements also have been developed for some endocrine tests. Transcutaneous glucose measurements using near-infrared spectroscopy correlate well with blood measurements. The GlucoWatch device is also being marketed for noninvasive monitoring of glucose.
QUALITY ASSURANCE

Quality Control Systems

Laboratory quality control programs are intended to ensure that the test procedures are being performed within defined limits. A critical component of control systems is the definition of acceptable performance criteria. Unfortunately, these criteria often are not well defined and many laboratories use floating criteria that change when assays change. Control limits are often set at the mean ±2 or 3 SDs, where the mean and SD are arbitrarily assigned based on measurements made in that laboratory. When reagents or equipment change, new limits are assigned. These types of control systems provide some assurance that the laboratory is functioning at a level of performance similar to that of the recent past, but they provide little assurance that measurements are adequate for clinical decisions.

Statistically, there are two major forms of analytic errors: random and systematic. Random error relates to reproducibility; systematic error relates to the offset or bias of the test values from the target or reference value. Performance criteria can be defined for each of these parameters, and quality control systems can be programmed to monitor compliance with these criteria. Control systems must have low false-positive rates as well as high statistical power to detect assay deviations. The multirule algorithms developed by Westgard and colleagues use combinations of control rules, such as two consecutive controls outside of warning limits, one control outside of action limits, or moving average trend analyzers outside of limits to achieve good statistical error detection characteristics.

Traditionally, quality control programs have focused primarily on precision; however, analytic bias also can cause major clinical problems. When fixed decision levels are used to trigger clinical actions, such as therapy and additional investigations, changes in the analytic set-point of an assay can cause major changes in the number of follow-up cases. This concept is illustrated in Figure 6-9 for TSH measurements.

Under stable laboratory testing conditions, approximately 122 per 1000 patients tested have TSH values above 5.0 mIU/L. If the test shifts upward by 20%, the number of patients with TSH values above 5.0 mIU/L increases to 189, which equates to more than a 50% increase in the number of patients flagged as abnormal. These changes in test value distributions can often be sensed by clinicians who encounter multiple patients with unexpected elevated test values, causing them to call the laboratory and inquire whether the "test is running high today." Some modern quality control systems use moving averages of patient test values to help monitor changes in analytic bias.

Some medical facilities are linking together into networks to provide more integrated patient care. This crossover of both physicians and patients is increasing the importance of harmonized testing systems. For endocrine tests, harmonization is best achieved when all the laboratories in the network use the same test systems. Differences in analytic specificity may cause across-method differences in patient test distributions even when the methods use the same reference standard. Full harmonization of testing requires not only standardization of equipment but also standardization of reagents (including using the same lot numbers) and standardization of laboratory protocols. Real-time quality control monitors with peer group comparisons across the laboratories in the health care network are necessary to ensure uniformity of testing.
Investigation of Discordant Test Values

The practice of modern endocrinology depends extensively on reliable and accurate test values; even in the best laboratories, however, erroneous results sometimes are reported. Careful correlation of pathophysiology with test values can help to identify values that are "discordant." Some of these discordant test values may be analytically correct, but others may be erroneous. Clinicians can help investigate these suspicious test values by requesting laboratories to perform a few simple validation procedures.

Repeated testing of the same specimen is a valuable first step. If the specimen has been stored under stable conditions, the absolute value of the difference between the initial and the repeated measurements should be less than 3 analytic SDs 95% of the time. Normally, the 95% confidence range is associated with the mean ±2 SDs; with repeated laboratory tests, however, errors are associated with the first as well as the second measurement. The confidence interval for the uncertainty of the difference between two measurements can be calculated using the statistical rules for propagation of errors.

To better understand this propagation of error, consider that 

\[ D = X_1 - X_2 \]

where \( X_1 \) is the first measurement, \( X_2 \) is the repeated measurement, and \( D \) is the difference.

The variance of \( D \) is the sum of the variance of \( X_1 \) and the variance of \( X_2 \). The SD of \( D \) is the square root of the variance of \( D \), or the square root of twice the variance of \( X_1 \). The SD of \( D \) equates to 2 multiplied by the SDs of \( S \). Therefore, 95% of the absolute values for \( D \) should be within 22 SD(X), or approximately 3 SD(X). If a repeat measurement exceeds this 3 SD(X) limit, the initial (or reagent) measurement is probably in error.

Linearity and recovery are valuable techniques for evaluating test validity. If the initial test value is elevated, serially diluting the specimen in the assay diluent and reassaying should be considered. If the specimen dilutes nonproportionally (Fig. 6-10), no meaningful value can be reported with that assay.

In the example, the undiluted specimen reads 22, the twofold dilution multiplies back to 34 (2 × 17), and the fourfold dilution multiplies back to 60 (4 × 15). Therefore, the result depends on the dilution factor, so that no reliable answer can be reported.

If the initial value is low, one may consider adding known quantities of the analyte to part of the specimen. Analyzing these spiked or diluted specimens with the original specimen allows one to evaluate both reproducibility and recovery. It may be helpful to analyze the linearity or recovery of the assay standards at the same time to provide internal controls of the dilution or spiking procedures and the appropriateness of the diluent and spiking material.

If the replication, dilution, or recovery experiment appears successful, further analytic troubleshooting will vary according to the method used. Immunoassays may be affected by interference caused by heterophile antibodies. Addition of nonimmune mouse serum or heterophile antibody-blocking solutions may neutralize these effects. Chromatographic assays are usually more robust than immunoassays. Specimens with suspected interference on one type of assay can be reanalyzed by means of an alternative methodology.

Water-soluble interferences have been reported for some direct assays for steroid measurements. Extraction of the hormones into organic solvents, followed by drying down and reconstitution in the assay zero standard, removes these interferences. Similarly, interferences with cross-reacting drugs and metabolic products can be minimized with selective extraction.
Summary

The analytic methods of assessing endocrine problems in patients are continually expanding. The newer systems are often based on analytic techniques similar to those outlined in this chapter, but the configurations are generally more user-friendly. These advances make the systems more convenient, but they also become more of a "black box" that conceals most of the details of the system. The performance validation steps outlined in this chapter become important procedures for ensuring that these systems continue to provide the reliable measurements needed for quality medical care.

This chapter first presents the concepts of neural secretion, the neuroanatomy of the hypothalamic-pituitary unit, and the CNS structures most relevant to the control of endocrine, autonomic, and behavioral responses. Thus, many homeostatic systems exist in which the classical neuroendocrine axes are important but not the only contributors. These areas include studies of neuropeptide structure, function, and mechanism of action; neural secretion; hypothalamic neuroanatomy; G protein-coupled receptor function and signaling; transport of substances into the brain; and the action of hormones on the brain. Many homeostatic systems involve integrated neural, endocrine, and behavioral mechanisms, demonstrating that much remains to be learned regarding the regulation of the hypothalamic releasing factors.

This technology will allow detailed study of important neuroendocrine neurons in the more native context of slice preparations or organotypic cultures. For example, investigators have already used this method to characterize directly the electrophysiologic properties of individual GnRH neurons. The adipostatic hormone leptin, discovered in 1994, is an example of a humoral factor that has profound effects on multiple neuroendocrine circuits as the factor that suppresses the thyroid and reproductive axes during the starvation response. The subsequent discovery of ghrelin, a stomach peptide that regulates appetite and also acts on multiple neuroendocrine axes, demonstrates that much remains to be learned regarding the regulation of the hypothalamic releasing hormones. Traditionally, it has been extremely difficult to study the regulation of releasing factor gene expression or the specific regulation of the releasing factor binding proteins. Traditionally, this has been problematic due to the rapidity of the binding proteins. Additionally, there is evidence that several neuroendocrine axes are involved in the control of the pituitary gland, without damage to the overlying hypothalamus, resulting in morbid obesity and neuroendocrine derangements similar to those of the patients described by Fröhlich. This and subsequent studies clearly established that an intact hypothalamus is required for normal endocrine function. However, the mechanisms by which the hypothalamus was involved in endocrine regulation remained unsettled for years to come. We now know that the phenotypes of Fröhlich’s syndrome and the ventromedial hypothalamic lesion syndrome are probably due to destruction of key hypothalamic neurons that respond to key metabolic signals including leptin. We now appreciate the fundamental role of the hypothalamus in controlling anterior pituitary function. It is noteworthy that this concept is relatively recent, although the fundamental role of the hypothalamus in controlling anterior pituitary function was long recognized. Over the past two decades, work in the field of neuroendocrinology has continued to advance across several fronts. Cloning and characterization of the specific G protein-coupled receptors used by the hypothalamic releasing factors have helped define signaling mechanisms utilized by the releasing factors. Furthermore, characterization of the distribution of these receptors has, in every case, demonstrated receptor expression in the brain and in peripheral tissues other than the pituitary, arguing for multifactorial roles for these factors. Finally, the last two decades have also seen tremendous advances in our understanding of both regulatory neuronal and humoral inputs to the hypophyseotropic neurons.

The field of neuroendocrinology has been further expanded, however, because many areas of basic research have often been fundamental to understanding the neuroendocrine system and thus championed by scientists in the field. These areas include studies of neuropeptide structure, function, and mechanism of action; neural secretion; hypothalamic neuroanatomy; G protein-coupled receptor structure, function, and signaling; transport of substances into the brain; and the action of hormones on the brain. Many homeostatic systems involve integrated endocrine, autonomic, and behavioral responses. Thus, many homeostatic systems exist in which the classical neuroendocrine axes are important but not autonomous pathways, such as energy homeostasis and immune function, and these subjects are also often studied in the context of neuroendocrinology.

This chapter first presents the concepts of neural secretion, the neuroanatomy of the hypothalamic-pituitary unit, and the CNS structures most relevant to the control of endocrine, autonomic, and behavioral responses.
of the neurohypophysis and hypophysis. The chapter then covers each classical hypothalamic-pituitary axis, followed by two homeostatic systems, energy homeostasis and immune function, which are heavily integrated with neuroendocrine function. Finally, the chapter reviews the pathophysiology of disorders of neural regulation of endocrine function.
NEURAL CONTROL OF GLANDULAR SECRETION

A fundamental principle of neuroendocrinology is the concept of regulated secretion of hormones, neurotransmitters, or neuromodulators by secretory cells. Endocrine cells and neurons are prototypical secretory cells, and both are characterized by the ability to be stimulated to cause the release of their products. In addition, secretory cells exist that can be broadly classified by their mechanisms of secretion. For example, endocrine cells secrete their contents directly into the blood stream, allowing these substances to act globally as hormones. In contrast, secretory cells in exocrine glands secrete substances into ductal systems. Cells classified as paracrine secrete their contents and affect the function of cells in the immediate vicinity. Similarly, autocrine secretory cells affect their own function by the local actions of their own secretions.

Neurosecretion

Neurons are specialized secretory cells that send their axons throughout the nervous system to release their neurotransmitters and neuromodulators into chemical synapses. A specialized subset of neurons are the neurohumoral or neurosecretory cells. Two examples of neurosecretory cells are neurohypophyseal and hypothalamic cells. The prototypical neurohypophyseal cells are the magnocellular neurons of the paraventricular and supraoptic nuclei in the hypothalamus. Hypophyseotropic cells are neurons that secrete their products into the pituitary portal vessels at the median eminence (see later).

In the most basic sense, neurosecretory cells are neurons that secrete substances directly into the blood stream to act as hormones. This concept of release is often referred to as neurosecretion (Fig. 7-2). The theory of neurosecretion evolved from the seminal work of Scharrer and Scharrer, who used morphologic techniques to identify stained secretory granules in the supraoptic and paraventricular hypothalamic neurons. They found that cutting the pituitary stalk led to an accumulation of these granules in the hypothalamus. These findings led them to hypothesize that the source of substances secreted by the neural lobe (posterior pituitary) was hypothalamic neurons. Of course, we now know that the axon terminals in the neural lobe arise from the supraoptic and paraventricular magnocellular neurons that contain oxytocin and arginine vasopressin (AVP).

The modern definition of neurosecretion has evolved to include the release of any neuronal secretory product from a neuron. Indeed, a basic principle of neuroscience is that all neurons in the CNS, including neurons that secrete AVP and oxytocin in the neural lobe, receive multiple synaptic inputs largely onto their dendrites and cell bodies. In addition, neurons have the basic ability to respond and integrate input from multiple neurons through specific receptors. They in turn fire action potentials that result in the release of neurotransmitters and neuromodulators into synapses formed with postsynaptic neurons. The vast majority of communication between neurons is accomplished by "classical" neurotransmitters (e.g., glutamate, -aminobutyric acid [GABA], acetylcholine) and neuromodulators (e.g., neuropeptides) acting at chemical synapses (see Fig. 7-2). Thus, neurosecretion represents a fundamental concept in understanding the mechanisms used by the nervous system to control behavior and maintain homeostasis.

In the era of elucidation of the human genome, the importance of these early observations is often not fully appreciated. However, accounts of these early studies are illuminating. Moreover, it is not an overstatement that the confirmation of the neurosecretion hypothesis represented one of the major advances in the field of neuroscience and neuroendocrinology. Indeed, this and other early experiments, including the pioneering work of Geoffrey Harris, led to the fundamental concept that the hypothalamus releases hormones directly into the blood stream (neurohypophyseal cells). These observations provided the principles on which the modern discipline of neuroendocrinology is built.
The Autonomic Nervous System Contribution to Endocrine Control

One of these fundamental principles of neuroendocrinology is that the nervous system controls or modifies, or both, the function of both endocrine and exocrine glands. The exquisite control of the anterior pituitary gland is accomplished by the release of releasing factor hormones (see later). Other endocrine and exocrine organs (e.g., pancreas, adrenal, pineal, salivary glands) are also regulated through direct innervation from the cholinergic and noradrenergic inputs from the autonomic nervous system. Although it is beyond the scope of this chapter, an appreciation of the functional anatomy and pharmacology of the parasympathetic and sympathetic nervous systems is fundamental in understanding the neural control of endocrine function.

The efferent arms of the autonomic nervous system comprise the sympathetic and parasympathetic systems. Both limbs are a classical two-neuron chain. Both are characterized by a preganglionic neuron that innervates a postganglionic neuron that targets an end organ. Preganglionic and postganglionic parasympathetic neurons are cholinergic. In contrast, preganglionic sympathetic neurons are cholinergic and postganglionic neurons are noradrenergic (except for those innervating sweat glands, which are cholinergic). Another basic concept is that autonomic neurons coexpress several neuropeptides. This coexpression is a common feature in neurons in both the central and peripheral nervous systems. For example, postganglionic noradrenergic neurons coexpress somatostatin and neuropeptide Y (NPY). Postganglionic cholinergic neurons coexpress neuropeptides including vasoactive intestinal polypeptide and calcitonin gene-related peptide.

The majority of the sympathetic preganglionic neurons lie in the intermediolateral cell column in the thoracicolumbar regions of the spinal cord. Most postganglionic neurons are located in sympathetic ganglia lying near the vertebral column (e.g., sympathetic chain and superior cervical ganglia). Postganglionic fibers, in turn, innervate target organs. Thus, as a rule, sympathetic preganglionic fibers are relatively short and the postganglionic fibers are long. In contrast, the parasympathetic preganglionic neurons lie in the midbrain (Edinger-Westphal nucleus of the third cranial nerve), the medulla oblongata (e.g., dorsal motor nucleus of the vagus and nucleus ambiguus), and the sacral spinal cord. Postganglionic neurons that innervate the eye and salivary glands arise from the ciliary, pterygopalatine, submandibular, and otic ganglia. Postganglionic neurons in thorax and abdomen typically lie in the target organs including the gut wall and pancreas. Thus, preganglionic neurons are relatively long and the postganglionic fibers are short.

The importance of coordinated neural control of endocrine organs is illustrated by the innervation of the pancreas. The endocrine pancreas receives both parasympathetic (cholinergic) innervation and sympathetic (noradrenergic) innervation. The cholinergic innervation is provided by the vagus nerve (dorsal motor nucleus of the vagus). The activity in this innervation is an excellent example of neural modulation as it is clear that the secretory activity of insulin-producing beta cells is affected by the cholinergic tone of the beta cell. For example, vagal input is thought to modulate insulin secretion before (cephalic phase), during, and after ingestion of food. In addition, noradrenergic stimulation of the endocrine pancreas can alter the secretion of glucagon and inhibits insulin release. It should be noted, of course, that a major regulator of insulin secretion by beta cells is glucose concentrations. In fact, glucose can induce insulin secretion in the absence of neural input. However, the exquisite control by the nervous system is illustrated by the fact that populations of neurons in the brain stem and hypothalamus, like the beta cell, have the ability to sense glucose levels in the blood stream. This information is integrated by the hypothalamus and ultimately results in alterations in the activity of the autonomic nervous system innervating the pancreas. Thus, neural control of the endocrine pancreas probably contributes to the physiologic control of insulin secretion and may contribute to the pathophysiology of disorders such as diabetes mellitus. Certainly, an increased understanding of this complex interplay between the CNS and endocrine function is needed to diagnose and clinically manage endocrine disorders.
HYPOTHALAMIC-PITUITARY UNIT

The hypothalamus is one of the most evolutionarily conserved and essential regions of the mammalian brain. Indeed, the hypothalamus is the ultimate brain structure that allows mammals to maintain homeostasis, and destruction of the hypothalamus is not compatible with life. Hypothalamic control of homeostasis stems from the ability of this collection of neurons to orchestrate coordinated endocrine, autonomic, and behavioral responses. A key principle is that the hypothalamus receives sensory inputs from the external environment (e.g., light, pain, temperature, odorants) and information regarding the internal environment (e.g., blood pressure, blood osmolality, blood glucose levels). In addition, of particular relevance to neuroendocrine control, hormones (e.g., glucocorticoids, estrogen, testosterone, thyroid hormone) exert negative feedback directly on the hypothalamus.

These sensory and hormonal cues are examples of a fundamental concept of neuroendocrinology: the hypothalamus integrates sensory and hormonal inputs and provides coordinated responses through motor outputs to key regulatory sites. These include the anterior pituitary gland, the posterior pituitary gland, the cerebral cortex, premotor and motor neurons in the brain stem and spinal cord, and autonomic (parasympathetic and sympathetic) preganglionic neurons. The patterned hypothalamic outputs to these effector sites ultimately result in coordinated endocrine, behavioral, and autonomic responses that maintain homeostasis. The focus of this section, the hypothalamic control of the pituitary gland, is an exquisitely controlled system and underlies the ability of mammals to coordinate endocrine functions that are necessary for survival.

Anatomy of the Hypothalamic-Pituitary Unit

The pituitary gland is regulated by three interacting elements: hypothalamic inputs (releasing factors or hypophyseotropic hormones), feedback effects of circulating hormones, and paracrine and autocrine secretions of the pituitary itself. In humans, the pituitary gland (hypophysis) can be divided into two major parts, the adenohypophysis and the neurohypophysis. The adenohypophysis in turn can be subdivided into three distinct lobes, the pars distalis (anterior lobe), pars intermedia (intermediate lobe), and pars tuberalis (Fig. 7-3). Whereas a well-developed intermediate lobe is found in most mammals, only rudimentary vestiges of the intermediate lobe are detectable in adult humans with the bulk of intermediate lobe cells being dispersed in the anterior and posterior lobes.

The neurohypophysis is composed of the pars nervosa (also known as the neural or posterior lobe), the infundibular stalk, and the median eminence. The infundibular stalk is surrounded by the pars tuberalis, and together they constitute the hypothyalalal stalk. The pituitary gland lies in the sella turcica (the Turkish saddle) of the sphenoid bone and underlies the base of the hypothalamus. This anatomic location explains the hypothalamic damage described by Fröhlich. In humans, the base of the hypothalamus forms a mound called the tuber cinereum, the central region of which gives rise to the median eminence (Fig. 7-4).

The anterior and intermediate lobes of the pituitary are derived from an outgrowth of the pharyngeal cavity called Rathke's pouch and migrate during development to surround the neural lobe. The intermediate lobe is in contact with the neural lobe and is the least prominent of the three lobes. With age, the intermediate lobe in humans decreases in size and is represented in the adult as a relatively small collection of POMC cells. In some species, these cells are responsible for secreting the POMC-derived product melanocyte-stimulating hormone (MSH).

In a strict sense, the neurohypophysis is made up of the neural lobe, the infundibular stalk, and the median eminence. The major component of the neural lobe is a collection of axon terminals arising from magnocellular secretory neurons from the paraventricular and supraoptic nuclei of the hypothalamus (Fig. 7-5). The blood supply to the neurohypophysis arises from the inferior hypophyseal vessels and the general circulation (Table 7-1). The blood supply to the neurohypophysis arises from the internal carotid artery. Scattered among the nerve terminals are glial-like cells called pituicytes. As the source of AVP to the general circulation, the paraventricular and supraoptic nuclei and their axon terminals in the neural lobe are the effector arms of the central regulation of blood osmolality, fluid balance, and blood pressure. (see "Circumventricular Organs").

The secretion of oxytocin by magnocellular neurons is also well characterized and is critical at the time of parturition, resulting in uterine myometrial contraction. In addition, the secretion of oxytocin is regulated by the classical milk let-down reflex. The exact neuroanatomic substrate underlying the milk let-down response is still unclear. However, it is apparent that mechanosensory information from the nipple reaches the magnocellular neurons, directly or indirectly, from the dorsal horn of the spinal cord, resulting in release of oxytocin into the general circulation. Oxytocin acts on receptors on myoepithelial cells in the mammary gland acini, leading to release of milk into the ductal system and ultimately the release of milk from the mammary gland.
The Median Eminence and Hypophyseotropic Neuronal System

The median eminence lies in the center of the tuber cinereum; it is composed of an extensive array of blood vessels and nerve endings and is the functional link between the hypothalamus and the anterior pituitary gland. The median eminence can be considered the functional link between the hypothalamus and pituitary and the site of the hypothalamic releasing factors from which the pituitary portal vessels arise. The median eminence is characterized by an extremely rich blood supply that arises from the superior hypophyseal artery (from the internal carotid artery). The artery sends off many small branches that form capillary loops. These small capillary loops extend into the internal and external zones (see later), form anastomoses, and drain into sinusoids that become the pituitary portal veins that enter the vascular pool of the pituitary gland. The flow of blood in these short loops is thought to be predominantly (if not exclusively) in a hypothalamic-to-pituitary direction. This well-developed plexus results in a tremendous increase in the vascular surface area. In addition, the vessels are fenestrated, allowing diffusion of the peptide-releasing factors to their site of action in the anterior pituitary gland. The vascular complex in the base of the hypothalamus and its “arterialized” venous drainage to the pituitary compose a circulatory system analogous to the portal vein system of the liver, hence the term hypophyseal portal circulation. Typically, three zones of the median eminence are discussed, the ependymal layer, the internal zone, and the external zone (Fig. 7-8). The innermost zone is made up of ependymal cells that form the floor of the third ventricle. These ependymal cells are unique in that they have microvilli rather than cilia. The ependymal layer also contains specialized cells called tanycytes that send processes into the other layers of the median eminence. There are tight junctions between the ependymal lining of the third ventricle forming a barrier between the cerebrospinal fluid (CSF) and the blood in the median eminence. In addition, tight junctions exist between tanycytes at the lateral edges of the median eminence that are thought to prevent the diffusion of releasing factors back into the basal hypothalamus.

The internal zone of the median eminence is composed of axons of passage of the supraoptic and paraventricular magnocellular neurons en route to the posterior pituitary (see Fig. 7-3C).

and the axons of the hypophyseotropic neurons destined for the external layer of the median eminence (see Fig. 7-8A and B). In addition, supportive cells are found in this layer. Finally, the external zone represents the exchange point of the hypothalamic releasing factors and the pituitary portal vessels. The external zone contains terminals from two general types of releasing factors, peptides (discussed in detail later) and monoamines (dopamine and norepinephrine). This zone represents the site of convergence where the peptides come in contact with portal vessels.

Two general types of tuberhypophyseal neurons project to the external zone of the median eminence: peptide-secreting (peptidergic) neurons (i.e., thyrotropin-releasing hormone [TRH], corticotropin-releasing hormone [CRH], and luteinizing hormone-releasing hormone [LHRH]; see Fig. 7-7 and Fig. 7-8) and neurons containing bioamines (e.g., dopamine and serotonin). Although the secretion of these substances into the portal circulation is an important control mechanism, some peptides and neurotransmitters in nerve endings are not released into the hypophyseal-portal circulation but instead function to regulate the secretion of other nerve terminals. The anatomical relationships of nerve endings, basement membranes, interstitial spaces, fenestrated (windowed) capillary endothelia, and glia in the median eminence are similar to those in the neural lobe. As in the case of the neurohypophysis, the release of neuropeptides is mediated by the depolarization of hypothalamic cells leading to secretion at the median eminence.

Non-neuronal supporting cells in the hypothalamus also play a dynamic role in hypothyseotropic regulation. For example, nerve terminal cells in the neurohypophysis are enveloped by glia (in the neural lobe they are called pituicytes); when the gland is inactive they surround the nerve endings, whereas the nerve ending is exposed when vasopressin secretion is enhanced as in states of dehydration. Within the median eminence, LHRH nerve endings are enveloped by the specialized ependymal cells called tanycytes, which also cover or uncover neurons with changes in functional status. Thus, supporting elements, with their own sets of receptors, can change the neuroregulatory milieu within the hypothalamus, median eminence, and pituitary.

The site of production, the genetics, and the regulation of synthesis and release of peptide releasing factors are discussed in detail in the following. Briefly, the cell groups in the hypothalamus that contain releasing factors that are secreted into the pituitary portal circulation are located in several cell groups of the medial hypothalamus (Table 7-2). These cell groups include the arcuate (infundibular) nucleus (see Fig. 7-9C), the paraventricular nucleus (see Fig. 7-9A and C), the periventricular nucleus, and a group of cells in the medial preoptic area near the organum vasculosum of the lamina terminals (OVLT) (Fig. 7-10). As discussed, magnocellular neurons in the supraoptic and paraventricular nucleus send axon terminals that traverse the median eminence and make up the neural lobe of the pituitary. In addition, a projection from magnocellular neurons to the external zone of the median eminence has been described. However, its functional significance is not clear.

The third structure often mentioned as a component of the median eminence is the pars tuberalis. The pars tuberalis is a subdivision of the adenohypophysis and is a thin glandular sheet of tissue that lies around the infundibulum and pituitary stalk. In some animals, the epithelial component may make up as much as 10% of the total glandular tissue of the anterior pituitary. The pars tuberalis contains cells making pituitary tropic hormones including luteinizing hormone (LH) and thyrotropin. A definitive physiologic function of the pars tuberalis is not established, but melatonin receptors are expressed in the pars tuberalis.
CIRCUMVENTRICULAR ORGANS

A fundamental principle of physiology and pharmacology is that the brain, including the hypothalamus, resides in an environment that is protected from humoral signals. This exclusion of macromolecules is due to the structural

specializations that make up the blood-brain barrier. These include tight junctions of brain vascular endothelial cells that preclude the free passage of polarized macromolecules including peptides and hormones. In addition, astrocytic foot processes and perivascular microglial cells contribute to the integrity of the blood-brain barrier. However, to exert homeostatic control, the brain, especially the hypothalamus, must assess key sensory information from the blood stream including hormone levels, metabolites, and potential toxins. For example, to monitor key signals the brain has "windows on the circulation" or circumventricular organs (CVOs) that serve as a conduit of peripheral cues into key neuronal cell groups that maintain homeostasis.

As the name implies, CVOs are specialized structures that lie on the midline of the brain along the third and fourth ventricles. These structures include the OVLT, subcomical organ (SFO), median eminence, neurohypophysis (posterior pituitary), subcomissural organ, and the area postrema. Unlike thevasculature in the rest of the brain, the blood vessels in CVOs have fenestrated capillaries that allow relatively free passage of molecules such as proteins and peptide hormones. Thus, neurons and glial cells that reside within the CVOs have access to these macromolecules. In addition to the distinct nature of the vessels themselves, the CVOs have an unusually rich blood supply, allowing them to act as integrators at the interface of the blood-brain barrier. As discussed in more detail later, several of the CVOs have major projections to hypothalamic nuclear groups that regulate homeostasis. Thus, the CVOs serve as a critical link between peripheral metabolic cues, hormones, and potential toxins with cell groups within the brain that regulate coordinated endocrine, autonomic, and behavioral responses. Detailed discussion of the physiologic roles of individual CVOs is beyond the scope of this chapter, but several in-depth reviews have assessed the function of each.

Median Eminence

The median eminence and neurohypophysis contain the neurosecretory axons that control pituitary function. The role of the median eminence as a link between the hypothalamus and the pituitary gland is covered in greater detail in other sections of this chapter (see Fig. 7-9) and Fig. 7-9 and "Hypothalamic-Pituitary Unit"). However, it is important to understand that the anatomic location of the median eminence places it in a position to serve as an afferent sensory organ as well. Specifically, the median eminence is located adjacent to several neuroendocrine and autonomic regulatory nuclei at the tuber level of the hypothalamus (see Fig. 7-9). These nuclear groups include the arcuate, ventromedial, dorsomedial, and paraventricular nuclei.

A role of cell groups surrounding the median eminence as afferent sensory centers is supported by several observations. For example, toxins such as monosodium glutamate and gold

thioglucose damage neurons in cell groups overlying the median eminence, resulting in obesity and hyperphagia. Experimental evidence suggests that the median eminence is a portal of entry for hormones such as leptin. Indeed, administration of radiolabeled peptides or hormones, such as -MSH or leptin, led to their accumulation around the median eminence. Moreover, leptin receptor messenger ribonucleic acid (mRNA) and leptin-induced gene expression are densely localized in the arcuate, ventromedial, dorsomedial, and ventral premammillary hypothalamic nuclei. As discussed in detail in other sections of this chapter, leptin is an established mediator of body weight and neuroendocrine function that acts on several cells in the hypothalamus including POMC neurons that reside in the arcuate nucleus (see Fig. 8-9). Notably, POMC neurons are also found embedded within the median eminence. Thus, it is likely that the median eminence is involved in conveying information from humoral factors such as leptin to key hypothalamic regulatory neurons in the medial basal hypothalamus.

| TABLE 7-1 – Sequences of the Principal Peptides of the Neurohypophysis |
|---|---|---|---|---|---|---|---|---|---|
| **Mammals (except pig)** | Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH₂ | Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly-NH₂, Arginine vasopressin |
| **Pig** | Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH₂ | Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Lys-Gly-NH₂, Lysine vasopressin |
| **Birds, reptiles, amphibians, lungfishes** | Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Ile-Gly-NH₂ | Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Arg-Gly-NH₂, Vasotocin |
| **Bony fishes (palcopterygians and neopterygians)** | Cys-Tyr-Ile-Ser-Asn-Cys-Pro-Ile-Gly-NH₂, Isotocin | Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Arg-Gly-NH₂, Vasotocin |

Thyrotropin-Releasing Hormone

Chemistry and Evolution

TRH, the smallest known peptide releasing hormone, is the tripeptide pyroGlu-His-Pro-NH₂. The TRH peptide sequence is repeated six times within the human TRH pre-prohormone gene (Fig. 7-13). The rat pro-TRH precursor contains five TRH peptide repeats flanked by dibasic residues (Lys-Arg or Arg-Arg), along with seven or more non-TRH peptides. Two prohormone convertases, PC1 and PC2, cleave the TRH tripeptides at the dibasic residues within the regulated secretory pathway. Carboxypeptidase E then removes the dibasic residues, leaving the sequence Gln-His-Pro-Gly. This peptide is then amidated at the C-terminus by peptidylglycine alpha-amidating monoxygenase, with Gly acting as the amide donor. The amino-terminal pyro-Glu residue results from cyclization of the Gin.

Although the TRH tripeptide is the only established hormone encoded within its large prohormone, the rat pro-TRH yields seven additional peptides that have unique tissue distributions.

Several biologic activities of these peptides have been observed: pre-pro-TRH (Fig. 7-13) may be a hypothalamic factor because it is released from hypothalamic slices and potentiates the thyrotropin-releasing effects of TRH.

TRH is a phylogenetically ancient peptide, being found in primitive vertebrates, such as the lamprey, and even invertebrates such as the snail. TRH is widely expressed in both CNS and periphery in amphibians, reptiles, and fishes but does not stimulate thyrotropin release in these poikilothermic vertebrates.

TRH has multiple peripheral and central activities and was co-opted as a hypophyseotropic factor midway during the evolution of vertebrates, perhaps specifically as a factor needed for coordinate regulation of temperature homeostasis.

Effects on the Pituitary Gland and Mechanism of Action

After intravenous injection of TRH in humans, serum thyrotropin levels rise within a few minutes (Fig. 7-14) followed by a rise in serum triiodothyronine (T₃) level. There is an increase in thyroxine (T₄) release as well, but a change in blood levels of T₄ is usually not demonstrable because the pool of circulating T₄ (most of which is bound to carrier proteins) is so large. The clinical applications of TRH testing are covered later in this chapter and in Chapter 10. TRH action on the pituitary is blocked by previous treatment with thyroid hormone, which is a crucial element in feedback control of pituitary thyrotropin secretion.

TRH is also a potent PRF (Fig. 7-14). The time course of response of blood PRL levels to TRH, the dose-response characteristics, and the suppression by thyroid hormone pretreatment (all of which parallel changes in thyrotropin secretion) suggest that TRH may be involved in the regulation of PRL secretion. Moreover, TRH is present in the hypophyseal-portal blood of lactating rats. However, it is unlikely to be a physiologic regulator of PRL secretion because the PRL response to nursing in humans is unaccompanied by changes in plasma thyrotropin levels. Nevertheless, TRH may occasionally cause hyperprolactinemia (with or without galactorrhea) in patients with hypothyroidism.

In normal individuals TRH has no influence on the secretion of pituitary hormones other than thyrotropin and PRL, but it enhances the release of human growth hormone (hGH) in acromegaly and of corticotropin in some patients with Cushing’s disease. Furthermore, prolonged stimulation of the pituitary by TRH also causes the release of hGH in some patients with uremia, hepatic disease, anorexia nervosa, and psychotic depression and in children with hypothyroidism. TRH inhibits sleep-induced hGH release through its actions in the CNS (see later in the section on extrapituitary actions of TRH).

Stimulatory effects of TRH are initiated by binding of the peptide to specific receptors on the plasma membrane of the thyrotroph. Neither thyroid hormone nor somatostatin, both of which antagonize the effects of TRH, interfere with its binding. TRH was originally thought to activate membrane adenylate cyclase to stimulate formation of cAMP and cAMP in turn was thought to stimulate thyrotropin secretion. However, cAMP does not increase under all conditions of TRH-induced thyrotropin release, and it is now clear that TRH action is mediated mainly through hydrolysis of phospholipidinositol, with phosphorylation of key protein kinases and an increase in intracellular free Ca²⁺ as the crucial step in postreceptor activation.

TRH is degraded to acid TRH and to the dipeptide histidylprolineamide, which cyclizes nonenzymatically to histidylproline diketopiperazine (cyclic His-Pro).

Figure 7-13 Structure of human thyrotropin-releasing hormone (TRH) gene and peptide, showing six repeating codons for the TRH sequence. CPE, carboxypeptidase E; PAM, peptidylglycine alpha-amidating monoxygenase; PC1, prohormone convertase 1. (From Yamada M, Radovick S, Wondisford FE, et al. Cloning and structure of human genomic DNA and hypothalamic cDNA encoding human preprothyrotropin-releasing hormone. Mol Endocrinol 1990; 4:551-556.)

Figure 7-14 Effect of intravenous injection of thyrotropin-releasing hormone on serum thyrotropin levels in humans. TRF, thyrotropin-releasing hormone; TSH, thyrotropin. (Replotted from data of Bowers C, Friesen HG, Hwang P, et al. Prolactin and thyrotropin release in man by synthetic pyroglutamylhistidyl-prolinamide. Biochem Biophys Res Commun 1971; 45:1033-1041.)
TRH has some behavioral effects in rats that are similar to those of TRH but no other proven actions. Cyclic His-Pro is reported to act as a PRF and to have other neural effects, including reversal of ethanol-induced sleep (TRH is also effective in this system), elevation of brain cyclic guanosine monophosphate levels, an increase in stereotyped behavior, modification of body temperature, and inhibition of eating behavior. Some of the effects of TRH may be mediated through cyclic His-Pro, but the fact that cyclic His-Pro is abundant in some areas and is not proportional to the amount of TRH suggests that the peptide may not be derived solely from TRH.

Extrahypothalamic Function

TRH is present in virtually all parts of the brain: cerebral cortex, circumventricular structures, neurohypophysis, pineal gland, and spinal cord. TRH is also found in pancreatic islet cells and in the gastrointestinal tract. Although it is present in low concentration, the total amount in extrahypothalamic tissues exceeds the amount in the hypothalamus.

The extensive extrahypothalamic distribution of TRH, its localization in nerve endings, and the presence of TRH receptors in brain tissue suggest that TRH serves as a neurotransmitter or neuromodulator outside the hypothalamus. TRH is a general stimulant of gonadal, pineal, neuroendocrine, and intestinal functions and induces hyperthermia on intracerebroventricular injection, suggesting a role in central thermoregulation.

Clinical Applications

The use of TRH for the diagnosis of hyperthyroidism is less common since the development of ultrasensitive assays for thyroid-stimulating hormone (TSH). see Chapter 10) Its use to discriminate between hypothalamic and pituitary causes of thyrotopin deficiency has also declined because of the test's poor specificity, but the application of ultrasensitive assays in conjunction with the TRH test has not been fully evaluated. TRH testing is also not of value in the differential diagnosis of causes of hyperprolactinemia but is useful for the demonstration of residual abnormal somatotropin-secreting cells in acromegalic patients who release hGH in response to TRH before treatment.

Studies of the effect of TRH on depression have shown inconsistent results, possibly because of poor blood-brain barrier penetration. Intrathecal administration of TRH may improve responses in depressed patients, but its clinical utility is unknown. Although a role for TRH in depression is not established, many depressed patients have a blunted thyrotropin response to TRH and changes in TRH responsiveness correlate with the clinical course. The mechanism by which the changes occur is unknown.

TRH has been proposed as a treatment for women with threatened premature labor to stimulate the production of lung surfactant in the preterm fetus. Despite encouraging results in early studies, several large-scale trials failed to show improvement in the survival of babies so treated.

TRH has been evaluated for the treatment of spinal muscle atrophy and amyotrophic lateral sclerosis; transient improvement in strength was reported in both disorders, but the combined experience at many centers using a variety of treatment protocols including long-term intrathecal administration failed to confirm efficacy. TRH administration also reduces the severity of experimentally induced spinal and ischemic shock. TRH has been used to treat children with neurologic disorders including West's syndrome, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy, and intractable epilepsy. TRH has been proposed to be an analeptic agent. Sleeping or drug-sedated animals were awakened by the administration of TRH but its clinical utility is unknown. Although a role for TRH in depression is not established, many depressed patients have a blunted thyrotropin response to TRH and changes in TRH responsiveness correlate with the clinical course. The mechanism by which the changes occur is unknown.

TRH has been proposed as a treatment for women with threatened premature labor to stimulate the production of lung surfactant in the preterm fetus. Despite encouraging results in early studies, several large-scale trials failed to show improvement in the survival of babies so treated.

TRH has been evaluated for the treatment of paraparesis due to amyotrophic lateral sclerosis; transient improvement was reported in both disorders. Although these results were not confirmed by the combined experience at many centers using a variety of treatment protocols including long-term intrathecal administration, preliminary studies in humans suggest that TRH treatment may improve recovery after spinal cord injury and head trauma. TRH has been used to treat children with neurologic disorders including West's syndrome, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy, and intractable epilepsy. TRH has been proposed to be an analeptic agent. Sleeping or drug-sedated animals were awakened by the administration of TRH but its clinical utility is unknown. Although a role for TRH in depression is not established, many depressed patients have a blunted thyrotropin response to TRH and changes in TRH responsiveness correlate with the clinical course. The mechanism by which the changes occur is unknown.

Regulation of Thyrotropin Release

The secretion of thyrotropin is regulated by two interacting elements: negative feedback by thyroid hormone and open-loop neural control by hypothalamic hypophyseotrophic factors.

![Figure 7-16 Regulation of the hypothalamic-pituitary-thyroid axis. AGRP, agouti-related protein; CART, cocaine and amphetamineregulated transcript; CRH, corticotropin-releasing hormone; NPY, neuropeptide Y; POMC, proopiomelanocortin; TSH, thyrotropin; T3, triiodothyronine; T4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyrotropin; DB-R, leptin receptor.](image)

Feedback Control: Pituitary-Thyroid Axis

In the context of a feedback system, the level of thyroid hormone in blood or of its unbound fraction is the controlled variable and the set-point is the normal resting level of plasma thyroid hormone. Secretion of thyrotropin is inversely regulated by the level of thyroid hormone so that deviations from the set-point of control lead to appropriate changes in the rate of thyrotropin secretion. Factors that determine the rate of thyrotropin secretion required to maintain a given level of thyroid hormone include the rate at which thyrotropin and thyroid hormone disappear from the blood (turnover rate) and the rate at which T4 is converted to its more active form, T3.

![Figure 7-17 Relationship between plasma thyrotropin levels and thyroid hormone as determined by plasma protein-bound iodine (PBI) measurements in humans and rats. These curves illustrate, in the human (A) and the rat (B), that plasma thyrotropin levels are a curvilinear function of plasma thyroid hormone level. Human studies were carried out by giving myxodematous patients successive increments of thyrotropin T3 at approximately 10-day intervals. Each point represents simultaneous measurements of plasma PBI and plasma thyrotropin at various times in the six patients studied. The rat studies were performed by treating thyrotoxicated animals with various doses of T3 for 2 weeks before assay of plasma thyrotropin and plasma PBI. These curves illustrate that the secretion of thyrotropin is regulated over the entire range of thyroid hormone levels. At the normal set point for T3, the small changes above and below the control level are followed by appropriate increases or decreases in plasma thyrotopin. TSH, thyroid; T3, thyroxine. (From Reichlin S, Utiger RD. Regulation of the pituitary thyroid axis in man: relationship of TSH concentration to concentration of free and total thyroid hormone in plasma. J Clin Endocrinol Metab 1967; 27:25135, copyright by The Endocrine Society B from Reichlin S, Martin JJB, Bosshard RL, et al: Measurement of TSH in plasma and pituitary of the rat by a radioimmunoassay utilizing bovine TSH: effect of thyroidectomy or thyroxine administration on plasma TSH levels. Endocrinology 1970; 87:10221031, copyright by The Endocrine Society.)](image)

Thyroid hormones act on both the pituitary and the hypothalamus. Feedback control of the pituitary by thyroid hormone is remarkably precise. Administration of small doses of T3 and T4 inhibited the thyrotropin response to TRH and barely detectable decreases in plasma thyroid hormone levels were sufficient to sensitize the pituitary to TRH. TRH stimulates thyrotropin secretion within a few minutes through its action on a membrane receptor, whereas thyroid hormone actions,
mediated by intranuclear receptors, require several hours to take effect (see Chapter 10).

The secretion of hypothalamic TRH is also regulated by thyroid hormone feedback. Systemic injections of T₃ or implants of tiny T₃ pellets in the paraventricular nucleus of hypothyroid rats (Fig. 7-18) (Figure Not Available) reduced the concentration of TRH mRNA and TRH prohormone in TRH-secreting cells. Thyroid hormone also suppressed TRH secretion into hypophyseal-portal blood in sheep.

T₃ in the blood gains access to TRH-secreting neurons in the hypothalamus by way of the CSF. The hormone is taken up by epithelial cells of the choroid plexus of the lateral ventricle of the brain, bound within the cell to locally produced transthyretin (TTR, binding prealbumin), and then secreted across the blood-brain barrier. Within the brain, T₃ is converted by type II deiodinase, and T₃ interacts with subtypes of the thyroid hormone receptor, TR₁, TR₂, and TR₃ in the paraventricular nucleus and other brain cells (see Chapter 10). Hence the set-point of the pituitary-thyroid axis is determined by thyroid hormone levels within the brain. T₃ in the circulation is not transported into brain in this manner but presumably gains access to the paraventricular TRH neurons across the blood-brain barrier. The brain T₃ transport and deiodinase system account for the fact that the higher blood levels of T₃ are required to suppress pituitary-thyroid function after administration of T₃ than after administration of T₄.

Transthyretin is present in the brain of early reptiles and in addition is synthesized by the liver in warm-blooded animals. During embryogenesis in mammals, transthyretin is first detected when the blood-brain barrier appears, ensuring thyroid hormone access to the developing nervous system.

The hypothalamus determines the set-point of feedback control around which the usual feedback regulatory responses are elicited. Lesions of the thyrrotropic area lower basal thyroid hormone levels and make the pituitary more sensitive to inhibition by thyroid hormone, and high doses of TRH raise thyrotrophin and thyroid hormone levels. Synthesis of TRH in the paraventricular nucleus is regulated by feedback actions of thyroid hormones. The hypothalamus can override normal feedback control through an open-loop mechanism involving neuronal inputs to the hypophyseotropic TRH neurons (see Fig. 7-16). For example, cold exposure caused a sharp increase in thyrotropin release in animals and in human newborns. Circadian changes in thyrotropin secretion are another example of brain-directed changes in the set-point of feedback control, but if thyroid hormone levels are sufficiently elevated, as in hyperthyroidism, TRH cannot overcome the inhibition.

Hypothalamic regulation of thyrotropin secretion is also influenced by two inhibitory factors, somatostatin and dopamine. Antisomatostatin antibodies increase basal thyroid levels and potentiate the response to stimuli that normally induce thyrotropin release in the rat, as cold exposure and TRH administration. Thyroid hormone in turn inhibits the release of somatostatin, implying coordinated, reciprocal regulation of TRH and somatostatin by thyroid hormone. GH stimulates hypothalamic somatostatin synthesis and can inhibit thyrotropin secretion. The role of somatostatin in the regulation of thyrotropin secretion in humans is uncertain.

Dopamine has modest effects on thyrotropin secretion, and blockade of dopamine receptors (in the human) stimulates thyrotropin secretion slightly. Changes in the metabolism of thyroid hormone also influence T₃ homeostasis within the brain. In states of thyroid hormone deficiency, brain T₃ levels are maintained by an increase in the deiodinase that converts T₄ to T₃, and in both healthy and in human newborns. The pineal gland has been reported to inhibit thyroid function in some but not all studies. The pineal gland contains TRH, and in the frog its content changes with the season and with light and dark cycles independently of hypothalamic thyrotropin.

Circadian Rhythm

 Plasma thyrotropin in humans is characterized by a circadian periodicity, with a maximum between 9 pm and 5 am and a minimum between 4 pm and 7 pm. Smaller ultradian thyrotropin peaks occur every 90 to 150 minutes, probably because of bursts of TRH release from the hypothalamus, and are physiologically important in controlling the synthesis and glycosylation of thyrotropin. Glycosylation is a determinant of thyrotropin potency.

Temperature

External cold exposure activates and high ambient temperature inhibits the pituitary-thyroid axis in animals, and analogous changes occur in humans under certain conditions. Exposure of infants to cold at the time of delivery causes an increase in blood thyroid levels, possibly because of alterations in the turnover and degradation of the thyroid hormones. Blood thyroid hormone levels are higher in the winter than in the summer in individuals in cold climates but not in other climates. However, it is difficult to show that changes in environmental or body temperature in adults influence thyrotropin secretion. For example, exposure to cold ambient temperature or central hypothalamic cooling does not modify thyrotropin levels in young men. Behavioral changes, activation of the sympathetic nervous system, and shivering appear to be more important in temperature regulation in adults than the thyroid response.

The autonomic nervous system and the thyroid axis work together to maintain temperature homeostasis in mammals, and TRH plays a role in both pathways. Hypothalamic TRH release is rapidly (30 to 45 minutes) increased in rats exposed to cold. Rapid inhibition of somatostatin release in the median eminence has also been demonstrated, and both changes appear to play important roles in the rise in plasma TSH induced by cold exposure. TRH mRNA is elevated within an hour of cold exposure (see Fig. 7-18 C and D) (Figure Not Available). The regulation of hypothalamic TRH release and expression by cold is largely mediated by catecholamines. Noradrenergic and adrenergic fibers, originating in the brain stem, are found in close proximity to TRH nerve endings in the median eminence, and a rapid rise in TRH release was seen after norepinephrine treatment of hypothalamic fragments containing mainly median eminence. Brain stem adrenergic and noradrenergic fibers also make synaptic contacts with TRH neurons in the PVH (see Fig. 7-16). and thus catecholamines are likely to be involved in the regulation of TRH gene expression by cold. TRH neurons in the PVH are densely innervated by NPY terminals, and a portion of the NPY terminals arising from the C1, C2, C3, and A1 cell groups of the brain stem and projecting to the PVH are shown to be catecholaminergic. Somatostatin, dopamine, and serotonin also play a variety of roles in the regulation of TRH.

Stress

Stress is another determinant of thyrotropin secretion. In humans physical stress inhibits thyrotropin release, as indicated by the finding that in the euthyroid sick syndrome low T₃ and T₄ do not cause compensatory increases in thyrotropin secretion as would occur in normal individuals. A number of observations demonstrate interactions between the thyroid and adrenal axes. Physiologically, the bulk of evidence suggests that glucocorticoids in humans act to blunt the thyroid axis through actions in the CNS. Some actions may be direct because the TRH gene (see Fig. 7-13) (Figure Not Available) contains the glucocorticoid response element consensus sequence and hypophyseotropic TRH neurons appear to contain glucocorticoid receptors.
TSH, but disruption of cortisol synthesis with metyrapone only modestly affects the TSH circadian rhythm.

Several lines of evidence, however, identify conditions in which elevated glucocorticoids are associated with stimulation of the thyroid axis. Human depression is often associated with hypercortisolism and hyperthyroxinemia, and TRH mRNA levels are elevated by glucocorticoids in a number of cell lines as well as in cultured fetal hypothalamic TRH neurons from the rat. Thus, although glucocorticoids probably stimulate TRH production in TRH neurons, their overall inhibitory effect on the thyroid axis results from indirect glucocorticoid negative feedback on structures such as the hippocampus. Disruption of hippocampal suppression of the hypothalamic-pituitary-adrenal (HPA) axis is proposed to be involved in the hypercortisolism commonly seen in affective illness, and disruption of hippocampal inputs to the hypothalamic have been shown to produce a rise in hypophysiotropic TRH in the rat.

**Starvation**

The thyroid axis is depressed during starvation, presumably to help conserve energy by depressing metabolism (see Fig. 7-18 E to G) (Figure Not Available). In humans, reduced T₃, T₄, and TSH are seen during starvation or fasting. There are also changes in the thyroid axis in anorexia nervosa, such as low blood levels of T₃ and low normal levels of T₄ (see Chapter 33). Inappropriately low levels of TSH are found, suggesting defective activation of TRH production by low thyroid hormone levels. During starvation in rodents, reduced TRH release into hypophysial portal blood and reduced pro-TRH mRNA levels are seen, despite lowered thyroid hormone levels. Reduced basal TSH levels are also usually present.

The hypothyroidism seen in fasting or in the leptin-deficient Lep⁻/⁻ Lep⁻/⁻ mouse can be reversed by administration of leptin, and the evidence suggests that the mechanism involves leptin's ability to up-regulate TRH gene expression in the PVH (see Fig. 7-18 E to G) (Figure Not Available). Leptin appears to act both directly through leptin receptors on hypophysiotropic TRH neurons and indirectly through its actions on other hypothalamic cell groups, such as arcuate nucleus POMC and NPY-agouti-related peptide (AgRP) neurons. TRH neurons in the PVH receive dense NPY-AgRP and POMC projections from the arcuate and express NPY and melanocortin-4 receptors. The regulation of TRH by metabolic state is likely to be under redundant control.

**Infection and Inflammation**

The molecular basis of infection- or inflammation-induced thyrotropin suppression is now established. Sterile abscesses or the injection of interleukin-1 (IL-1; endogenous pyrogen, a secretory peptide of activated lymphocytes) or of tumor necrosis factor (TNF-) inhibits thyrotropin secretion. TNF- inhibits thyrotropin secretion directly and induces functional changes in the rat characteristic of the "sick euthyroid" state. It is likely that the thyrotropin inhibition in animal models of the sick euthyroid syndrome is due to cytokine-induced changes in hypothalamic and pituitary function.
Area Postrema

The area postrema lies at the caudal end of the fourth ventricle adjacent to the nucleus of the solitary tract (see Fig. 7-10 and Fig. 8-66). In experimental animals such as the rat and mouse, it is a midline structure lying above the nucleus of the solitary tract. However, in humans the area postrema is a bilateral structure. As the area postrema overlies the nucleus of the solitary tract, it also receives direct visceral afferent input from the glossopharyngeal nerve (including the carotid sinus nerve) and the vagus nerve. In addition, the area postrema receives direct input from several hypothalamic nuclei. The efferent projections of the area postrema include projections to the nucleus of the solitary tract, ventral lateral medulla, and the parabrachial nucleus. Consistent with a role as a sensory organ, the area postrema is enriched with receptors for several peptide hormones including glucagon-like peptide-1 and cholecystokinin. It also contains chemosensory neurons that include osmoreceptors. Notably, the area postrema is thought to be critical in the detection of potential toxins and can induce vomiting in response to foreign substances. In fact, the area postrema is often referred to as the chemoreceptor trigger zone.

The best-described physiologic role of the area postrema is probably the coordinated control of blood pressure. For example, the area postrema contains binding sites for angiotensin II, AVP, and atrial natriuretic peptide. Moreover, lesions of the area postrema in rats blunt the rise in blood pressure induced by angiotensin II. Finally, administration of angiotensin II induces the expression of Fos in neurons of the area postrema. The area postrema has also been hypothesized to play a role in responding to inflammatory cytokines during the acute febrile response (see Fig. 7-50 and Fig. 7-51 and "Neuroendocrine-Immune Interactions").
Subcommissural Organ

The subcommissural organ (SCO) is located below the posterior commissure near the junction of the third ventricle and cerebral aqueduct below the pineal gland (see Fig. 7-10). The SCO is composed of specialized ependymal cells that secrete a highly glycosylated protein of unknown function. The secretion of this protein leads to aggregation and formation of the so-called Reissner fibers. The glycoproteins are extruded through the aqueduct, the fourth ventricle, and the spinal cord lumen to terminate in the caudal spinal canal. In humans, intracellular secretory granules are identifiable in the SCO but Reissner’s fibers are absent. The SCO secretion in humans is therefore presumed to be more soluble and to be absorbed directly from the CSF. Compared with other CVOs, relatively little is known about the physiologic role of the SCO. Hypothesized roles for the SCO include clearance of substances from the CSF.
PINEAL GLAND

Historically, the functional significance of the pineal gland has been difficult to discern. For example, Descartes called the pineal gland the "seat of the soul." The pineal gland is both an endocrine and a circumventricular organ; it is derived from cells of the roof of the third ventricle and lies above the posterior commissure near the level of the habenular complex and the sylvian aqueduct. However, neuroanatomic studies have established that light-encoded information is relayed to the pineal in an indirect and multisynaptic fashion. This series of synapses ultimately results in innervation of the gland by noradrenergic sympathetic nerve terminals that are critical regulators of melatonin production and release. Specifically, the retina provides direct innervation to the suprachiasmatic nucleus (SCN) of the hypothalamus through the retinohypothalamic tract. The SCN in turn provides input to the paraventricular nucleus of the hypothalamus (PVH), a key cell group in neuroendocrine and autonomic control. This input is provided through direct and indirect pathways by intrahypothalamic projections. The PVH in turn provides direct innervation to sympathetic preganglionic neurons in the intermediolateral cell column of the thoracic regions of the spinal cord. Sympathetic preganglionic neurons innervate postganglionic neurons in the superior cervical ganglion, which in turn provide the noradrenergic innervation to the pineal (see "Hypothalamic-Pituitary Unit"). This rather circuitous pathway is thought to represent the anatomic substrate for light to regulate the secretion of melatonin. It is important to note that in the absence of light input, the pineal gland rhythms persist but are not entrained to the external light-dark cycle.

The Pineal Is the Source of Melatonin

The predominant hormone secreted by the pineal gland is melatonin. However, the pineal also contains biogenic amines, peptides, and GABA. Pineal-derived melatonin is synthesized from tryptophan, through serotonin, with the rate-limiting

The final step of melatonin synthesis is catalyzed by hydroxyindole-O-methyltransferase (HIOMT). These enzymes are expressed in a pineal specific manner; however, hydroxyindole-O-methyltransferase is also expressed in the retina and red blood cells. It is now established that melatonin plays a key role in regulating a myriad of circadian rhythms, and a fundamental principle of circadian biology is that the synthesis of melatonin is exquisitely controlled. This control is exerted at several levels. NAT mRNA levels, NAT activity, and melatonin synthesis and release are regulated in a circadian fashion and are entrained by the light-dark cycle, with darkness thought to be the most important signal. For example, melatonin and NAT levels are highest during the dark and decrease sharply with the onset of light. Melatonin is not thought to be stored to any degree and thus is released into blood or CSF directly.

The CNS control of melatonin secretion during the dark is mediated by the neuroanatomic pathway already outlined. Lack of light ultimately results in the release of norepinephrine from postganglionic sympathetic nerve terminals that act on -adrenergic receptors in pinealocytes, resulting in an increase in adenylate cyclase activity. The resultant increased levels of cyclic adenosine monophosphate (cAMP) activate signal transduction cascades, including increased protein kinase activity and phosphorylation of cAMP response element binding protein. Notably, cAMP response elements have been identified in the promoter of NAT. Thus, light (or lack of it) acting through the sympathetic nervous system induces an increase in cAMP, representing a fundamental regulator of NAT transcription and melatonin synthesis that ultimately results in a dramatic change of melatonin levels across the day.
Physiologic Roles of Melatonin

One of the best characterized roles of melatonin is the regulation of the reproductive axis, including gonadotropin secretion and the timing and onset of puberty (see "Gonadotropin-Releasing Hormone and Control of the Reproductive Axis"). The potent regulation of the reproductive axis by melatonin is established in rodents and domestic animals such as the sheep. It was observed experimentally with the demonstration that removal of the pineal leads to precocious puberty and ameliorates the effects of constant darkness to induce gonadal involution. In addition, male rats exposed to constant darkness or made blind experimentally display testicular atrophy and decreased levels of testosterone. These profound effects are normalized by removal of the pineal gland. The physiologic significance of melatonin is probably most important in species referred to as seasonal breeders. Indeed, the role of melatonin in regulating reproductive capacity in species such as the sheep and the horse is now established. This type of reproductive strategy probably evolved to synchronize the length of day with the gestational period of the species to ensure that the offspring are born at favorable times of the year and maximize the viability of the young. Despite the potent effects of day length on reproduction in these species, exact mechanisms of melatonin regulation of GnRH release are unsettled. However, melatonin inhibits LH release from the rat pars tuberalis. The role of the pineal in human reproduction is even more unsettled. Earlier onset of menarche in blind women has been reported. In addition, a decline in melatonin at puberty has been described. However, it was not found in other studies. Thus, the role of melatonin in human reproduction is not clear. Nonetheless, the therapeutic potential of melatonin in regulating and shifting biologic rhythms in humans has received great attention.
Melatonin Receptors

It is now established that melatonin mediates its effects by acting on a family of G protein-coupled receptors, which have been characterized by pharmacologic, neuroanatomic, and molecular approaches. The first member of the family, Mel$_{1a}$, is a high-affinity receptor that was isolated originally from *Xenopus* melanophores. The second, Mel$_{1b}$, has approximately 60% homology with the Mel$_{1a}$ receptor. A third receptor, the Mel$_{1c}$ melatonin receptor, has been cloned from zebra fish, *Xenopus*, and chickens but not as yet from mammals.

The mechanisms for the effects of melatonin on regulating and entraining circadian rhythms are becoming increasingly understood. For example, melatonin inhibits the activity of neurons in the SCN of the hypothalamus, the master circadian pacemaker in the mammalian brain. Melatonin can entrain several mammalian circadian rhythms, probably by the inhibition of neurons in the SCN. Neuroanatomic evidence suggests that many of the effects of melatonin on circadian rhythms involve actions on Mel$_{1a}$ receptors, as the distribution of Mel$_{1a}$ mRNA overlaps with radiolabeled melatonin binding sites in the relevant brain regions. These sites include the SCN, the retina, and the pars tuberalis of the adenohypophysis. The Mel$_{1b}$ melatonin receptor is also expressed in retina and brain; however, this is thought to be at much lower levels.

Genetic studies in mice have also helped to illuminate the relative roles of each melatonin receptor in mediating the effects of this hormone. Targeted deletion (knockout) of the Mel$_{1a}$ receptor abolished the ability of melatonin to inhibit the activity of SCN neurons. Several studies have suggested that the inhibition of SCN neurons by melatonin is of great physiologic significance. For example, Reppert and colleagues have suggested that elevations of melatonin at night could decrease the responsiveness of the SCN to activity-related stimuli that could result in phase shifts. As noted, light potently inhibits melatonin synthesis and release. Thus, melatonin may underlie the mechanism by which light induces phase shifts. However, it should be noted that lack of the Mel$_{1a}$ gene does not block the ability of melatonin to induce phase shifts. These unexpected and somewhat confusing results have resulted in the hypothesis that Mel$_{1b}$ is involved in melatonin-induced phase shifts, as this receptor may be expressed in the human brain.
Melatonin Therapy in Humans

The role of melatonin as a "wonder drug" has received great attention from the lay press. The proposed beneficial and therapeutic uses of melatonin include treatment of jet lag, slowing or reversing the progression of aging, and enhancing immune function. As noted earlier, the most studied and established role of melatonin is that of phase shifting and resetting circadian rhythms. In this context, melatonin has been used to treat jet lag and may be effective in treating circadian-based sleep disorders. In addition, melatonin administration has been shown to regulate sleep in humans. Specifically, melatonin has a hypnotic effect at relatively low doses. Melatonin therapy has also been suggested as a way to treat seasonal affective disorders.

It is important to note that melatonin is now available over the counter and without a prescription throughout the United States. However, there is a striking paucity of controlled clinical studies of the relative efficacy and safety of melatonin administration. This should be viewed as problematic because melatonin is an endocrine hormone, and most hormones are not widely available without a prescription. Clearly, controlled clinical studies are needed to assess fully the therapeutic potential and safety of melatonin in humans.
HORMONAL FEEDBACK CONTROL SYSTEMS

HYPOTHALAMIC-REGULATED HORMONES AND NEUROENDOCRINE AXES

With the demonstration by the first half of the 1900s that pituitary secretion was controlled by hypothalamic hormones released into the portal circulation, the search was on for the hypothalamic releasing factors. The search for hypothalamic neurohormones with anterior pituitary regulating properties focused on extracts of stalk, median eminence, neural lobe, and hypothalamus from sheep and pigs. To give some idea of the herculean nature of this effort, approximately 250,000 hypothalamic fragments were required to purify and characterize the first such factor, TRH. The identification and characterization of TRH in 1970 and of other releasing hormones ultimately led to the Nobel Prize in Medicine in 1977 for Andrew Schally and Roger Guillemin. Such hypothysotropic substances were initially called releasing factors but are now more commonly called releasing hormones.

All of the hypothalamic-pituitary regulating hormones are peptides with the exception of dopamine, which is a biogenic amine that is the principal prolactin-inhibiting factor (PIF) (Table 7-3). All are now available for human investigation and treatment, and therapeutic analogues have been synthesized for dopamine, GnRH, and somatostatin.

In addition to regulating hormone release, some hypothysisotropic factors control pituitary cell differentiation and proliferation and hormone synthesis. Somatostatin and dopamine are inhibitory, and some act on more than one pituitary hormone. For example, TRH is a potent releaser of prolactin (PRL) and of thyrotropin and under some circumstances releases corticotropin and growth hormone (GH). GnRH releases both LH and follicle-stimulating hormone (FSH). Somatostatin inhibits the secretion of GH, thyrotropin, and a wide variety of nonpituitary hormones. The principal inhibitor of PRL secretion, dopamine, also inhibits secretion of thyrotropin, gonadotropin, and, under certain conditions, GH. Dual control is exerted by the interaction of inhibitory and stimulatory hypothalamic hormones. For example, somatostatin interacts with growth hormonereleasing hormone (GHRH) and TRH to control secretion of GH and thyrotropin, respectively, and dopamine interacts with prolactin-releasing factors (PRFs) to regulate PRL secretion. Some hypothalamic hormones act synergistically; for example, CRH and vasopressin act together to regulate the release of pituitary adrenocorticotropic hormone (ACTH).

Secretion of the releasing hormones in turn is regulated by

neurotransmitters and neuropeptides released by a complex array of neurons synapsing with hypothysotropic neurons. Control of secretion is also exerted through feedback control by hormones such as glucocorticoids, gonadal steroids, thyroid hormone, anterior pituitary hormones (short-loop feedback control), and hypothysisotropic factors themselves (ultrashort-loop feedback control).

The distribution of the hypothysotropic hormones is not limited to the hypothalamus. Most are also found in nonhypothysotropic hypothalamic neurons, in extrahypothalamic regions of the brain, and in other organs where they may have functions (e.g., effects on behavior or homeostasis) unrelated to pituitary regulation. Most, although not all, of the peptides, hormones, and neurotransmitters involved in the regulation of hypothalamic-pituitary control belong to the G protein-coupled receptor family (Table 7-4).

Feedback Concepts in Neuroendocrinology

In order to understand the regulation of each hypothalamic-pituitary-target organ axis, it is important to understand some basic concepts of homeostatic systems. A simplified account of feedback control in relation to neuroendocrine regulation is presented in this section. Hormonal systems form part of a feedback loop in which the controlled variable (generally the blood hormone level or some biochemical surrogate of the hormone) determines the rate of secretion of the hormone. In negative feedback systems the controlled variable inhibits hormone output, and in positive feedback control systems the controlled variable increases...
hormone secretion. Both negative and positive endocrine feedback control systems can be part of a closed loop, in which regulation is entirely restricted to the interacting regulatory glands, or an open loop, in which the nervous system influences the feedback loop. All pituitary feedback systems have nervous system inputs that either alter the set-point of the feedback control system or introduce open-loop elements that can influence or override the closed-loop control elements.

In engineering formulations of feedback, three controlled variables can be identified: a sensing element that detects the concentration of the controlled variable, a reference input that defines the proper control levels, and an error signal that determines the output of the system. The reference input is the set-point of the system.

Hormonal feedback control systems resemble engineering systems in that the concentration of the hormone in the blood (or some function of the hormone) regulates the output of the controlling gland. Hormonal feedback differs from engineering systems in that the sensor element and the reference input element are not readily distinguishable. The set-point of the controlled variable is determined by a complex cascade beginning with the kinetics of binding to a receptor and the activities of successive intermediate messengers. Sophisticated models incorporating control elements, compartmental analysis, and hormone production and clearance rates have been developed for many systems.
Virtually all functions of living animals (regardless of their position on the evolutionary scale) are subject to periodic or cyclic changes, many of which are influenced mainly by the nervous system (see Table 7-5 for definitions). Most periodic changes are free-running; that is, they are intrinsic to the organism independent of the environment and are driven by a biologic “clock.”

Most free-running rhythms can be coordinated (entrained) by external signals (cues), such as light-dark changes, meal patterns, cycles of the lunar periods, or the ratio of the length of day to the length of night. External signals of this type (zeitgeber or time givers) do not bring about the rhythm but provide

Some receptors have intrinsic tyrosine phosphorylase activity, others have intrinsic tyrosine hydroxylase activity. The former stimulate phosphorylation of tyrosine kinases; the latter stimulate breakdown of tyrosine kinase.

The designation of functional type is oversimplified. Many examples can be cited in which receptor activation can stimulate both adenylate cyclase and phosphoinositide turnover.

Receptors cited are human or rat if human not available.

Thyrotropin-Releasing Hormone

Chemistry and Evolution

TRH, the smallest known peptide hormone, is the tripeptide pyroGlui-His-Pro-NH₂. The TRH peptide sequence is repeated six times within the human TRH pre-prohormone gene (Fig. 7-13) (Figure Not Available). The rat pro-TRH precursor contains five TRH peptide repeats flanked by dibasic residues (Lys-Arg or Arg-Ang), along with seven or more non-TRH peptides. Two prohormone convertases, PC1 and PC2, cleave the TRH tripeptides at the dibasic residues within the regulated secretory pathway. Carboxypeptidase E then removes the dibasic residues, leaving the sequence Gin-His-Pro-Gly. This peptide is then amidated at the C-terminus by peptidylglycine alpha-amidating monoxygenase, with Gly acting as the amide donor. The amino-terminal pyro-Glu residue results from cyclization of the Gin.

Although the TRH tripeptide is the only established hormone encoded within its large prohormone, the rat pro-TRH yields seven additional peptides that have unique tissue distributions. Several biologic activities of these peptides have been observed: pre-pro-TRH may be a hypophysiotropic factor because it is released from hypothalamic slices and potentiates the thyrotropin-releasing effects of TRH. Pro-TRH is also released from the median eminence and appears to inhibit ACTH release.

TRH is a phylogenetically ancient peptide, being found in primitive vertebrates, such as the lamprey, and even invertebrates such as the snail. TRH is widely distributed in the hypothalamic cDNA encoding human preprothyrotropin-releasing hormone. Mol Endocrinol 1990; 4:551-556.

TRH is a phylogenetically ancient peptide, being found in primitive vertebrates, such as the lamprey, and even invertebrates such as the snail. TRH is widely expressed in both CNS and periphery in amphibians, reptiles, and fishes but does not stimulate thyrotropin release in these poikilothermic vertebrates. Thus, TRH has multiple peripheral and central activities and was co-opted as a hypophysiotropic factor midway during the evolution of vertebrates, perhaps specifically as a factor needed for coordinate regulation of temperature homeostasis.

Effects on the Pituitary Gland and Mechanism of Action

After intravenous injection of TRH in humans, serum thyrotropin levels rise within a few minutes (Fig. 7-14) followed by a rise in serum triiodothyronine (T₃) levels. There is an increase in thyroxine (T₄) release as well, but a change in blood levels of T₄ is usually not demonstrable because the pool of circulating T₄ (most of which is bound to carrier proteins) is so large. The clinical applications of TRH testing are covered later in this chapter and in Chapter 10. TRH action on the pituitary is blocked by previous treatment with thyroid hormone, which is a crucial element in feedback control of pituitary thyrotropin secretion.

TRH is also a potent PRF (Fig. 7-15). The time course of response of blood PRL levels to TRH, the dose-response characteristics, and the suppression by thyroid hormone pretreatment (all of which parallel changes in thyrotropin secretion) suggest that TRH may be involved in the regulation of PRL secretion. Moreover, TRH is present in the hypophysial-portal blood of lactating rats. However, it is unlikely to be a physiologic regulator of PRL secretion because the PRL response to nursing in humans is unaccompanied by changes in plasma thyrotropin levels. Nevertheless, TRH may occasionally cause hyperprolactinemia (with or without galactorrhea) in patients with hypothyroidism.

In normal individuals TRH has no influence on the secretions of pituitary hormones other than thyrotropin and PRL, but it enhances the release of human growth hormone (hGH) in acromegaly and of corticotropin in some patients with Cushing’s disease. Furthermore, prolonged stimulation of the normal pituitary with GHRH can sensitize it to the hGH-releasing effects of TRH. TRH also causes the release of hGH in some patients with uremia, hepatic disease, anorexia nervosa, and psychotic depression and in children with hypothyroidism. TRH inhibits sleep-induced hGH release through its actions in the CNS (see later in the section on extrapituitary actions of TRH).

Stimulatory effects of TRH are initiated by binding of the peptide to specific receptors on the plasma membrane of the thyrotroph. Neither thyroid hormone nor somatostatin, both of which antagonize the effects of TRH, interfere with its binding. TRH was originally thought to activate membrane adenylate cyclase to stimulate formation of cAMP and cAMP in turn was thought to stimulate thyrotropin secretion. However, CAMP does not increase under all conditions of TRH-induced thyrotropin release, and it is now clear that TRH action is mediated mainly through hydrolysis of phosphatidylinositol, with phosphorylation of key protein kinases and an increase in intracellular free Ca²⁺ as the crucial step in postreceptor activation. TRH effects can be mimicked by exposure to a Ca²⁺ ionophore and are partially abolished by a Ca²⁺-free medium. TRH stimulates the formation of mRNAs coding for thyrotropin and PRL, confirming that this peptide is trophic as well as a releasing factor.

TRH is degraded to acid TRH and to the dipeptide histidylprolineamide, which cyclizes nonenzymatically to histidylproline diketopiperazine (cyclic His-Pro). Acid

Figure 7-13 Structure of human thyrotropin-releasing hormone (TRH) gene and peptide, showing six repeating codons for the TRH sequence. CPE, carboxypeptidase E; PAM, peptidylglycine alpha-amidating monoxygenase; PC1, prohormone convertase 1. (From Yamada M, Radvick S, Wendtson FE, et al. Cloning and structure of human genomic DNA and hypothalamic cDNA encoding human preprothyrotropin-releasing hormone. Mol Endocrinol 1990; 4:551-556.)

Figure 7-15 Prolactin (PRL) and thyrotropin (TSH) secretory responses to intravenous injection of 800 µg of thyrotropin-releasing hormone (TRH) in humans. This figure shows that TRH induces discharge of both PRL and thyrotrophin, that the effect in females is greater than that in males (presumably owing to estrogen sensitization of the pituitary), and that thyrototoxicosis inhibits the response of both PRL and thyrotropin to TRH. An inhibitory effect on the TRH response is noted at the upper limit of the normal range of thyroid hormone levels and is a sensitive test of minor degrees of thyroid hormone excess. Although TRH is a potent prolactin-releasing factor (PRF), there is evidence that there is another PRF physiologically connected to PRL regulation. (Replotted from data of Bowers C, Friesen HG, Hwang P, et al. Prolactin and thyrotropin release in man by synthetic pyroglutamylhistidyl-prolinamide. Biochem Biophys Res Commun 1971; 45:1033-1041.)
TRH has some behavioral effects in rats that are similar to those of TRH but no other proven actions. Cyclic His-Pro is reported to act as a PRF and to have other neural effects, including reversal of ethanol-induced sleep (TRH is also effective in this system), elevation of brain cyclic guanosine monophosphate levels, an increase in stereotypic behavior, modification of body temperature, and inhibition of eating behavior. Some of the effects of TRH may be mediated through cyclic His-Pro, but the fact that cyclic His-Pro is abundant in some areas and is not proportional to the amount of TRH suggests that the peptidoe may not be derived solely from TRH.

Extrapituitary Function

TRH is present in virtually all parts of the brain: cerebral cortex, circumventricular structures, neuropehysis, pineal gland, and spinal cord. TRH is also found in pancreatic islet cells and in the gastrointestinal tract. Although it is present in low concentration, the total amount in extrahypothalamic tissues exceeds the amount in the hypothalamus.

The extensive extrahypothalamic distribution of TRH, its localization in nerve endings, and the presence of TRH receptors in brain tissue suggest that TRH serves as a neurotransmitter or neuromodulator outside the hypothalamus. TRH is a general stimulant and induces hyperthermia on intracerebroventricular injection, suggesting a role in central thermoregulation.

Clinical Applications

The use of TRH for the diagnosis of hyperthyroidism is less common since the development of ultrasensitive assays for thyroid-stimulating hormone (TSH). Its use to discriminate between hypothalamic and pituitary causes of thyrotropin deficiency has also declined because of the test’s poor specificity, but the application of ultrasensitive assays in conjunction with the TRH test has not been fully evaluated. TRH testing is also not of value in the differential diagnosis of causes of hyperprolactinemia but is useful for the demonstration of residual abnormal somatotropin-secreting cells in acromegalic patients who release hGH in response to TRH before treatment.

Studies of the effect of TRH on depression have shown inconsistent results, possibly because of poor blood-brain barrier penetration. Intrathecal administration of TRH may improve responses in depressed patients, but its clinical utility is unknown. Although a role for TRH in depression is not established, many depressed patients have a blunted thyrotropin response to TRH and changes in TRH responsiveness correlate with the clinical course. The mechanism by which blunting occurs is unknown.

TRH has been proposed as a treatment for women with threatened premature labor to stimulate the production of lung surfactant in the preterm fetus. Despite encouraging results in early studies, several large-scale trials failed to show improvement in the survival of babies so treated.

TRH has been evaluated for the treatment of spinal muscle atrophy and amyotrophic lateral sclerosis; transient improvement in strength was reported in both disorders, but the combined experience at many centers using a variety of treatment protocols including long-term intrathecal administration failed to confirm efficacy. TRH administration also reduces the severity of experimentally induced spinal and ischemic shock and head trauma. TRH has been used to treat children with neurologic disorders including West's syndrome, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy, and intractable epilepsy. TRH has been proposed to be an analeptic agent. Sleeping or drug-sedated animals were awakened by the administration of TRH, reportedly reversed sedative effects of ethanol in humans, and TRH is said to have awakened a patient with a profound sleep disorder caused by a hypothalamic and midbrain eosinophilic granuloma.

Regulation of Thyrotropin Release

The secretion of thyrotropin is regulated by two interacting elements: negative feedback by thyroid hormone and open-loop neural control by hypothalamic hypothypsyedetic factors.

In the context of a feedback system, the level of thyroid hormone in blood or of its unbound fraction is the controlled variable and the set-point is the normal resting level of plasma thyroid hormone. Secretion of thyrotropin is inversely regulated by the level of thyroid hormone so that deviations from the set-point of control lead to appropriate changes in the rate of thyrotropin secretion. Factors that determine the rate of thyrotropin secretion required to maintain a given level of thyroid hormone include the rate at which thyrotropin and thyroid hormone disappear from the blood (turnover rate) and the rate at which T4 is converted to its more active form, T3.

TRH reportedly reversed sedative effects of ethanol in human and T4 inhibition of the thyrotropin response to TRH, and barely detectable decreases in plasma thyroid hormone levels were sufficient to sensitize the pituitary to TRH. TRH stimulates thyrotropin secretion within a few minutes through its action on a membrane receptor, whereas thyroid hormone actions,
mediated by intranuclear receptors, require several hours to take effect (see Chapter 10).

The secretion of hypothalamic TRH is also regulated by thyroid hormone feedback. Systemic injections of $T_3$ or implantations of tiny $T_3$ pellets in the paraventricular nucleus of hypothyroid rats (Fig. 7-18) (Figure Not Available) reduced the concentration of TRH mRNA and TRH prohormone in TRH-secreting cells. Thyroid hormone also suppressed TRH secretion into hypophyseal-portal blood in sheep.

$T_3$ in the blood gains access to TRH-secreting neurons in the hypothalamus by way of the CSF. The hormone is taken up by epithelial cells of the choroid plexus of the lateral ventricle of the brain, bound within the cell to locally produced transferrin ($T_4$-binding protein), and then secreted across the blood-brain barrier. Within the brain, $T_3$ is converted to $T_2$ by type II deiodinase, and $T_2$ interacts with subtypes of the thyroid hormone receptor, $TR_1$, $TR_2$, and $TR_3$ in the paraventricular nucleus and other brain cells (see Chapter 10). The set-point of the pituitary-thyroid axis is determined by thyroid hormone levels within the brain. $T_3$ in the circulation is not transported into brain in this manner but presumably gains access to the paraventricular TRH neurons across the blood-brain barrier. The brain $T_3$ transport and deiodinase system account for the fact that higher levels of $T_3$ are required to suppress pituitary-thyroid function after administration of $T_3$ than after administration of $T_4$.

Transferrin is present in the brain of early reptiles and in addition is synthesized by the liver in warm-blooded animals. During embryogenesis in mammals, transferrin is first detected when the blood-brain barrier appears, ensuring thyroid hormone access to the developing nervous system.

**Neural Control**

The hypothalamus determines the set-point of feedback control around which the usual feedback regulatory responses are elicited. Lesions of the thyrotropic area lower basal thyroid hormone levels and make the pituitary more sensitive to inhibition by thyroid hormone, and high doses of TRH raise thyrotropin and thyroid hormone levels. Synthesis of TRH in the paraventricular nucleus is regulated by feedback actions of thyroid hormones. The hypothalamus can override normal feedback control through an open-loop mechanism involving neuronal inputs to the hypothysyrotropic TRH neurons (see Fig. 7-16). For example, cold exposure caused a sharp increase in thyrotropin release in animals and in human newborns. Circadian changes in thyrotropin secretion are another example of brain-directed changes in the set-point of feedback control, but if thyroid hormone levels are sufficiently elevated, as in hyperthyroidism, TRH cannot overcome the inhibition.

Hypothalamic regulation of thyrotropin secretion is also influenced by two inhibitory factors, somatostatin and dopamine. Antisomatostatin antibodies increase basal thyrotropin levels and potentiate the response to stimuli that normally induce thyrotropin release in the rat, such as cold exposure and TRH administration. Thyroid hormone in turn inhibits the release of somatostatin, implying coordinated, reciprocal regulation of TRH and somatostatin by thyroid hormone. GH stimulates hypothalamic somatostatin synthesis and can inhibit thyrotropin secretion. The role of somatostatin in the regulation of thyrotropin secretion in humans is uncertain.

Dopamine has modest effects on thyrotropin secretion, and blockade of dopamine receptors (in the human) stimulates thyrotropin secretion slightly. Changes in the metabolism of thyroid hormone also influence $T_3$ homeostasis within the brain. In states of thyroid hormone deficiency, brain $T_3$ levels are maintained by an increase in the deiodinase that converts $T_2$ to $T_3$.

The pineal gland has been reported to inhibit thyroid function in some but not all studies. The pineal gland contains TRH, and in the frog its content changes with the season and with light and dark cycles independently of hypothalamic thyrotropin.

**Circadian Rhythm**

Plasma thyrotropin in humans is characterized by a circadian periodicity, with a maximum between 9 AM and 5 PM and a minimum between 4 PM and 7 PM. Smaller ultradian thyrotropin peaks occur every 90 to 180 minutes, probably because of bursts of TRH release from the hypothalamus, and are physiologically important in controlling the synthesis and glycosylation of thyrotropin. Glycosylation is a determinant of thyrotropin potency.

**Temperature**

External cold exposure activates and high ambient temperature inhibits the pituitary-thyroid axis in animals, and analogous changes occur in humans under certain conditions. Exposure of infants to cold at birth causes an increase in blood thyrotropin levels, possibly because of alterations in the turnover and degradation of the thyroid hormones. Blood thyroid hormone levels are higher in the winter than in the summer in individuals in cold climates but not in other climates. However, it is difficult to show that changes in environmental or body temperature in adults influence thyrotropin secretion. For example, exposure to cold ambient temperature or central hypothalamic cooling does not modify thyrotropin levels in young men. Behavioral changes, activation of the sympathetic nervous system, and shivering appear to be more important in temperature regulation in adults than the thyroid response.

The autonomic nervous system and the thyroid axis work together to maintain temperature homeostasis in mammals, and TRH plays a role in both pathways. Hypothalamic TRH release is rapidly (30 to 45 minutes) increased in rats exposed to cold. Rapid inhibition of somatostatin release in the median eminence has also been documented, and both changes appear to play important roles in the rise in plasma TSH induced by cold exposure. TRH mRNA is elevated within an hour of cold exposure (see Fig. 7-18 C and D) (Figure Not Available). The regulation of hypothalamic TRH release and expression by cold is largely mediated by catecholamines. Noradrenergic and adrenergic fibers, originating in the brain stem, are found in close proximity to TRH nerve endings in the median eminence, and a rapid rise in TRH release was seen after noradrenaline treatment of hypothalamic fragments containing mainly median eminence. Brain stem adrenergic and noradrenergic fibers also make synaptic contacts with TRH neurons in the PVH (see Fig. 7-16), and thus catecholamines are likely to be involved in the regulation of TRH gene expression by cold. TRH neurons in the PVH are densely innervated by NPY terminals, and a portion of the NPY terminals arising from the C1, C2, and C3, and A1 cell groups of the brain stem and projecting to the PVH are shown to be catecholaminergic. Somatostatin, dopamine, and serotonin also play a variety of roles in the regulation of TRH.

**Stress**

Stress is another determinant of thyrotropin secretion. In humans physical stress inhibits thyrotropin release, as indicated by the finding that in the euthyroid sick syndrome low $T_3$ and $T_4$ do not cause compensatory increases in thyrotropin secretion as would occur in normal individuals.

A number of observations demonstrate interactions between the thyroid and adrenal axes. Physiologically, the bulk of evidence suggests that glucocorticoids in humans and rodents act to blunt the thyroid axis through actions in the CNS. Some actions may be direct because the TRH gene (see Fig. 7-13) (Figure Not Available) contains the glucocorticoid response element consensus sequence and hypothalamic TRH neurons appear to contain glucocorticoid receptors. The diurnal rhythm of cortisol is opposite that of TSH (see Fig. 7-12) (Figure Not Available) and acute administration of glucocorticoids can block the nocturnal rise in
TSH, but disruption of cortisol synthesis with metyrapone only modestly affects the TSH circadian rhythm.  

Several lines of evidence, however, identify conditions in which elevated glucocorticoids are associated with stimulation of the thyroid axis. Human depression is often associated with hypercortisolism and hyperthyroxinemia, and TRH mRNA levels are elevated by glucocorticoids in a number of cell lines as well as in cultured fetal hypothalamic TRH neurons from the rat. Thus, although glucocorticoids probably stimulate TRH production in TRH neurons, their overall inhibitory effect on the thyroid axis results from indirect glucocorticoid negative feedback on structures such as the hippocampus. Disruption of hippocampal suppression of the hypothalamic-pituitary-adrenal (HPA) axis is proposed to be involved in the hypercortisolemia commonly seen in affective illness, and disruption of hippocampal inputs to the hypothalamus have been shown to produce a rise in hypophysiotropic TRH in the rat.  

Starvation  

The thyroid axis is depressed during starvation, presumably to help conserve energy by depressing metabolism (see Fig. 7-18 E to G) (Figure Not Available). In humans, reduced T3, T4, and TSH are seen during starvation or fasting. There are also changes in the thyroid axis in anorexia nervosa, such as low blood levels of T3 and low normal levels of T4 (see Chapter 33). Inappropriately low levels of TSH are found, suggesting defective activation of TRH production by low thyroid hormone levels. During starvation in rodents, reduced TRH release into hypophyseal portal blood and reduced pro-TRH mRNA levels are seen, despite lowered thyroid hormone levels. Reduced basal TSH levels are also usually present.

The hypothyroidism seen in fasting or in the leptin-deficient Lepob/Lepob mouse can be reversed by administration of leptin, and the evidence suggests that the mechanism involves leptin's ability to up-regulate TRH gene expression in the PVH (see Fig. 7-18 E to G) (Figure Not Available). Leptin appears to act both directly through leptin receptors on hypophysiotropic TRH neurons and indirectly through its actions on other hypothalamic cell groups, such as arcuate nucleus POMC and NPY-agouti-related peptide (AgRP) neurons. TRH neurons in the PVH receive dense NPY-AgRP and POMC projections from the arcuate and express NPY and melanocortin-4 receptors, and -MSH administration partially prevents the fasting-induced drop in thyroid hormone levels. Indeed, the TRH promoter contains a signal transducer and activator of transcription (STAT) response element and a cAMP response element that have been demonstrated to mediate induction of TRH gene expression by leptin and -MSH, respectively, in a heterologous cell system (see Fig. 7-13) (Figure Not Available).  

The regulation of TRH by metabolic state is likely to be under redundant control, however, because, unlike rodents, leptin-deficient children are euthyroid, and both melanocortin-4 receptor (MC4R)deficient rodents and humans are euthyroid. Central TRH outside the paraventricular nucleus also plays a role in thermoregulation through the autonomic nervous system.  

Infection and Inflammation  

The molecular basis of infection- or inflammation-induced thyrotropin suppression is now established. Sterile abscesses or the injection of interleukin-1 (IL-1; endogenous pyrogen, a secretory peptide of activated lymphocytes) or of tumor necrosis factor (TNF-) inhibits thyrotropin secretion, TNF- inhibits thyrotropin secretion directly and induces functional changes in the rat characteristic of the "sick euthyroid" state. It is likely that the thyrotropin inhibition in animal models of the sick euthyroid syndrome is due to cytokine-induced changes in hypothalamic and pituitary function. IL-6, IL-1, and TNF- contribute to the suppression of TSH in the sick euthyroid syndrome.
Corticotropin-Releasing Hormone

Chemistry and Evolution

The HPA axis is the humoral component of an integrated neural and endocrine system that functions to respond to internal and external challenges to homeostasis (stressors). The system comprises the neuronal pathways linked to release of catecholamines from the adrenal medulla (fight-or-flight response) and the hypothalamic-pituitary control of ACTH release in the control of glucocorticoid production by the adrenal cortex. Pituitary ACTH release is stimulated primarily by CRH and to a lesser extent by AVP (see Chapter 9). The hypophysiotropic CRH neurons are located in the paraventricular division of the PVH and project to the median eminence (see Fig. 7-6 (Figure Not Available) Fig. 7-7 Fig. 7-8 Fig. 7-9).

In a broader context, the CRH system in the CNS is also quite important in the behavioral response to stress. This complex system includes not only nonhypophysiotropic CRH neurons but also three CRH-like peptides (urocortin I, urocortin II or stresscopin-like peptide, and urocortin III or stresscopin), at least two cognate receptors (CRH-R1 and CRH-R2), and a high-affinity CRH-binding protein, each with distinct and complex distributions in the CNS.

The Schally and Guillemin laboratories demonstrated in 1955 that extracts from the hypothalamus stimulated ACTH release from the pituitary. The primary active principle, CRH, was purified and characterized from the sheep in 1981 by Vale and colleagues. Human CRH is an amided 41-amino-acid peptide that is cleaved from the carboxyl terminus of a 196-amino-acid pro-hormone precursor by PC1 and PC2 and amidated (Fig. 7-7B). In general, the peptide is highly conserved; the human peptide is identical in sequence to the mouse and rat peptides but differs at seven residues from the ovine sequence. CRH and urocortin I, II, and III in mammals, fish urotensin, anuran sauvagine, and the insect diuretic peptides are members of an ancient family of peptides that evolved from an ancestral precursor early in the evolution of metazoans, approximately 500 million years ago. Comparison of peptide sequences in the vertebrate suggests grouping of the peptides into two families, CRH-urotensin-urocortin-sauvagine and urocortin II-urocortin III (Fig. 7-29). Urocortin and sauvagine appear to represent tetrapod orthologues of fish urotensin. Sauvagine, isolated originally from Phyllomedusa sauvagei, is an osmoregulatory peptide produced in the skin of certain frogs; urotensin is an osmoregulatory peptide produced in the cauliflower secretory system of the fish. Whereas isolation of CRH required 250,000 ovine hypothalami, the cloning of urocortin II and III was accomplished by computer search of the human genome database.

The CRH peptides signal by binding to CRH-R1 and CRH-R2 receptors that are members of the gut-brain family of G protein-coupled receptors and couple to Gs and activation of adenyl cyclase. Two splice variants of the latter that differ in the extracellular amino-terminal domain, CRH-R2 and CRH-R2, have been found in both rodents and humans, and a third N-terminal splice variant, CRH-R2, has been reported in the human. CRH, urotensin, and sauvagine are all potent agonists of CRH-R1, urocortin is a potent agonist of both receptors, and urocortins II and III are specific agonists of CRH-R2. CRH-mediated activation of the HPA axis appears to be exclusively mediated through CRH-R1 expressed in the corticotroph. The PVH is the site of the majority of CRH neurons projecting to the median eminence, although some CRH neurons projecting to the median eminence are found in most hypothalamic nuclei (Fig. 7-21A). Some CRH fibers in the PVH also project to the brain stem, and CRH neurons are also found elsewhere, primarily in limbic structures involved in processing sensory information and in regulating the autonomic nervous system. Sites include the prefrontal, insular, and cingulate cortices; amygdala; substantia nigra; periaqueductal gray; locus coeruleus; nucleus of the solitary tract; and parabrachial nucleus. In the periphery, CRH is found in human placenta, where it is up-regulated 6-fold to 40-fold during the third trimester; lymphocytes; autonomic nerves; and gastrointestinal tract. Urocortin is found at highest levels in the Edinger-Westphal nucleus, lateral superior oliv, and supraoptic nuclei of the rostral brain with, additional sites including the substantia nigra, ventral tegmental area, and dorsal raphe (Fig. 7-21B). In the human, urocortin is widely distributed with highest levels in the frontal cortex, temporal cortex, and hypothalamus and has also been reported in the Edinger-Westphal and olivary nuclei. In the periphery, urocortin is seen in placenta, mucosal inflammatory cells in the gastrointestinal tract, lymphocytes, and cardio myocytes. The tissue distribution of urocortins II and III is not well characterized as of this writing.

In addition to its expression in pituitary corticotrophs, CRH-R1 is found in the neocortex and cerebellar cortex, subcortical limbic structures, and amygdala, with little to no expression in the hypothalamus (Fig. 7-21C). CRH-R1 is also found in a variety of peripheral sites in humans, including ovary, endometrium, and skin. CRH-R2 is found mainly in the brain in rodents, with high levels of expression seen in the ventromedial hypothalamic nucleus and lateral septum (see Fig. 7-21C). CRH-R2 is seen centrally in cerebral arterioles and peripherally in gastrointestinal tract, heart, and muscle. In contrast, in humans CRH-R2 is seen in brain and periphery, and the and subtypes are primarily central. Little CRH-R2 message is seen in pituitary. Although CRH-R1 appears to be exclusively involved in regulation of pituitary ACTH synthesis and release, both receptors have been found to be expressed in the rodent adrenal cortex. Data suggest that this intra-adrenal CRH-ACTH system may be involved in fine-tuning of adrenocortical corticosterone release.

The CRH system is also regulated in both brain and periphery by a 37-kd high-affinity CRH-binding protein. This factor was initially postulated from the observation that CRH levels rise dramatically during the second and third trimesters of pregnancy without activating the pituitary-adrenal axis. Among hypophysiotropic factors, CRH is the only one for which a specific binding protein (in addition to the receptor) exists in tissue or blood. The placenta is the principal source of pregnancy-related CRH-binding protein. Human and rat CRH-binding proteins are homologous (85% amino acid identity), but in the rat the protein is expressed only in brain. The binding protein is species specific; bovine CRH, which is almost identical in sequence to rat-human CRH, has a lower affinity of binding to the human binding protein.

The functional significance of the CRH-binding protein is not fully understood. CRH-binding protein does not bind to the CRH receptor but does inhibit CRH action. For this reason CRH-binding protein probably acts to modulate CRH actions at the cellular level. Corticophin cells in the anterior pituitary have membrane CRH receptors and intracellular CRH-binding protein; conceivably, the binding protein acts to sequester or terminate the action of membrane-bound CRH. CRH-binding protein is present in many regions of the CNS, including cells that synthesize CRH and cells that receive innervation from CRH-containing neurons. The anatomic distribution of the protein, the variability of its location in relation to the presence of CRH, and its relative sparseness in the CRH tuberohypophysal neuronal system suggest a control system that is as yet poorly understood.

Figure 7-19 Structure of human corticotropin-releasing hormone (CRH) gene and protein. The sequence coding for CRH occurs at the terminus of the prohormone. Cleavage sites and the terminal Gly position are shown. PAM, peptidylglycine alpha-amidating monooxygenase; PC1/PC2, prohormone convertases 1 and 2; CRE, glucocorticoid regulating element; AMP, cyclic AMP-responsive element; UTR, untranslated. (Redrawn from data of Shibahara S, Morimoto Y, Furutani Y, et al. Isolation and sequence analysis of the human corticotropin-releasing factor precursor gene. EMBO J 1983;2:75779.)

Figure 7-20 Sequence comparison of members of the corticotropin-releasing hormone (CRH) peptide family. SPP, stresscopin related peptide; SCP, stresscopin.
Structure-activity relationship studies have demonstrated that C-terminal amidation and an -helical secondary structure 129 are both important for biologic activity of CRH. The first CRH antagonist described was termed -helical CRH12. A second, more potent antagonist, termed astressin, had the structure cyclo(3033)(-Phe11, Nle12, Gu13, Lys15, JhCRH27). Both peptides are somewhat nonspecific, antagonizing both CRH-R1 and CRH-R2. Because of the anxiogenic activity of CRH and urocortin, a number of pharmaceutical companies have developed small molecule CRH antagonists; several of the

(From Swanson LW, Sawchenko PE, Rivier J, et al. Organization of ovine corticotropin-releasing factor immunoreactive cells and fibers in the rat brain: an immunohistochemical study. Neuroendocrinology 1983; 36:165186; Bittencourt et al. J Comp Neurol 1999; 415:285, Fig. 17; Steckler and Holste. Biol Psychol 1999; 46:1490, Fig. 1.)

molecules are currently in clinical trials for anxiety and depression (discussed in more detail later). Thus far, this structurally diverse group of small molecule compounds, such as antalarmin, CP-154,526, and NBI27914, are potent antagonists of CRH-R1, with little activity at CRH-R2. The efficacy of these compounds across the entire behavioral, neuroendocrine, and autonomic repertoire of response to stress has been demonstrated in a number of laboratory animal studies. For example, oral administration of antalarmin in a social stress model in the primate (introduction of strange males) reduced behavioral measures of anxiety such as lack of exploratory behavior, decreased plasma ACTH and cortisol, and reduced plasma epinephrine and norepinephrine. A peptide antagonist with 100-fold selectivity for the CRH 2 receptor, ( -Phe11, His13, Jh14, Jh15) sauvagine 1140 or antisauvagine-30, has also been described. 130 Effects on the Pituitary and Mechanism of Action

Administration of CRH to humans causes prompt release of corticotropin into the blood, followed by secretion of cortisol (Fig. 7-22) and other adrenal steroids including aldosterone. 131,132 Most studies have used ovine CRH, which is more potent and longer acting than human CRH, but human and porcine CRHs appear to have equal diagnostic value. 133 The effect of CRH is specific to corticotropin release and is inhibited by glucocorticoids.

As mentioned before, CRH acts on the pituitary corticotroph primarily by binding to CRH-R1 and activating adenyl cyclase. The concentration of cAMP in the tissue is increased in parallel with the biologic effects and is reduced by glucocorticoids. The rate of transcription of the mRNA that encodes the corticotropin prohormone POMC is also enhanced by CRH, indicating that CRH is a trophic factor as well as a releasing hormone.

Figure 7-22 Changes in plasma levels of corticotropin and serum levels of cortisol after intravenous injection of corticotropin-releasing hormone in a group of six normal men. The initial prompt response in corticotropin is followed by a delayed secondary change in cortisol. To convert corticotropin values to picograms per liter, multiply by 0.2202. To convert cortisol values to milligrams per liter, multiply by 27.59. ACTH, adrenocorticotropic hormone. (From Grossman A, Kruysseman ACN, Perry L, et al. New hypothalamic hormone, corticotropin-releasing factor, specifically stimulates the release of adrenocorticotropic hormone and cortisol in man. Lancet 1982; 1:921922.)

Extrapituitary Functions

CRH and the urocortin peptides have a wide range of biologic activities in addition to the hypophyseotropic role of CRH in regulating ACTH synthesis and release. Centrally, these peptides have behavioral activities in anxiety, mood, arousal, locomotion, reward, and feeding 134,135,136 and increase sympathetic activation. Many of the nonhypophyseotropic behavioral and autonomic functions of these peptides can be viewed as complementary to activation of the HPA axis in the maintenance of homeostasis under exposure to stress. In the periphery, activities have been reported in immunity, cardiac function, gastrointestinal function, and reproduction.

The CRH and urocortin peptides have a repertoire of behavioral and autonomic actions after central administration that suggests a role for these pathways in mediating the behavioral-autonomic components of the stress response. Hyperactivity of the HPA axis is a common neuroendocrine finding in affective disorders (Fig. 7-23) (for reviews see references 133,137,138). Furthermore, normalization of HPA regulation is highly predictive of successful treatment. Defective dexamethasone suppression of CRH release, implying defective corticosterone receptor signaling, 139 is seen not only in depressed patients but also in healthy subjects with a family history of depression. 140 Depressed patients also show elevated levels of CRH in the CSF. 141

Central administration of CRH or urocortin activates neuronal cell groups involved in cardiovascular control and increases blood pressure, heart rate, and cardiac output. 142 However, urocortin is expressed in cardiac myocytes, 143 and intravenous administration of CRH or urocortin decreases blood pressure and increases heart rate in most species, including humans. 144 This hypertensive effect is probably mediated peripherally because ganglion blockade did not disrupt the hypotensive effects of intravenous urocortin. 145 Furthermore, high levels of CRH-R2 have been seen in the cardiac atria and ventricles. 146,147,148,149 and knockout of the CRH-R2 gene in the mouse removed the hypotensive effects of intravenous urocortin administration. 145,147,148

CRH and AVP also play an important role in the regulation of inflammatory responses. As described later (“Neuroendocrine-Immune Interaction”), cytokines play an important role in extinguishing inflammatory responses through activation of CRH and AVP neurons in the paraventricular nucleus and subsequent elevation of antiinflammatory glucocorticoids. Interestingly, CRH is generally seen to be proinflammatory in the periphery, where it is found in sympathetic efferents, sensory afferent nerves, leukocytes, and in macrophages in some species. 150

CRH is also made as a paracrine factor by the endometrium, where it may play a role in decidualization and implantation and act as a uterine vasodilator. 151

The relative contributions of each of the CRH-urocortin peptides and receptors to the different biologic functions reported has been the topic of considerable analysis, given the receptor-specific antagonists already described as well as the CRH. 129 CRH-R1, 132 CRH-R2, 152,153 and knockout mice available for study. 152,153 Examining three potent stressorstrastress, ether, and fastingthese studies demonstrated that other ACTH secretagogues, such as vasopressin, oxytocin, and catecholamines, could not replace CRH in its role in mounting the stress response. In contrast, augmentation of glucocorticoid secretion by a stressor after prolonged stress was not effective in the CRH knockout mouse, implicating CRH-independent mechanisms. 154

Although CRH is a potent anxiogenic peptide, 155 the CRH knockout mouse exhibits normal anxiety behaviors in, for example, conditioned fear paradigms. 156 The nonpeptide CRH-R1 specific antagonist CP-154,526 was anxiolytic in a shock-induced freezing paradigm in both wild-type and CRH knockout mice, 156 suggesting that the anxiogenic activity is a CRH-like peptide acting at the CRH-R1 receptor.
CRH and urocortin peptides also have potent anorexigenic activity, implicating the CRH system in stress-induced inhibition of feeding. Stress-induced inhibition of feeding remained intact, however, in the CRH knockout mouse.\textsuperscript{364} Likewise, suppression of the proestrous LH surge by restraint was intact in the CRH knockout mouse.\textsuperscript{365} Both CRH-R1 and CRH-R2 knockout strains had normal weight and feeding behavior but were distinctly different from wild-type mice in the anorexigenic response to centrally administered urocortin or CRH. The CRH-R1 deficient mice lacked the acute anorexigenic response (0 to 1.5 hours) to urocortin seen in wild-type mice.\textsuperscript{366} Both wild-type and CRH-R1 / mice exhibited comparable reduction in feeding 3 to 11 hours after administration. In contrast, the late phase of urocortin responsiveness appeared to depend on the presence of CRH-R2.\textsuperscript{367} Thus, signaling through CRH-R1 and CRH-R2 appears to play a complex role in the acute effects of stress on feeding behavior.

Clinical Applications

No useful therapeutic applications of CRH or CRH-like peptides have been reported, although the peptide has been demonstrated to have a number of activities in human and primate studies. For example, intravenous administration of CRH was found to stimulate energy expenditure and has been proposed for use in weight loss. The development of small molecule, orally available, CRH-R1 antagonists has, however, led to phase I clinical trials for anxiety and depression. An early study of 20 patients demonstrated significant reductions in scores of anxiety and depression, using ratings determined by either patient or clinician.\textsuperscript{368}

Feedback Control

The administration of glucocorticoids inhibits corticotropin secretion; removal of the adenals (or administration of drugs that impair secretion of glucocorticoids) leads to increased corticotropin release. The set-point of pituitary feedback is determined by the hypothalamus acting through hypothalamic releasing hormones CRH and vasopressin. The synthesis of their respective mRNAs are inhibited.\textsuperscript{369} Glucocorticoids act on both the pituitary corticotrophs and the hypothalamic neurons that secrete CRH and vasopressin. These regulatory actions are analogous to the control of the pituitary-thyroid axis. However, whereas thyrotropin becomes completely unresponsive to TRH when thyroid hormone levels are sufficiently high, severe neurogenic stress and large amounts of CRH can break through the feedback inhibition by glucocorticoids. A still higher level of feedback control is exerted by glucocorticoid-responsive neurons in the hippocampus that project to the hypothalamus; these neurons affect the activity of CRH hypophysiotropic neurons and determine the set-point of pituitary responsiveness to glucocorticoids.\textsuperscript{370}

Glucocorticoids are lipid soluble and enter the brain through the blood-brain barrier.\textsuperscript{371} In brain and pituitary they can bind to two receptors, type I (the mineralocorticoid receptor, so named because it binds aldosterone and glucocorticoids with high affinity) and type II (the glucocorticoid receptor, which has low affinity for mineralocorticoids).\textsuperscript{372} Glucocorticoid action involves binding of the steroid-receptor complex to regulator sequences in the genome.\textsuperscript{373} Type I receptors are saturated by basal levels of glucocorticoids, whereas type II receptors are not saturated under basal conditions but approach saturation during peak phases of the circadian rhythm and during stress. These differences and differences in regional distribution within the brain suggest that type I receptors determine basal activity of the hypothalamic-pituitary axis and that type II receptors mediate stress responses.

In the pituitary, glucocorticoids inhibit secretion of corticotropin and the synthesis of POMC mRNA in the hypothalamus, the secretion of CRH and vasopressin and the synthesis of their respective mRNAs is inhibited.\textsuperscript{374} Glucocorticoids may also act directly on neuronal cell membranes to change corticotropin secretion rapidly.\textsuperscript{375}

Glucocorticoids block stress-induced corticotropin release. The latency of the inhibitory effect is so short (less than 30 minutes)\textsuperscript{376} that it is possible that gene regulation is not the sole basis of the response. Long-term suppression (more than 1 hour) clearly acts through genomic mechanisms. Glucocorticoid receptors are also found outside the hypothalamus in the septum and amygdala,\textsuperscript{377} structures that are involved in the emotional changes in hypercortisolism and hypocortisolism. Hippocampal neurons are damaged by prolonged elevation of glucocorticoids during prolonged stress.

Neural Control

Significant physiologic or psychological stressors evoke an adaptive response that commonly includes activation of both the HPA axis and the sympathoadrenal axis. The end products of these pathways then help to mobilize resources to cope with the physiologic demands in emergency situations, acutely through the fight-or-flight response and over the long term through systemic effects of glucocorticoids on functions such as gluconeogenesis and energy mobilization (see Chapter 33). The HPA axis also has unique stress-specific homeostatic roles, the best example being the role of glucocorticoids in down-regulating immune responses after infection and other events that stimulate cytokine production by the immune system (see “Neuroendocrine-Immune Interactions”).

The paraventricular nucleus is the primary hypothalamic nucleus responsible for providing the integrated whole-animal response to stress.\textsuperscript{378} This nucleus contains three major types of effector neurons that are spatially distinct from one another within it: (1) magnocellular oxytocin and vasopressin neurons that project to the posterior pituitary and participate in the regulation of blood pressure, fluid homeostasis, lactation, and parturition; (2) neurons projecting to the brain stem and spinal cord that regulate a variety of autonomic responses including sympathoadrenal activation; and (3) parvocellular CRH neurons that project to the median eminence and regulate ACTH synthesis and release. Many CRH neurons coexpress AVP, which acts as an auxiliary ACTH secretagogue, synergistic with CRH to maintain regular circadian variation in parvocellular versus magnocellular neurons but is also regulated somewhat differently from CRH by stresses on parvocellular cells expressing both peptides.\textsuperscript{379} Different stressors result in different patterns of activation of the three major visceromotor cell groups within the paraventricular nucleus, as measured by the general neuronal activation marker c-fos (Fig. 7-24).\textsuperscript{380} For example, salt loading down-regulates CRH mRNA in parvocellular CRH cells, up-regulates CRH in a small number of magnocellular CRH cells, but only activates magnocellular cells. Hemorrhage activates every division of the paraventricular nucleus, whereas cytokine administration primarily activates parvocellular CRH cells with some minor activation of magnocellular and autonomic divisions.

The synthesis and release of AVP, which regulates renal water absorption and vascular smooth muscle, are controlled mainly by the volume and toxicity of the blood. This information is relayed to the magnocellular AVP cell through the nucleus of the solitary tract and A1 noradrenergic cell group of the ventrolateral medulla and projections from a triad of CVGs lining the third ventricle, the SFO, MePO, and OVLT. Oxytocin is primarily involved in reproductive functions, such as parturition, lactation, and milk ejection, although it is cosecreted with AVP in response to osmotic and volume challenges, and oxytocin cells receive direct projections from the nucleus of the solitary tract as well as from the SFO, median preoptic nucleus (MePO), and OVLT. In contrast to the neurosecretory neurons functionally defined by the three peptides, CRH, oxytocin, and AVP, PVH neurons projecting to brain stem and spinal cord include neurons expressing each of these peptides.

In the rodent, a wide variety of stressors have been determined to activate parvocellular CRH neurons, including cytokine injection, salt loading, hemorrhage, adrenalectomy, restraint, foot shock, hypoglycemia, fasting, and other exposure. Thus, in contrast to the simplicity of inputs to magnocellular cells (Fig. 7-25A), it is not surprising that parvocellular CRH neurons receive a diverse and complex assortment of inputs (Fig. 7-26; see Fig. 7-25B). These may be divided into three major categories, brain stem, limbic forebrain, and hypothalamus. Because the PVH is not known to receive any direct projections from the cerebral cortex or thalamus, stressors involving emotional or cognitive processing must induce activity to the PVH.

Visceral sensory input to the PVH involves primarily two pathways. The nucleus of the solitary tract, the primary recipient of sensory information from the thoracic and abdominal viscera, sends dense catecholaminergic projections to the PVH, both directly and through relays in the ventrolateral medulla.\textsuperscript{384} These brain stem projections account for about half of the NPY fibers present in the PVH, exclusively through projections to the thalamus, stressors involving emotional or cognitive processing must involve activity to the PVH. By contrast, what are termed neurogenic, emotional, or psychological stressors involve, in addition, nociceptive or somatosensory pathways as well as cognitive and affective brain centers. Using elevation of c-fos as an indicator of neuronal activation, detailed studies have compared PVH-projecting neurons activated by IL-1
treatment (systemic stressor) versus foot shock (neurogenic stressor). Only catecholaminergic solitary tract nucleus and ventrolateral medulla neurons were activated by moderate doses of IL-1. In contrast, foot shock activated neurons of the solitary tract nucleus and ventrolateral medulla but also cell groups in the limbic forebrain and hypothalamus. Notably, pharmacologic or mechanical disruption of the ascending catecholaminergic fibers blocked IL-1-mediated activation but not foot shock-mediated activation of the HPA axis. Data suggest that pathways activated by other neurogenic and systemic stressors may overlap significantly with those activated by foot shock and IL-1 treatment, respectively.

Except for the catecholaminergic neurons of the nucleus of the solitary tract and ventrolateral medulla, parts of the bed nucleus of the stria terminals, and the dorsomedial nucleus of the hypothalamus, many inputs to the paraventricular nucleus, such as those deriving from the prefrontal cortex and lateral septum, are thought to act indirectly through local hypothalamic glutamatergic and GABAergic neurons with direct synapses to the CRH neurons. The bed nucleus of the stria terminals is the only limbic region with prominent direct projections to the PVH. With substantial projections from the amygdala, hippocampus, and septal nuclei, it may thus serve as a key integrative center for transmission of limbic information to the PVH.

Other Factors Influencing Secretion of Corticotropin

Circadian Rhythms

Levels of corticotropin and cortisol (in humans) peak in the early morning, fall during the day to reach a nadir at about midnight, and begin to rise between 1 AM and 4 AM (see Fig. 7-12) (Figure Not Available). Within the circadian cycle approximately 15 to 18 pulses of corticotropin can be discerned, their height varying with the time of day. The set-point of feedback control by glucocorticoids also varies in a circadian pattern. Pituitary-adrenal rhythms are entrained to the light-dark cycle and can be changed over several days by exposure to an altered light schedule. It has long been assumed that the rhythm of corticotropin secretion is driven by CRH rhythms, and CRH knockout mice were found to exhibit no circadian rhythm in corticosterone production. Remarkably, however, a diurnal rhythm in corticosterone was restored by a constant infusion of CRH to the CRH knockout mouse, suggesting that CRH is necessary to permit pituitary or adrenal responsiveness to another diurnal rhythm generator.

Corticotropin Releaseinhibiting Factor

Disconnection of the pituitary from the hypothalamus in several species leads to increased basal levels of corticotropin, and certain responses to physical stress (in contrast to psychological stress) are retained in such animals. These observations have led several investigators to postulate the existence of a corticotropin inhibitory factor analogous to dopamine in the control of PRL secretion and to somatostatin in the control of GH secretion. Candidate hypothalamic peptides to inhibit corticotropin release at the level of the pituitary include atrial natriuretic peptide, activins and inhibins, and sequence 178 to 199 of the TRH prohormone. There is not yet a consensus on the existence of a physiologically relevant corticotropin releaseinhibiting factor or on its identity.
HYPOPHYSOTROPIC HORMONES AND NEUROENDOCRINE AXES (Continued)

Growth HormoneReleasing Hormone

Evidence for neural control of GH secretion came from studies of its regulation in animals with lesions of the hypothalamus and from the demonstration that hypothalamic extracts stimulate the release of GH from the pituitary. When it was shown that GH is released episodically, follows a circadian rhythm, responds rapidly to stress, and is blocked by pituitary stalk section, the concept of neural control of GH secretion became a certainty. However, it was only with the discovery of the paraneoplastic syndrome of ectopic GHRH secretion by pancreatic adenomas in humans that sufficient starting material became available for peptide sequencing and subsequent cloning of a complementary deoxynucleotidic acid (cDNA).

Two principal molecular forms of GHRH occur in human hypothalamus: GHRH(144)-NH₂ and GHRH(140)-OH (Fig. 7-27). As with other neuropeptides, the various forms of GHRH arise from post-translational modification of a larger prohormone. The NH₂-terminal tyrosine of GHRH (or histidine in rodent GHRHs) is essential for bioactivity, but a COOH-terminal NH₂ group is not. Fragments as short as (129)-NH₂ are active, but GHRH(127)-NH₂ is inactive. A circulating type IV dipeptidylpeptidase potently inactivates GHRH to its principal and more stable metabolite, GHRH(344)-NH₂, which accounts for most of the immunoreactive peptide detected in plasma. As in the case of LHRH, there are species differences among GHRHs; the peptides from seven species range in sequence homology with the human peptide from 93% in the pig to 67% in the rat. The COOH-terminal end of GHRH exhibits the most sequence diversity among species, consistent with the exon arrangement of the gene and dispensability of these residues for GHRH receptor binding.

Despite its importance for the elucidation of GHRH structure, ectopic secretion of the peptide is a rare cause of acromegaly. Fewer than 1% of acromegalic patients have elevated plasma levels of GHRH (see Chapter 8). Approximately 20% of pancreatic adenomas and 5% of carcinoid tumors contain immunoreactive GHRH, but most are clinically silent.

In addition to expression in the hypothalamus, the GHRH gene is expressed eutopically in human ovary, uterus, and placenta, although its function in these tissues is not known. Studies in rat placenta indicate that an alternative transcriptional start site 10 kilobases upstream from the hypothalamic promoter is utilized together with an alternatively spliced exon 1a.

The GHRH receptor is a member of a subfamily of G protein-coupled receptors that includes receptors for VIP, pituitary adenyl cyclase-activating peptide, secretin, glucagon, glucagon-like peptide 1, calcitonin, parathyroid hormone or parathyroid hormone-related peptide, and gastric inhibitory polypeptide. GHRH elevates intracellular cAMP by its receptor coupling to a stimulatory G protein (Gs), which activates adenyl cyclase, increases intracellular free Ca²⁺, releases preformed GH, and stimulates GH mRNA transcription and new GH synthesis (see Chapter 8). GHRH also increases pituitary phosphatidylinositol turnover. Nonsense mutations in the human GHRH receptor gene are the cause of rare familial forms of GH deficiency and indicate that no other gene product can fully compensate for the specific receptor in pituitary.

Effects on the Pituitary and Mechanism of Action

Intravenous administration of GHRH to individuals with normal pituitaries caused a prompt, dose-related increase in serum GH that peaked between 15 and 45 minutes, followed by a return to basal levels by 90 to 120 minutes (Fig. 7-28). A maximally stimulating dose of GHRH is approximately 1 µg/kg, but the response differs considerably between individuals and within the same individual tested on different occasions, presumably because of cosecretagogue and somatostatin tone that exists at the time of GHRH injection. Repeated bolus administration or sustained infusions of GHRH over several hours cause a modest decrease in the subsequent GH secretory response to acute GHRH administration. However, unlike the marked desensitization of the LHRH receptor and decline in circulating gonadotropins that occur in response to continuous LHRH exposure, pulsatile GH secretion and insulin-like growth factor I (IGF-I) production are maintained by constant GHRH in the human. This response suggests the involvement of additional factors that mediate the intrinsic
GH secretion is regulated by hypothalamic GHRH and somatostatin interacting with circulating hormones and additional modulatory peptides at the level of both the pituitary hormones other than GH may also limit the applicability of GHS therapy. Finally, apart from actions on GH secretion, both GHRH and GHSs are being exploited in a cloning strategy that led to the identification of a G protein-coupled receptor GHS-R that is highly selective for the GH secretagogue class of ligands. The GHS-R is unrelated to the GHRH receptor and is highly expressed in the anterior pituitary gland and multiple brain areas, including the medial basal hypothalamus, the hippocampus, and the mesencephalic nuclei that are centers of dopamine and serotonin production. Peptidyl and nonpeptidyl GHSs are active when administered by intranasal and oral routes, are more potent on a weight basis than GHRH itself, are more effective in vivo than in vitro, synergize with coadministered GHRH and are almost ineffective in the absence of GHRH, and do not suppress somatostatin secretion. Prolonged infusions of GHRP amplify pulsatile GH secretion in normal men. GHRP administration, like that of GHRH, facilitates slow wave sleep. Patients with hypothalamic disease leading to GH deficiency have low or no response to hexarelin; similarly, pediatric patients with complete absence of the pituitary stalk have no GH secretory response to hexarelin.

GHRH has several known extrapituitary functions. The most important may be its activity as a sleep regulator. The administration of nocturnal GHRH boluses to normal men significantly increased the density of slow wave sleep, as also shown in other species. Furthermore, there is a striking correlation between the age-related declines in slow wave sleep and daily integrated GH secretion in healthy men. These and other data suggest that central GH secretion is under circadian entrainment and nocturnal elevations in GH secretion amplitude or frequency directly mediate sleep stage and sleep-induced increases in GH secretion.

GHRH has been reported to stimulate food intake in rats and sheep, and the effect is dependent on route of administration, time of administration, and macronutrient composition of the diet. The neuropeptide's physiologic relevance to feeding in humans is unknown, although a study indicated that GHRH stimulated food intake in patients with anorexia nervosa but reduced it in patients with bulimia or in normal female control subjects.

**Extrapituitary Functions**

GHRH has few known extrapituitary functions. In studies of the opioid control of GH secretion, several peptide analogues of met-enkephalin were found to be potent GH secretagogues. These include the GH-releasing peptide GHRP-6 (Fig. 7-29) (Figure Not Available), hexarelin (His-D2MeTrp-Ala-Trp-DPhe-Lys-NH2), and other more potent analogues including cyclic peptides and modified pentapeptides. Subsequently, a series of nonpeptidyl GHRP mimetics were synthesized with greater oral bioavailability, including the spiropiperidine MK-0677 and the shorter acting benzylpiperidine L-163,540 (see Fig. 7-29). Common to all these compounds, and the basis of their differentiation from GHRH in pharmacologic activity screens, is their activation of phospholipase C and inositol 1,4,5-trisphosphate. This property was exploited in a cloning strategy that led to the identification of a G protein-coupled receptor GHS-R that is highly selective for the GH secretagogue class of ligands. The GHS-R is unrelated to the GHRH receptor and is highly expressed in the anterior pituitary gland and multiple brain areas, including the medial basal hypothalamus, the hippocampus, and the mesencephalic nuclei that are centers of dopamine and serotonin production. Peptidyl and nonpeptidyl GHSs are active when administered by intranasal and oral routes, are more potent on a weight basis than GHRH itself, are more effective in vivo than in vitro, synergize with coadministered GHRH and are almost ineffective in the absence of GHRH, and do not suppress somatostatin secretion. Prolonged infusions of GHRP amplify pulsatile GH secretion in normal men. GHRP administration, like that of GHRH, facilitates slow wave sleep. Patients with hypothalamic disease leading to GH deficiency have low or no response to hexarelin; similarly, pediatric patients with complete absence of the pituitary stalk have no GH secretory response to hexarelin.

The potent biologic effects of GHRPs and the identification of the GHS-R suggested the existence of a natural ligand for the receptor that is involved in the physiologic regulation of GH secretion. A probable candidate for this ligand is the acylated peptide ghrelin, produced and secreted into the circulation from the stomach (see Fig. 7-29). The effects of ghrelin on GH secretion in humans are identical to or more potent than those of the non-natural GHRPs (see Fig. 7-26). In addition, ghrelin acutely increases circulating PRL, ACTH, cortisol, and aldosterone levels. There is debate concerning the extent and localization of ghrelin expression in the brain that must be resolved before the implications of gastric-derived ghrelin in the regulation of pituitary hormone secretion are fully understood. A proposed role for ghrelin in appetite and regulation of food intake is discussed later in this chapter.

**Clinical Applications**

GHRH stimulates growth in children with intact pituitaries, but the optimal dosage, route, and frequency of administration, as well as possible usefulness by the nasal route, have not been determined. The availability of recombinant hGH (which requires post-translational modification among the known neuropeptides.}
Negative feedback control of GH release is mediated by GH itself and by IGF-I, which is synthesized in the liver under control of GH. Direct GH effects on the hypothalamus are produced by short-loop feedback, whereas those involving IGF-I and other circulating factors influenced by GH, including free fatty acids and glucose, are long-loop systems analogous to the pituitary-thyroid and pituitary-adrenal axes. Control of GH secretion thus includes two closed-loop systems (GH and IGF-I) and one open-loop regulatory system (neural).

Although most of the evidence for a direct role of GH in its own negative feedback has been derived from animals, an elegant study in normal men demonstrated that GH pretreatment blocks the subsequent GH secretory response to GHRH by a mechanism that is dependent on somatostatin. The mechanism responsible for GH feedback through the hypothalamus has been largely elucidated in rodent models. GH receptors are selectively expressed on somatostatin neurons in the hypothalamic periventricular nucleus and on NPY neurons in the arcuate nucleus. C-fos gene expression is acutely elevated in both populations of GH receptor-positive neurons by GH administration, indicating an activation of hypothalamic circuitry that includes these neurons. Similarly, GHRH neurons in the arcuate nucleus are acutely activated by MK-0677 because of their selective expression of the GHS-R. Zheng and colleagues showed in the latter group of neurons that c-fos induction after MK-0677 administration was blocked by pretreatment of mice with GH. The effect must be indirect because there are no GH receptors on GHRH neurons. However, there are type 2 somatostatin receptors expressed on GHRH neurons, and the somatostatin analogue octreotide also significantly blocked c-fos activation in the arcuate nucleus by MK-0677. The inhibitory effects of either GH or octreotide pretreatment were abolished in knockout mice lacking the specific somatostatin receptor. Together with data from many other experiments, these results strongly support a model of GH negative feedback regulation that involves the primary activation of periventricular somatostatin neurons by GH. These tuberoinfundibular neurons then inhibit GH secretion directly by release of somatostatin in the median eminence, but they also indirectly inhibit GH secretion by way of collateral axonal projections to the arcuate nucleus that synapse on and inhibit GHRH neurons. It is probable from evidence in rodents that NPY and galanin also play a part in the short-loop feedback of GH secretion, but a definitive mechanism in humans is not yet established.

IGF-I has a major inhibitory action on GH secretion at the level of the pituitary gland. IGF-I receptors are expressed on human somatotroph adenoma cells and inhibit both spontaneous and GHRH-stimulated GH release. In addition, gene expression of both GH and the pituitary-specific transcription factor Pit-1 is inhibited by IGF-I. Conflicting data among species suggest that circulating IGF-I may also regulate GH secretion by actions within the brain. The feedback effects of IGF-I account for the fact that in conditions in which circulating levels of IGF-I are low, such as anorexia nervosa, protein-calorie starvation, and Laron dwarfism (the result of a defect in the GH receptor), serum GH levels are elevated.

The predominant hypothalamic influence on GH release is stimulatory, and section of the pituitary stalk or lesions of the basal hypothalamic cause reduction of basal and induced GH release. When the somatostatinergic component is inactivated (e.g., by antisomatostatin antibody injection in rats), basal GH levels and GH responses to the usual provocative stimuli are enhanced.

GH-containing nerve fibers that terminate adjacent to portal vessels in the external zone of the median eminence arise principally from within, above, and lateral to the infundibular nucleus in the hypothalamus, corresponding to rodent arcuate and ventromedial nuclei. Perikarya of the tuberoinfundibular somatostatin neurons are located almost completely in the median eminence and parvocellular component of the anterior paraventricular nucleus. Neuroanatomic and functional evidence suggests a bidirectional synaptic interaction between the two peptidergic systems. Multiple extrahypothalamic brain regions provide effenter connections to the hypothalamus and regulate GHRH and somatostatin neuronal activity. Somatosensory and affective information is integrated and filtered through the amygdaloid complex. The basolateral amygdala provides an excitatory input to the hypothalamus, and the central extended amygdala, which includes the central and medial nuclei of the amygdala together with the bed nucleus of the stria terminals, provides a GABAergic inhibitory input. Many intrinsic neurons of the hypothalamus also release GABA, often with a peptide cotransmitter. Excitatory cholinergic fibers arise to a small extent from forebrain projection nuclei but mostly from hypothalamic cholinergic interneurons, which...
The inhibitory actions of NPY and CRH on GH secretion are firmly established in the rodent and are secondary to increased somatostatin tone. Contradictory evidence exists in the human for both.

In many instances, the inhibition can be demonstrated only as a suppression of GH release induced by a pharmacologic stimulus. Serotonin's effect on GH release in humans was difficult to decipher because of the large number of receptor subtypes. However, clinical studies with the receptor-selective agonist clonidine reliably stimulates GH release, and for this reason a clonidine test was a standard diagnostic tool in pediatric endocrinology. The stimulatory effect is blocked by the specific \( \alpha_2 \)-agonist clonidine, which appears to involve a dual mechanism of action, inhibition of somatostatin neurons and activation of GHRH neurons. In addition, partial attenuation of the effects of clonidine by mixed 5-hydroxytryptamine type 1 and type 2 antagonists suggests that some of the relevant receptors are located presynaptically on serotoninergic nerve terminals and increase serotonin release. Both norepinephrine and epinephrine play physiologic roles in the adrenergic stimulation of GH secretion. The \( \alpha_2 \)-agonists have no effect on GH secretion in humans, but \( \alpha_2 \)-agonists such as the bronchodilator salbutamol inhibit GH secretion by stimulating the release of somatostatin from nerve terminals in the median eminence. These effects are blocked by propranolol, a nonspecific \( \beta \)-receptor antagonist. Dopamine generally has a net effect to stimulate GH secretion, but the mechanism is not clear because of multiple dopamine receptor subtypes and the apparent activation of both GHRH and somatostatin neurons.

Serotonin's effect on GH release in humans was difficult to decipher because of the large number of receptor subtypes. However, clinical studies with the receptor-selective agonist clonidine reliably stimulates GH release, and for this reason a clonidine test was a standard diagnostic tool in pediatric endocrinology. Somatostatin clearly implicate the 5-hydroxytryptamine 1D receptor subtype in the stimulation of basal GH levels. The drug also potentiates the effect of a maximal dose of GHRH, suggesting that the recurring theme of GH disinhibition by inhibition of hypothalamic somatostatin neurons in its mechanism of action. Histaminergic pathways acting through H1 receptors play only a minor, conditional stimulatory role in GH secretion in humans.

Acetylcholine appears to be an important physiologic regulator of GH secretion. Blockade of acetylcholinergic muscarinic receptors reduces or abolishes GH secretory responses to GHRH, glucagon and arginine, morphine, and exercise. In contrast, drugs that potentiate cholinergic transmission increase basal GH levels and enhance the GH response to GHRH in normal individuals or in subjects with obesity or Cushing's disease. In vitro acetylcholine inhibits somatostatin release from hypothalamic fragments, and acetylcholine can act directly on the pituitary to inhibit GH release. There may even be a paracrine cholinergic control system within the pituitary. However, the sum of evidence suggests that the primary mechanism of action of M1 agonists is inhibition of somatostatin neuronal activity or the release of peptide from somatostatinergic terminals. Short-term cholinergic blockade with the M1 muscarinic receptor antagonist pirenzipine reduced the GH excess of patients with poorly controlled diabetes mellitus. However, in the long term, cholinergic blockade did not prevent complications associated with the hyperinsulinemic state.

Many neuropeptides in addition to GHRH and somatostatin are involved in the modulation of GH secretion in humans. Among these, the evidence is most compelling for a stimulatory role of galanin acting in the human hypothalamus by a GHRH-dependent mechanism. Many GHRH neurons are immunopositive for galanin as well as neuropeptide and tyrosine hydroxylase. Galanin's actions may be explained, in part, by presynaptic facilitation of catecholamine release from nerve terminals and subsequent direct adrenergic stimulation of GHRH release. Opioid peptides also stimulate GH release, probably by activation of GHRH neurons, but under normal circumstances endogenous opioid tone in the hypothalamus is presumed to be low because opioid antagonists have little acute effect on GH secretion.

A larger number of neuropeptides are known or suspected to inhibit GH secretion in humans, at least under certain circumstances. The list includes NPY, CRH, calcitonin, oxytocin, neurotensin, VIP, and TRH. Inhibitory actions of NPY are well established in the rat. The effect on GH secretion is secondary to stimulation of somatostatin neurons and is of particular interest because of the presumed role in GH auto-feedback (discussed earlier) and the integration of GH secretion with regulation of energy intake and expenditure (discussed in a later section). Finally, TRH has the well-established paradoxical effect of increasing GH secretion in patients with acromegaly, type 1 diabetes mellitus, hypothyroidism, or hepatic and renal failure.

Factors Influencing Secretion of Growth Hormone

Human Growth Hormone Rhythms

The unraveling of rhythmic GH secretion has relied on a combination of technical innovations in sampling and GH assay, and sophisticated mathematical modeling including deconvolution analysis and the calculation of approximate entropy as a measure of orderliness or regularity in minute-to-minute secretory patterns. At least three distinct categories of GH rhythms, which differ markedly in their time scales, can be considered here. The daily GH secretion rate varies over two orders of magnitude from a maximum of nearly 2.0 mg/day in late puberty to a minimum of 20 µg/day in older or obese adults. The neonatal period is characterized by markedly amplified GH secretory bursts followed by a prepubertal decade of stable, moderate GH secretion of 200 to 600 µg/day. There is a marked increase in daily GH secretion during puberty that is accompanied by a commensurate rise in plasma IGF-I levels that constitute a state of physiologic hypersomatotropism. This pubertal increase in GH secretion is due to increased GH mass per secretory burst and not to increased pulse frequency. Although the changes are clearly related to the increases in gonadal steroid hormones and can be mimicked by administration of estrogen or testosterone to hypogonadal children, the underlying neuroendocrine mechanisms are not fully understood. Gonadal sex steroids play both an organizational and activational role in the adult, regulating expression of the genes for many of the peptides and receptors central to GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism.

The neuroendocrine basis for sex differences in the ultradian rhythm of GH secretion is not fully understood. Gonadal sex steroids play both an organizational role during development of the hypothalamus and an activational role in the adult, regulating expression of the genes for many of the peptides and receptors central to GH regulation. In the human, unlike the rat, the hypothalamic actions of testosterone appear to be predominantly due to its aromatization to 17-estradiol and interaction with estrogen receptors. Hypothalamic somatostatin appears to play a more prominent role in men than in women in the regulation of pulsatile GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism.

External and Metabolic Signals

The various peripheral signals that modulate GH secretion in humans are summarized in Table 7-6 (also see Fig. 7-30 and Fig. 7-32). Of particular importance are factors related to energy intake and metabolism because they provide a common signal between the peripheral tissues and hypothalamic centers regulating nondiocrine homeostatic signaling pathways as well as to the classical hypothalaseurotropic neurons. It is also in this complex arena that species-specific regulatory responses are particularly prominent, making extrapolations between rodent experimental models and human GH regulation less reliable. The neuroendocrine basis for sex differences in the ultradian rhythm of GH secretion is not fully understood. Gonadal sex steroids play both an organizational role during development of the hypothalamus and an activational role in the adult, regulating expression of the genes for many of the peptides and receptors central to GH regulation. In the human, unlike the rat, the hypothalamic actions of testosterone appear to be predominantly due to its aromatization to 17-estradiol and interaction with estrogen receptors. Hypothalamic somatostatin appears to play a more prominent role in men than in women in the regulation of pulsatile GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism. Important triggers of GH release include the normal decrease in blood glucose level after intake of a carbohydrate-rich meal, absolute hypoglycemia, exercise, physical and emotional stress, and high intake of protein (mediated by amino acids). Some of the pathologic causes of elevated GH represent extremes of these physiologic signals and include protein-calorie starvation, anorexia nervosa, liver failure, and type 1 diabetes mellitus. A critical concept is that many of these GH triggers work through the same final common mechanism of somatostatin withdrawal and consequent disinhibition of GH secretion. In contrast, postprandial hyperglycemia, glucose infusion, elevated plasma free fatty acids, type 2 diabetes mellitus (with obesity and insulin resistance), and obesity are all associated with inhibition of GH secretion. The role of leptin in mediating either increases or decreases in GH release is complicated by its multiple sites of action and coexistent secretory environment. Similarly, other members of the cytokine family including IL-1, IL-2, IL-6, and endotoxin have been inconsistently shown to stimulate GH in humans.

The actions of steroid hormones on GH secretion in humans are complex because of their multiple loci of action within the proximal hypothalamic-pituitary components in addition to secondary effects on other neural and endocrine systems. Glucocorticoids in particular produce opposite responses that are dependent on the chronicity of administration. Moreover, glucocorticoid effects follow an inverted U-shaped dose-response curve. Both low and high glucocorticoid levels reduce GH secretion, the former because of decreased GH gene expression and somatotroph responsiveness to GHRH and the latter because of increased hypothalamic somatostatin tone and decreased GHRH. Similarly, physiologic levels of thyroid hormones are necessary to maintain GH secretion and promote GH gene expression. Excessive thyroid hormone is also inhibitory to the GH axis, and the mechanism is speculated to be a combination of increased hypothalamic somatostatin tone, GH deficiency, and suppressed pituitary GH production.
Somatostatin, the peptide responsible for this inhibition of GH secretion and the inhibition of insulin secretion by a pancreatic islet cell, was eventually isolated from hypothalamus and sequenced by Brazeau and colleagues in 1973. The term somatostatin was originally applied to a cyclic peptide containing 14 amino acids (somatostatin-14 [SST-14]; see Fig. 7-33). Subsequently, a second form, N-extended somatostatin-28 (SST-28), was identified as a secretory product. Both forms of somatostatin are derived by independent cleavage of a common prohormone by prohormone convertases. In addition, the isolation of SST-28(112) in some tissues suggests that SST-14 can be secondarily processed from SST-28. SST-14 is the predominant form in the brain (including the hypothalamus), whereas SST-28 is the major form in the gastrointestinal tract, especially the duodenum and jejunum.

The name somatostatin is descriptively inadequate because the molecule also inhibits thyrotropin secretion from the pituitary and has nonpituitary roles including activity as a neurotransmitter or neuromodulator in the central and peripheral nervous systems and as a regulatory peptide in gut and pancreas. As a pituitary regulator, somatostatin is a true neurohormone, that is, a neuronal secretory product that enters the blood (hypophyseseal-portal circulation) to affect cell function at remote sites. In the gut, somatostatin is present in both the myenteric plexus, where it acts as a neurotransmitter, and epithelial cells, where it influences the function of adjacent cells as a paracrine secretion. Somatostatin can influence its own secretion from delta cells (an autocrine function) in addition to acting as a paracrine factor in pancreatic islets. Gut exocrine secretion can be modulated by intraluminal action, so it is also a lumone. Because of its wide distribution, broad spectrum of regulatory effects, and evolutionary history, this peptide can be regarded as an archetypal pan-system modulator.

The genes that encode somatostatin in humans (see Fig. 7-33) and a number of other species exhibit striking sequence homology, even in primitive fish such as the anglerfish. Furthermore, the amino acid sequence of SST-14 is identical in all vertebrates. Formerly, it was accepted that all tetrapods have a single gene encoding both SST-14 and SST-28 whereas teleost fish have two nonallelic pre-prosomatostatin genes (PPSI and PPSII), each of which encodes only one form of the mature somatostatin peptides. This situation implied that a common ancestral gene underwent a duplication event after the split of teleosts from the descendants of tetrapods. However, both lampreys and amphibians, which predate and postdate the teleost evolutionary divergence, respectively, have now been shown to have at least two PPS genes. A more distantly related gene has been identified in mammals that encodes cortistatin, a somatostatin-like peptide that is highly expressed in cortex and hippocampus. Cortistatin-14 differs from SST-14 by three amino acid residues but has high affinity for all known subtypes of somatostatin receptors (see later). The human gene sequence predicts a tripeptide-extended cortistatin-17 and a further N-terminally extended cortistatin-29. A revised evolutionary concept of the somatostatin gene family is that a primordial gene underwent duplication at or before the advent of chordates and the two resulting genes underwent mutation at different rates to produce the distinct pre-prosomatostatin and pre-procortistatin genes in mammals. A second gene duplication probably occurred in teleosts to generate PPSI and PPSII from the ancestral somatostatin gene.

Apart from its expression in neurons of the periventricular and arcuate hypothalamic nuclei and involvement in GH secretion discussed earlier, somatostatin is highly expressed in the cortex, lateral septum, extended amygdala, reticular nucleus of the thalamus, hippocampus, and many brain stem nuclei. Cortistatin is present in the brain at a small fraction of the levels of somatostatin and in a more limited distribution primarily confined to cortex and hippocampus. The molecular mechanisms underlying the development and hormonal regulation of somatostatin gene transcription have been most extensively studied in pancreatic islet cells. Less is known concerning the regulation of somatostatin gene expression in neurons except that activation is strongly controlled by binding of the phosphorylated transcription factor cAMP response element binding protein to its cognate cAMP response element contained in the promoter sequence. Enhancer elements in the somatostatin gene promoter that bind complexes of homeodomain-containing transcription factors (PAX6, PBX, PREP1) and up-regulate gene expression in pancreatic islets may actually represent core somatostatin elements in neurons (see Fig. 7-33), promoter elements TSE, and UE-A). Conversely, another related cis element in the somatostatin gene (see Fig. 7-33, promoter element TSE) apparently binds a homeodomain transcription factor PDX1 (also called STF1/ID2/ID1/PF1) that is common to developing brain, pancreas, and foregut and regulates gene expression in both the CNS and gut.

The function of somatostatin in GH and thyrotropin regulation was considered earlier in this chapter. Its actions in the extrahypothalamic brain and diagnostic and therapeutic roles are considered in the remainder of this section and in Chapter 8. An additional function of somatostatin in pancreatic islet cell regulation is described in Chapter 29, and the manifestations of somatostatin excess as in somatostatinoma are described in Chapter 35.

Somatostatin Receptors

Five somatostatin receptor subtypes (SSTR1 to SSTR5) have been identified by gene cloning techniques (Table 7-7), and one of these (SSTR2) is expressed in two alternatively spliced forms. These subtypes are encoded by separate genes located on different chromosomes, are expressed in unique or partially overlapping distributions in multiple target organs, and differ in their coupling to second messenger signaling molecules and therefore in their range and mechanism of intracellular actions. The subtypes also differ in their binding affinity to specific somatostatin analogues. Certain of these differences have important implications for the use of somatostatin analogues in therapy and in diagnostic imaging.

All SSTR subtypes are coupled to pertussis toxinsensitive G proteins and bind SST-14 and SST-28 with high affinity in the low nanomolar range, although SST-28 is a uniquely high affinity for SSTR5. SSTR1 and SSTR2 are the most abundant subtypes in brain and probably function as presynaptic autoreceptors in the hypothalamus and limbic forebrain, respectively, in addition to their postsynaptic actions. SSTR4 is most prominent in hippocampus. All the subtypes are expressed in the pituitary, but SSTR2 and SSTR5 are the most abundant on somatotrophs. These two subtypes are also the most physiologically important in pancreatic islets, with SSTR5 responsible for inhibition of insulin secretion from beta cells and SSTR2 responsible for inhibition of glucagon from alpha cells.

Binding of somatostatin to its receptor leads to activation of one or more plasma membranebound inhibitory G proteins, which in turn inhibit adenyl cyclase activity and lower intracellular cAMP. Other G proteinmediated actions common to all SSTRs are activation of a vanadate-sensitive phosphotyrosine phosphatase and modulation of mitogen-activated protein kinase (MAPK). Different subsets of SSTRs are also coupled to inwardly rectifying K+ channels, voltage-dependent Ca2+.
channels, an Na+/H+ exchanger, -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-kainate glutamate receptors,

phospholipase C, and phospholipase A2. The lowering of intracellular cAMP and Ca\(^{2+}\) is the most important mechanism for the inhibition of hormone secretion, and actions on phosphotyrosine phosphatase and MAPK are postulated to play a role in somatostatin's antiproliferative effect on tumor cells.

Effects on Target Tissues and Mechanism of Action

In the pituitary, somatostatin inhibits secretion of GH and thyrotropin and, under certain conditions, of PRL and ACTH as well. It exerts inhibitory effects on virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder (Table 7-8). Somatostatin inhibits secretion by the salivary glands and, under some conditions, the secretion of parathyroid hormone and calcitonin. Somatostatin blocks hormone release in many endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and some gastrinomas.

The physiologic actions of somatostatin in extrahypothalamic brain remain the subject of investigation. In the striatum, somatostatin increases the release of dopamine from nerve terminals by a glutamate-dependent mechanism. It is widely expressed in GABAergic interneurons of limbic cortex and hippocampus, where it modulates the excitability of pyramidal neurons. Temporal lobe epilepsy is associated with a marked reduction in somatostatin-expressing neurons in the hippocampus consistent with a putative inhibitory action on seizures. A wealth of correlative data has linked reduced forebrain and CSF concentrations of somatostatin with Alzheimer's disease, major depression, and other neuropsychiatric disorders, raising speculation about the role of somatostatin in modulating neural circuits underlying cognitive and affective behaviors.

Clinical Applications of Somatostatin Analogues

An extensive pharmaceutical discovery program has produced somatostatin analogues with receptor subtype selectivity and improved pharmacokinetics and oral bioavailability compared with the native peptide. Initial efforts focused on the rational design of constrained cyclic peptides that incorporated \(\alpha\)-amino acid residues and included the Trp\(^1\)-Lys\(^8\) dipeptide of somatostatin, which was shown by structure-function studies to be necessary for high-affinity binding to its receptor (see Fig. 7-33). Many such analogues have been studied in clinical trials including octreotide, lanreotide, vapreotide, and the hexapeptide MK-678. These compounds are agonists with

GH, growth hormone; ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin; VIP, vasoactive intestinal peptide.
Similarly high-affinity binding to SSTR2 and SSTR5, moderate binding to SSTR3, and no (or low) binding to SSTR1 and SSTR4. A combinatorial chemistry approach has led to a new generation of nonpeptidyl somatostatin agonists that bind selectively and with subnanomolar affinity to each of the five SSTR subtypes. In contrast to the marked success in development of potent and selective somatostatin agonists, there is a relative paucity of useful antagonists.

The actions of octreotide (SMS 201-995 or Sandostatin) illustrate the general potential of somatostatin analogues in therapy. It controls excess secretion of GH in acromegaly in most patients and shrinks tumor size in about one third. Octreotide is also indicated for the treatment of thyrotropin-secreting adenomas that recur after surgery. It is used to treat other functioning metastatic neuroendocrine tumors, including carcinoid, VIPoma, glucagonoma, and insulinoma, but is seldom of use for the treatment of gastrinoma. It is also useful in the management of many forms of diarrhea (acting on salt and water excretion mechanisms in the gut) and in reducing external secretions in pancreatic fistulae (thus permitting healing). A decrease in blood flow to the gastrointestinal tract is the basis for its use in bleeding esophageal varices, but it is not effective in the treatment of bleeding from a peptic ulcer.

The only major undesirable side effect of octreotide is reduction of bile production and of gallbladder contractility, leading to "sludging" of bile and an increased incidence of gallstones. Other common adverse effects including nausea, abdominal cramps, diarrhea secondary to malabsorption of fat, and flatulence usually subside spontaneously within 2 weeks of continued treatment. Impaired glucose tolerance is not associated with long-term octreotide therapy, despite an inhibitory effect on insulin secretion, because of compensating reductions in carbohydrate absorption and GH and glucagon secretion that are also caused by the drug.

Somatostatin analogues labeled with a radioactive tracer have been used as external imaging agents for a wide range of disorders. A 111In-labeled analogue of octreotide (OctreoScan) has been approved for clinical use in the United States and several other countries. The majority of neuroendocrine tumors and many pituitary tumors that express somatostatin receptors are visualized by external imaging techniques after administration of this agent; a variety of nonendocrine tumors and inflammatory lesions are also visualized, all of which have in common the expression of somatostatin receptors. Such tumors include nonsmall cell cancer of the lung (100%), meningioma (100%), breast cancer (74%), and astrocytomas (67%). Because activated T cells of the immune system display somatostatin receptors, inflammatory lesions that take up the tracer include sarcoidosis, Wegener's granulomatosis, tuberculosis, and many cases of Hodgkin's disease and non-Hodgkin's lymphoma. Although the tracer lacks specificity in differential diagnosis, its ability to identify the presence of abnormality and the extent of the lesion provides important information for management, including tumor staging. The use of a small hand-held radiation detector in the operating room makes it possible to ensure the completeness of removal of medullary thyroid carcinoma metastases.

New developments in the synthesis of tracers chelated to octreotide for positron emission tomography have allowed the sensitive detection of somatostatin receptor expression. The majority of neuroendocrine tumors and inflammatory lesions are also visualized, all of which have in common the expression of somatostatin receptors. Such tumors include nonsmall cell cancer of the lung (100%), meningioma (100%), breast cancer (74%), and astrocytomas (67%). Because activated T cells of the immune system display somatostatin receptors, inflammatory lesions that take up the tracer include sarcoidosis, Wegener's granulomatosis, tuberculosis, and many cases of Hodgkin's disease and non-Hodgkin's lymphoma. Although the tracer lacks specificity in differential diagnosis, its ability to identify the presence of abnormality and the extent of the lesion provides important information for management, including tumor staging. The use of a small hand-held radiation detector in the operating room makes it possible to ensure the completeness of removal of medullary thyroid carcinoma metastases.

The use of somatostatin to inhibit the growth of normal and some neoplastic cell lines and to reduce the growth of experimentally induced tumors in animal models has stimulated interest in somatostatin analogues for the treatment of cancer. Somatostatin's tumoristatic effects may be a combination of direct actions on tumor cells related to inhibition of growth factor receptor expression, inhibition of MAPK, and stimulation of phosphorylase phosphatase. SSTR1, SSTR2, SSTR4, and SSTR5 can all promote cell cycle arrest associated with induction of the tumor suppressor retinoblastoma and p21, and SSTR3 can trigger apoptosis accompanied by induction of the tumor suppressor p53 and the proapoptotic protein Bax. In addition, somatostatin has indirect effects on tumor growth by its inhibition of circulating, paracrine, and autocrine tumor growth-promoting factors and it can modulate the activity of immune cells and influence tumor blood supply. Despite this promise, the therapeutic utility of octreotide as an antineoplastic agent remains controversial.

Two new treatment approaches in preclinical models may yet effectively utilize somatostatin receptors in the arrest of cancer cells. The first is receptor-targeted radionuclide therapy using octreotide chelated to a variety of gamma- or beta-emitting radioisotopes. Theoretical calculations and empirical data suggest that radiolabeled somatostatin analogues can deliver a tumoricidal radiotherapeutic dose to some tumors after receptor-mediated endocytosis. A variation on this theme is the chelation of a cytotoxic chemotherapeutic agent to a somatostatin analogue. A second approach involves somatic cell gene therapy to transfact SSTR-negative pancreatic cancer cells with an SSTR gene. Therapeutic results can be obtained with the creation of autocrine or paracrine inhibitory growth effects or the addition of targeted radionuclide treatments.
Prolactin-Regulating Factors

Dopamine

It is well known that PRL secretion, unlike the secretion of other pituitary hormones, is primarily under tonic inhibitory control by the hypothalamus. Destruction of the stalk median eminence or transplantation of the pituitary gland to ectopic sites causes a marked constitutive increase in PRL secretion, in contrast to a decrease in the release of GH, TSH, ACTH, and the gonadotropins. Many lines of evidence indicate that dopamine is the principal, physiologic prolactin-inhibiting factor (PIF) released from the hypothalamus. Dopamine is present in hypophysial-portal vessel blood in sufficient concentration to inhibit PRL release, and dopamine inhibits PRL secretion from lactotrophs both in vivo and in vitro. Mutant mice with a targeted disruption of the D2 receptor gene uniformly developed lactotroph hyperplasia, hyperprolactinemia, and eventually lactotroph adenomas, further emphasizing the importance of dopamine in the physiologic regulation of lactotroph proliferation in addition to hormone secretion.

The intrinsic dopamine neurons of the medial-basal hypothalamus constitute a dopaminergic population with regulatory properties that are distinct from those in other areas of the brain. Notably, they lack D2 autoreceptors but express PRL receptors, which are essential for positive feedback control as discussed in detail later. In the rat, these neurons are subdivided by location into the A12 group within the arcuate nucleus and the A14 group in the anterior periventricular nucleus. The caudal A12 dopamine neurons are further classified as tuberoinfundibular (TIDA) because of their axonal projections to the external zone of the median eminence. Tuberohypophyseal (THDA) neuronal soma are located more rostrally in the arcuate nucleus and project to both the neural lobe and intermediate lobe through axon collaterals that are found in the internal zone of the median eminence. Finally, the A14 periventricular hypophyseal (PHDA) neurons send their axons only to the intermediate lobe of the pituitary gland.

Although the TIDA neurons are generally considered to be the major source of dopamine to the anterior lobe through the long portal vessels originating in the median eminence, dopamine can also reach the anterior lobe from the neural and intermediate lobes by the interconnecting short portal veins. Consistent with this pathway for dopamine access to the anterior lobe, surgical removal of the neurointermediate lobe in rats caused a significant increase in basal PRL levels. In addition to direct actions of dopamine on lactotrophs, central dopamine can indirectly affect PRL secretion by altering the activity of inhibitory interneurons that in turn synapse on the TIDA neurons. These effects are complicated by opposing intracellular signaling pathways linked to D1 and D2 receptors located on different populations of interneurons.

The binding of dopamine or selective agonists such as bromocriptine to the D2 receptor has multiple effects on lactotroph function. D2 receptors are coupled to pertussis toxin-sensitive G proteins and inhibit adenyl cyclase and decrease intracellular cAMP levels. Other effects include activation of an inwardly rectifying K⁺ channel, increase of voltage-activated K⁺ currents, decrease of voltage-activated Ca²⁺ currents, and inhibition of inositol phosphate production. Together, this spectrum of intracellular signaling events decreases free Ca²⁺ concentrations and inhibits exocytosis of PRL secretory granules. Dopamine also has a modest effect on thyrotrophs to inhibit the secretion of TSH.

There is continuing debate concerning the mechanism by which D2 receptor activation inhibits transcription of the PRL gene. Likely pathways involve the inhibition of MAPK or protein kinase C, with a resultant reduction in the phosphorylation of Ets family transcription factors. Ets factors are important for the stimulatory responses of TRH, insulin, and epidermal growth factor on PRL expression and they interact cooperatively with the pituitary-specific POU protein Pit1, which is essential for cAMP-mediated PRL gene expression. The second messenger pathways used by the D2 receptor to inhibit lactotroph cell division are also unsettled. A study using primary pituitary cultures from rats demonstrated forskolin treatment, which activates protein kinase A and elevates intracellular cAMP, or insulin treatment, which activates a potent receptor tyrosine kinase, were both effective mitogenic stimuli for lactotrophs. Bromocriptine competitively antagonized the proliferative response caused by elevated cAMP. Furthermore, inhibition of MAPK signaling by PD98059 markedly suppressed the mitogenic action of both insulin and forskolin, suggesting an interaction of MAPK and protein kinase A signaling.

Another study used immortalized mammosomatotroph tumor cells that were transfected with a D2 receptor expression vector and concluded that stimulation of a phosphoinositide phosphatase activity was an important component of dopamine's antiproliferative action. Therefore, it is clear that dopamine actions on lactotrophs involve multiple different intracellular signaling pathways linked to activation of the D2 receptor, but different combinations of these pathways are relevant for the inhibitory effects on PRL secretion, PRL gene transcription, and lactotroph proliferation.

The other major action of dopamine in the pituitary is the inhibition of hormone secretion from the POMC-expressing cells of the intermediate lobe, although, as noted earlier, the adult human differs from most other mammals in the rudimentary nature of this lobe. THDA and PHDA axon terminals provide a dense plexus of synaptic-like contacts on melanotrophs. Dopamine release from these terminals is inversely correlated with serum MSH levels and also regulates POMC gene expression and melanotroph proliferation.

Other hypothalamic factors probably play a role secondary to that of dopamine as additional PIFs. The primary reason to conjecture the existence of these PIFs is the frequent inconsistency between portal dopamine levels and circulating PRL in different rat models. GABA is the strongest candidate and most likely acts through GABAₐ receptors in the anterior pituitary. Melanotrophs, like lactotrophs, are inhibited by both dopamine and GABA but with the principal involvement of GABAergic and metabotropic GABAₐ receptors. Because basal dopamine tone is high, the measurable inhibitory effects of GABA on PRL release are generally small under normal circumstances. Other putative PIFs include somatostatin and calcitonin.

Protein Releasing Factors

Although tonic suppression of PRL release by dopamine is the dominant effect of the hypothalamus on PRL secretion, a number of stimuli promote PRL release, not only...
merely by disinhibition of PIF effects but by causing release of one or more neurohormonal PRFs (see Fig. 7-35). The most important of the putative PRFs are TRH, oxytocin, and VIP, but vasopressin, angiotensin II, NPY, galanin, substance P, bombesin-like peptides, and neuropeptide C can also trigger PRL release under different physiologic circumstances. TRH was discussed in a previous section of this chapter (see Fig. 7-15). In humans there is an imperfect correlation between pulsatile PRL and TSH release, suggesting that TRH cannot be the sole physiologic PRF under basal conditions.

Like TRH, oxytocin, vasopressin, and VIP fulfill all the basic criteria for a PRF. They are produced in paraventricular hypothalamic neurons that project to the median eminence. Concentrations of the hormones in portal blood are much higher than in the peripheral circulation and are sufficient to stimulate PRL secretion in vitro. Moreover, there are functional receptors for each of the neurohormones in the anterior pituitary gland and either pharmacologic antagonism or passive immunization against each hormone can decrease PRL secretion, at least under certain circumstances. Vasopressin is released during stress and hypovolemic shock, as is PRL, suggesting a specific role for vasopressin as a PRF in these contexts. Similarly, another candidate PRF, peptide histidine isoleucine, may be specifically involved in the secretion of PRL in response to stress. Peptide histidine isoleucine and the human homologue PRP are structurally related to VIP and synthesized from the same prohormone precursor in their respective species. Both peptides are coexpressed with CRH in parvocellular paraventricular neurons and presumably released by the same stimuli that cause release of CRH into the hypophyseal-portal vessels.

There is evidence suggesting that dopamine itself may also act as a PRF, in contrast to its predominant function as a PIF. At concentrations three orders of magnitude lower than that associated with maximal inhibition of PRL secretion, dopamine was shown to be capable of stimulating secretion from primary cultures of rat pituitary cells. These cultures were extended to in vivo model by Arex and colleagues, who demonstrated that low-dose dopamine infusion in cannulated rats caused a further increase in circulating PRL above the already elevated baseline produced by pharmacologic blockade of endogenous dopamine biosynthesis. The physiologic relevance of these findings to humans has yet to be established.

Finally, reports of "new" PRFs continue to be published. Much excitement was generated by the isolation of a peptide from bovine hypothalamus named prolactin-releasing peptide (PRP). PRP binds with high affinity to an orphan G protein-coupled receptor (hGR3/GPR10) expressed specifically in human pituitary anterior lobe cells. PRP stimulates PRL release from rat pituitary cells with a potency similar to that of TRH. However, PRP is expressed predominantly in a subpopulation of noradrenergic neurons in the medulla and a serious question of whether PRP reaches the anterior pituitary and actually causes PRL secretion. Subsequent studies found no direct evidence for release of PRP in the arcuate nuclei/median eminence, further suggesting that the peptide is not a hypophyseotropic neurohormone. However, PRP probably does function as a neuromodulator within the hypothalamus.

CNS at sites receiving its receptor and may be involved in the neural circuitry mediating satiety.

Intrapituitary Regulation of Prolactin Secretion

Probably more than that of any other pituitary hormone, the secretion of PRL is regulated by autocrine-paracrine factors within the anterior lobe and by neurointermediate lobe factors that gain access to venous sinusoids of the anterior lobe by way of the short portal vessels. The wealth of local regulatory mechanisms within the anterior pituitary has been reviewed extensively and is also discussed in Chapter 8. Galanin, VIP, endothelin-like peptides, angiotensin II, epidermal growth factor, basic fibroblast growth factor, LHRH, and the cytokine IL-6 are among the most potent local stimulators of PRL secretion. Locally produced inhibitors include PRL itself, acetylcholine, transforming growth factor beta, and calcitonin. Although none of these stimulatory or inhibitory factors plays a dominant role in the regulation of lactotroph function and much of the research in this area has not been directly confirmed in human pituitary, it seems apparent that the local milieu of autocrine and paracrine factors plays an essential regulatory role in determining the responsiveness of lactotrophs to hypophysiotropic factors in different physiologic states.

As noted earlier, a proportion of the inhibitory dopamine tone to the anterior lobe lactotrophs is derived from the neurointermediate lobe. It was therefore unanticipated that surgical removal of this structure in rats would block suckling-induced PRL release over the moderate baseline increase attributed to partial dopamine disinhibition. Further studies showed that exposure of the anterior pituitary to intermediate lobectomy extracts (devoid of VIP, vasopressin, and other known PRFs) stimulated PRL secretion. At least two kinds of PRF activity have been isolated from intermediate lobe tumors of the mouse, but the specific molecules involved have yet to be identified. Other researchers have suggested a more passive role for the neurointermediate lobe in the regulation of PRL secretion. Melanotropin-derived N-acetylated MSH appears to act as a lactotroph responsiveness factor by recruiting nonsecretory cells to an active state and sensitizing secreting lactotrophs to the actions of other direct PRFs. However, the relevance of the neurointermediate lobe for PRL regulation in primates (including humans) is not clear because of its atrophied structure in these species.

Neuroendoctrine Regulation of Prolactin Secretion

Secretion of PRL, like that of other anterior pituitary hormones, is regulated by hormonal feedback and neural influences from the hypothalamus. Feedback is exerted by PRL itself at the level of the hypothalamus. PRL secretion is regulated by many physiologic states including the estrous and menstrual cycles, pregnancy, and lactation. Furthermore, PRL is stimulated by several extrereceptive stimuli including light, ultrasonic vocalization of pups, olfactory cues, and various modalities of stress. Expression and secretion of PRL are also influenced strongly by estrogens at the level of both the lactotrophs and TIDA neurons (see Fig. 7-35) and by paracrine regulators within the pituitary such as galanin and VIP.

Feedback Control

Negative feedback control of PRL secretion is mediated by a unique short-loop mechanism within the hypothalamus. PRL activates PRL receptors, which are expressed on all three subpopulations of A12 and A14 dopamine neurons, leading to increased tyrosine hydroxylase expression and dopamine synthesis and release. Ames dwarf mice that secrete virtually no PRL, GH, or TSH have decreased numbers of arcuate dopamine neurons and this hypoplasia can be reversed by neonatal administration of PRL, suggesting a trophic action on the neurons. However, another mouse model of isolated PRL deficiency generated by gene targeting appears to have normal numbers of hypofunctioning dopamine neurons secondary to the loss of PRL feedback.

Neural Control

Lactotrophs have spontaneously high secretory activity, and therefore the predominant effect of the hypothalamus on PRL secretion is tonic suppression, which is mediated by regulatory hormones synthesized by tuberohypophyseal neurons. Secretory bursts of PRL are caused by the acute withdrawal of dopamine inhibition, stimulation by PRFs, or combinations of both events. At any given moment, locally produced autocrine and paracrine regulators further modulate the responsiveness of individual lactotrophs to neurohormonal PIFs and PRFs.

Multiple neurotransmitter systems impinge on the hypothalamic dopamine and PRF neurons to regulate their neurosecretion (see Fig. 7-35). Nicotinic cholinergic and glutamatergic afferents activate TIDA neurons, whereas histamine, acting predominantly through H2 receptors, inhibits these neurons. An inhibitory peptidergic input to TIDA neurons of major physiologic significance is that associated with the endogenous opioid peptides enkephalin and dynorphin and their cognate - and -receptor subtypes. Opioid inhibition of dopamine release has been associated with increased PRL secretion under virtually all physiologic conditions, including the basal state, different phases of the estrous cycle, lactation, and stress.

Ascending serotoninergic inputs from the dorsal raphe nucleus are the major activator of PRF neurons in the paraventricular nucleus. There is still debate concerning the identity of the specific 5-hydroxytryptamine receptors involved in this activation.

The PRL regulatory system and its monoaminergic control have been scrutinized in detail because of the frequent occurrence of syndromes of PRL hypersecretion (see Chapter 8). Both the pituitary and the hypothalamus have dopamine receptors, and unfortunately the response to dopamine receptor stimulation and blockade does not distinguish between central and peripheral actions of the drug. Many commonly used neuroleptic drugs influence PRL secretion. Reserpine (a catecholamine depletor) and phenoxybenzamine such as chlorpromazine and haloperidol enhance PRL release by disinhibition of dopamine action on the pituitary, and the PRL response is an excellent predictor of the antipsychotic effects of phenothiazines because of its correlation with D2 receptor binding and activation.
antipsychotic neuroleptic agents act on brain dopamine receptors in the mesolimbic system and in the pituitary-regulating tuberoinfundibular system. Consequently, treatment of such patients with dopamine agonists such as bromocriptine can reverse the psychiatric benefits of such drugs. A report of three patients with psychosis and concomitant prolactinomas recommended the combination of clozapine and quinagolide as the treatment of choice to manage both diseases simultaneously.

Factors Influencing Secretion

Circadian Rhythm

PRL is detectable in plasma at all times during the day but is secreted in discrete pulses superimposed on basal secretion and exhibits a diurnal rhythm with peak values in the early morning. There is a true circadian rhythm in humans because it is maintained in a constant environment independent of the sleep rhythm. The combined body of data examining TIDA neuronal activity, dopamine concentrations in the median eminence, and manipulations of the SCN suggests that endogenous diurnal alterations in dopamine tone that are entrained by light constitute the major neuroendocrine mechanism underlying the circadian rhythm of PRL secretion.

External Stimuli

The suckling stimulus is the most important physiologic regulator of PRL secretion. Within 1 to 3 minutes of nipple stimulation, PRL levels rise and remain elevated for 10 to 20 minutes. This reflex is distinct from the milk let-down, which involves oxytocin release from the neurohypophysis and contraction of mammary alveolar myoepithelial cells. These reflexes provide a mechanism by which the infant regulates both the production and the delivery of milk. The nocturnal rise in PRL secretion in nursing women and in non-nursing women may have evolved as a mechanism of milk maintenance during prolonged nonsuckling periods at night.

Pathways involved in the suckling reflex arise in nerves innervating the nipple, enter the spinal cord by way of spinal afferent neurons, ascend the spinal cord through spinothalamic tracts to the midbrain, and enter the hypothalamus by way of the median forebrain bundle. In most of the pathway, neurons regulating the oxytocin-dependent milk let-down response accompany those involved in PRL regulation and then separate at the level of the paraventricular nuclei. The suckling reflex brings about an inhibition of PIF activity and a release of PRFs, although the identity of an undisputed suckling-induced PRF is unsettled.

Although the significance for PRL regulation in humans is not certain, environmental stimuli from seasonal changes in light duration and auditory and olfactory cues are clearly of great importance to many mammalian species. Seasonal breeders, such as the sheep, exhibit a reduction in PRL secretion in response to shortened days. The specific ultrasound vocalization of rodent pups is among the most potent stimuli for PRL secretion in lactating and virgin female rats. Olfactory stimuli from pheromones also have potent actions in rodents. A prime example is the Bruce effect or spontaneous abortion induced by exposure of a pregnant female rat to an unfamiliar male. It is mediated by a well-studied neural circuitry involving the vomeronasal nerves, corticomedial amygdala, medial preoptic area of the hypothalamus, and finally activation of TIDA neurons and a reduction in circulating PRL that is essential for maintenance of luteal function in the first half of pregnancy.

Stress in many forms dramatically affects PRL secretion, although the teleologic significance is uncertain. It may be related to actions of PRL on cells of the immune system or some other aspect of homeostasis. Different stressors are associated with either a reduction or an increase in PRL secretion, depending on the local regulatory environment at the time of the stress. However, whereas well-documented changes in PRL are associated with relatively severe forms of stress in laboratory animal models, a study of academic stress in college students failed to show any significant correlation among the time periods before, during, or after final examinations and diurnal PRL levels.
Gonadotropin-Releasing Hormone and Control of the Reproductive Axis

Chemistry and Evolution

The hypothalamic neuropeptide that controls the function of the reproductive axis is GnRH. GnRH is a 10-amino-acid peptide that is synthesized as part of a larger precursor molecule and is then enzymatically cleaved to remove a signal peptide from the N-terminus and GnRH-associated peptide (GAP) from the C-terminus (Fig. 7-36). All forms of the decapeptide have a pyroGlu at the N-terminus and Gly-amide at the C-terminus, indicating the functional importance of the terminal regions throughout evolutionary biology.

Within mammals, two genes encoding GnRH have been identified. The first encodes a 92-amino-acid precursor protein. This form of GnRH is now referred to as GnRH-I and is the form found in hypothalamic neurons that serves as a releasing factor to regulate pituitary gonadotropin function. The second GnRH gene, GnRH-II, encodes a decapetide that differs from the first by three amino acids. This form of GnRH is found in the midbrain region and serves as a neurotransmitter rather than as a pituitary releasing factor. Both GnRH-I and GnRH-II are found in phylogenetically diverse species, from fish to mammals, suggesting that these multiple forms of GnRH diverged from one another early in vertebrate evolution. A third form of GnRH, GnRH-III, has been identified in neurons of the telencephalon in teleost fish. This form of GnRH may have been lost in higher vertebrates or simply not yet discovered in other species.

As discussed subsequently in more detail, GnRH-I and GnRH-III are found in cells that originate in the olfactory placode in early embryonic development. In contrast, GnRH-I-containing cells are derived from the midbrain ventricle. GnRH is also found in cells outside the brain. The roles of GnRH peptides produced outside the brain are not well understood but are an area of current investigation.

All GnRH genes have the same basic structure, with the pre-prohormone mRNA encoded in four exons. Exon 1 contains the 5' untranslated region of the gene; exon 2 contains the signal peptide, GnRH, and the N-terminus of GAP; exon 3 contains the central portion of GAP; and exon 4 contains the C-terminus of GAP and the 3' untranslated region (see Fig. 7-36). Among species, the nucleotide sequences encoding the GnRH decapetide are highly homologous.

Two transcriptional start sites have been identified in GnRH genes at +1 and -579, with the +1 promoter being active in hypothalamic neurons and the other promoter active in placenta. The first 173 base pairs of the promoter are highly conserved among species. In the rat, this promoter region has been shown to contain two Oct-1 binding sites; three regions that bind the Pou domain family of transcription factors, SCIP, Oct-6, and Tst-1; and three regions that can bind the progesterone receptor. In addition, a variety of promoters and second messengers have been shown to regulate GnRH gene expression, and the majority of the cis-acting elements thus far characterized for hormonal control of GnRH transcription have been localized to the proximal promoter region. The 5' untranslated region of the GnRH gene also contains a 300-base-pair enhancer region that is 1.8 kilobases upstream of the transcription start site. It contains binding sites for Pou homeodomain transcription factors and GATA factors.

In this chapter, we focus on the hypothalamic GnRH that is derived from GnRH-I mRNA and plays an important role in the regulation of the hypothalamic-pituitary-gonadal axis. A mutant strain of mice with a deletion of the GnRH-I gene have hypogonadism, and the homozygous animals are infertile.

Anatomic Distribution

GnRH neurons are small, diffusely located cells that are not concentrated in a nucleus (Fig. 7-37A). They are generally bipolar and fusiform in shape, with long thin axons that can exhibit spines. The location of hypothalamic GnRH neurons is species-dependent. In the rat, hypothalamic GnRH neurons are concentrated in rostral areas including the medial preoptic area, the diagonal band of Broca, the septal areas, and the anterior hypothalamus. In primates, the majority of hypothalamic GnRH neurons are located more dorsally in the medial basal hypothalamus, the infundibulum, and periventricular to the third ventricle. Throughout the hypothalamus, neuroendocrine GnRH neurons, which extend their axon terminals to the median eminence, are interspersed with non-neuroendocrine GnRH neurons, which extend their axons to other regions of the brain including other hypothalamic regions and various regions of the cortex. GnRH secreted from non-neuroendocrine neurons has been implicated in the control of sexual behavior in rodents but not in higher primates.

Embryonic Development

GnRH neuronal development is an unusual neuronal population in that they originate outside the CNS, from the epithelial tissue of the nasal placode. During embryonic development GnRH neurons migrate across the surface of the brain and into the hypothalamus, with the final hypothalamic location differing somewhat among species. Migration is dependent on a scaffolding of neurons and glial cells along which the GnRH neurons move, with neural cell adhesion molecules playing a critical role in guiding the migration process.

Failure of GnRH neurons to migrate properly leads to a clinical condition, Kallman's syndrome, in which GnRH neuroendocrine neurons do not reach their final destination and thus do not stimulate pituitary gonadotropin secretion. Patients with Kallman's syndrome do not enter puberty spontaneously. X-linked Kallman's syndrome results from a deficiency of the KAL-1 gene, which encodes a putative protein of 680 amino acids and contains four fibronectin type III repeats and a four-disulfide core motif. However, this form of Kallman's syndrome accounts for only a small percentage (about 8%) of cases, and the cause of other forms remains unknown. Administration of exogenous GnRH effectively treats this form of hypothalamic hypogonadism. Patients with Kallman's syndrome often have other congenital midline defects, including anosmia, which results from hypoplasia of the olfactory bulb and tract.

Action at the Pituitary

Receptors

GnRH binds to a membrane receptor on pituitary gonadotrophs and stimulates both LH and FSH synthesis and secretion. The GnRH receptor is a seven-transmembrane-domain G protein-coupled receptor, but it lacks a typical intracellular C-terminal cytoplasmic domain. Under physiologic conditions, the GnRH receptor number varies and is usually directly correlated with the gonadotropin secretory capacity of pituitary gonadotrophs. For example, across the rat estrous cycle, a rise in GnRH receptors is seen just before the surge of gonadotropins that occurs on the afternoon of proestrus. GnRH receptor message levels are regulated by a variety of hormones and second messengers including steroid hormones (estradiol can both suppress and stimulate, and progesterone suppresses), gonadotropins (which suppress), and calcium and protein kinase C (which stimulate).

G_Na1 is the primary guanosine triphosphate-binding protein mediating GnRH responses; however, there is evidence that GnRH receptors can couple to other guanosine triphosphate-binding proteins including G_s and G_i. With activation, the GnRH receptor couples to a phosphoinoside-specific phospholipase C, which leads to increases in calcium transport into gonadotrophs and calcium release from internal stores through a diacylglycerol protein kinase C pathway. Increased calcium entry is a critical step in GnRH-stimulated release of gonadotropin secretion.

However, the MAPK cascade is also stimulated by GnRH.
When there is a decline in GnRH stimulation to the pituitary, as occurs in a variety of physiologic conditions including states of lactation, undemnurbation, or seasonal periods of reproductive quiescence, the number of GnRH receptors on pituitary gonadotrophs declines dramatically.\textsuperscript{2+} Subsequent exposure of the pituitary to pulses of GnRH restores receptor number by a Ca\textsuperscript{2+}-dependent mechanism that requires protein synthesis.\textsuperscript{3+} The effect of GnRH to induce its own receptor is termed up-regulation or self-priming. Only certain physiologic frequencies of pulsatile GnRH can augment GnRH receptor production, and these frequencies appear to differ among species.\textsuperscript{4+} Up-regulation of GnRH receptors after a period of low GnRH stimulation to the pituitary can take hours to days of exposure to pulsatile GnRH, depending on the duration and extent of the prior decrease in GnRH. The self-priming effect of GnRH to up-regulate its own receptors also plays a crucial role in the production of the gonadotropin surge that occurs at midcycle in females of spontaneously ovulating species and triggers ovulation. Just before the gonadotropin surge, two factors, the increased frequency of pulsatile GnRH release and a sensitization of the pituitary gonadotrophs by rising levels of estradiol, make the pituitary exquisitely sensitive to GnRH and allow an output of LH that is an order of magnitude greater than the release seen during the rest of the female reproductive cycle. This surge of LH triggers the ovulatory process at the ovary.

In contrast to up-regulation of GnRH receptors by pulsatile regimens of GnRH, continuous exposure to GnRH leads to down-regulation of GnRH receptors and an accompanying decrease in LH and FSH synthesis and secretion, termed desensitization.\textsuperscript{5+} Down-regulation does not require calcium mobilization or gonadotropin secretion.\textsuperscript{6+} It involves a rapid uncoupling of receptor from G proteins and sequestration of the receptors from the plasma membrane, followed by internalization and proteolytic degradation of the receptors.\textsuperscript{7+}

The concept of down-regulation has a number of clinical applications. For example, the most common current therapy for precocious puberty of hypothalamic origin (i.e., precocious GnRH secretion) is to treat the child with a long-acting

\end{figure}

GnRH agonist, which down-regulates pituitary GnRH receptors and effectively turns off the reproductive axis.\textsuperscript{8+} Children with precocious puberty can be maintained with long-acting GnRH agonists for years to suppress the premature activation of the reproductive axis, and at the normal age of puberty agonist treatment can be withdrawn, allowing a reactivation of pituitary gonadotrophs and a downstream increase in gonadal steroid hormone production. Long-acting GnRH agonists are also used in the treatment of forms of breast cancer that are estrogen-dependent as well as other gonadal steroid-dependent cancers.\textsuperscript{9+} Long-acting antagonists of GnRH have been developed that can also be used for these therapies.\textsuperscript{10} Antagonists have the advantage of not having a flare effect, that is, an acute stimulation of gonadotropin secretion that is seen during the initial treatment of individuals with superagonists.

\caption{A, Schematic diagram of the hypothalamic-pituitary-gonadal axis showing neural systems that regulate GnRH secretion and feedback of gonadal steroid hormones at the level of the hypothalamus and pituitary: CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, -aminobutyric acid; LH, luteinizing hormone; NPY, neuropeptide Y. Frequent blood samples from the peripheral blood stream is used to define the pulsatile nature of LH secretion (i.e., frequency and amplitude of LH pulses), and pulsatile LH is used as an indirect measure of the activity of the GnRH secretory system. Indirect measurement of GnRH secretion is thus used in many animal studies examining the factors that govern the regulation of the pulsatile activity of the reproductive neuroendocrine axis. Unlike}
\end{figure}

Pulsatile Gonadotropin-Releasing Hormone Stimulation

Because a single pulse of GnRH stimulates the release of both LH and FSH and chronic exposure of the pituitary to pulsatile GnRH supports the synthesis of both LH and FSH, many people believe that there is only one releasing factor regulating the synthesis and secretion of LH and FSH.\textsuperscript{11+} However, in a number of physiologic conditions there are divergent patterns of LH and FSH secretion, and thus a second FSH-releasing peptide has been proposed, but such a peptide has not been isolated to date.\textsuperscript{12+} Other mechanisms, discussed in more detail later, are likely to account for the differential regulation of LH and FSH release.

The ensemble of GnRH neurons in the hypothalamus that send axons to the portal blood system in the median eminence fire in a coordinated, repetitive, episodic manner, producing distinct pulses of GnRH in the portal blood stream.\textsuperscript{13} The pulsatile nature of GnRH stimulation to the pituitary leads to the release of distinct pulses of LH into the peripheral blood stream.\textsuperscript{14} In experimental animals, in which it is possible to collect blood samples simultaneously from the portal and peripheral blood stream, GnRH and LH pulses have been found to correspond in about a one-to-one ratio at most physiologic rates of secretion (Fig. 7-38) (Figure Not Available).\textsuperscript{15} Because the portal blood stream is generally inaccessible in humans, the collection of

\end{figure}

LH secretion, FSH secretion is not always pulsatile, and even when it is pulsatile, there is only partial concordance between LH and FSH pulses.\textsuperscript{16+}

It is possible to place multiple unit recording electrodes in the medial basal hypothalamus of monkeys and other species and find spikes of electrical activity that are concordant with the pulsatile discharge of LH secretion.\textsuperscript{17} It is unknown, however, whether these bursts of electrical activity reflect the activity of GnRH neurons themselves or the activity of neurons that impinge on GnRH neurons and govern their firing. With the development of mice in which the gene for green fluorescent protein has been under the regulation of the GnRH promoter, it has been possible to identify GnRH neurons in hypothalamic tissue slices using fluorescence microscopy and record from them intracellularly.\textsuperscript{18} These studies

\caption{The influence of gonadotropin-releasing hormone (GnRH) pulse frequency on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion in a female mule monkey with an acute nucleus lesion abating endogenous GnRH support of the pituitary. Decreasing GnRH pulse frequency from 1 pulse/hour to 1 pulse/3 hours leads to a decrease in plasma LH concentrations but an increase in plasma FSH concentrations. (Redrawn from Wilt L, Haueter A, Marshall G, et al. Endocrinology 1987; 109:376385.)}
\end{figure}

have shown that many, but not all, GnRH neurons show a bursting pattern of electrical activity. A central, unsolved question in the field of reproductive neuroendocrinology is what causes GnRH neurons to pulse in a coordinated manner. Studies using a line of clonal GnRH neurons have shown that these neurons grown in culture can release GnRH in a pulsatile pattern, suggesting that the pulse-generating capacity of GnRH neurons may be intrinsic.\textsuperscript{19} The term GnRH pulse generator is often used to acknowledge the fact that GnRH secretion occurs in pulses and to refer to the central mechanisms responsible for pulsatile GnRH
A critical factor governing LH and FSH secretion and release is the rate of pulsatile GnRH stimulation of the gonadotropes. Experimental studies in which the hypothalamus was lesioned and GnRH was replaced by pulsatile administration of exogenous GnRH showed that different frequencies of GnRH can lead to differential ratios of LH to FSH secretion from the pituitary. Figure 7-39 shows that in a monkey with a hypothalamic lesion, replacement of one pulse of GnRH per hour led to a relatively low ratio of FSH to LH secretion. Subsequent institution of a slower pulse frequency of one pulse of GnRH every 3 hours led to a decrease in LH secretion but an increase in FSH secretion such that the ratio of FSH to LH secretion was greatly elevated. It is likely that this effect of pulse frequency on the ratio of FSH to LH secretion accounts, at least in part, for the clinical finding that at times when the GnRH pulse generator is just turning on, such as at the onset of puberty and during recovery from chronic undernutrition, the ratio of FSH to LH is higher than when it is measured in adults experiencing regular reproductive function. As discussed subsequently, steroid hormones act at both the hypothalamus and pituitary to influence strongly the rate of pulsatile GnRH release and amount of LH and FSH secreted from the pituitary.

GnRH pulse frequency not only influences the rate of pulsatile gonadotropin release and the ratio of FSH to LH secretion but also plays an important role in modulating the structural makeup of the gonadotropins. LH and FSH are structurally similar glycoprotein hormones. Each of these hormones is made up of an α subunit and a β subunit, and each has a unique subunit that conveys tissue specificity to the intact hormone. Before secretion of gonadotropins, terms such as LH and FSH are attached to their respective gonadotropin molecule. The sugars include sialic acid, galactose, α-acetylgalactosamine, and mannose, but the most important is sialic acid. The extent of glycosylation of LH and FSH is important for the physiologic function of these hormones. Forms of gonadotropin with more sialic acid have a longer half-life because they are protected from degradation by the liver. Forms of gonadotropin with less sialic acid can have more potent effects at their biologic receptors. Both the rate of GnRH stimulation and ovarian hormone feedback at the level of the pituitary regulate the degree of LH and FSH glycosylation. For example, slow frequencies of GnRH, seen during follicular development, are associated with greater degrees of FSH glycosylation, which would provide sustained FSH support to growing follicles. In contrast, faster frequencies of GnRH, seen just before the midcycle gonadotropin surge, are associated with lesser degrees of FSH glycosylation, providing a more potent but shorter lasting form of FSH at the time of ovulation.

Regulatory Systems

Many neurotransmitter systems from the brain stem, limbic system, and other areas of the hypothalamic convey information to GnRH neurons (see Fig. 7-37; Fig. 7-38). These systems include suprachiasmatic, serotonergic, GABA-ergic, and a number of other peptide neurotransmitters. Glutamate and norepinephrine play important roles in providing stimulatory drive to the reproductive axis, whereas GABA and endogenous opioid peptides provide a substantial portion of the inhibitory drive to GnRH neurons. Influences of specific neurotransmitter systems are discussed where appropriate in later sections on the physiologic regulation of GnRH neurons.

GnRH neurons are surrounded by glial processes, and only a small percentage of their surface area is available to receive dendritic contacts fromafferent neurons. Changes in the steroid hormone milieu influence the degree of glial sheathing and may play important roles in regulating afferent input to GnRH neurons by this mechanism. Some glial cells also secrete substances that can modulate the activity of GnRH neurons. For example, alpupherty there is an increase in the hypothalamic expression of transforming growth factor, and transforming growth factor can stimulate GnRH release by acting on astroglial cells to stimulate their release of PGE₂, which is stimulatory to GnRH neurons.

Feedback Regulation

Steroid hormone receptors are abundant in the hypothalamus and in many neural systems that impinge on GnRH neurons, including noradrenergic, serotonergic, -endorphincontaining, and NPY neurons. Early studies identifying regions of the brain that bound labeled estrogens showed that in rodents the preoptic area and ventromedial hypothalamus had the highest concentrations of estrogen receptors in the brain. Further localization studies, identifying estrogen receptors by immunocytochemistry or in situ hybridization, confirmed the strong presence of estrogen receptors in the hypothalamus and in brain areas with strong connections to the hypothalamus, including the amygdala, septal nuclei, bed nucleus of the stria terminalis, medial part of the nucleus of the solitary tract, and lateral portion of the parabrachial nucleus. In 1986 a new member of the steroid hormone receptor superfamily with high sequence homology to the classical estrogen receptor (now referred to as estrogen receptor ) was isolated from rat prostate and named estrogen receptor . This novel estrogen receptor was shown to bind estradiol and to activate transcription by binding to estrogen response elements.

In situ hybridization studies examining the localization of estrogen receptor mRNA have shown that these receptors are present throughout the rostral-caudal extent of the brain, with a high level of expression in the preoptic area, bed nucleus of the stria terminalis, paraventricular and supraoptic nuclei, amygdala, and laminae II to VI of the cerebral cortex. Specific receptors for progesterone are induced by estrogen in hypothalamic regions of the brain, including the preoptic area, the ventromedial and ventrolateral nuclei, and the infundibular-arcuate nucleus, although there is also evidence for constitutive expression of progesterone receptors in some hypothalamic regions. Androgen receptor mRNA is found in the distribution of androgen and estrogen receptors throughout the brain. The highest density of androgen receptors was found in hypothalamic nuclei known to participate in the control of reproduction and sexual behaviors, including the arcuate nucleus, paraventricular nucleus, medial preoptic nucleus, ventromedial nucleus, and brain regions with strong connections to the hypothalamus including the amygdala, nuclei of the septal region, bed nucleus of the stria terminalis, nucleus of the solitary tract, and lateral division of the parabrachial nucleus.

The anterior pituitary also contains receptors for all of the gonadal steroid hormones. Steroid hormones can dramatically alter the pattern of pulsatile release of GnRH and of the gonadotropins through actions at both the hypothalamus and the pituitary (Fig. 7-40 and Fig. 7-41). At the hypothalamus, estradiol, progesterone, and testosterone can all act to slow the frequency of GnRH release into the portal blood stream, an action referred to as negative feedback. Because GnRH neurons have generally been shown to lack steroid hormone receptors, it is likely that the effects of steroid hormones on the firing rate of GnRH neurons are mediated by steroid hormone actions on other neural systems that provide afferent input to GnRH neurons. For example, progesterone-mediated negative feedback on GnRH secretion in primates appears to be regulated by -endorphincontaining neurons in the hypothalamus, acting primarily through μ-opioid receptors. If a μ-opioid antagonist, such as naloxone, is administered along with progesterone, the negative feedback action of progesterone on GnRH secretion can be blocked.

Negative feedback of steroid hormones can also occur directly at the level of the pituitary. For example, estradiol has been shown to be capable of binding to the pituitary, decreasing LH and FSH synthesis and release, and decreasing the sensitivity of pituitary gonadotropes to the actions of GnRH such that less LH and FSH are released when a pulse of GnRH stimulates the pituitary. Evidence for such a direct pituitary action of estradiol came from studies with rhesus monkeys that had been rendered deficient in endogenous GnRH by a lesion in the arcuate nucleus and showed a decline in endogenous gonadotropin secretion. When these monkeys received exogenous GnRH gonadotropin secretion, subsequent estradiol infusions dramatically suppressed the responsiveness of the pituitary to GnRH and suppressed the gonadotropin secretion that was being driven by the pulsatile administration of GnRH. Steroid hormones can have direct negative feedback actions at the pituitary; however, the extent of hypothalamic versus pituitary negative feedback actions is species-specific. In primate species including humans, there is considerable feedback of estradiol at the pituitary, but most of the progesterone and testosterone negative feedback occurs at the level of the hypothalamus.

Most of the time, the hypothalamic-pituitary axis is under the negative feedback influence of gonadal steroid hormones. If the gonads are removed surgically or their normal secretory function of steroid hormones is suppressed pharmacologically, there is a dramatic increase (10-fold to 20-fold) in circulating levels of LH and FSH secretion. This type of "castration response" occurs normally at the menopause in women, when...
Regulation of the Ovarian Cycle

Ovarian follicular development and thus ovarian production of large quantities of estradiol and progesterone decrease and eventually cease.

In addition to negative feedback, estradiol can have a positive feedback action at the level of the hypothalamus and pituitary to lead to a massive release of LH and FSH from the pituitary.

This massive release of gonadotropins occurs once each menstrual cycle and is referred to as the LH-FSH surge. The positive feedback action of estradiol acts as a response to the rising tide of estradiol that is produced during the process of dominant follicle development in the late follicular phase of the menstrual cycle. In women, elevated estradiol levels are generally maintained at about 500 pg/mL for about 36 hours prior to stimulation of the gonadotropin surge.

Experiments have shown that both a critical concentration of plasma estradiol and a critical duration of elevated estradiol are necessary to achieve positive feedback and a resulting gonadotropin surge (see Fig. 7-41). Moreover, the duration of estradiol elevation that is required to trigger a surge depends on the concentration of estradiol. If supra-physiological doses of estradiol are administered, the surge can occur as early as 18 hours after their administration. Because the ovary is responsible for the production of estradiol and the time course and magnitude of estradiol release control the rate of positive feedback, the ovary has been referred to as the zeitgeber of the menstrual cycle. The dependence of the positive feedback system on the magnitude of estradiol production helps explain the fact that the portion of the menstrual cycle that varies most in length is the follicular phase. Production of higher levels of estradiol by a dominant follicle in one cycle would lead to a more rapid positive feedback action with earlier ovulation and thus a shorter follicular phase compared with a cycle in which the dominant follicle produced lower levels of estradiol.

As with negative feedback in response to estradiol, the positive feedback actions of estradiol occur both at the hypothalamus, to increase GnRH secretion, and at the pituitary, to enhance greatly pituitary responsiveness to GnRH. At the pituitary, estradiol increases pituitary sensitivity to GnRH by increasing the synthesis of new GnRH receptors and by enhancing the responsiveness to GnRH at a postreceptor site of action. At the level of the hypothalamus in rodent species, estradiol appears to act at a “surge center” to induce the ovulatory surge of GnRH. Lesions in areas adjacent to the medial preoptic area, near the anterior commissure and sepal complexes, block the ability of estradiol to induce a surge in these species without blocking negative feedback effects of estradiol. In primate species, there does not appear to be a separate surge center mediating the positive feedback actions of estradiol. The cellular mechanisms that mediate the switch from negative to positive feedback of estradiol are not fully understood, but there is support for the concept that estrogen induction of various transcription factors and receptors (notably progesterone receptors) may play an important role in mediating this switch. Alternatively, estrogen has been shown to have biphasic actions on hypothalamic GABAergic neurons that impinge on GnRH neurons and are strong regulators of their activity, with the switch in action dependent on the duration of estradiol exposure. The molecular mechanisms by which estradiol influences GnRH gene expression are also not well understood, but it is likely that these influences occur through actions of neural systems afferent to GnRH because GnRH neurons do not appear to have estrogen receptors. Much more is known about the molecular mechanisms by which estradiol acts at the pituitary to regulate gonadotropin gene expression. Expression of LH subunit is strongly regulated (10-fold to 14-fold) by estradiol, but expression of FSH and subunits is regulated to a lesser extent (4-fold to 8-fold and 2-fold to 3-fold, respectively). Although in vivo studies indicate strong negative feedback actions of estradiol on LH gene transcription, such actions have not been replicated in in vitro studies with isolated pituitaries, leading to the conclusion that estradiol negative feedback on gonadotropin synthesis occurs predominantly by extrapituitary mechanisms. In contrast, estradiol can stimulate LH mRNA transcription directly at the level of the pituitary, acting by binding to an estrogen response element in the 5’ promoter region of the LH gene.

Regulation by Inhibins and Activins

Negative feedback of pituitary FSH secretion is also exerted by a family of peptide hormones produced by the gonads, the inhibins. Inhibins are produced by follicular and luteal cells of the ovary and by Sertoli cells in the testes. Inhibins are members of the transforming growth factor superfamily and comprise two subunits, an and a subunit. There are two forms of the subunit, A and B. Inhibins selectively inhibit the release of LH and FSH from gonadotrophs. Activins selectively suppress FSH secretion without simultaneous suppression of the LH secretion; thus, they provide one of the mechanisms whereby the pituitary can release differential amounts of LH and FSH, even though there appears to be only a single GnRH receptor. Alternatively, estrogen has been shown to have biphasic actions on hypothalamic GABAergic neurons that impinge on GnRH neurons and are strong regulators of their activity, with the switch in action dependent on the duration of estradiol exposure.

Activins received their name from their ability to facilitate FSH release. Activins have been shown to stimulate both basal and GnRH-induced FSH release from the anterior pituitary as well as increase FSH mRNA levels by enhancing transcription. An important role of endogenous activins in stimulating FSH secretion is supported by the finding that transgenic mice deficient in activin receptor IIa have reduced serum FSH levels. Activins have other actions in pituitary gonadotrophs as well, including up-regulation of GnRH receptors and enhancement of GnRH-stimulated LH release. Activins and inhibins also have local actions within the ovary influencing granulosa cell growth and differentiation, the responsiveness of the ovary to gonadotropins, steroid hormone production, follicular development, and oocyte maturation.

Regulation of the Ovarian Cycle

Whereas in males spermatogenesis occurs continually throughout the adult years, females show a cyclic pattern of ovarian activity with intermittent maturation and release of ova from the ovaries. Cyclic activity in the ovary is controlled by an interplay between steroid hormones produced by the ovary and the hypothalamic-pituitary neuroendocrine components of the reproductive axis. The duration of each phase of the ovarian cycle is species-dependent, but the general mechanisms controlling the cycle are similar in all species that have spontaneous ovarian cycles. In the human menstrual cycle, day 1 of the cycle is designated as the first day of menstrual bleeding. At this time, small and medium-sized follicles are present in the ovaries and only small amounts of estradiol are produced by the follicular cells. As a result, there is a low level of negative feedback to the hypothalamic-pituitary axis, LH pulse frequency is relatively fast (one pulse about every 60 minutes), and FSH concentrations are slightly elevated compared with much of the rest of the cycle. FSH acts at the level of the ovarian follicles to stimulate development and causes an increase in follicular estradiol production, which in turn provides increased negative feedback to the hypothalamic-pituitary unit.

A result of the increased negative feedback is a slowing of pulsatile LH secretion over the course of the follicular phase to a rate of about one pulse every 90 minutes. However, as the growing follicle (or follicles, depending on the species) secretes more estradiol, a positive feedback action of estradiol is triggered that leads to an increase in GnRH release and a surge release of LH and FSH. The surge of gonadotropins acts at the fully developed follicle to stimulate the dissolution of the follicular wall and leads to ovulation of the matured ovum into the nearby fallopian tube, where fertilization takes place if sperm are present.
after about 14 days and progesterone and estradiol secretion diminishes. This reduces the negative feedback signals to the hypothalamus and pituitary and allows an increase in FSH and LH secretion. The fall in progesterone is also a withdrawal of steroid hormone support to the endometrial lining of the uterus, and as a result the endometrium is shed as menses and a new cycle begins.

In other species, the interplay between the neuroendocrine and ovarian hormones is similar but the timing of events is different and other factors, such as circadian and seasonal regulatory factors, play a role in regulating the cycle. The rat has a 4- or 5-day ovarian cycle with no menses (the endometrial lining is absorbed rather than shed). The rat also shows strong circadian rhythmicity in the timing of the LH-FSH surge, with the surge always occurring in the afternoon of the day of proestrus. Sheep are an example of a species that has a strongly seasonal pattern of ovarian cyclicity. During the breeding season they have 15-day cycles, with a very short follicular phase and an extended luteal phase; during the nonbreeding season signals relay information about day length through the visual system, pineal, and SCN cause a dramatic suppression of GnRH neuronal activity, and cyclic ovarian function is prevented by a decrease in trophic hormonal support from the pituitary.

Early Development and Puberty

Neuroendocrine stimulation of the reproductive axis is initiated during fetal development, and in primates in midgestation circulating levels of LH and FSH reach values similar to those in castrated adults. Later in gestational development, gonadotropin levels decline, restrained by rising levels of circulating gonadal steroids. The steroids that have this effect are probably placental in origin in that after parturition there is a rise in circulating gonadotropin levels that is apparent for variable periods of the first year of life, depending on the species. The decline in reproductive hormone secretion in the postnatal period appears to be due to a decrease in GnRH stimulation of the reproductive axis because it occurs even in the castrate state and gonadotropin and gonadal steroid secretion can be supported by administration of pulses of GnRH.

Pubertal reawakening of the reproductive axis occurs in late childhood and is marked initially by nighttime elevations in gonadotropin and gonadal steroid hormone levels. The mechanisms controlling the pubertal reawakening of the GnRH pulse generator have been an area of intense investigation for the past two decades. Although the mechanisms are not fully understood, significant progress has been made in identifying central changes in the hypothalamus that appear to play a role in this process. There appear to be both a decrease in transsynaptic inhibition to the GnRH neuronal system at puberty and an increase in stimulatory input to GnRH neurons at this time. One of the major inhibitory inputs to the GnRH system is provided by GABAergic neurons. Studies in rhesus monkeys have shown that hypothalamic levels of GABA decrease early in puberty and that blocking GABAergic input before puberty, by intrahypothalamic administration of antiseizure oligodeoxynucleotides against the enzymes responsible for GABA synthesis, results in premature activation of the GnRH neuronal system.

It has been suggested, on the basis of findings that a subset of glutamate receptors (i.e., kainate receptors) increase in the hypothalamus at puberty, that the pubertal decrease in GABA tone may be caused by an increase in glutamatergic transmission. Further evidence for a role for glutamate comes from studies showing that administration of glutamate to prepubertal rhesus monkeys can drive the reawakening of the reproductive axis. Increased stimulatory drive to the GnRH neuronal system also appears to come from increases in norepinephrine and NPY at the time of puberty. Furthermore, as discussed earlier, there is evidence that growth factors act through release of prostaglandin from glial cells at puberty to play a role in stimulating GnRH neurons.

Despite an increased understanding of the neural changes occurring at puberty, the question of what signals trigger the pubertal awakening of the reproductive axis is unanswered at this time. Availability of food and nutritional status have been shown to affect the timing of puberty, but these signals appear to be only modulators of the pubertal process because puberty can be only moderately advanced by increasing food availability. Determining whether there is a genetic timing mechanism that regulates the timing of puberty or whether other signals from the body or the brain are responsible for timing the reactivation of the reproductive axis awaits further research.

Reproductive Function and Stress

Many forms of physical stresses, such as energy restriction, exercise, temperature stress, infection, pain, and injury, as well as psychological stresses, such as being subordinate in a dominance hierarchy or being acutely psychologically stressed, can suppress the activity of the reproductive axis. If the stress exposure is brief, there may be acute suppression of circulating gonadotropins and gonadal steroid hormones and in females disruption of normal menstrual cyclicity, but fertility is unlikely to be impaired. In contrast, prolonged periods of significant stress exposure can lead to complete impairment of reproductive function, also characterized by low circulating levels of gonadotropins and gonadal steroids. Stress appears to decrease the activity of the reproductive axis by decreasing GnRH drive to the pituitary because in all cases in which it has been examined, administration of exogenous GnRH can reverse the effects of the stress-induced decline in reproductive hormone secretion. Although we do not know the neural circuits through which many forms of stress suppress GnRH neuronal activity, some forms of stress-induced suppression of reproductive function are better understood.

In the case of foot shock stress in rats and immune stress (i.e., injection of IL-1) in primates, the suppression of gonadotropin secretion that occurs has been shown to be reversible by administration of a CRH antagonist, implying that endogenous CRH secretion mediates the effects of these stresses on GnRH neurons. In other studies, naloxone, a -opioid receptor antagonist, has been shown to be capable of reversing stress-induced suppression of gonadotropin secretion in monkeys; however, naloxone is ineffective in reversing the suppression of gonadotropin secretion that occurs during insulin-induced hypoglycemia. In the case of metabolic stresses, multiple regulators appear to mediate changes in the neural drive to the reproductive axis.

Various metabolic fuels including glucose and fatty acids can regulate the function of the reproductive axis, and blocking cellular utilization of these fuels can lead to suppression of gonadotropin secretion and decreased gonadal activity. Leptin, a hormone produced by fat cells, can also modulate the activity of the reproductive axis. Transgenic mice deficient in leptin or leptin receptors are infertile, and fertility can be restored by administration of leptin. Moreover, leptin administration has been shown to reverse the suppressive effects of undernutrition on the reproductive axis in some situations. Leptin receptors are found in several populations that are known to have a strong influence on the reproductive axis, notably NPY neurons.

In summary, it appears that a number of neural circuits can mediate effects of stress on the GnRH neuronal system and that the neural systems involved are at least somewhat specific to the type of stress that is experienced.
Leptin and the Brain-Gut-Adipose Axis

Long-term energy, stored as fat in adipose tissue, is homeostatically maintained by a hypothalamic system termed the lipostat or adipostat. Inputs to this system are many, including acute hormonal, nutritional, and vagal signals of hunger and satiety; the signal of long-term energy stores derived from the adipocyte hormone leptin; and powerful olfactory, visual, emotional, and cognitive inputs from higher brain centers. Outputs include those directed toward energy intake, primarily determined by feeding behavior, and energy expenditure, which can be broken down into basal metabolism, voluntary and involuntary activity, and diet-induced thermogenesis. As described throughout this chapter, energy homeostasis is maintained through the triad of behavioral, autonomic, and endocrine pathways. Thus, energy homeostasis is maintained by a complicated hypothalamic-brain stem-target organ axis that may be referred to as the brain-gut-adipose axis (Fig. 7-43).

The regulation of leptin levels is complex. For example, the hypothalamic system that regulates leptin release and action is under the influence of a variety of factors such as acute hormonal, nutritional, and vagal signals of hunger and satiety. Leptin is secreted primarily from the adipocyte; however, minor levels of regulated leptin expression also occur in other sites such as skeletal muscle, liver, heart, placenta, and stomach.

Effects of Leptin on the Hypothalamus and Neuropeptide Axes

A reduction in leptin levels occurs because of loss of adipose mass such as in anorexia nervosa, weight loss induced by diet or exercise, or starvation and is crucial to metabolic adaptation to a state of negative energy balance. This metabolic adaptation includes a decrease in metabolic rate that allows extended survival periods; inhibition of the reproductive, GH, and thyroid axes; and, at least in rodents, inhibition of the activity of the sympathetic nervous system and activation of the HPA axis.

In addition, leptin is a critical signal in the initiation of puberty. Leptin is a signal from the adipocyte tissue directed to the CNS that conveys readiness to proceed into puberty and is essential for fertility in the adult. Presumably, the leptin signal is a mechanism for the organism to determine whether adequate energy stores are present to maintain a pregnancy through term. For example, leptin administration restored fertility to db/db mice and prevented the starvation-induced delay in ovulation in female mice and rats.

Mechanism of Action

After secretion, leptin circulates in plasma in both free and bound forms. It is assumed that the binding protein is a soluble form of the leptin receptor, but other alternatives are being evaluated. In humans, the half-life of leptin is approximately 75 minutes.

The precise mechanism of the transport of leptin into the CNS is unknown. Active uptake of leptin has been described in the capillary endothelium and microvascularature of brains from humans and mice, suggesting a role of short isoforms of the leptin receptor. In addition, the transport of leptin into the choroid plexus is saturable.

After its transport through the blood-brain barrier, leptin binds to specific receptors in the hypothalamus. Leptin receptor mRNA is densely concentrated in the arcuate nucleus, and lower levels are found in the ventromedial and dorsomedial hypothalamic nuclei.

The leptin receptor is a member of the cytokine receptor superfamily. The leptin receptor binds Janus kinases (JAKs), tyrosine kinases involved in intracellular
signal transducer and activator of transcription (STAT) family of proteins. In turn, these STAT proteins activate transcription of leptin target genes.

A great deal of effort has gone into characterizing the mechanism of leptin action in the hypothalamus. Leptin appears to inhibit feeding and stimulate metabolism by acting on a small number of nuclei in the hypothalamus and brain stem, including the ventromedial hypothalamus and the arcuate, dorsomedial, and paraventricular hypothalamic nuclei. In these neurons, leptin up-regulates the expression of an assortment of anorexigenic peptides, such as -MSH, derived from the POMC pro-hormone gene (Fig. 7-46), cocaine and amphetamine-regulated transcript (CART), and neuropeptide Y, and decreases the expression of orexigenic peptides, NPY, AgRP, and melanin-concentrating hormone. Furthermore, leptin has been shown to depolarize and activate the firing rate of the anorexigenic POMC neurons and hyperpolarize the adjacent orexigenic NPY-ArgP neurons.

NPY, long known as a potent stimulator of feeding, was proved to have a role in leptin action when deletion of the NPY gene relieved a significant component of the obesity phenotype of the ob/ob mouse. The role of the NPY system in energy homeostasis was originally discovered from studies on the agouti mouse, one of the five naturally occurring monogenic obesity strains in the mouse. Intracerebroventricular administration of -MSH agonists and antagonist analogues inhibited stimulated feeding behavior, respectively. Furthermore, deletion of the melanocortin-4 receptor (MC4R), the primary neuronal receptor for the melanocortin peptides, caused an obesity syndrome identical to that seen in the obese leathal yellow agouti animal. The structure and distribution of the POMC and NPY-ArgP circuits are highly conserved in humans (Fig. 7-47) (Fig. Not Available). Furthermore, a null mutation in the POMC gene in humans caused an obesity syndrome similar to that seen in the leathal yellow mouse along with ACTH insufficiency and red hair (see

"Neuroendocrine Disease"). Thus, it appears that the central melanocortin system subserves the same purposes in mouse and humans. Although obesity related to genetic defects in leptin or the leptin receptor is rare in humans, haploinsufficiency of the MC4R appears to be responsible for up to 3% to 5% of severe pediatric obesity. Thus, the arcuate nucleus, site of the POMC-CART and NPY-ArgP neurons described earlier, is an important site of leptin action in humans.

Clinical Applications

Leptin deficiency and leptin receptor defects in humans are rare. In fact, serum leptin levels in humans are generally proportional to adipose mass. Thus, the vast majority of obese humans may be considered to manifest a leptin-resistant state rather than a deficient state. This concept of leptin resistance also remains poorly understood. However, it is thought that one mechanism of leptin resistance may be impaired leptin transport into the brain. Thus, suboptimal leptin transport through the blood-brain barrier may be one mechanism that underlies the development of leptin resistance in humans. Furthermore, the concept of leptin resistance leads to some reservations concerning the ability of exogenously administered leptin to overcome this leptin resistance and cause effective weight reduction in obese humans.

Clinical studies have now demonstrated that leptin treatment is safe and well tolerated and clearly effective in individuals with congenital leptin deficiency. In this study, low doses of methionyl leptin (met-leptin) were given to subjects with congenital deficiency that resulted in leptin levels 10% of that predicted on the basis of body fat. Leptin in this study was well tolerated and resulted in dramatic declines in appetite, body weight, and food intake. However, in individuals with common obesity, leptin had only modest effects on appetite and body weight. For example, studies evaluated the safety and efficacy of recombinant human met-leptin administration as well as pegylated human leptin. The first study was a double-blind, placebo-controlled, escalating-dose cohort trial in 54 lean and 73 obese subjects. Higher doses of met-leptin (0.01 to 0.3 mg/kg daily) were also given for 4 to 24 weeks. Met-leptin treatment resulted in significant dose-dependent weight loss: -1.3 kg (placebo...
Figure 7-48 Average plasma ghrelin, insulin, and leptin concentrations during a 24-hour period in 10 human subjects consuming breakfast (B), lunch (L), and dinner (D) at the times indicated (0800, 1200, and 1730 hours, respectively) (Reprinted with permission from Cummings DE, et al. A preprandial rise in plasma ghrelin levels suggest a role in meal initiation in humans. Diabetes 2001; 50:17141719.).

Of note, 95% of the weight loss achieved in the two highest dose cohorts was due to loss of fat mass and not any significant changes in fat free mass. The findings have supported the idea that leptin resistance may be partially overcome by a high enough overall leptin concentration.

Another study evaluated the efficacy of another long-acting leptin compound (A-200) in 200 obese subjects in a 24-week randomized, placebo-controlled pilot study with mild dietary intervention (500 calories below daily requirement). Results indicated that A-200 was safe, well tolerated, and resulted in a statistically significant decline in body weight and fat mass. Most of the weight loss again was determined to be secondary to decreases in fat mass. In a randomized, double-blind trial, 30 patients received either 20 mg of polyethylene glycol (PEG)-leptin or placebo weekly for 12 weeks. At the end of the study, patients receiving placebo had increased appetite and hunger levels in the fasting state, compared with reduced appetite and hunger in the treatment group. However, the treatment group did not experience reductions in daily food intake or body mass or changes in body composition compared with the control group. These findings led researchers to conclude that PEG-leptin has central rather than peripheral biologic activity in obese men.

Studies in rodents have demonstrated that leptin is highly efficacious as an antidiabetic agent in lipodystrophy, in which leptin deficiency is directly responsible for a hyperinsulinemic diabetic syndrome. The National Institute of Diabetes and Digestive and Kidney Diseases is currently studying the long-term efficacy of leptin replacement in patients with lipodystrophy (www.clinicaltrials.gov, National Institutes of Health protocols 02-DK-0146 and 02-DK-0022). Results from these studies are not yet available.

Feedback Control

Little is known about the cellular pathway involving leptin secretion. However, the rapid effects of -adrenergic stimulation on leptin release from adipose tissue suggest that leptin secretion is regulated by cAMP. As well, leptin secretion is upregulated by the hormones insulin and cortisol working synergistically and down-regulated by catecholamines, norepinephrine, and epinephrine. A report also suggests that cholecystokinin may regulate leptin secretion directly. Finally, TNF may be an important paracrine regulator of leptin secretion.

The interesting phenomenon of leptin resistance in obesity was initially suggested on the basis of the elevation of plasma leptin levels in obese humans. It turns out that, as with other cytokine receptors, activation of the leptin receptor induces expression of a protein called suppressor of cytokine signaling-3 (SOCS-3), which may inhibit further leptin signal transduction. The contribution of SOCS-3 to acquisition of leptin resistance and obesity remains an active area of investigation. As well, leptin receptors are expressed in the endothelial cells of the blood-brain barrier and it is plausible that dysfunction of this process may also lead to a state of obesity and leptin resistance.
Neuroendocrine-Immune Interactions

Stimulation of the immune system by foreign pathogens leads to a stereotyped set of responses orchestrated by the CNS. These responses are the result of the complex interaction of the immune system and the CNS and are often referred to as the cerebral component of the acute phase reaction. This constellation of stereotyped responses is adaptive, is mediated in large part by the hypothalamus, and includes coordinated autonomic, endocrine, and behavioral components. These responses include fever, alterations in the activity of nearly every neuroendocrine axis, changes in the sleep-wake cycle, anorexia, and inactivity.

It is now clear that cytokines produced by white blood cells of the immune system mediate the CNS responses. Early evidence supporting this hypothesis was provided by the seminal observations that cytokines such as IL-1 can activate the HPA axis. In fact, these and other observations provided the framework for a new area of research in neuroscience and neuroendocrinology. This discipline is often referred to as neuroimmunology. Thus, the term neuroimmunomodulation has been used to describe the study of the interactions of immune system cues and nervous system function.

Although it is established that cytokines modulate hypothalamic activity, it is also important to note that the immune system is modulated by the nervous system. This modulation occurs largely by two routes, endocrine mechanisms and direct innervation. The innervation includes lymphoid organs such as the thymus and spleen, which receive direct inputs from the autonomic nervous system. As noted earlier in the section on CRH, the hallmark of cytokine action on the hypothalamus is the activation of the HPA axis. The resultant glucocorticoid secretion acts as a classical negative feedback to the immune system to damp the immune response. This general, glucocorticoids inhibit most limits of the immune response, including lymphocyte proliferation, production of immunoglobulins, cytokines, and cytotoxicity. These inhibitory reactions form the basis of the anti-inflammatory actions of glucocorticoids.

Glucocorticoid feedback on immune responses is regulatory and beneficial because loss of this function makes animals with adrenal insufficiency vulnerable to inflammation. Moreover, this feedback response can have pathophysiologic consequences, as chronic activation of the HPA axis can certainly be detrimental. Indeed, it is now established that chronic stress can lead to immunosuppression. The fact that products of inflammation such as IL-1 can activate the HPA axis suggests the operation of a negative feedback control loop to regulate the intensity of inflammation. The role of the hypothalamus in regulating pituitary-adrenal function is an excellent example of neuroimmunomodulation.

This section addresses several of the hypothesized mechanisms by which cytokines engage neural pathways to mediate neuroendocrine and autonomic effects. In addition, some of the autonomic and endocrine pathways that are engaged by immune system cues are briefly discussed. It is important to note that many nonlymphocytic cells including endocrine and adipose cells and neurons also synthesize cytokines that exert effects independent of immunomodulation. Examples of cytokines secreted by adipocytes include leptin, adipin, and TNF, which have profound effects on metabolism.

Cytokines Signal the Central Nervous System

Cytokines made outside the CNS can alter the activity and function of populations of hypothalamic neurons. Although the interactions of cytokines with the nervous system have been studied extensively, the mechanisms by which immune signals influence the CNS remain unsettled. LPS (or endotoxin) is a cell wall component of all gram-negative bacteria that is a potent immune system stimulant. LPS administration is widely used as an experimental model and induces the secretion of several pyrogenic cytokines including IL-1, TNF, and IL-6 that mimic the patterns of cytokine production seen in natural infections.

Other cytokines secreted by adipocytes include leptin, adipin, and TNF, which have profound effects on metabolism.

Interaction of Cytokines with the Circumventricular Organs

The CVOs, described in detail earlier, are specialized regions on the margins of the ventricular system that have fenestrated capillaries and therefore no blood-brain barrier. Many circulating hormones such as angiotensin II act on neurons in the CVOs, converting blood-borne signals into CNS responses. Several models of fever production have hypothesized that cytokines may enter the CNS through the CVOs, particularly at the level of the OVLT (Fig. 7-50; see Fig. 7-49). However, definitive evidence establishing this model as a predominant mechanism is still lacking.

Large lesions of the preoptic area of the hypothalamus including the OVLT block fever, but they inevitably damage nearby regions that are critical for thermoregulation. Small lesions of the OVLT do not block fever or corticosterone responses. However, an inherent limitation of this type of study is that the lesion itself breaches the blood-brain barrier, allowing entry of cytokines. Moreover, knife cuts just caudal to the OVLT, interrupting connections from the OVLT to the PVH, did not block activation of the HPA axis by IL-1.

Other studies have focused on the area postrema, a CVO located in the medulla oblongata lying along the surface of the nucleus of the solitary tract at the caudal end of the fourth ventricle (see Fig. 7-50 and Fig. 7-51). Lesions of the area postrema can block the IL-1-induced activation of the HPA axis and the induction of c-fos mRNA in the PVH. However, the hypothalamic-pituitary-adrenal (HPA) axis by immune system stimulation. The immune system probably uses several pathways and sites of entry to communicate with the brain. This model predicts that circumventricular organs (organs devoid of blood-brain barrier; CVOs) and the blood vessels (bv) are crucial target sites of cytokines of systemic origin produced during the acute-phase response, whereas activated regions of the brain stem and deep limbic system might play a determinate role in the integration of information received from the periphery. Among these integrative structures, the PVN is critical in coordinating autonomic and endocrine responses including the activity of the HPA axis. For example, corticotropin-releasing factor (CRF) neurons of the paraventricular PVN expressed c-fos messenger ribonucleic acid, and that transcription of the gene coding CRF is activated essentially in this hypothalamic nucleus indicates the importance and the specificity of this neuroendocrine component of the acute phase reaction, particularly at the OVLT (Fig. 7-50). In general, glucocorticoids inhibit most limits of the immune response, including lymphocyte proliferation, production of immunoglobulins, cytokines, and cytotoxicity. These inhibitory reactions form the basis of the anti-inflammatory actions of glucocorticoids.

Although it is established that cytokines modulate hypothalamic activity, it is also important to note that the immune system is modulated by the nervous system. This modulation occurs largely by two routes, endocrine mechanisms and direct innervation. The innervation includes lymphoid organs such as the thymus and spleen, which receive direct inputs from the autonomic nervous system. As noted earlier in the section on CRH, the hallmark of cytokine action on the hypothalamus is the activation of the HPA axis. The resultant glucocorticoid secretion acts as a classical negative feedback to the immune system to damp the immune response (Fig. 7-50). Instead of this feedback response can have pathophysiologic consequences, as chronic activation of the HPA axis can certainly be detrimental. Indeed, it is now established that chronic stress can lead to immunosuppression. The fact that products of inflammation such as IL-1 can activate the HPA axis suggests the operation of a negative feedback control loop to regulate the intensity of inflammation. The role of the hypothalamus in regulating pituitary-adrenal function is an excellent example of neuroimmunomodulation.
nucleus in endotoxin-treated animals. The mechanisms and the circuitry controlling the CRF release and the activity of the HPA axis might also be different from those involved in the biosynthetic circuitry of CRF during immune challenge. ACTH, adrenocorticotropic hormone; AP, area postrema; ARC, arcuate nucleus; BNST, bed nucleus of the stria terminalis; bv, blood vessels; cP, choroid plexus; CeA, central nucleus of the amygdala; COX-2, cyclooxygenase-2; DMH, dorsomedial nucleus of the hypothalamus; EP, proopiomelanocortin E receptor; IL-1, interleukin 1; IL-1RI, IL-1 type 1 receptor; IL-6, interleukin 6; IFN, interferon; LC, locus coeruleus; LDT, laterodorsal tegmental nucleus; LPS, lipopolysaccharide; LRMN, lateral reticular nucleus medialis; ME, median eminence; MPDA, medial preoptic area; NF, nuclear factor; NTS, nucleus of the solitary tract; OVL, organum vasculosum of the lamina terminalis; PGE, prostaglandin E2; PB, parabrachial nucleus; PP, posterior pituitary; PVN, paraventricular nucleus of the hypothalamus; PVH, paraventricular nucleus [pc] and magnocellular [pm] divisions; SFO, subfornical organ; SON, supraoptic nucleus; TNF, tumor necrosis factor; VM, ventromedial nucleus.

Figure 7-51 Immune stimulation activates key brain regions. A series of photomicrographs demonstrating the distribution of Fos-like immunoreactivity (Fos-IR) in the rat brain 2 hours after intravenous injections of lipopolysaccharide (LPS; 125 µg/kg). LPS administration is a commonly used model of immune stimulation, and LPS-IR is a widely used marker of neuronal activation. LPS activates (induces Fos-IR) in the ventral medial preoptic area (vmPVT) and medial (mp) parvicellular and posterior magnocellular (pm) divisions. Also note that LPS activates neurons in the circumventricular organs (OVLT, SFO, AP); 3, third ventricle.

Macrophages (Fig. 7-62)_. Regardless of the cell type, it seems clear that circulating LPS or cytokines induce COX 2 in cells in the perivascular space, which in turn may produce prostaglandins to stimulate nearby brain regions inside the blood-brain barrier.

PGE 2, the predominant endogenous isoform of PGE in the brain, is thought to be an essential mediator of cytokine modulation of hypothalamic function. This claim is supported by the finding that microinjections of PGE receptor agonists into the brain of rats and other species produce fever. The preoptic area of the hypothalamus surrounding the OVL T is thought to be critical in the response to PGE 2 (see Fig. 7-51A). For example, microinjections of as little as 1 ng of PGE 2 into the anteroventral periaqueductal area of rats reliably produced fever. Conversely, the COX-2 inhibitor ketorolac attenuated LPS-induced fever with injections placed in the same region. This PGE-sensitive zone is the same as the region containing the highest concentrations of PGE 2 binding sites. The cloning of the prostaglandin E (EP) receptors has allowed more definitive analysis of the receptors in the hypothalamus that mediate the effects of PGE 2 (see Fig. 7-50).

Four EP receptor subtypes have been identified, EP 1, EP 2, EP 3, and EP 4. All four subtypes are expressed in the preoptic area of the hypothalamus. Despite the established role of PGE in producing fever and activating the HPA axis, the EP receptor subtypes that are crucial in the febrile response are not yet established. Pharmacologic evidence suggests that EP 1 and EP 2 receptor agonist administration has an effect mimicking PGE 2-induced fever. Moreover, an EP 1 receptor antagonist blocked PGE 2 fever. In contrast, targeted deletion of the EP 2 gene resulted in mice that did not show an early phase of fever after intracerebroventricular injection of LPS or PGE 2. Interestingly, there is up-regulation of EP 2 receptor expression in several areas of the brain, including the CRH neurons of the paraventricular nucleus, after immune challenge. In addition, paraventricular neurons that express Fos after intracerebroventricular PGE 2 also express EP 2 receptors. Thus, production of PGE 2 is certainly an obligate step in the pathogenesis of the febrile response; the identity of the EP receptor subtypes required for distinct components of the response remains to be established.

Entry of Cytokines into the Brain

Circulating cytokines are proteins that cannot easily penetrate the blood-brain barrier. The kinetics of entry of cytokines into the brain have been examined, and evidence suggests that there is saturable transport of IL-1, IL-6, and TNF into the brain. However, it is not clear whether sufficient levels of cytokines are detectable in brain after acute intravenous administration to account for CNS responses to acute infection. Thus, the physiologic setting and significance of this mechanism remain to be established.

Moreover, it is noteworthy that levels of circulating IL-1 do not rise significantly during immune challenges. In contrast, large increases in circulating and brain IL-6 are found during fever. Although it is not completely understood, it appears that synthesis of IL-6 within the blood-brain barrier and not peripheral IL-6 crossing the barrier is critical in the production of fever. Moreover, several studies have demonstrated that cells located at the blood-brain barrier and cells within the meninges respond to LPS stimulation with induction of IL-1 and TNF, the nuclear factor B inhibitor IB, and the LPS receptor CD14 (Fig. 7-52). Cells with a similar morphology lining the blood vessels that penetrate the CNS and the meninges that cover it also have IL-1 receptors, suggesting that they may respond to cytokines as well. Hence, endothelial and perivascular cells at the blood-brain interface may have the ability to elaborate cytokines after an LPS or cytokine signal. The physiologic role of centrally produced cytokines in the response to peripheral immune cues has been reviewed in detail.

Interactions of Cytokines with Peripheral Nerves

Another proposed model by which cytokines may alter the activity of CNS neurons involves stimulation of peripheral sensory nerves, the prototypical example being the vagus nerve. Several pieces of experimental evidence support the idea that the vagus may provide a conduit for cytokines to activate CNS pathways. For example, IL-1 receptor antagonist binds to vagal paranganglia. In addition, neurons in the nodose ganglia (vagal sensory neurons) expressed type 1 IL-1 receptor mRNA. Peripheral administration of LPS induced Fos expression, a marker of neuronal activation, in the vagal sensory nodose ganglia, and this could be blocked by prior vagotomy. Similarly, IL-1 administration induced the expression of Fos in neurons in the nodose ganglia and increased the firing rate of other vagal nerve fibers. The IL-1-induced response was blocked by pretreatment with a COX inhibitor, demonstrating the need for prostaglandin production in this model as well.

Severing the vagus nerve below the diaphragm blocked fever, sickness behavior, and induction of IL-1 mRNA and Fos protein in the brain after intraperitoneal LPS or IL-1. These observations suggest that, although vagal sensory mechanisms may contribute to CNS responses to immune stimuli, particularly with local
infections in the abdominal or thoracic cavities, blood-borne immune challenge may activate the CNS by other routes. In the end, it is likely that redundant mechanisms exist by which the CNS is made aware of inflammatory signals in the periphery. The relative contribution of distinct mechanisms may depend upon the route of administration and dose of inflammatory mediators, and future studies should increase our understanding of these mechanisms.

Cell Groups Throughout the Brain Responsive to Cytokines

Many studies have used the expression of immediate early genes such as c-fos or its protein product, Fos, as a marker of neuronal activity. In this way, investigators have assessed the involvement of extended neuronal systems during the complex physiologic responses after immune challenge. Mapping the patterns of activation in the CNS after either IL-1 or LPS administration has yielded new insights into the functional neuroanatomy underlying the coordinated autonomic, endocrine, and behavioral responses during the febrile response. Immune activation using moderate to high doses of LPS and IL-1 activates central autonomic and endocrine structures at nearly every level of the neuraxis including several neuroendocrine regulator sites such as the central nucleus of the amygdala, paraventricular hypothalamic nucleus, arcuate nucleus of the hypothalamus, SFO, OVLT, and ventral medial preoptic area. Immune activation of cells was found in the dorsal parvicellular division of the paraventricular nucleus in the hypothalamus. These results suggest that neurons in the parvicellular PVH specifically innervate sympathetic preganglionic neurons in the spinal cord that regulate LPS-induced fever. Furthermore, as noted earlier, activation of CRH neurons of the PVH is a signature of the CNS response to immune stimulation. Thus, the paraventricular hypothalamic nucleus is a key site for mediating both neuroendocrine and autonomic responses to immune stimulation.

noradrenergic cell group in the ventral pons, the caudal part of the nucleus of the solitary tract, the ventromedial medulla including the medullary raphe nuclei, and the rostral ventrolateral medulla, including the C1 adrenergic cell group. Lesions interrupting the input from the C1 cells to the PVH prevent the HPA response to IL-1. These studies suggest that the activation of C1 cells by locally produced prostaglandins may play a critical role in activating the HPA axis in response to IL-1.

Sympathetic preganglionic neurons in the intermediolateral cell column (IML), extending from the first thoracic through the upper lumbar segments of the spinal cord, also show Fos expression in response to LPS. Preganglionic neurons in the upper thoracic (T1 to T4) levels mediate thermogenesis by brown adipose tissue, which is a key mechanism used by rats to control heat production and body temperature. Sympathetic preganglionic neurons in the T2 to T5 levels are important for control of the heart, which is important because there are changes in cardiac output in the febrile state. Another important concept is that sympathetic preganglionic neurons receive direct, monosynaptic input from a series of well-defined nuclei in the brain stem and the hypothalamus. These cells provide another way in which the hypothalamus can contribute to the coordinated autonomic response to inflammatory signals. The major input to the sympathetic preganglionic column arises from neurons in the hypothalamus. This innervation includes the paraventricular nucleus (dorsal, ventral, and lateral parvicellular subnuclei), the lateral hypothalamic area, and the arcuate nucleus and retrochiasmatic area. Direct projections to the intermediolateral cell column also arise in the brain stem from the A5 noradrenergic cell group in the ventral pons, the caudal part of the nucleus of the solitary tract, the ventromedial medulla including the medullary raphe nuclei, and the rostral ventrolateral medulla, including the C1 adrenergic cell group. LPS-activated cells that innervate the IML are found in the rostral ventrolateral medulla (C1 adrenergic cell group) and the A5 noradrenergic cell group in the brain stem. Moreover, a prominent population of cells was found in the dorsal parvicellular division of the paraventricular nucleus in the hypothalamus. These results suggest that neurons in the parvicellular PVH specifically innervate sympathetic preganglionic neurons in the spinal cord that regulate LPS-induced fever. Furthermore, as noted earlier, activation of CRH neurons in the PVH is a signature of the CNS response to immune stimulation. Thus, the paraventricular hypothalamic nucleus is a key site for mediating both neuroendocrine and autonomic responses to immune stimulation.
NEUROENDOCRINE DISEASE

Disease of the hypothalamus can cause pituitary dysfunction, neuropsychiatric and behavioral disorders, and disturbances of autonomic and metabolic regulation. In the diagnosis and treatment of suspected hypothalamic or pituitary disease, four issues must be kept in mind: the extent of the lesion, the physiologic impact, the specific cause, and the psychosocial setting. The etiology of hypothalamic neuroendocrine disorders categorized by age and syndrome is summarized in Table 7.9 and Table 7.10.

Manifestations of pituitary insufficiency secondary to hypothalamic or pituitary stalk damage are not identical to those of primary pituitary insufficiency. Hypothalamic injury causes decreased secretion of most pituitary hormones but can cause hypersecretion of hormones normally under inhibitory control by the hypothalamus, as in hypersecretion of PRL after damage to the pituitary stalk and precocious puberty caused by loss of the normal restraint over gonadotropin maturation. Impairment of inhibitory control of the neurohypophysis can lead to the syndrome of inappropriate vasopressin secretion (SIADH) (see Chapter 9). More subtle abnormalities in secretion can result from impairment of the control system. For example, loss of the normal circadian rhythm of corticotropin secretion may occur after loss of pituitary-adrenal secretory reserve. and responses to physiologic stimuli may be paradoxical. Because hypothalamic hormone levels cannot be measured directly and pituitary secretion is regulated by complex, multilayered controls, assay of pituitary hormones in blood does not necessarily give a meaningful picture of events at hypothalamic and higher levels. Rarely, tumors secrete excessive amounts of releasing peptides and cause hypersecretion of hormones from the pituitary.

Disorders of the hypothalamic-pituitary unit can result from lesions at several levels. Defects can arise from destruction of the pituitary (as by tumor, infarct, inflammation, or autoimmune disease) or from a hereditary deficiency of a particular hormone as in rare cases of isolated FSH, GH, or POMC deficiency. Selective loss of thyroid hormone receptors in the pituitary can give rise to increased thyrotropin secretion and thyrotoxicosis. Furthermore, disorders can arise through disruption of the stalkmedian eminence contact zone, the stalk itself, or the nerve terminals of the tuberohypophyseal system; such disruption occurs after surgical stalk section, with tumors involving the stalk, and in some inflammatory diseases. At a higher level, tonic inhibitory and excitatory inputs can be lost as manifested by absence of circadian rhythms or the development of precocious puberty. Physical stress, cytokine products of inflammatory cells, toxins, and reflex inputs from peripheral homeostatic monitors also impinge on the tuberoinfundibular system. At the highest level of control, emotional stress and psychological disorders can activate the pituitary-adrenal stress response and suppress gonadotropin secretion (e.g., psychogenic amenorrhea) or inhibit GH secretion (e.g., psychosocial dwarfism) (see Chapter 23). Intrinsic disease of the anterior pituitary is reviewed in Chapter 6, and disturbances in neurohypophyseal function are discussed in Chapter 9. This chapter considers diseases of the hypothalamic-pituitary unit.

Pituitary Isolation Syndrome

Destructive lesions of the pituitary stalk, as occur with head injury, surgical transection, tumor, or granuloma, produce a characteristic pattern of pituitary dysfunction. Central diabetes insipidus (DI) develops in a large percentage of patients, depending on the level at which the stalk has been sectioned. If the cut is close to the hypothalamus, DI is almost always produced, whereas if the section is low on the stalk, the incidence is lower. The extent to which nerve terminals in the upper stalk are preserved determines the clinical course. The

Although head injury, granulomas, and tumors are the most common causes of acquired DI, other cases develop in the absence of a clear-cut cause. Some cases may be due to autoimmune disease of the hypothalamus as suggested by the finding of autoantibodies to neurohypophysial cells in a third of cases of “idiopathic” DI in one series. However, autoantibodies were also frequently found in association with histiocytosis-X. Later reports suggest the importance of continued vigilance in cases of idiopathic DI because a definite cause is frequently uncovered in time, including a high proportion of occult germinomas whose detection by magnetic...
resonance imaging may be preceded by elevated levels of human chorionic gonadotropin (hCG) in CSF.

| CRH, corticotropin-releasing hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin. |  |

Congenital DI can be part of a hereditary disease. DI in the Brattleboro rat is due to an autosomal recessive genetic defect that impairs production of vasopressin but not of oxytocin. Inherited forms of DI in humans have been attributed to mutations in the vasopressin V2 receptor gene or less frequently in the aquaporin or
Menstrual cycles cease after stalk section although urinary gonadotropins may still be detectable, unlike the situation after hypophysectomy. Plasma glucocorticoid levels and urinary excretion of cortisol and 17-hydroxycorticoids decline after hypophysectomy and stalk section, but the change is slower after stalk section. A transient increase in cortisol secretion after stalk section is believed to be due to release of ACTH from preformed stores. The ACTH response to the lowering of blood cortisol is markedly reduced but ACTH release after stress may be normal, possibly because of CRH-independent mechanisms. Reduction in thyroid function after stalk section is similar to that seen with hypophysectomy. The fall in GH secretion is said to be the most sensitive indication of damage to the stalk; however, the insidious nature of this endocrinologic change in adults who have suffered traumatic brain injuries may cause it to be overlooked and therefore contribute to delayed rehabilitation.

Humans with stalk sections or with tumors of the stalk region have widely varying levels of hyperprolactinemia and may have galactorrhea. PRL responses to hypoglycemia and to TRH are blunted, in part because of loss of neural connections with the hypothalamus. PRL responses to dopamine agonists and antagonists in the pituitary isolation syndrome are similar to those in patients with prolactinomas. Interestingly, PRL secretion continues to show a diurnal variation in patients with either hypothalamic-pituitary disconnection or microprolactinoma. Both forms of hyperprolactinemia are characterized by a similarly increased frequency of PRL pulses and a marked rise in nonpulsatile or basal PRL secretion, although the disruption is greater in the tumoral hyperprolactinemia.

An incomplete pituitary isolation syndrome may occur with the empty sella syndrome, intrasellar cysts, or pituitary adenomas. Anterior pituitary failure after stalk section is in part due to loss of specific neural and vascular links to the hypothalamus and in part due to pituitary infarction.
Selective pituitary failure can be due to a deficiency of specific pituitary cell types or a deficiency of one or more hypothalamic hormones. Isolated GnRH deficiency is the most common hypophyseotropic hormone deficiency. In Kallmann’s syndrome (gonadotropin deficiency commonly associated with hyposmia), hereditary agenesis of the olfactory lobe may be demonstrable by magnetic resonance imaging. Abnormal development of the GnRH system is due to defective migration of the GnRH-containing neurons from the olfactory nasal epithelium in early embryologic life (see the earlier section on GnRH). Other malformations of the cranial midline structures, such as absence of the septum pelucidum in septo-optic dysplasia (De Morsier’s syndrome), can cause hypogonadotropic hypogonadism (HH) or, less commonly, precocious puberty. A surprisingly large percentage of children with septo-optic dysplasia who otherwise have multiple hypothalamic-pituitary abnormalities actually retain normal gonadotropin function and enter puberty spontaneously. The genetic basis of HH has now been established in approximately 10% of patients. Mutations in the KAL (Kallmann’s syndrome) gene and the AHC-DAX1 (adrenal hypoplasia congenital-HH) gene cause X-linked recessive disease. Autosomal recessive HH has been associated with mutations in the GnRH receptor, leptin, leptin receptor, FSH, LH, PROP-1 (combined pituitary deficiency), and HESX (septo-optic dysplasia) genes.

The GnRH response test is of little value in the differential diagnosis of hypothyroidism. Most patients with GnRH deficiency show little or no response to an initial test dose, but normal responses are seen after repeated injection. This slow response has been attributed to down-regulation of GnRH receptors in response to prolonged GnRH deficiency. Furthermore, with intrinsic pituitary disease the response to GnRH may be absent or normal. Consequently, it is not possible to distinguish between hypothalamic and pituitary disease with a single injection of GnRH. Prolonged infusions or repeated administration of GnRH agonists after an initial test dose, but normal responses are seen after repeated injection. This slow response has been attributed to down-regulation of GnRH receptors in response to prolonged GnRH deficiency. Furthermore, with intrinsic pituitary disease the response to GnRH may be absent or normal. Consequently, it is not possible to distinguish between hypothalamic and pituitary disease with a single injection of GnRH. Prolonged infusions or repeated administration of GnRH agonists after hormone replacement therapy priming may aid in the diagnosis or provide therapeutic options for women with Kallmann’s syndrome wishing to become pregnant.

Deficiency of TRH secretion gives rise to hypothyroidism, also called tertiary hypothyroidism. This can occur in hypothyroidism or more rarely as an isolated defect. Molecular genetic analyses have revealed infrequent autosomal recessive mutations in the TRH and TRH receptor genes in the etiology of central hypothyroidism. Hypothalamic and pituitary causes of TSH deficiency are most readily distinguished by imaging methods. Although theoretically reasonable, the TRH stimulation test for the differentiation of hypothyroidism from pituitary disease is of limited value. The typical pituitary response to TRH administration in patients with TRH deficiency is an enhanced and somewhat delayed peak, whereas the response with pituitary failure is subnormal or absent. The hypothalamic type of response has been attributed to an associated GH deficiency that sensitizes the pituitary to TRH (possibly through suppression of somatostatin secretion), but GH also affects T₄ metabolism and may alter pituitary responses as well. In practice, the responses to TRH in hypothalamic and pituitary disease overlap so much that they cannot be used reliably for a differential diagnosis. Persistent failure to demonstrate responses to TRH is good evidence for the presence of intrinsic pituitary disease, but the presence of a response does not mean that the pituitary is normal. Deficient TRH secretion leads to delayed TSH biosynthesis by the pituitary, including impaired glycosylation. Poorly glycosylated TSH has low biologic activity, and dissociation of bioactive and immunoreactive TSH can lead to the paradox of normal or elevated levels of TSH in hypothyroidism.

GHRH deficiency appears to be the principal cause of hGH deficiency in children with idiopathic dwarfism. This condition is frequently associated with abnormal electroencephalograms, a history of birth trauma, and breech delivery. Furthermore, magnetic resonance imaging scans show that a substantial proportion of children with idiopathic hGH deficiency have evidence of a torn pituitary stalk, which is presumed evidence for birth trauma as the cause. Human GH is the most vulnerable of the anterior pituitary hormones when the pituitary stalk is damaged. It can be difficult to differentiate between primary pituitary disease and GHRH deficiency by standard tests of GH reserve. However, a substantial GH secretory response to a single administration of hexarelin occurs only in the presence of at least a partially intact vascular stalk.

In many children with dwarfism, the anatomic abnormalities of the intrasellar contents and pituitary stalk together with the frequent occurrence of other midline defects, such as those in septo-optic dysplasia, are consistent with the alternative hypothesis of a developmental defect occurring in embryogenesis. There has been a remarkable advance in our understanding of the molecular ontogeny of the hypothalamic-pituitary unit, much of it based on mutant mouse models. Parallel genetic analyses have been conducted in children with isolated GH deficiency or combined pituitary hormone deficiencies. These studies have identified autosomal recessive mutations in both structural and regulatory genes including the GHRH receptor, PTP1, PROP1, and HESX1 that are responsible for a sizable proportion of congenital hypothalamic-pituitary disorders once considered idiopathic.

Adrenal insufficiency is another manifestation of hypothyroidism and can be due to CRH deficiency. Isolated ACTH deficiency is uncommon, but there is suggestive evidence in at least one family of genetic linkage to the CRH gene locus. Later investigations have revealed mutations in the TPIT gene, a T box transcription factor expressed only in pituitary corticotrophs and melanotrophs, associated with cases of isolated ACTH deficiency. The CRH stimulation test does not distinguish hypothalamic from pituitary failure as a cause of corticotropin deficiency.

Apart from intrinsic diseases of the hypothalamus such as tumors and granulomas, two environmental causes of central hypophyseotropic deficiencies are of increasing clinical importance. These are trauma to the brain, particularly from motor vehicle accidents, and the sequelae of chemotherapy and radiation therapy for intracranial lesions in children and adults. Improved short-term survival from head injuries associated with coma and CNS malignancies has greatly increased the prevalence of long-term neuroendocrine consequences.
Hypophyseotropic Hormone Hypersecretion

Pituitary hypersecretion is occasionally caused by tumors of the hypothalamus. GnRH-secreting hamartomas can cause precocious puberty. CRH-secreting gangliocytomas can cause Cushing's syndrome, and GHRH-secreting gangliocytomas of the hypothalamus can cause acromegaly. Although they do not arise from the hypothalamus, paraneoplastic syndromes can also cause pituitary hypersecretion, as with CRH-secreting tumors and GHRH-secreting tumors of the bronchi and pancreas. Bronchial carcinoids and pituitary islet cell tumors are the usual causes of this phenomenon.
Precocious puberty is a relatively unusual manifestation of maturation, and some of these tumors have histologic and functional characteristics of choriocarcinomas. Diagnosis is confirmed by the combination of a mass lesion, two or more germ cell layers also occur in the pineal region. Chorionic tissue in teratomas and germinomas may secrete hCG in sufficient amounts to cause gonadal insufficiency, and visual abnormalities. Germinomas may also occur in the anterior hypothalamus or the floor of the third ventricle, where they are often associated with the clinical triad of DI, pituitary dysfunction, and visual abnormalities.

The most common tumors of the pineal gland are actually germinomas (a form of teratoma), so designated because of their presumed origin in germ cells. Pineal cysts, arachnoid cysts, and cavernous hemangioma. Pinealocytes give rise to primitive neuroectodermal tumors, the so-called small blue cell tumors that are oat cell carcinomas of the lung. pineal gland tumors account for only a small percentage of intracranial neoplasms. They occur as a central midline mass with an enhancing lesion on magnetic resonance imaging frequently accompanied by hydrocephalus. Pinealomas cause a variety of neurologic abnormalities. (Table 7-12), Parinaud's syndrome, which consists of paralysis of upward gaze, pupillary areflexia (to light), paralysis of convergence, and a wide-based gait, occurs with about half of pinealomas. Gait disturbances can also occur because of brain stem or cerebellar compression.

Several discrete cytopathologic entities account for mass lesions in the pineal region. The most common non-neoplastic conditions are degenerative pineal cysts, arachnoid cysts, and cavernous hemangioma. Pinealocytes give rise to primitive neuroectodermal tumors, the so-called small blue cell tumors that are immunopositive for the neuronal marker synaptophysin and negative for the lymphocyte marker CD45. True pinealomas can be relatively well-differentiated pineocytomas, middle neuroepithelial differentiation or the less differentiated pineoblastomas, which are typically the same as medulloblastomas, neuroblastomas, and oat cell carcinomas of the lung.

The most common tumors of the pineal gland are actually germinomas (a form of teratoma), so designated because of their presumed origin in germ cells. Germinomas may also occur in the anterior hypothalamus or the floor of the third ventricle, where they are often associated with the clinical triad of DI, pituitary insufficiency, and visual abnormalities. Identical tumors can be found in the testis and anterior mediastinum. Intracranial germinomas have a tendency to spread locally, infiltrate the hypothalamus, and metastasize to the spinal cord and CSF. Extracranial metastases (to the skin, lung, or liver) are rare. Teratomas derived from two or more germ cell layers also occur in the pineal region. Chorionic tissue in teratomas and germinomas may secrete hCG in sufficient amounts to cause gonadal maturation, and some of these tumors have histologic and functional characteristics of chorionicarcinomas. Diagnosis is confirmed by the combination of a mass lesion, cytologic analysis of CSF, and radioimmunoassay detection of hCG in the CSF.

Precocious puberty is a relatively unusual manifestation of...
A. Germ Cell Tumors

1. Germinoma
   a. Posterior third ventricle and pineal lesions
   b. Anterior third ventricle, suprasellar or intrasellar lesions
   c. Combined lesions in anterior and posterior third ventricle, apparently noncontiguous, with or without foci of cystic or solid teratoma

2. Teratoma
   a. Evidencing growth along two or three germ lines in varying degrees of differentiation
   b. Dermoid and epidermoid cysts with or without solid foci of teratoma
   c. Histologically malignant forms with or without differentiated foci of benign, solid, or cystic teratoma-teratocarcinoma, choriocarcinoma, embryonal carcinoma (endodermal-sinus tumor or yolk-sac carcinoma), combinations of these with or without foci of germinoma, chemodectoma

B. Pineal Parenchymal Tumors

1. Pinealocytes
   a. Pineocytoma
   b. Pineoblastoma
   c. Ganglioglioma and chemodectoma
   d. Mixed forms exhibiting transitions between these

2. Glia
   a. Astrocytoma
   b. Ependymoma
   c. Mixed forms and other less frequent gliomas (e.g., glioblastoma, oligodendroglioma)

C. Tumors of Supporting or Adjacent Structures

1. Meningioma

2. Hemangiopericytoma

D. Non-neoplastic Conditions of Neurosurgical Importance

1. "Degenerative" cysts of pineal lined by fibrillary astrocytes

2. Arachnoid cysts

3. Cavernous hemangioma

Management of tumors in the pineal region is not straightforward. Operative mortality rates can be high, but the rationale for an aggressive approach to the pineal region is based on the need to make a histologic diagnosis, the variety of lesions found in this region, the possibility of cure of an encapsulated lesion, and the effectiveness of chemotherapeutic agents for germinomas and chorocarcinoma. Stereotaxic biopsy of the pineal region provided diagnosis in 33 of 34 cases in one series, suggesting that this is a useful alternative to open surgical exploration for diagnostic purposes. Long-term palliation or cure of many pineal region tumors is possible by combinations of surgery, radiation, gamma knife, or chemotherapy, depending on the nature of the lesion. Hence causes premature puberty almost exclusively in boys. The prevalence of elevated hCG levels in children with premature puberty related to tumors in the pineal region is unknown, but the fact that this phenomenon occurs further challenges the theory that nonparenchymal tumors cause precocious puberty by damaging the normal pineal gland. Rarely, pinealomas cause delayed puberty, raising speculation about a role of melatonin in inhibiting gonadotropin secretion in these cases.

Management of Sexual Precocity

Several groups have reviewed the diagnostic approach to suspected central precocious puberty. Although guidelines differ, the index of suspicion is clearly inversely proportional to the age of the patient. A GnRH stimulation test to assess gonadotropin release and thereby differentiate between primed and inactive gonadotrophs is probably the single most important endocrinologic measure. If LH and FSH levels are not stimulated and there is no evidence of gonadal germ cell maturation, the cause of precocious puberty lies outside the hypothalamic-pituitary axis and the diagnostic process should focus on the adrenal glands and gonads (see Chapter 13 and Chapter 15). Magnetic resonance imaging studies are central to the work-up for exclusion or characterization of organic lesions in the areas of the sella, optic chiasm, suprasellar hypothalamus, and interpeduncular cistern. Precocious puberty is stressful to both the child and...
the parents, and it is essential that psychological support be provided.

Psychogenic Amenorrhea

Menstrual cycles can cease in young nonpregnant women with no demonstrable abnormalities of the brain, pituitary, or ovary in several situations, including pseudocyesis (false pregnancy), anorexia nervosa, excessive exercise, psychogenic disorders, and hyperprolactinemic states. Psychogenic amenorrhea, the most common cause of secondary amenorrhea except for pregnancy, can occur with major psychopathology or minor psychic stress and is often temporary. Psychogenic amenorrhea is probably mediated by excessive endogenous opioid activity because naloxone or naltrexone (opiate receptor blockers) can induce ovulation in some patients with this disorder.

Exercise-induced amenorrhea may be a variant of psychogenic amenorrhea or may result from loss of body fat. The syndrome is associated with intense and prolonged physical exertion such as running, swimming, or ballet dancing. Such women are always below ideal body weight and have low stores of fat. If the activity is begun before puberty, normal sexual maturation can be delayed for many years. The mass of fat may be a regulator of gonadotropin secretion with adipocyte-derived leptin as the principal mediator between peripheral energy stores and hypothalamic regulatory centers. Studies in nonhuman primates showed a direct role of caloric intake in the pathogenesis of amenorrhea associated with long-distance running. Exercise and psychogenic amenorrhea can have adverse effects because of the associated estrogen deficiency and accompanying osteopenia (also see Chapter 23).

Neurogenic Hypogonadism in Males

A discussion of neurogenic hypogonadism in males should begin with an account of Fröhlich's syndrome (adiposogenital dystrophy), originally characterized as delayed puberty, hypogonadism, and obesity associated with a tumor that impinges on the hypothalamus. It was subsequently recognized that either hypothalamic or pituitary dysfunction can induce hypogonadism and the presence of obesity indicates that the appetite-regulating regions of the hypothalamus have been damaged. Several organic lesions of the hypothalamus can cause this syndrome, including tumors, encephalitis, microcephaly, Friedreich's ataxia, and demyelinating diseases. Other important causes of hypogonadotropic hypogonadism are Kallmann's syndrome, a disorder caused by failure of GnRH-containing neurons to migrate normally (see earlier in the section on GnRH and hypophyseotropic hormone deficiency), and a subset of the Prader-Willi syndrome.

However, most males with delayed sexual development do not have serious neurologic conditions. Furthermore, most obese boys with delayed sexual development have no structural damage to the hypothalamus but have constitutional delayed puberty, which is commonly associated with obesity. It is not known whether there is a functional disorder of the hypothalamus in this condition. It is generally believed that psychosexual development of brain maturation depends on the presence of androgens and that hypogonadism in boys (regardless of cause) should be treated by the middle teen years (15 years at the latest).

In adult men, hypogonadism (including reduced spermatogenesis) can be induced by emotional stress or severe exercise, but this abnormality is seldom diagnosed because the symptoms are more subtle than menstrual cycle changes in similarly stressed women. Prolonged physical stress and sleep and energy deficiency can also decrease testosterone and gonadotropin levels. Chronic intrathecal administration of opiates for the control of intractable pain syndromes is strongly associated with hypogonadotropic hypogonadism, and to a lesser extent hypocorticism and GH deficiency, in both men and women. Finally, critical illness with multiple causes is well known to be associated with hypogonadism and ineffectual altered pulsation of GnRH.
Neurogenic Disorders of Prolactin Regulation

Neurogenic causes of hyperprolactinemia include irritative lesions of the chest wall (herpes zoster, thoracotomy), excessive tactile stimulation of the nipple, and lesions within the spinal cord such as ependymoma. Prolonged mechanical stimulation of the nipples by suckling or the use of a breast pump can initiate lactation in some women who are not pregnant, and neurologic lesions that interrupt the hypothalamic-pituitary connection can cause hyperprolactinemia, as discussed earlier. Hyperprolactinemia also occurs after certain forms of epileptic seizures. In one series, six of eight patients with temporal lobe seizures had a marked increase in PRL, whereas only one in eight frontal lobe seizures led to hyperprolactinemia. Agents that block dopamine receptors (such as the phenothiazines) or prevent dopamine release (e.g., reserpine and methyldopa) must be excluded in all cases.

Because the nervous system exerts such profound effects on PRL secretion, patients with hyperprolactinemia (including those with adenomas) may have a deficit of PIF or an excess of PRF activity. In studies of PRL secretion in patients apparently cured of hyperprolactinemia by removal of a pituitary microadenoma, regulatory abnormalities persisted in some but not all patients. Persistence of regulatory abnormalities may be due to incomplete removal of tumor, abnormal function of the remaining part of the gland, or underlying hypothalamic abnormalities.
Neurogenic Disorders of Growth Hormone Secretion

Hypothalamic Growth Failure

Loss of the normal nocturnal increase in GH secretion and loss of GH secretory responses to provocative stimuli occur early in the course of hypothalamic disease and may be the most sensitive endocrine indicator of hypothalamic dysfunction. As noted earlier, anatomic malformations of midline cerebral structures are associated with abnormal GH secretion, presumably related to failure of the development of normal GH regulatory mechanisms. Such disorders include optic nerve dysplasia and midline prosencephalic malformations (absence of the septum pellucidum, abnormal third ventricle, and abnormal lamina terminalis). Certain complex genetic disorders including Prader-Willi syndrome also commonly involve reduced GH secretory capacity. Idiopathic hypopituitarism with GH deficiency was considered earlier in this chapter.

Maternal Deprivation Syndrome and Psychosocial Dwarfism

Infant neglect or abuse can impair growth and cause failure to thrive (the maternal deprivation syndrome). Malnutrition interacts with psychological factors to cause growth failure in children with the maternal deprivation syndrome, and each case should be carefully evaluated from this point of view. Older children with growth failure in a setting of abuse or severe emotional disturbance (termed psychosocial dwarfism) may also have abnormal circadian rhythms and deficient hGH release after insulin-induced hypoglycemia or arginine infusion (see Chapter 8). Deficient release of corticotropin and gonadotropins may also be present. A new variant termed hyperphagic short stature has been identified. These disorders are reversible by placing the child in a supportive milieu where growth and neuroendocrine hGH responses rapidly return to normal. The pathogenesis of altered GH secretion in children in response to deprivation is unknown. In the adult human, furthermore, physical or emotional stress usually causes an increase in hGH secretion, as noted earlier.

Neuroregulatory Growth Hormone Deficiency

The availability of biosynthetic hGH for treatment of short stature has brought into focus a group of patients who grow at low rates (below the third percentile) and have low levels of serum IGF-I but a normal hGH secretory reserve. Studies of 24-hour hGH secretion profiles indicate that many of these children do not have normal spontaneous hGH secretion (abnormal ultradian and circadian rhythms and decreased number or amplitude of secretory bursts, or both). These children with idiopathic short stature may have a functional regulatory disturbance of the hypothalamus and appear to grow normally when given exogenous hGH.

There is considerable uncertainty about the criteria for the diagnosis of neuroregulatory hGH deficiency. Many normally growing children have profiles of hGH secretion that are indistinguishable from those in children with the postulated syndrome. Patterns of hGH secretion do not predict which child will benefit from therapy, and there is a poor correlation between hGH secretion and growth. Furthermore, the results of repeated tests in children show considerable variability. It has been suggested that specific genetic defects may underlie the pathogenesis of a subset of children with this heterogeneous syndrome of growth failure. The prevalence of an hGH neuroregulatory deficiency syndrome is thus unclear, and the decision to treat short children with hGH should be made cautiously.

Neurogenic Hyperscretion of Growth Hormone

Diencephalic Cachexia

Children and infants with tumors in and around the third ventricle frequently become cachectic, which is often associated with elevated hGH levels and paradoxical GH secretory responses to glucose and insulin. GH hypersecretion may be due to a hypothalamic abnormality or to malnutrition. Deficits of pituitary-adrenal regulation are less common.

A striking feature is an alert appearance and seeming euphoria despite the wasted state. A variety of associated neurologic abnormalities may be present (Table 7-13); the tumors that produce this syndrome are summarized in Table 7-14 and include a high proportion of chiasmatic-hypothalamic gliomas.

Syndrome of Inappropriate Growth Hormone Hypersecretion

Apparent inappropriate hGH hypersecretion (the syndrome of inappropriate somatotropin secretion) occurs with uncontrolled diabetes mellitus, hepatic failure, uremia, anorexia nervosa, and protein-calorie malnutrition. Nutritional factors are probably important in this response because in normal persons obesity inhibits and fasting stimulates episodic GH hypersecretion. In diabetes mellitus cholinergic blockers reverse the abnormality, possibly by inhibiting hypothalamic somatostatin secretion (see earlier in the section on neurotransmitter regulation of GH). Loss of inhibition of GH secretion by IGF-I may also play a role because most disorders in which this syndrome occurs are associated with low IGF-I levels.
Neurogenic Disorders of Corticotropin Regulation

Hypothalamic CRH hypersecretion is the likely cause of sustained pituitary-adrenal hyperfunction in at least two situations: Cushing's syndrome caused by the rare CRH-secreting gangliocytomas of the hypothalamus and severe depression.

Severe depression is associated with pituitary-adrenal abnormalities, including inappropriately elevated corticotropin levels, abnormal cortisol circadian rhythms, and resistance to dexamethasone suppression. The dexamethasone suppression test has, in fact, been used as an aid to the diagnosis of depressive illness. Patients with depression also have diminished responses to CRH, suggesting that depressed individuals hypersecrete CRH (see earlier section on CRH). Another possible example of disordered neurogenic control of CRH associated with stress is the metabolic syndrome. This syndrome is characterized by mild hypercortisolism, blunted dexamethasone suppression of the HPA axis, visceral obesity, and hypertension and may be strongly associated with greater risks for cardiovascular disease and stroke.

A unique syndrome of corticotropin hypersecretion termed periodic hypothalamic discharge (Wolff's syndrome) has been described in one young man. The patient had a recurring cyclic disorder characterized by high fever, paroxysms of glucocorticoid hypersecretion, and electroencephalographic abnormalities.
Genetic Obesity Disorders Involving Hypothalamic Circuits

In the past 5 years there have been a number of important discoveries related to genetic mutations underlying certain human obesity disorders. These clinical advances have closely paralleled the advances of basic research in the neuro-endocrine control of energy homeostasis discussed in an earlier section. Linkage studies and quantitative trait loci analyses have strongly implicated the POMC gene locus as an important determinant of weight homeostasis in humans of many, but not all, different ethnic populations, although specific alleles associated with obesity have not yet been demonstrated. Because no mutations within the coding region of the POMC gene that alter peptide activity have been identified in these populations, a current hypothesis is that mutations in regulatory regions of the gene decrease the level of POMC expression in the brain.

However, a small number of children from consanguineous parents have been found to have null mutations in the POMC gene resulting in absence of detectable circulating ACTH. These children presented with a syndrome of red hair, adrenal insufficiency, and severe, early-onset obesity (see Fig. 7-54). In addition, both dominant and recessive mutations in the MC4R gene have been found in the human population, and MC4R mutations have been proposed to play a role in as many as 5% of pediatric obesity cases. The genetic mirror image may also be true; an association between a polymorphism linked to the gene encoding the MC4R antagonist agouti-related protein and anorexia nervosa has been reported. Taking all these data into account, it is safe to say that obesity in a subpopulation of humans can be considered a genetic disorder of the hypothalamus.
Nonendocrine Manifestations of Hypothalamic Disease

The hypothalamus is involved in the regulation of diverse functions and behaviors. Psychological abnormalities in hypothalamic disease include antisocial behavior; attacks of rage, laughing, and crying; disturbed sleep patterns; excessive sexuality; and hallucinations. Both somnolence (with posterior lesions) and pathologic wakefulness (with anterior lesions) occur, as do bulimia and profound anorexia. The abnormal eating patterns are analogous to the syndromes of hyperphagia produced in rats by destruction of the ventromedial nucleus or of connections to the paraventricular nucleus. Lateral hypothalamic damage causes profound anorexia.

Patients with hypothalamic damage may experience hyperthermia, hypothermia, unexplained fluctuations in body temperature, and poikilothermy. Disturbances of sweating, acrocyanosis, loss of sphincter control, and diencephalic epilepsy are occasional manifestations. Hypothalamic damage also causes loss of recent memory, believed to be due to damage of the mammillothalamic pathways. Severe memory loss, obesity, and personality changes (apathy, loss of ability to concentrate, aggressive antisocial behavior, severe food craving, inability to work or attend school) may occur with suprasellar extension of pituitary tumors, hypothalamic radiation, or damage incurred from surgical removal of parasellar tumors. Hypothalamic tumors grow slowly and may reach a large size while producing minimal disturbance of behavior or visceral homeostasis, whereas surgery of limited extent can produce striking functional abnormalities. Presumably, this is because slowly growing lesions permit compensatory responses to develop. These potential consequences should be weighed carefully with the neurosurgeon, patient, and patient's family in planning the therapeutic approach. Adverse effects of treatment have led to more conservative surgical guidelines for the treatment of craniopharyngioma.

A convergence of functional genomics from two animal species, the dog and mouse, has refocused attention on neuropeptide circuits of the hypothalamus in the control of sleep. Positional cloning was used to identify mutations in the hypocretin-orexin receptor 2 as the cause of canine narcolepsy. Knockout of the gene encoding the hypocretin-orexin peptide precursor produced an equivalent narcoleptic syndrome in mice, further establishing this neuropeptide system as a major component of sleep-modulating neural circuits. Histaminergic neurons of the tuberomammillary nucleus express both forms of the orexin receptor and make reciprocal synaptic connections with orexin neurons in the lateral hypothalamus. Furthermore, orexin is an excitatory transmitter for the histamine neurons, suggesting that the two populations cooperate in the regulation of rapid eye movement sleep. Targeted ablation of orexin neurons in the lateral hypothalamus of rats by means of a hypocretin receptor 2saporin conjugate produced narcoleptic-like sleep behavior, closely paralleling the clinical findings and selected loss of hypocretin-orexin neurons in the lateral hypothalamus of humans with narcolepsy. These new discoveries add to the list of other neuropeptides including GHRH, somatostatin, and cortistatin with established function in modulation of the sleep cycle.

Chapter 8 - Anterior Pituitary

Shlomo Melmed
David Kleinberg

DEVELOPMENT, ANATOMY, AND OVERVIEW OF CONTROL OF HORMONE SECRETION

The pituitary gland situated within the sella turcica derives its name from the Greek *pituis*, Latin *pituita*, phlegm, reflecting its nasopharyngeal origin. Galen hypothesized that nasal phlegm originated from the brain and drained through the pituitary gland. It is now clear that together with the hypothalamus the pituitary orchestrates the structural integrity and function of endocrine glands, including the thyroid gland, adrenal gland, and gonads, in addition to target tissues including cartilage and breast. The pituitary stalk serves as an anatomic and functional connection to the hypothalamus. Preservation of the hypothalamic-pituitary unit is critical for integration of anterior pituitary control of sexual function and fertility, linear and organ growth, lactation, stress responses, energy, appetite, and temperature regulation and secondarily for carbohydrate and mineral metabolism.

Integration of vital body functions by the brain was first proposed by Descartes in the 17th century. In 1733, Morgagni recorded the absence of adrenal glands in an anencephalic neonate, providing early evidence for functional and developmental connection between the brain and the adrenal glands. In 1849 Claude Bernard set the stage for the subsequent advances in neuroendocrinology by demonstrating that central lesions in the area of the fourth ventricle resulted in polyuria. Subsequent studies led to the identification and chemical isolation of pituitary hormones, and astute clinical observations led to the realization that pituitary tumors were associated with functional hypersecretory syndromes, including acromegaly and Cushing's disease.

In 1948 Geoffrey Harris, the founder of modern neuroendocrinology, in reviewing anterior pituitary gland hormone control, proposed their hypothalamic regulation, predicting the subsequent discovery of specific hypothalamic regulating hormones.

Anatomy

The pituitary gland comprises the predominant anterior lobe, the posterior lobe, and a vestigial intermediate lobe (Fig. 8-1) (Figure Not Available). The gland is situated within the bony sella turcica and is overlain by the dural diaphragma sella, through which the stalk connects to the median eminence of the hypothalamus. The adult pituitary weighs approximately 600 mg (range, 400 to 900 mg) and measures about 13 mm in the longest transverse diameter, 6 to 9 mm in vertical height, and about 9 mm antero-posteriorly. Structural variation may occur in multiparous women, and gland volume also changes during the menstrual cycle. During pregnancy these measurements may be increased in either dimension, with pituitary weight increasing up to 1 g. Normal pituitary hypertrophy without evidence for the presence of an adenoma was described in seven eugonadal women with pituitary height greater than 9 mm and a convex upper gland boundary observed on magnetic resonance imaging (MRI).

The sella turcica located at the base of the skull forms the thin bony roof of the sphenoid sinus. The lateral walls comprising either bone or dural tissue abut the cavernous sinuses, which are traversed by the third, fourth, and sixth cranial nerves and internal carotid arteries (Fig. 8-2). The cavernous sinuses are vulnerable to pressure effects by an expanding pituitary mass, which is likely to follow the path of least tissue resistance by lifting the diaphragma sella (Fig. 8-3). The sinus contents are vulnerable to increased intrasellar expansion. The dural roofing protects the gland from compression by fluctuant cerebrospinal fluid (CSF) pressure. The optic chiasm, located anterior to the pituitary stalk, is directly above the diaphragma sella. The optic tracts and central structures are therefore vulnerable to pressure effects by an expanding pituitary mass, which is likely to follow the path of least tissue resistance by lifting the diaphragma sella (Fig. 8-3) (Figure Not Available). The intimate relationship of the pituitary and chiasm is borne out in optic chiasmal hypoplasia associated with developmental pituitary dysfunction seen in patients with septo-optic dysplasia. The posterior pituitary gland, in contrast to the anterior pituitary, is directly innervated by suprapontocerebellar hypophysial and tubero-hypophysial nerve tracts of the posterior stalk. Hypothalamic neuronal lesions, stalk disruption, or direct systemically derived metastases are therefore often associated with attenuated vasopressin (diabetes insipidus) or oxytocin secretion, or both.

The hypothalamus contains nerve cell bodies that synthesize hypophysiotropic releasing and inhibiting hormones as well as the neurohypophyseal hormones of the posterior pituitary (arginine vasopressin and oxytocin). Five distinct hormone-secreting cell types are present in the mature anterior pituitary gland. Corticotroph cells express pro-opiomelanocortin (POMC) peptides including adrenocorticotropic hormone (ACTH); somatotroph cells express growth hormone (GH); thyrotrroph cells express the common glycoprotein subunit and the specific thyroid-stimulating hormone (TSH) subunit; gonadotrophs express the and subunits for both follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

Figure 8-2 (Figure Not Available) Coronal section of the sellar structures and cavernous sinus showing the relationship of the oculomotor (III), trochlear (IV), trigeminal ophthalmic and maxillary divisions (V1 and V2), and abducens (VI) cranial nerves to the pituitary gland. (From Sliter SL, Sharpe JA. Neuro-ophthalmologic evaluation of pituitary tumors. In Thapar K, Kovacs K, Schilthauer BW, Lloyd RV [eds]. Diagnosis and Management of Pituitary Tumors. Totowa, NJ, Humana Press, 2001, pp 173200.)
Pituitary Development

The pituitary gland arises from within the rostral neural plate. Rathke's pouch, a primitive ectodermal invagination anterior to the roof of the oral cavity, is formed by the fourth to fifth week of gestation and gives rise to the anterior pituitary gland (Fig. 8-4) (Figure Not Available).

Rathke's pouch is directly connected to the stalk and hypothalamic infundibulum and ultimately becomes distinct from the oral cavity and nasopharynx. Rathke's pouch proliferates toward the third ventricle, where it fuses with the diverticulum and subsequently obliterates its lumen, which may persist as Rathke's cleft. The anterior lobe is formed from Rathke's pouch, and the diverticulum gives rise to the adjacent posterior lobe. Remnants of pituitary tissue may persist in the nasopharyngeal midline and rarely give rise to functional ectopic hormone-secreting tumors in the nasopharynx. The neurohypophysis arises from neural ectoderm associated with third-ventricle development.

Functional development of the anterior pituitary cell types involves complex spatiotemporal regulation of cell lineagespecific transcription factors expressed in pluripotential pituitary stem cells as well as dynamic gradients of locally acting soluble factors. Critical neuroectodermal signals for organizing the dorsal gradient of pituitary morphogenesis include infundibular bone morphogenetic protein 4 (BMP4) required for the initial pouch invagination, fibroblast growth factor 8 (FGF-8), Wnt 5, and Wnt 4. Subsequent ventral developmental patterning and transcription factor expression are determined by spatial and graded expression of BMP2 and sonic hedgehog protein (shh), which appears critical for directing early patterns of cell proliferation.

The human fetal Rathke pouch is evident at 3 weeks, and the pituitary grows rapidly in utero. By 7 weeks, the anterior pituitary vasculature begins to develop, and by 20 weeks the entire hypophyseal-portal system is already established. The anterior pituitary undergoes major cellular differentiation during the first 12 weeks, by which time all the major secretory cell compartments are structurally and functionally intact, except for lactotrophs. Totipotential pituitary stem cells give rise to acidophilic (mammosomatotroph, somatotroph, and lactotroph) and basophilic (corticotroph, thyrotroph, and gonadotroph) differentiated pituitary cell types, which appear at clearly demarcated developmental stages. Corticotroph cells are morphologically identifiable at 6 weeks, and immunoreactive ACTH is detectable by 7 weeks. At 8 weeks, somatotroph cells are evident with abundant immunoreactive cytoplasmic GH expression. Glycoprotein hormonesecreting cells express a common subunit, and at 12 weeks differentiated thyrotrophs and gonadotrophs express immunoreactive subunits for TSH, LH, and FSH. Interestingly, gonadotrophs expressing LH and FSH are equally distributed in females, whereas in the male fetus, LH-expressing gonadotrophs predominate. Fully differentiated PRL-expressing lactotrophs are evident only late in gestation (after 24 weeks). Prior to that time, immunoreactive PRL is detectable only in mixed mammosomatotrophs, also expressing GH, reflecting the common genetic origin of these two hormones.
Pituitary Transcription Factors

Determination of anterior pituitary cell type lineages results from a temporally regulated cascade of homeodomain transcription factors. Although most pituitary developmental information has been acquired from murine models, histologic and pathogenetic observations in human subjects have largely corroborated these developmental mechanisms (see Fig. 8-4). Early cell differentiation requires intracellular Rpx and Ptx expression. Rathke’s pouch expresses several transcription factors of the LIM homeodomain family, including Lhx3, Lhx4, and IsI-1, which are early determinants of functional pituitary development. Pitx1 is expressed in the oral ectoderm and subsequently in all pituitary cell types, particularly those arising ventrally. Rieger’s syndrome, characterized by defective eye, tooth, umbilical cord, and pituitary development, is caused by defective related Pitx2.

Ptx behaves as a universal pituitary regulator and activates transcription of -GSU (the -subunit of gonadotroph hormones), POMC and LH (Ptx1), and GH (Ptx2). Lhx3 determines GH-PRL and TSH cell differentiation, and Prop-1 behaves as a prerequisite for Pit-1, which activates GH, PRL, TSH, and growth hormone-releasing hormone (GHRH) receptor transcription. TSH and gonadotropin-expressing cells share a common subunit (GSU) expression under developmental control of GATA-2. These specific anterior pituitary transcription factors participate in a highly orchestrated cascade leading to the commitment of the five differentiated cell types (see Fig. 8-4). The major proximal determinant of pituitary cell lineage derived from a totipotential stem cell is thus Prop-1 expression, which determines subsequent development of Pit-1-dependent and gonadotroph cell lineages.

POU1F1, the renamed Pit-1, is a POU-homeodomain transcription factor that determines development and appropriate temporal and spatial expression of cells committed to GH, PRL, TSH, and GHRH receptor expression. POU1F1 binds to specific deoxyribonucleic acid (DNA) motifs and activates somatotroph, lactotroph, and thyrotroph development and mature secretory function. Signal-dependent coactivating factors also cooperate with Pit-1 to determine specific hormone expression. Thus, in POU1F1-containing cells, high estrogen receptor levels induce a commitment to express PRL, whereas thyrotroph embryonic factor (TEF) favors TSH expression. Selective pituitary cell type specificity is also perpetuated by binding of POU1F1 to its own DNA regulatory elements as well as those contained within the GH, PRL, and TSH genes. Steroidogenic factor-1 (SF-1) and dosage-sensitive sex reversal, adrenal hypoplasia congenita, X-chromosome factor (DAX-1) determine subsequent gonadotroph development.

Corticotroph cell commitment, although occurring earliest during fetal development, is independent of POU1F1-determined lineages, and Tpit protein appears to be a prerequisite for POMC expression. Hereditary mutations arising within these transcription factors may result in isolated or combined pituitary hormone failure syndromes (see later).
Pituitary Blood Supply

The pituitary gland enjoys an abundant blood supply derived from several sources (see Fig. 8-1). The superior hypophyseal arteries branch from the internal carotid arteries to supply the hypothalamus, where they form a capillary network in the median eminence, external to the blood-brain barrier. Long and short hypophyseal portal vessels originate from infundibular plexuses and the stalk, respectively. These vessels form the hypothalamic-portal circulation, the predominant blood supply to the anterior pituitary gland. They deliver hypothalamic releasing and inhibiting hormones to the trophic hormone-producing cells of the adenohypophysis without significant systemic dilution, allowing the pituitary cells to be sensitively regulated by timed hypothalamic hormone secretion.

Vascular transport of hypothalamic hormones is also locally regulated by a contractile internal capillary plexus (gomotoli) derived from stalk branches of the superior hypophyseal arteries. Retrograde blood flow toward the median eminence also occurs, facilitating bidirectional functional hypothalamic-pituitary interactions. Systemic arterial blood supply is maintained by inferior hypophyseal arterial branches, which predominantly supply the posterior pituitary. Disruption of stalk integrity may lead to compromised pituitary portal blood flow, depriving the anterior pituitary cells of hypothalamic hormone access.
Pituitary Control

Three levels of control subserve the regulation of anterior pituitary hormone secretion. Hypothalamic control is mediated by adenohypophysiotropic hormones secreted into the portal system and impinging directly upon anterior pituitary cell surface receptors. G protein-linked cell surface membrane binding sites are highly selective and specific for each of the hypothalamic hormones and elicit positive or negative signals mediating pituitary hormone gene transcription and secretion. Peripheral hormones also participate in mediating pituitary cell function, predominantly by negative feedback regulation of trophic hormones by their respective target hormones. Intrapituitary paracrine and autocrine soluble growth factors and cytokines act locally to regulate neighboring cell development and function.

The net result of these three tiers of complex intracellular signals is the controlled pulsatile secretion of the six pituitary trophic hormones, ACTH, GH, PRL, TSH, FSH, and LH, through the cavernous sinus, petrosal veins, and ultimately the systemic circulation through the superior vena cava. The temporal and quantitative control of pituitary hormone secretion is critical for physiologic integration of peripheral hormonal systems such as the menstrual cycle, which relies on complex and precisely regulated pulse control.
PITUITARY MASSES

Pituitary Mass Effects

An expanding pituitary mass may inexorably alter the sellar size and shape by bone erosion and remodeling. Although the exact time course of this process is unknown, it appears to be slowly progressive over years or decades. The tumor may invaginate soft tissue, and the dorsal sellar roof presents the least resistance to expansion from within the confines of the bony sella. Nevertheless, both suprasellar and parasellar compression and invasion may occur with an enlarging mass, with resultant clinical manifestations. As tumors impinge upon the optic chiasm, they interfere with vision. Because of the anatomy of the chiasm, pressure from below affects temporal visual fields, starting superiority and ultimately extending to the entire temporal field. Loss of nasal fields also occurs and may result in blindness. Long-standing optic chiasmal pressure results in optic disc pallor.

Figure 8-7 Magnetic resonance coronal section of a normal pituitary gland (top). A large pituitary adenoma is seen lifting and distorting the optic chiasm (arrow) and is also invading the sphenoid sinus (middle). A sagittal section of a large macroadenoma with bone invasion and impinging brain structures is shown (bottom).

Lateral invasion of pituitary lesions may invade the dural wall of the cavernous sinus affecting the third, fourth, and sixth cranial nerves as well as the ophthalmic and maxillary branches of the fifth cranial nerve and surround the internal carotid artery. Varying degrees of diplopia, ptosis, ophthalmoplegia, and decreased facial sensation may infrequently occur, depending on the extent of the neural involvement by the cavernous sinus mass. Downward extension into the sphenoid sinus indicates that the parasellar mass has eroded the bony sellar floor. Aggressive tumors may invade the roof of the palate and cause nasopharyngeal obstruction, infection, and CSF leakage. Infrequently, temporal or frontal lobes may be invaded, causing uncinate seizures, personality disorders, and anosmia. In addition to the anatomic lesions caused by the expanding mass, direct hypothalamic involvement of the encroaching mass may lead to important metabolic sequelae discussed in Chapter 7.

Patients with intrasellar tumors commonly present with headaches, even in the absence of demonstrable suprasellar extension. Small changes in intrasellar pressure caused by a microadenoma within the confined sella are sufficient to stretch the dural plate with resultant headache. Headache severity does not correlate with the size of the adenoma or the presence of suprasellar extension. Relatively minor diaphragmatic distortions or dural impingement may be associated with persistent headache. Successful medical management of small functional pituitary tumors with dopamine agonists or somatostatin analogues is often accompanied by a remarkable improvement in or disappearance of headache.

Regardless of their etiology or size, pituitary masses, including adenomas, may be associated with compression of surrounding healthy tissue and resultant hypopituitarism. In 49 patients undergoing transsphenoidal resection of pituitary adenomas, mean intrasellar pressure was elevated twofold to threefold in patients with pituitary failure. Furthermore, prevalence of headache and elevated PRL levels correlated positively with intrasellar pressure levels, suggesting interrupted portal delivery of hypothalamic hormones. Thus, surgical decompression of a sellar mass may lead to recovery of compromised anterior pituitary function. In the patients who do not recover pituitary function postoperatively, ischemic necrosis is likely to have occurred. Stalk compression may result in pituitary failure caused by encroachment of the portal vessels that normally provide pituitary access to the hypothalamic hormones. Stalk compression also usually leads to hyperprolactinemia and concomitant failure of other pituitary trophic hormones.
Pituitary Adenomas

Pathogenesis

Pituitary tumors account for about 15% of all intracranial neoplasms and are commonly encountered at autopsy. The Brain Tumor Registry of Japan reported that 15.8% of 28,424

cases were historically confirmed pituitary adenomas. They are benign monoclonal adenomas that may express and secrete hormones autonomously, leading to hyperprolactinemia, acromegaly, and Cushing's disease, or may be functionally silent and initially diagnosed as a sellar mass. Although these adenomas are invariably benign, their neoplastic features represent a unique tumor biology that is reflected in their important local and systemic manifestations. These monoclonal neoplasms have a slow doubling time and, if small, may rarely resolve spontaneously. Nevertheless, they can be aggressive and locally invasive or compressive to vital central structures. They usually express a single gene product, but polyclonal expression may reflect a primitive stem cell or mature bimorphic cellular origin. Hypothalamic factors may have a specific role in the pathogenesis of pituitary tumors, in addition to regulating pituitary hormone gene expression and secretion (Table 8-2). Ectopic GHRH-secreting tumors (bronchial carcinoids, pancreatic islet cell tumors, or small cell lung carcinomas) result in GH hypersecretion, acromegaly, somatotroph hyperplasia, and occasionally somatotroph adenoma formation. In transgenic mice overexpressing a GHRH transgene, the pituitary size increased dramatically because of somatotroph hyperplasia, and older mice developed GH-secreting adenomas. However, adenomatous hormonal secretion is usually independent of physiologic hypothalamic control, and the surgical resection of small well-defined adenomas usually results in definitive cure of hormonal hypersecretion. These observations imply that these tumors do not arise because of excessive polyclonal pituitary cell proliferation related to generalized hypothalamic stimulation. However, hypothalamic factors may promote and maintain growth of already transformed pituitary adenomatous cells.

Normal and hyperplastic pituitary tissues are polyclonal, and pituitary adenomas arise as the result of monoclonal pituitary cell proliferation. Using X-chromosomal inactivation analysis, the monoclonal origin of adenomas secreting GH, PRL, and ACTH is confirmed and nonfunctioning pituitary tumors was confirmed in female patients heterozygous for variant alleles of the X-linked genes hypoxanthine phosphoribosyltransferase (HPRT) and phosphoglycerate kinase (PGK). Thus, an intrinsic somatic pituitary cell genetic alteration probably gives rise to clonal expansion of a single cell, resulting in adenoma formation. (Table 8-3).

Activating gsp mutations are present in up to 40% of human GH-secreting adenomas. These somatic heterozygous activating point mutations of the G protein subunit (Gs) gene involving either arginine 201 (replaced by cysteine or histidine) or glutamine 227 (replaced with arginine or leucine) constitutively activate the Gs protein and convert it into an oncogene (gsp). This G protein activation increases cyclic adenosine monophosphate (cAMP) levels and activates protein kinase A, which in turn phosphorylates the cAMP response element binding protein (CREB) and leads to sustained constitutive GH hypersecretion and cell proliferation. The gsp-bearing adenomas are smaller, have mildly lower GH levels and enhanced intratumoral cAMP, do not respond briskly to GHRH, and are extremely sensitive to the inhibitory effect of somatostatin. These gsp activating mutations do not occur in PRL-secreting or in TSH-producing adenomas and are rarely present in nonfunctioning pituitary tumors or ACTH-secreting tumors (<10%).

Similar early postzygotic somatic mutations in codon 201 of Gs were identified in tissues derived from patients with McCune-Albright syndrome, including GH-producing pituitary adenomas. Transgenic mice overexpressing inactive pituitary CREB mutant exhibited a dwarf phenotype and somatotroph hypoplasia. Thus, cAMP probably stimulates somatotroph proliferation by CREB phosphorylation. This was borne out by the observation that 15 human GH-secreting pituitary adenomas contained elevated levels of phosphorylated CREB. However, only four of these tumors also contained the mutant gsp oncogene, and CREB phosphorylation was also demonstrated in adenomas overexpressing wild-type Gs protein, suggesting a role of CREB independent of G protein actions.

Ras mutations are rare in pituitary adenomas. Ras gene mutations were identified in an invasive prolactinoma and in distant metastatic pituitary carcinomas but not in their respective primary pituitary tumors or in noninvasive adenomas. Thus, ras genetic alterations may be important in the rare progression to metastasis formation and growth. Pituitary tumor transforming gene (PTTG) was isolated from experimental pituitary tumors and shown to be highly abundant in all pituitary tumors.

Multiple endocrine neoplasia type 1 (MEN-1) is an autosomal dominant hereditary disorder characterized by combined tumor formation or hyperfunction of pancreatic islets and anterior pituitary and, less commonly, parathyroid, thyroid, and adrenal tumors. The MEN-1 syndrome is fully described in Chapter 36. Unlike those in pituitary tumors constituting the MEN-1 syndrome, MEN-1 gene mutations were not identified in familial pituitary adenomas. Patients with sporadic pituitary adenomas do not demonstrate germ line or somatic pathogenic changes in the coding sequence of the MEN-1 gene, even in tumors with loss of heterozygosity of 11q13, and only two cases of sporadic pituitary adenomas (of 94 tumors studied)

had specific MEN-1 mutations. Thus, MEN-1 gene mutations do not appear to play a role in pituitary tumorigenesis in most sporadic adenomas.

Loss of heterozygosity for chromosomes 11q13, 13, and 9 has been observed in about 15% of spontaneous pituitary adenomas, often correlating with tumor size and invasiveness. However, no distinct tumor suppressor gene has been identified for sporadic pituitary tumors. Loss of heterozygosity in proximity to the retinoblastoma (RB) locus on chromosome 13q14 was detected in malignant or highly invasive pituitary tumors and in their metastases, but immunohistochemical studies have shown the presence of RB protein in these malignant tumors with 13q14 allelic loss, suggesting that the RB gene itself is not involved in pituitary adenoma development and that another suppressor gene located near the RB locus may play a role in invasive or malignant pituitary tumors. p53 gene mutations were not detected in secreting and nonsecreting pituitary tumors or in pituitary carcinomas and their metastases.

Although no mutations in the GHRH, corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), or gonadotropin-releasing hormone (GnRH) receptor have been identified in pituitary adenomas, several GH-secreting adenomas express an alternatively spliced truncated GHRH receptor. The insulin-like growth factor I (IGF-I) receptor subunit in GH adenomas exhibited intact regions of the receptor critical for signal transduction. The dopamine D2 receptor gene appears intact in PRL-producing and TSH-producing or nonfunctioning adenomas. Therefore, there is no apparent role of pituitary cell surface receptor mutations of hypothalamic releasing and inhibitory factors in pituitary tumorigenesis.

FGF-2 (basic FGF) is expressed in pituitary tissues and induces basal and stimulated PRL secretion from normal and pituitary adenoma cells. Human pituitary adenomas express FGF-4, and transfected FGF-4 enhances PRL secretion and tumor vascularity. FGF-4 is immunodetected in about a third of prolactinomas and is undetectable in normal pituitaries and other adenoma types.

Carney’s complex is an autosomal dominant disorder comprising benign mesenchymal tumors including cardiac myxomas, schwannomas, and thyroid and pituitary adenomas associated with spotty skin pigmentation (Table 8-4). The disorder has been mapped to chromosome 17q24 and results from a mutated R1 regulatory subunit of the cAMP-dependent protein kinase A (PRKARIA), an apparent tumor suppressor gene.

In summary, multifactorial mechanisms subserve the multistep pathogenetic process of pituitary adenoma formation, including early initiating chromosomal mutations that result in mutated pituitary stem cells (see Table 8-2). The transformed pituitary cell is subjected to signals facilitating clonal expansion, and several permissive factors, including hypothalamic hormone receptor signals, intrapituitary growth factors, and disordered cell cycle regulation, may determine the ultimate biologic fate of the tumor. Autonomous anterior pituitary hormone production and secretion and cell proliferation, which are the hallmarks of pituitary adenomas, result. However, the subcellular events initiating the formation of most secreting and nonfunctional pituitary adenomas have not yet been elucidated.

### Classification

Pituitary adenomas arise from hormone-secreting adenohypophyseal cells, and their secretory products depend on the cell of origin (Table 8-5). Previously clinically inapparent pituitary adenomas are found in about 11% of autopsies (Table 8-6). They are often localized to unique areas of the gland, reflecting relative cell type abundance and intragland distribution (Fig. 8-8) (Figure Not Available). Radiologic and surgical classifications are based on tumor localization, size, and degree of invasiveness (Fig. 8-9) (Figure Not Available). Microadenomas are intrasellar and generally less than 10 mm in widest diameter. Macroadenomas are larger than 10 mm and usually impinge on adjacentellar structures. Specific tumor types are considered subsequently for each respective cell type.

Immunocytochemistry detects pituitary cell gene products at both the light and electron microscopic level and allows classification of pituitary tumors on the basis of their function. Unlike the corticotroph, somatotroph, lactotroph, and thyrotroph cell tumors, which hypersecrete their respective hormones, gonadotroph cell tumors are usually clinically silent and do not secrete their gene products efficiently. Double immunostaining identifies mixed tumors expressing combinations of hormones, which are often macroadenomas secreting GH concomitantly with PRL, TSH, or ACTH. Generally, immunohistochemical identification of pituitary hormones correlates with tumor-specific messenger ribonucleic acid (mRNA) markers measured either in whole tissue extracts by Northern analysis or at the single-cell level by in situ hybridization techniques. With the exception of the glycoprotein subunit, immunohistochemical positivity of more than 5% of cells making up the tumor is usually reflective of peripheral circulating hormone.

Data are derived from studying a relatively stable 1 million catchment population surrounding Stoke-on-Trent, UK (Clayton RN, Clin Endo & Metab 13:451, 1999), and from Kovacs & Horvath 1986; Scheithauer 1994; Minderman & Wilson, Clin Endo 1994; Asa 1993. In Endocrine Tumours, Blackwell). Levels. Quantification of immunostaining intensity is subjective, and a scale of intensity should also include a description of the extent of staining, that is, whether occasional, scattered, or most tumor cells express the immunodetectable protein.

Electron microscopy is useful for assessing the ultrastructure of hormone secretory granules and their size and distribution. Other subcellular features important for diagnosis include large mitochondria in nonfunctioning oncocytes and the secretory nature of Golgi and endoplasmic reticulum, especially for prolactinomas. Peroxidase or colloidal gold particles of different diameters are also sensitive electron microscopic markers for identifying and localizing intracellular hormone signals. Because even invasive pituitary tumors grow slowly, use of mitotic markers including proliferating cell nuclear antigen (PCNA) and Ki-67 is of limited utility. 

![Bookmark URL](167.html/top)
Other Parasellar Masses

Clinical features of hypothalamic masses are fully described in Chapter 7, and parasellar masses (Table 8-7) are described here. Teramoto

Rathke's Cyst

The anterior and intermediate lobes of the pituitary gland arise embryologically from Rathke's pouch. Inadequate pouch obliteration results in the cysts or cystic remnants at the interface between the anterior and posterior pituitary lobes found in about 20% of pituitary glands at autopsy. Pituitary adenomas may also occasionally contain small cleft cysts. They are lined by cuboidal or columnar ciliated epithelium surrounding mucoid cyst fluid, arising from midline rudiments of failed Rathke's cyst invagination, and account for about 3% of pituitary mass lesions. In contrast, pituitary epidermoid cysts are lined by squamous epithelium, which rarely becomes malignant.

Rathke's cysts vary in size and may also extend to the supra-sellar region. These lesions have heterogeneous MRI characteristics and may arise with panhypopituitarism with or without diabetes insipidus. Most, however, are not symptomatic and should be observed expectantly. The extent of headache or visual disturbance is determined by the size and location of the cyst. Cyst formation is associated with sellar enlargement and hyperdense or hypodense masses seen on either T1-weighted or T2-weighted MR images, and computed tomography (CT) shows homogeneous hypodense areas that may be distinguished from pituitary adenomas. These patients should all be evaluated for hypopituitarism. After surgical resection or drainage, MRI should be performed during long-term follow-up for signs of cyst recurrence.

Arachnoid, epidermoid, and dermoid cysts develop mainly in the cerebellopontine angle but may also arise in the suprasellar region. Dermoid cysts containing greasy sebaceous products or hair follicles are rarely encountered in the pituitary, and the cyst lining may be calcified. Acquired pituitary cysts may be secondary to intrasellar hemorrhage, usually associated with an underlying adenoma, and these rarely cause pituitary failure.

compression causes internal hydrocephalus, visual disturbances, GH or ACTH deficiency, hyperprolactinemia, and diabetes insipidus. Rarely, squamous cell carcinoma may arise in the cyst.

Granular Cell Tumors

Pituitary choristomas, or schwannomas, usually arise only after the age of 20. Their abundant cytoplasmic granules do not contain pituitary hormones, but these lesions may occur with diabetes insipidus. Pituitary adenomas are occasionally coincidentally associated with these tumors.

Chordomas

These slow-growing cartilaginous tumors arise from midline notochord remnants, are locally invasive, and may metastasize. Most arise from the vertebrae, and about one third involve the clivus region. Chordomas contain a mucin-rich matrix that allows diagnosis by fine-needle aspiration. Patients present with headaches, asymmetric visual disturbances, hormone deficiency, and occasional nasopharyngeal obstruction. The tumor mass is associated with osteolytic bone erosion and calcification, and MRI may allow the normal pituitary gland to be distinguished from the very heterogeneous and often floroculent tumor mass. At surgery, the tumors are rough, heterogeneous, and lobular. Markers for epithelial cells, including cytokeratin and vimentin, are present. Recurrences are common after surgical excision, and mean survival of patients is about 5 years. Rarely, chordomas undergo sarcomatous transformation with an aggressive natural history and require extensive surgical dissection.
Craniopharyngiomas

This parasellar tumor constitutes about 3% of all intracranial tumors and up to 10% of childhood brain tumors. The tumor is commonly diagnosed during childhood and adolescence. Tumors arise from embryonic squamous remnants of Rathke's pouch extending dorsally toward the diencephalon; they may be large (> 10 cm in diameter) and invade the third ventricle and associated brain structures. Over 60% arise from within the sella, with others arising from parasellar cell rests. When intrasellar, they can often be distinguished from pituitary adenomas by a separate visible rim of normal pituitary tissue seen on MRI. The cystic mass is usually filled with cholesterol-rich viscous fluid, which may leak into the CSF and cause aseptic meningitis. The tumors may also contain calcifications and immunoreactive human chorionic gonadotropin (hCG).

Histologically, these tumors comprise two cell populations; cysts are lined with a squamous epithelium containing islands characterized by columnar cells, and a mixed inflammatory reaction may also occur with calcification. Although large craniopharyngiomas may obstruct CSF flow, they rarely undergo malignant transformation. Increased intracranial pressure results in headache, projectile vomiting, papilledema, and somnolence, especially in children. Only about one third of patients are older than 40 years, and they commonly present with asymmetric visual disturbances, including papilledema, optic atrophy, and field deficits. If cavernous sinus invasion is present, other cranial nerves may also be involved.

On CT imaging, most children and about half of all adults exhibit characteristic flocculent or convex calcifications. Rarely, however, pituitary adenomas, other parasellar tumors, and vascular lesions within the sella are also calcified. In contrast to pituitary adenomas, which rarely cause diabetes insipidus, craniopharyngiomas are often associated with this disorder as the earliest feature. These patients may also experience partial or complete pituitary deficiency. GH deficiency, with short stature and diabetes insipidus, and gonadal failure are common. Pituitary stalk compression or damage to hypothalamic dopaminergic neurons results in hyperprolactinemia. Thus, a craniopharyngioma may mimic a prolactinoma in terms of intrapituitary imaging, presence of hyperprolactinemia, and favorable biochemical response to dopamine agonists.

The treatment of these lesions may involve radical surgery, radiotherapy, or a combination of these modalities. Stereotactic radiation has some success. A detailed discussion of the neurosurgical management of this disorder is beyond the scope of this text. Nevertheless, regardless of the form of therapy chosen, ablation of the mass invariably results in anterior or posterior pituitary hormone deficiencies. Postoperative recurrence may occur in about 20% of patients undergoing radical surgical excision, and there is no difference in outcome in those who undergo a subtotal surgical excision followed by radiotherapy. Pure papillary squamous cellular elements in the tumor may portend a higher surgical recurrence rate. Long-term effects of childhood radiation for these tumors are considered elsewhere.

Meningiomas

Meningiomas arise from arachnoid and meningioendothelial cells, and those occurring in the sellar and parasellar region account for about one fifth of all meningiomas. Sellar meningiomas are usually well circumscribed and do not attain the size of craniopharyngiomas. Suprasellar meningiomas may invade the pituitary ventrally, and intrasellar tumor origins are rare. Coexisting functional pituitary adenomas have been described in patients with parasellar meningiomas. Secondary hypopituitarism and visual deficits occur in up to half of patients, who usually present with local mass effects including headache and progressive visual disturbances accompanied by optic atrophy.

The differential distinction between a suprasellar meningioma with downward extension and an upwardly extending pituitary adenoma may be difficult. With MRI, meningiomas are isodense on both T1 and T2 imaging, in contrast to other parasellar lesions, which are usually hyperdense on T2 imaging. Dural calcification may be evident on CT scanning. Because of their rich vascularization, these tumors pose an intracranial risk for hemorrhage and a resultant higher surgical mortality rate than usually encountered for pituitary adenoma resection.

Gliomas

Optic gliomas and low-grade astrocytomas arise from within the optic chiasm or optic tract and often infiltrate the optic nerve; less than one third are intraorbital. Von Recklinghausen's disease is the underlying cause in about one third of the patients. These tumors may occasionally be associated with growth retardation, delayed or precocious puberty, and mass effects including visual disturbances, diencephalic syndrome, diabetes insipidus, and hydrocephalus. Rarely, gliomas arise within the sella associated with hyperprolactinemia, and they should be considered in the uncommon differential diagnosis of a PRL-secreting pituitary adenoma. Important distinguishing features include the young age of these patients (80% are younger than 10 years), relatively intact pituitary function, gross visual disturbances, and localization of the mass as visualized on MRI. Gliomas, unlike hamartomas, are usually enhanced after injection of contrast material.

Mucocles

Mucocles are expanding accumulations of fluid within the sphenoid sinus and may compress parasellar structures. Headaches, visual disturbances (usually unilateral), and exophthalmos are characteristic features. On MRI, the homogeneous sphenoid mass may be quite prominent but may be distinguished from the pituitary gland dorsally.

Parasellar Aneurysms

Parasellar aneurysms may mimic pituitary adenomas and intraoperative rupture may be catastrophic, underlying the absolute need for preoperative diagnosis. Differentiating features of aneurysms from other parasellar masses may be subtle, including eye pain, intense headaches, and relatively sudden onset of cranial nerve palsies. Although imaging techniques usually distinguish blood and hemorrhage from solid tumor or tissue, a highly vascular meningioma may be confused with an aneurysm.

Pituitary Infections

Acute pituitary abscesses and periselar arachnoiditis are encountered with sinus infections, especially after transsphenoidal surgery. Pituitary abscess may develop from hematogenous or direct local spread of infectious agents. Abscesses may arise within a preexisting pituitary adenoma and may be difficult to distinguish from an adenoma because these patients may not have fever or signs of meningitis. On MRI imaging, an isointense central cavity with surrounding ring enhancement is characteristic of an abscess.

Gram-positive streptococci or staphylococci may originate from nasopharyngeal passages. Disseminated Entamoeba histolytica and Pneumocystis carinii may also seed to the pituitary.

Figure 8-9 (Figure Not Available) Classification of pituitary tumors. (Adapted from Thapar K, Laws ER: Growth hormonesecreting pituitary tumors: operative management. In Krisht AF, Tindal GT [eds]: Pituitary Disorders. Philadelphia, Lippincott Williams & Wilkins, 1999; and Aa SL: In Tumors of the Pituitary Gland. Pituitary Adenomas. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1980.)
lead to pituitary damage and insufficiency. Common viral infections, including influenza, measles, mumps, and herpes, are rarely associated with pituitary damage and insufficiency. Although tuberculosis is rarely confined to the pituitary gland, most of the fewer than 20 reported patients exhibited suprasellar extension of the pituitary mass, compromised pituitary function, and visual defects. Although evidence for systemic tuberculosis is usually present, isolated sellar tuberculosis have been described.

**Hematologic Malignancies**

Primary central nervous system lymphomas are usually B-cell non-Hodgkin's types, and nine such patients with pituitary lymphoma have been described. The pituitary mass may be an isolated presentation of the underlying disease. The disorder is usually diagnosed by histologic examination of tissue obtained by excision biopsy. Six of nine patients had headache, and five had cranial nerve abnormalities with varying degrees of hypopituitarism. MRI reveals cavernous sinus invasion and isointense T1-weighted and T2-weighted images that are enhanced by gadolinium. Patients with solitary pituitary plasma-cytomas have been reported who did not have classical multiple myeloma. Acute lymphoblastic leukemia may be associated with periglandular pituitary infiltrates with minimal pituitary dysfunction.

**Pituitary Granulomas**

**Sarcoidosis**

Infiltrative sarcoidosis of the hypothalamic-pituitary region occurs in most patients with central nervous system sarcoid involvement. These patients may present with varying degrees of anterior pituitary failure with or without diabetes insipidus. Hypothalamic granulomatous involvement is commonly encountered in patients with central nervous system sarcoidosis and may be the sole manifestation of the disease. The hypothalamus, pituitary stalk, and posterior pituitary are diffusely invaded by noncaseating granulomas, consisting of giant cells, macrophages, and lymphocytes. Sarcoidosis may be progressive and eventually result in pituitary damage and even an empty sella. Onset of diabetes insipidus with no obvious features of a pituitary disorder should alert the physician to exclude hypothalamic sarcoid deposits, especially in the presence of a thickened stalk on MRI.

**Hand-Schüller-Christian Disease**

Hand-Schüller-Christian disease (histiocytosis X) may comprise sleep disorders, adipsia, and morbid obesity. Other features of granulomatous involvement, including axillary skin rash, history of recurrent pneumothorax, and classical bone lesions, should be sought, especially in young patients with new-onset diabetes insipidus. The disorder may be associated with granulomatous damage to the hypothalamus or posterior pituitary, or both, with characteristic diabetes insipidus. The pituitary lesions consist of dendritic Langerhans cells, and pituitary MRI may reveal stalk thickening or a diminished posterior pituitary bright spot. Adults with the disorder should be carefully evaluated for anterior pituitary hormone deficits, which should be appropriately replaced.

**Metastases to the Pituitary Region**

Pituitary metastases are found in up to 3.5% of patients with cancer. As the vascular supply to the posterior pituitary is derived directly from the systemic circulation through the internal carotid arteries, the posterior pituitary is the preferred site for blood-borne metastatic spread. Carcinomas that metastasize to the pituitary include breast, lung, and gastrointestinal tract cancers. Up to one quarter of patients with metastatic breast cancer have pituitary metastases. Symptomatic

Forces Institute of Pathology, 1998, p 51.)
pituitary metastases (usually diabetes insipidus) may be the presenting sign of occult malignancy and of malignancy of unknown origin. Rarely, isolated metastatic stalk deposits may also occur with pituitary failure.

If extensive bone erosion is present and disease onset is rapid, the diagnosis is more readily apparent. However, pituitary imaging may not clearly distinguish metastatic deposits from a pituitary adenoma, these lesions may masquerade as an adenoma, and the diagnosis is made only by histologic study of the resected specimen. When the diagnosis is clear-cut in the presence of a primary cancer, relatively low-dose pituitary radiation may be sufficient to shrink the metastasis and decrease morbidity.

Iron storage diseases, including hemochromatosis and hemosiderosis, result in predominantly gonadotroph cell damage. Idiopathic retroperitoneal fibrosis may also be associated with a suprasellar mass and hypothalamic panhypopituitarism. 

**Primary Hypophysitis**

Pituitary mass lesions composed of inflammatory cells may arise as primary disorders exclusively confined to the hypophysis. At least three distinct clinicopathologic forms have been described.

**Lymphocytic Hypophysitis**

This apparently autoimmune inflammatory disorder occurs predominantly during pregnancy or in postpartum women but has also been reported after menopause, and about 15% of reported cases occurred in men. Of the disorders that develop in association with pregnancy, about 50% occur during the first 6 postpartum months. The disorder is characterized by a lymphocytic and plasma cell pituitary infiltrate, which may be isolated or associated with other recognized endocrinopathies. Circulating antipituitary antibodies have occasionally been reported, and the presence of isolated pituitary hormone deficiency may imply an autoimmune process selectively targeted to pituitary cell types.

Although the natural history is often brief, the few comprehensive pathologic evaluations suggest that secondary adenohypophyseal atrophy, with a resultant empty sella, is a frequent outcome. Pathologic criteria for diagnosis include islands of anterior pituitary cells surrounded by diffuse lymphocytic (T-cell and B-cell) infiltrates. Over 125 cases have been reported, and the diagnosis has been definitively confirmed by histology in only about 10%. Some patients have been reported with lymphocytic, plasma cell, and macrophage infiltrates ultimately resulting in cell destruction, fibrosis, and an irreversible chronic hypophysitis.

**Clinical Features**

More than half the patients present with headache and visual field impairment, and pituitary deficiency accounts for the remaining cases. MRI reveals a

pituitary mass, often indistinguishable from an adenoma. An associated partially empty sella and contrast enhancement of the pituitary mass may be helpful in distinguishing MRI features. The inflammatory process often resolves with time, and pituitary function may be restored or remain chronically compromised. Limited numbers of patients have been reported with histologically proven lymphocytic hypophysitis and documented spontaneous regression of pituitary mass on follow-up imaging. In two patients with histologically proven hypophysitis, spontaneous resolution of the pituitary mass was followed by subsequent successful pregnancies. Diabetes insipidus, encountered in 20% of patients, may be attributed to posterior pituitary or stalk infiltration. In one third of patients, other autoimmune conditions, including thyroiditis, hypoadrenalism, parathyroid failure, atrophic gastritis, systemic lupus erythematous, and Sjögren's syndrome, are also present. The differential diagnosis includes prolactinoma and other sellar masses, and a careful history and demonstrated loss of the posterior pituitary bright spot on MRI are useful for supporting the diagnosis.

**Laboratory Results**

The erythrocyte sedimentation rate is often elevated; antibodies to a 49-kd cytosolic protein were detected in 70% of patients with histologically confirmed lymphocytic hypophysitis and in 10% of control subjects. Although the specificity of this antibody and two additional antibodies to 68- and 43-kd human pituitary membrane antigens is high, all three were detected in only 5 of 13 patients with lymphocytic hypophysitis and 1 of 12 patients with infundibuloneurohypophysitis. PRL levels are usually elevated in both female and male patients, hyperprolactinemia is expected during pregnancy and during the early postpartum period, and the mass effect of the infiltrate may also contribute to stalk compression and secondary hyperprolactinemia. GH and ACTH responses to hypothalamic hormone challenges may be blunted. Rarely, isolated ACTH or TSH deficiencies have been reported.

**Treatment**

If the diagnosis is convincingly supported and compressive visual field disturbances are absent, surgical therapy should be withheld, pituitary hormone deficits appropriately replaced, and spontaneous resolution of the inflammatory mass observed expectantly. Treatment with adrenal steroids is advocated; it often resolves the sellar mass and improves endocrine dysfunction. Steroids are also indicated if adrenal reserve is compromised. Transsphenoidal surgery may be required to confirm the tissue diagnosis and may also relieve compression symptoms, but the degree of surgical resection should be constrained by the need to conserve viable pituitary tissue, particularly in view of frequent spontaneous resolution.

**Granulomatous Hypophysitis**

Granulomatous hypophysitis is not usually associated with pregnancy and has an equal female-male incidence. Rarely, the condition may coexist with lymphocytic
hypophysitis in the same gland. Pituitary histology shows histiocytes, multinucleated giant cells, and other features of chronic inflammation and granuloma. Patients present with headache and may have aseptic meningitis. MRI can reveal a thickened pituitary stalk or a characteristic tongue-shaped extension of the lesion under the hypothalamus. Granulomatous hypophysitis may reflect an underlying systemic disorder such as sarcoidosis or Takayasu's disease.

Xanthomatous Hypophysitis

This least common primary pituitary inflammatory process also occurs with the same frequency in both sexes and consists of lipid-laden macrophages, which resemble postinfectious cell debris. MRI often reveals a highly cystic lesion, leading to the suggestion that this entity reflects an inflammatory response to a damaged or ruptured pituitary cyst.

Hemorrhage and Infarction

Intrapituitary hemorrhage and infarction are usually caused by ischemic damage to the hypophyseal-portal system and may be catastrophic. These acute events cause significant damage to the pituitary gland, and small clinically silent microinfarcts are found in up to 5% of unselected autopsies. Pituitary cells are relatively resilient to vascular insult, and pituitary insufficiency is clinically apparent only when about 75% of the gland is chemically damaged. Ten percent residual functional pituitary cell mass appears sufficient to mask complete pituitary failure. Ischemic damage is limited to the anterior lobe and posterior pituitary function usually remains intact, reflecting the predominant neural control of oxytocin and arginine vasopressin secretion. Acute intrapituitary hemorrhage can cause significant life-threatening damage to the pituitary and its surrounding vital structures.

Postpartum Pituitary Infarction.

During pregnancy, the pituitary gland normally enlarges in response to estrogen stimulation. The hypervascular gland is thus particularly vulnerable to arterial pressure changes and prone to hemorrhage. Sheehan's syndrome, classically described after severe postpartum hemorrhage, is less commonly encountered with modern obstetric care. Development of hypovolemic shock in these women results in adenohypophysial vessel vasospasm and pituitary necrosis.

Pituitary Apoplexy

Pituitary apoplexy may result from spontaneous hemorrhage into a pituitary adenoma or occur after head trauma, skull base fracture, or in association with hypertension and diabetes mellitus, sickle cell anemia, or acute hypovolemic shock.

Clinical Features.

Pituitary apoplexy is an endocrine emergency. The condition may evolve over 1 to 2 days with severe headache, neck stiffness, and progressive cranial nerve damage, cardiovascular collapse, and change in consciousness. Signs include severe hypotension, bilateral visual disturbances, hypoglycemia, fever, central nervous system hemorrhage, and coma. Acute adrenal insufficiency may also be superimposed because of disordered intravascular clotting disorders, heparin administration, or acute effects of central nervous system hemorrhage. Pituitary imaging without contrast usually reveals signs of intrapituitary or intra-adenoma hemorrhage, stalk deviation, compression of normal pituitary tissue, and, in severe cases, signs of parasellar hemorrhage.

Management.

Most patients recover spontaneously but may experience long-term pituitary insufficiency. Patients who are fully alert and conscious with no visual symptoms may be observed. The decision to initiate therapy with high-dose glucocorticoids depends on the clinical status. Ophthalmoplegia, which is common, may resolve spontaneously over time. Failure of optic tract pressure to resolve or signs of progressive pituitary compression are indications for urgent transsphenoidal surgical decompression. Postoperative recovery of visual function correlates inversely with the time elapsed since the acute hemorrhage. Cranial nerve palsies, however, often improve whether or not surgery is undertaken. Pituitary function does not commonly recover after resolution of the acute hemorrhage, and patients require adrenal, thyroid, or gonadal steroid hormone replacement. The subsequent atrophy of infarcted pituitary tissue often results in the development of a complete or partially empty sella evident on MRI.
Evaluation of Pituitary Masses

Approach to the Patient Harboring a Pituitary Mass

Ninety-one percent of 1120 patients undergoing transphenoidal surgery for sellar masses were diagnosed with pituitary adenomas. Thus, the differential diagnosis of a pituitary mass should be aimed at excluding the diagnosis of a pituitary adenoma before considering other rare sellar lesions. The management of and prognosis for anterior pituitary adenomas differ markedly from those for other nonpituitary masses, and an important diagnostic challenge is to distinguish a pituitary adenoma from other parasellar masses.

Several physiologic states are associated with pituitary enlargement. Lactotroph hyperplasia is seen during pregnancy, and thyrotroph or gonadotroph hyperplasia occurs in the presence of long-standing primary thyroid or gonadal failure, respectively. Pituitary enlargement may also occur as a result of ectopic GHRIH or CRH secretion with resultant hyperplasia of somatotroph or corticotroph cells. Autopsy series show that up to 20% of subjects harbor an incidentally clinically silent pituitary adenoma. Incidental pituitary cysts, hemorrhages, and infarctions are also discovered at autopsy.

With the widespread use of sensitive imaging techniques for nonpituitary indications including head trauma, chronic sinusitis, or headaches, previously inapparent pituitary lesions are being identified with increasing frequency. Pituitary abnormalities compatible with the diagnosis of microadenoma are detectable in about 10% of the normal adult population undergoing MRI. Recognizing that approximately 90% of observed pituitary lesions represent pituitary adenomas, initial assessment should determine whether the mass is hormonally functional and whether local mass effects are apparent at the time of diagnosis or likely to develop in the future.

As clinical features associated with disordered hormone secretion have an insidious onset and may be unnoticed for years or decades, endocrine function should always be tested (Table 8-9). Clinical evaluation for changes compatible with hypersecretion or hyposecretion of GH, gonadotropins, PRL, or ACTH may reveal unique long-term sequelae requiring distinct therapies. In the absence of clinical features of a humoral hypersecretory syndrome, cost-effective laboratory screening should be performed. Serum PRL levels higher than 200 µg/L strongly suggest the presence of a prolactinoma, whereas lower PRL levels would indicate secondary stalk interruption by a pituitary mass. Elevated age-matched and gender-matched IGF-I levels indicate the presence of a GH-secreting adenoma, and a high 24-hour urinary free cortisol level is an effective screen for most patients with Cushing's disease. Nevertheless, the incidence of functional hormone-secreting tumors in asymptomatic subjects with incidentally discovered pituitary masses is low.

ACTH, adrenocorticotropic hormone; IGF-I, insulin-like growth factor I; MRI, magnetic resonance imaging; OGTT, oral glucose tolerance test; PRL, prolactin.

The presence of, or the potential for, local compressive effects must also be considered. Because the risk of microadenoma enlargement toward a compressive macroadenoma is low, no direct intervention may be warranted. For parasellar masses of uncertain origin, histologic tissue examination may be the best approach to obtain an accurate diagnosis. Although MRI or CT imaging features may be helpful in diagnosing a nonpituitary sellar mass, the final diagnosis may remain elusive until pathologic confirmation is obtained.

Parasellar masses include neoplastic and nonneoplastic lesions and are manifest clinically by local compression of surrounding vital structures or metabolic or hormonal derangements (see Table 8-9). Rarely, sellar masses may be the presenting feature of a previously undiagnosed systemic disorder such as lymphoma or tuberculosis. Fever with or without associated sterile or septic meningitis may rarely be caused by fluid leakage into the subarachnoid space from Rathke's cleft, dermoid and epidermoid cysts, and craniopharyngioma and apoplexy. Patients with pituitary masses may present with hemorhage and infarction, especially during pregnancy when the normal pituitary is adenomatous and swollen; diabetes mellitus; and hypertension or hypotension, which may be found in elderly people with unsuspected pituitary tumors. Rarely, these adenomas occur with CSF leakage, which may predispose to meningitis. Pituitary masses may also undergo silent infarction leading to development of a partially or totally empty pituitary sella with normal pituitary reserve, implying that the surrounding rim of pituitary tissue is fully functional. Large sellar cysts may be mistaken for an empty sella.

Rarely, functional pituitary adenomas may arise within the remnant pituitary tissue, and these tumors may not be visible by sensitive MRI (i.e., <2 mm in diameter) despite their endocrine hyperactivity. Acute or chronic infection with abscess formation rarely occurs within the mass. Compromised pituitary hormone hyposecretion may be due to direct pressure effects of the expanding mass on hormone-secreting cells or to parasellar pressure effects that attenuate synthesis or secretion of hypophyseal hormones, with resultant pituitary failure. Hypophyseal masses (gangliocytomas) may overproduce a specific releasing hormone with resultant stimulation of secretion of a specific pituitary hormone.

Tumors of the pituitary gland are best diagnosed with MRI because it has better resolution than other radiologic modalities for identifying soft tissue changes. When a pituitary tumor or other parasellar mass is suspected, MRI specifically focused on the pituitary should be requested because brain MRI is often inadequate for optimal visualization of pituitary tumors and may miss the tumor completely. High-resolution T1-weighted sections in the coronal and sagittal planes both before and after administration of gadolinium pentetic acid for contrast distinguish most pituitary masses. Slice thickness should be less than 3 mm to obtain a pixel of 1 mm. Contiguous sections are therefore required to diagnose lesions of 1 to 3 mm. If necessary, especially for diagnosing high-signal hemorrhage, T2-weighted images provide additional diagnostic information.

MRI thus clearly delineates the pituitary gland, stalk, optic tracts, and surrounding soft tissues. The gland may be concave, convex, or flat. The posterior pituitary lobe exhibits a discrete bright spot of high signal intensity on T1-weighted images, which declines with age and is absent in diabetes insipidus and most posterior pituitary lesions. This T1 shortening may reflect the presence of arginine vasopressin localized within neurosecretory vesicles.

Tumors of the pituitary gland enlarge transiently during adolescence, during pregnancy, and after childbirth, and teenage girls exhibit increasing gland convexity during the menstrual cycle.
the gland should normally not exceed 10 to 12 mm and the stalk should not exceed 4 mm in diameter. A thickened stalk may indicate the presence of hypophysitis, granuloma, or atypical chondomas.

After gadolinium administration, microadenomas are usually hypodense compared with the normal gland, especially when multiple thin-section echo sequences are examined in the first few minutes after injection of the contrast agent. It has been suggested that this hypointensity may reflect compromised microadenoma vasculature. 

Microadenomas may also cause gland asymmetry or stalk deviation. In contrast, macroadenomas, which are significantly more vascular than microadenomas, have a higher affinity for gadolinium. They often enlarge the sella turcica by remodeling the bony fossa, suggesting a gradual long-term process. These tumors can grow upward toward the optic apparatus and cause draping of the nerves over the tumor, often accompanied by visual field abnormalities. Tumors can also extend into the sphenoid sinus and not infrequently invade connective tissue separating the pituitary from the cavernous sinus.

Radiologically, visible tumor tissue surrounding the carotid artery confirms cavernous sinus invasion. Infrequently, these patients experience palsies of third, fourth, or sixth cranial nerves. MRI readily distinguish pituitary adenomas from other masses, including hyperplasias, craniopharyngiomas, meningiomas, chondomas, cysts, and hypophysitis. Secondary distinguishing features such as visualization of distinct uninvolved pituitary tissue, mass consistency, calcification, hemorrhage, and suprasellar involvement usually allow an imaging diagnosis of these masses, but these can often be confirmed only by direct tissue histology. Preoperative localization of carotid artery aneurysms can also be confirmed by MRI or magnetic resonance angiography.

Pituitary CT allows visualization of bony structures, including the sellar floor and clinoid bones, and their invasion. CT also recognizes calcifications that characterize craniopharyngiomas, meningiomas, and rarely aneurysms. Calcifications are not evident on MRI. Occasionally, pituitary adenomas may calcify. Pituitary CT scanning is indicated for discovery of hemorrhagic lesions, metastatic deposits, and chondomas and evidence of calcification.

**Receptor Imaging**

Because prolactinomas express D2 receptors, they can be imaged with a radiolabeled D2 receptor antagonist by using iodine 123-labeled iodobenzamine single photon emission scanning. Failure to visualize nonfunctioning tumors by this technique has led some to advocate its use to distinguish the two tumor types. Radiolabeled indium pentetreotide has been used for in vivo tumor imaging. Most pituitary adenomas express somatostatin receptor subtypes to a varying degree, thus limiting the specificity of the procedure. Single photon emission CT (SPECT) has a sensitivity of about 1 cm and can detect normal pituitary tissue receptor expression. Because most adenomas and normal tissue are identified by this technique, its utility is limited for tumor detection, but it may be helpful for imaging ectopic ACTH-secreting tumors.

**Neuro-ophthalmologic Assessment of Pituitary Masses**

The optic tracts are particularly vulnerable to compression by expanding pituitary masses, and expanding pituitary tumors affect mostly the chiasm. Accurate neuro-ophthalmologic evaluation is helpful for tumor diagnosis, for determining pretreatment baseline visual status, and for post-treatment monitoring or detection of mass recurrence. The relationships of the optic chiasm and the intracranial components of the optic nerves with the pituitary gland and surrounding vessels are depicted in Figure 8-2 (Figure Not Available). A 10-mm posteriorly angled gap separates the optic chiasm and diaphragma sellae (see Fig. 8-3) (Figure Not Available). Therefore, extensive suprasellar mass extension is required before visual function is compromised. Decussation of neural fibers originating from the nasal half of each retina occurs at the chiasm, and those originating from the temporal retinal halves are situated ipsilaterally. Fibers from the superior and inferior retinal aspect are segregated in the corresponding chiasmal regions. Local vascular compromise or chiasmal stretching contributes to the pathogenesis of selective visual compromise. Reversibility of visual effects may correlate inversely with acuteness of the compressive insult.

**Visual Symptoms.**

An abnormal visual examination may unmask the presence of a pituitary mass in an asymptomatic patient. Before the availability of sophisticated assay and imaging techniques, patients with virtually all pituitary masses presented with visual loss. Currently, less than 10% of patients present with visual loss, and most of these harbor clinically nonfunctioning pituitary adenomas often detected by incidental imaging. Unilateral or bilateral temporal or central visual loss is usually asymmetric and may be quite insidious, remitting, or recurring. Rarely, sudden visual loss occurs in a previously asymptomatic patient. Other symptoms include diplopia, impaired depth perception, and rarely visual hallucinations.

**Clinical Signs.**

Impingement of the inferior crossing chiasmal fibers leads to bitemporal visual loss, especially in the superior field portions, accounting for about half of all pituitary-related visual defects. Pituitary-related defects preferentially marginate at the vertical field midline, whereas bitemporal defects of other causes tend to occur away from the midline. Despite prominent field defects, many of which can be directly correlated with defined tumor location by MRI, visual acuity in the remaining fields is invariably normal in over 95% of patients.
Management of Pituitary Masses

The goals of therapy for masses are to alleviate local compressive mass effects, to suppress hormone hypersecretion, and to relieve hormone hyposecretion while maintaining intact pituitary trophic function. The three modes of therapy available are surgical, radiotherapeutic, and medical approaches. In general, the benefits of each therapy should be weighed against the respective risks, and comprehensive awareness on the part of the physician and the patient is required to individualize treatment approaches.

Surgical Management of Pituitary Tumors and Sellar Masses

Pituitary surgery is indicated for excision of mass lesions causing central pressure effects, primary correction of hormonal hypersecretion (other than prolactinomas), or functional

---

**Figure 8-12** Threshold field test showing bitemporal hemianopsia in a patient with pituitary tumor compressing the optic chiasma (A) and superior bitemporal field cuts (B)

tumor resection in patients resistant to medical treatment. Unusual sellar lesions may require diagnostic tissue evaluation, and primary or secondary parasellar malignancies require excessive excision.

In 1904, Horsley reported the surgical resection of a pituitary tumor by a lateral middle fossa approach. The first successful transsphenoidal approach for pituitary tumor resection was reported by Schloffer in 1907 and subsequently refined by Cushing, who operated on 231 patients harboring pituitary tumors between 1910 and 1925 with a remarkably low mortality rate of 5.6%. Cushing used a sublabial incision to enable an endonasal approach for removing the septum and improved visualization using Kanavel's headlight. Hardy later improved the technique by using the operating microscope and intraoperative fluoroscopy, resulting in markedly reduced morbidity and mortality compared with those usually encountered with craniotomy, and this became the mainstay surgical technique for resecting these tumors.

Craniotomy is indicated only for the rare invasive parasellar mass extending into the frontal or middle cranial fossa or optic nerves or having extensive posterior clival invasion. Suprasellar extension contained by a small diaphragmatic aperture ("hourglass configuration") may also require a transcranial approach. The transsphenoidal approach precludes invasion of the cranial cavity and removes the need for the brain tissue manipulation required during a subfrontal surgical approach. A ventral sphenoid approach for resection of pituitary masses likewise does not violate the cranial fossa.

Thus, transsphenoidal surgery is associated with minimal morbidity and mortality, most patients are ambulatory within 6 to 9 hours, and the hospital stay is generally about 3 days. Furthermore, the transsphenoidal approach allows a clearly visible operative field with high magnification and internal illumination. Normal pituitary can be clearly distinguished from tumor tissue, facilitating microdissection and small tumor resection.

Enhanced MRI sensitivity and precision as well as intraoperative

---

**Figure 8-13** Transsphenoidal pituitary surgery. A, B, Route of the transsphenoidal approach (lateral view) and surgical corridor of the transsphenoidal approach and positioning of the retractor. Adenoma (sagittal sections): parasellar extension; invasion of the sphenoid sinus and of the clivus (f). (Adapted from Honegger J, Buchfelder M, Fahrbusch R. Surgery for pituitary tumors. In Sheaves R, Jenkins PJ, Wass JAH [eds]. Clinical Endocrine Oncology. Cambridge, Mass, Blackwell Science, 1977, p 179.)

MRI allows clear delineation of the location, size, and invasiveness of the tumor, all critical determinants of surgical success.

Goals of Surgery

The goal of pituitary surgery is total resection limited to the lesion without compromising postoperative endogenous pituitary function. Careful selective mass resection may be difficult for poorly encapsulated lesions, those embedded deeply within the gland body, and those extending into cavernous sinuses or parasellar lesions. Poor operative field visibility also limits resection precision. Normal tissue excision or even gland manipulation should be avoided unless critical for effective dissection. Occasionally, hemihypophysectomy or even nonelective total gland resection may be indicated for multifocal tumors, when the surrounding normal gland is necrotic, or when no mass lesion is discernible despite an accurate clinical and biochemical diagnosis (especially for ACTH cell tumors).

Successful surgery should decompress central visual defects and compromised trophic hormone secretion. For children and young adults, the consideration of adequate normal tissue for subsequent growth patterns and reproductive function is an important determinant in intraoperative decision making. Nevertheless, especially for functional tumors, small residual remnants attached to the dura are difficult to reach but remain hypersecretory with persistent clinical progression. Thus, the skilled neurosurgeon carefully balances maximally effective tumor removal with the requirement to preserve nontumorous pituitary trophic function.

 Advances have enabled improved surgical results, although the long-term outcomes with these new techniques have not yet been rigorously compared with those after standard operations performed by skilled surgeons. Image-guided approaches
enable intraoperative surgical neuronavigation by three-dimensional imaging. Intraoperative ultrasonography and MRI technologies allow real-time assessment of the dimensions and extent of the pituitary mass and the progress of surgery. Intraoperative MRI is performed while the surgical field is still open, allowing the surgeon to assess directly the need for further dissection, and also provides an excellent baseline for postoperative follow-up. In contrast, postoperative image stabilization may not be evident for months after surgery.

Endonasal transsphenoidal endoscopy avoids use of a retractor or speculum, does not require nasal packing, and sometimes leads to a shorter operating time, resulting in decreased postoperative morbidity and a shorter hospital stay (Fig. 8-15). The advantages of the technique include a clear panoramic view of bone landmarks and access to suprasellar and parasellar tumor extensions into the cavernous sinuses. Disadvantages of this relatively new approach include the need for management of perioperative intrasellar bleeding and CSF leaks as well as the added requirement for a preoperative CT scan.

**Indications for Transsphenoidal Surgery**

A pituitary mass that may or may not be compressing local vital structures should be evaluated for surgical resection (Table 8-10). Although surgical resection offers a rapid resolution of hormone hypersecretion and many of the resultant clinical features of functioning adenomas, indications for the procedure differ depending on the tumor type (see later). In general, patients who are intolerant of or resistant to medical therapy require surgery. Surgery is indicated primarily for well-circumscribed GH-secreting adenomas and all ACTH-secreting, TSH-secreting, and nonfunctioning macroadenomas. Surgery may also be indicated when tissue histology is required to determine the nature of an enigmatic sellar mass. Progressive compressive features, including visual field loss, compromised pituitary function, or other central nervous system functional change, are indications for surgical debulking and sellar decompression. Hemorrhage into the enced bony sella turcica, usually occurring within a known or previously unknown adenoma, may require immediate surgical decompression. Urgent surgical decompression is required for acute pituitary hemorrhage that may result in apoplexy related to partial or complete infarction, especially in patients with signs of progressive compressive signs.

When pituitary function after surgery was assessed in 234 patients, 52 patients had new trophic hormone dysfunction and 45 of 93 patients with preoperative evidence for hypopituitarism had recovered between one and three previously suppressed axes. Significant factors determining restoration of postoperative pituitary function were no visible tumor remnants as assessed by MRI (P < 0.001) and no tumor invasion as determined by the neurosurgeon as well as by pathologic examination of surrounding tissue (P < 0.049). Therefore, because about half of all patients with preoperative pituitary failure recover function, depending on the clinical circumstance, patients should be considered for retesting before initiating postoperative substitution therapy except for adrenal steroid replacement, which requires greater caution. Indications for second surgery in the same patient include tumor recurrence, persistent hormonal hypersecretion by tumor remnants, or repair of a CSF leak.

After surgery, patients should be kept in bed rest at an angle of 30 to 45 degrees and urine and serum osmolality and serum electrolytes should be measured every 6 hours. Indications for postoperative vasopressin replacement include urine output greater than 300 mL/hour for 3 consecutive hours with serum osmolality above 285 mOsm/L, elevated serum sodium concentrations, and inappropriately low urine osmolality. Postoperative polyuria alone is not an indication for vasopressin replacement unless it is a reflection of compromised posterior pituitary function.

**Side Effects**

The success of surgery is largely determined by the skill and experience of the neurosurgeon. Tumor size, degree of invasiveness, preoperative hormone levels, and previous pituitary surgery are all determinants of surgical outcome. CSF leakage, transient diabetes insipidus, and inappropriate arginine vasopressin secretion are the most commonly encountered transient side effects, occurring in up to 20% of patients (see Table 8-10). Local damage may also result in arachnoiditis, vascular bleeding, hematoma formation, and epistaxis. Rarely, pulmonary embolism, narcolepsy, and local abscess have been reported. Intracranial hypopituitarism, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH) have been reported in up to 10% of patients. Rarely, the central nervous system may be permanently damaged with hemiparesis, cranial nerve palsies, or encephalopathy.

A triphasic postoperative diabetes insipidus has been described in which the transient disorder is followed by an interphase on days 6 to 11 with no polydipsia or polyuria. During this later phase, hyponatremia with features of inappropriate antidiuretic hormone secretion has also been reported. Cognitive dysfunction, including deficits in anterograde memory and executive function, has been reported in several retrospective studies.

Acromegaly
Cushing's disease
Clinically nonfunctioning macroadenoma
Prolactinoma (rarely indicated)
Nelson's syndrome
TSH-secreting adenoma

Side Effects
Transient
Diabetes insipidus
Cerebrospinal fluid leak and rhinorrhea
Inappropriate ADH secretion
Arachnoiditis
Meningitis
Postoperative psychosis
Local hematoma
Arterial wall damage
Epistaxis
Local abscess
Pulmonary embolism
Narcolepsy

Permanent (up to 10%)
Diabetes insipidus
Total or partial hypopituitarism
Visual loss
Inappropriate ADH secretion
Vascular occlusion
CNS damage
Oculomotor palsy
Hemiparesis
Encephalopathy
Nasal septum perforation

Surgery-Related Mortality (up to 1%)
Brain, hypothalamic injury
Vascular damage
Postoperative meningitis
Cerebrospinal leak
Pneumocephalus
Acute cardipulmonary disease
Anesthetic
Seizure

ADH, antidiuretic hormone; CNS, central nervous system; TSH, thyroid-stimulating hormone.

studies after transsphenoidal surgery. \[164\] \[165\] Mortality has been reported in less than 1% of patients undergoing pituitary surgery and may be related to direct hypothalamic or cerebrovascular damage, meningitis, pneumocephalus formation, or anesthetic complications. Surgical failure may result from a nonpituitary-related event, including anesthesia-related complication or bleeding disorder. Incomplete tumor removal may also be due to inaccurate preoperative MRI localization or identification. Rarely, a previously undiagnosed functioning pituitary tumor or ectopic source of ACTH may be unmasked after initially unsuccessful pituitary surgery.

Pituitary Radiation

Principles
High-energy ionizing radiation can be delivered to deep tissues by megavoltage techniques. The challenge of this approach is to provide maximal localized necrotizing radiation to the pituitary lesion while minimally exposing surrounding normal structures to radiation damage. Several advances have improved both efficacy and safety, including highly precise tumor localization, a high-voltage (6 to 15 MEv) linear accelerator, and accurate simulation models with isocentric rotational arcing that allow repeated head positioning at exactly the same points in the patient's subsequent visits. Up to a maximum of 4500 rads is administered as 180-rad daily fractions for about 5 to 6 weeks. High-precision techniques such as stereotactic conformal radiotherapy \[166\] and the gamma knife \[167\] allow delivery of high energy to the pituitary lesion while minimizing the mass of normal brain exposed to radiation (Fig. 8-16) (Figure Not Available)

Indications
The use of radiation for treating pituitary tumors is highly individualized and depends on the expertise of the treating center, conviction of the treating physician in weighing the potential benefits and risks of the procedure, and the patient's preference based on informed choice (Table 8-11). In general, radiation techniques are indicated for persistent hormone hypersecretion or residual mass effects after surgery or when surgery for a compressive mass is contraindicated. As GH-secreting and PRL-secreting tumors are generally amenable to medical therapy, indications for radiation are rare. Most indications for radiation are adjuvant to either surgical or medical treatment. Radiation may be indicated after resection of a potentially recurring or inadequately resected pituitary mass, such as a nonfunctioning pituitary adenoma, craniopharyngioma, or chordoma. In acromegaly, use of radiation as primary treatment is generally not recommended, \[168\] but for resistant, aggressively growing prolactinomas the procedure may prevent further local invasion. Recurrent pituitary-dependent Cushing's disease appears to be particularly amenable to radiation, especially in younger patients.
Hypopituitarism.

Pituitary failure occurs commonly in patients who have received pituitary radiation. Within 10 years after radiation, up to 80% of patients may have gonadotroph, somatotroph, thyrotroph, or corticotroph deficits. The mechanism for hypopituitarism appears to involve damage to hypothalamic releasing hormone cells as well as direct pituitary damage. These patients require lifelong endocrine follow-up for pituitary reserve testing and hormone replacement when appropriate.

Second Brain Tumors.

Thirty-two cases of glioma occurring after conventional pituitary radiation for adenomas and craniopharyngioma have been reported with a mean latency period of 11.5 years from initial diagnosis. In a meta-analysis of results of irradiation for pituitary tumors, the standardized incidence ratio for second brain tumors was approximately 6 (confidence interval 3.16 to 10.69). This analysis was based on 12 diagnosed second tumors with a latency of 6 to 24 years in three separate cohorts. Because patients harboring pituitary tumors are more likely to undergo routine brain imaging during follow-up, it is not clear whether observed meningiomas are coincidental findings. As this complication, which occurs in less than 5% of patients, also appears dose-related, fractionated doses not exceeding 4500 rads should be given. Use of conformal radiation techniques to irradiate a smaller tissue volume, including radiosurgery, fractionated stereotactic radiotherapy, and proton beam radiation, may minimize this adverse effect. Nevertheless, prospectively controlled surveillance studies are required to evaluate this critical question rigorously.

Visual Damage.

Approximately 2% of patients experience impaired vision related to optic nerve damage. The risk of visual damage is minimized by fractionating dosages to less than 200 rads per treatment session. Consequent blindness, however, has been reported in two patients who received 4500 rads in 180-rad fractions.

Brain Necrosis.

Dose-related radiation-induced brain necrosis was documented by MRI in 14 of 45 patients, with temporal lobe atrophy and cystic and diffuse cerebral atrophy. Cognitive dysfunction, especially memory loss, has also been reported.

Radiosurgery

The proton beam, the gamma knife using focused cobalt 60 emissions, and the linear accelerator deliver high-dose radiation while sparing surrounding tissue. Delivery of high energy by gamma knife directly targeted at the pituitary tumor minimizes the radiation exposure of surrounding tissues. Early reports indicated more rapid reduction of hormone hypersecretion, although long-term efficacy and safety outcomes are not yet apparent. It appears that this procedure is best suited for intrasellar and cavernous lesions distant from the optic nerves.

Medical

Pituitary tumors often express receptors mediating hypothalamic control of hormone secretion, and appropriate ligands for the dopamine D2 receptor and the somatotropin release-inhibiting factor (SRIF) receptor subtype 2 are employed to suppress PRL or GH hypersecretion, to block tumor growth, and often to shrink tumor size. A novel approach has employed a peripheral receptor antagonist to block GH action without targeting the pituitary tumor source. Medical ablation of target glands, including thyroid and adrenal, may also be useful in mitigating the deleterious impact of pituitary tumor hypersecretion. Each of these medical approaches is fully considered in the following.
PHYSIOLOGY AND DISORDERS OF PITUITARY HORMONE AXES

Prolactin

Lactotroph Cells

Lactotroph cells constitute about 15% to 25% of functioning anterior pituitary cells (Fig. 8-17) (Figure Not Available). Although their absolute number does not change with age, lactotroph hyperplasia does occur during pregnancy and lactation \(^{180}\) and resolves within several months of delivery (Fig. 8-18) (Figure Not Available). Most PRL-expressing cells appear to arise from GH-producing cells. Ablation of somatotrophs by expression of GH-diphtheria toxin and GH-thymidine kinase fusion genes inserted into the germ line of transgenic mice eliminated most lactotrophs, suggesting that the majority of PRL-producing cells arose from postmitotic somatotrophs. \(^{181}\)

Two cell forms expressing the PRL gene are large polyhedral cells found throughout the gland and smaller angulated or elongated cells clustered mainly in the lateral wings and median wedge. Large PRL secretory granules (250 to 800 nm) are present in the evenly distributed cells, and the laterally localized cells are sparsely populated by smaller (200 to 350 nm) granules (Fig. 8-19) (Figure Not Available). Occasional mammosomatotroph cells may also cosecrete both PRL and GH, often stored within the same granule (Fig. 8-20) (Figure Not Available). In animal models, lactotroph cell function is heterogeneous. Thus, dopamine or TRH responsiveness and shifting proportions of PRL-secreting and GH-secreting cells may depend on cell localization within the pituitary as well as the surrounding hormonal milieu, especially that of estrogen. \(^{182}\)

Prolactin History

Shortly after its discovery and partial characterization, \(^{183}\) \(^{184}\) \(^{185}\) PRL was prominently featured in The New York Times on December 3, 1937, indicating that it held the "key to peace in the world." The article, based on a lecture delivered by Prof. C. R. Stockard, proposed that "higher forms of life" were "governed by a 'glandocracy,' with the glands of internal secretion as the supreme rulers [in this instance PRL], exerting absolute control not only over the functioning of the individual from conception to death but also over the relationship of men and other vertebrate animals to each other."
The identification of PRL in humans was elusive until 1970 because human GH is highly lactogenic and active in bioassays used to isolate and measure PRL. Furthermore, GH is present in human pituitary glands in much higher concentrations (5 to 10 mg) than PRL (100 μg). To distinguish human PRL from GH, lactogenic activity was neutralized with GH antisera; sera from postpartum women and patients with galactorrhea had high lactogenic activity in the presence of GH antibodies. Human PRL, bioassayed by stimulating pregnant mouse mammary milk production, was elevated in patients with nonpuerperal galactorrhea resulting from pituitary tumors, exposure to phenothiazines, and withdrawal from oral contraceptives. The purification and isolation of PRL by Frisen and colleagues and the development of a specific radioreimmunoassay underscored the new place of PRL in understanding human disease.

Prolactin Structure

The human PRL gene, located on chromosome 6, apparently arose from a single common ancestral gene giving rise to the relatively homologous PRL, GH, and placental lactogen-related proteins (Fig. 8-21) (Figure Not Available). Several factors influence PRL gene expression, including estrogen, dopamine, TRH, and thyroid hormones. PRL is a 199-amino-acid polypeptide containing three intramolecular disulfide bonds. It circulates in blood in various sizes: monomeric PRL ("little" PRL: 23 kd), dimeric PRL ("big" PRL: 48 to 56 kd), and polymeric forms (also known as "big, big" PRL: > 100 kd). The monomeric form is the most bioactive PRL. In response to TRH, the proportion of the more active monomeric form increases.

Regulation of Prolactin Secretion

PRL secretion is under the inhibitory control of dopamine, which is largely produced by the tuberoinfundibular (TIDA) cells, and the hypothalamic tuberohypophyseal dopaminergic system. DA reaches the lactotrophs through the hypothalamic pituitary portal system and inhibits PRL secretion by binding to the D2 receptors on pituitary lactotrophs. In turn, participates in negative feedback to control its release by increasing tyrosine hydroxylase activity in the TIDA neurons. In PRL-deficient animals, DA was decreased in the median eminence. Mice lacking the D2 receptor experienced hyperprolactinemia and lactotroph proliferation.

Factors other than DA inhibit PRL secretion, including endothelin-1 and transforming growth factor 1, which act as paracrine PRL inhibitors. and calcitonin, which may be derived from the hypothalamus. Several substances act as PRL-releasing factors. Basic FGF and epidermal growth factor induce PRL synthesis and secretion. Vasoactive intestinal polypeptide (VIP) stimulates PRL synthesis through cAMP. A hypothalamic PRL-releasing peptide produced in the hypothalamus acts through a specific receptor in normal pituitary glands and in a subset of PRL-secreting tumors. Oxytocin and pituitary adenylate cyclase activating protein also release PRL. TRH stimulates PRL but probably does not play an important role in PRL secretion. Estrogen stimulates PRL gene transcription and secretion; explaining why women have higher PRL levels and why cycling women have a higher PRL pulse frequency than postmenopausal women and men. Galanin is synthesized in both the pituitary and hypothalamus and may act as a PRL releasing factor. The physiologic role of amnouretic acid, neurotensin, substance P, bombesin, and cholecystokinin in regulating human PRL secretion is unresolved.

Serotonin may be additive with VIP in releasing PRL, and infusion of 5-hydroxytryptophan, a serotonin precursor, elicits PRL release. Nocturnal PRL secretion is attenuated by cyproheptadine. Thus, patients may mediate nocturnal PRL secretion and also participate with VIP in the sucking reflex. Opiates acutely induce PRL release, although naloxone does not consistently suppress PRL levels. GHRH, when administered in high doses, moderately induces PRL secretion, and patients harboring ectopic GHRH-producing tumors have mild to moderate hyperprolactinemia. GHRH also stimulates PRL in women, especially during the periovulatory period. Although posterior pituitary hormones have been shown to regulate rat PRL secretion, the role of vasopressin or oxytocin or other neurohypophyseal molecules in regulating human PRL remains unresolved. Histamine may act on the hypothalamus to regulate PRL, and H₂ blockers induce PRL secretion. A short-loop feedback of PRL has been proposed, and transgenic mice with deleted PRL were found to have a decreased hypothalamic dopaminergic complex.

Prolactin Receptor

The PRL receptor gene is a member of the cytokine receptor superfamily. Localizes to chromosome 5p13, and has 10 exons. The receptor gene has two 5' promoters that direct transcription of a 598-amino-acid peptide comprising an extracellular domain, a hydrophobic transmembrane domain, and an intracytoplasmic region homologous to the GH receptor. Similarly, PRL receptor dimerization occurs with ligand binding and subsequent phosphorylation of intracellular Janus kinases (JAKs) and signal transducer and activator of transcription (STATs) molecules. Two binding sites and activating helices 1 and 4 and helices 1 and 3 on the PRL receptor gene is a member of the cytokine receptor superfamily and has 10 exons. The receptor gene has two 5' promoters that direct transcription of a 598-amino-acid peptide comprising an extracellular domain, a hydrophobic transmembrane domain, and an intracytoplasmic region homologous to the GH receptor. Similarly, PRL receptor dimerization occurs with ligand binding and subsequent phosphorylation of intracellular Janus kinases (JAKs) and signal transducer and activator of transcription (STATs) molecules. Two binding sites and activating helices 1 and 4 and helices 1 and 3 on the PRL receptor gene are critical for formation of the trimeric ligand-receptor complex and subsequent signaling (see Fig. 8-21) (Figure Not Available). The PRL receptor promotes the development of Jak2 kinase and STATs 1 to 5. STATs phosphorylation mediates transcriptional activation of the -caspase gene. PRL receptors are expressed in breast, pituitary, liver, adrenal cortex, kidneys, prostate, ovary, testes, intestine, epidermis, pancreatic islets, lung, myocardium, brain, and lymphocytes. Estrogen also induces liver PRL receptor expression. Regulation of milk production occurs through a cascade of intracellular events. Homozygous mice in which the PRL receptor was inactivated were infertile; heterozygous animals were fertile but unable to nurse their first litters, presumably because of inadequate PRL receptor expression after the first but not subsequent pregnancies.

Functions of Prolactin

PRL is essential for human survival because of its role in milk production during pregnancy and lactation. Additional biologic functions ascribed to PRL include reproductive and metabolic effects, mammary development, pigment carp sac activity, fresh water survival, melanin synthesis, water-seeking behavior of news, motility, and parental behavior. Although PRL and its receptor are clearly crucial in lower animals, the impact of PRL on maternal behavior in humans has not been fully delineated.

Mammary Gland Development and Lactation

Figure 8-20 (Figure Not Available) Normal mammosomatotrophs. Occasional cells resembling densely granulated somatotrophs exhibit atypical features consistent with prolactin secretion; the secreting granules are highly pleomorphic and there is misplaced exocytosis, that is, extrusion of secretory material along the lateral cell border (arrow). (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 17.)

Figure 8-19 (Figure Not Available) Electron micrograph of a normal lactotroph shows a well-developed rough endoplasmic reticulum that forms concentric whorls. A prominent Golgi complex is seen in a juxtaparticular location and harbors forming pleomorphic secretory granules. The cytoplasm is otherwise sparsely granulated. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 16.)

Figure 8-18 (Figure Not Available) Prolactin cell hyperplasia. In the third trimester of pregnancy, prolactin cell hyperplasia occurs; cells containing immunoreactive prolactin make up almost 50% of the cell population of the gland. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 15.)

Figure 8-17 (Figure Not Available) Lactotroph cell. Normal prolactin-secreting cells express strong positivity for prolactin within the cytoplasm of polygonal cells, which have elongated cell processes. Some processes surround adjacent immunoreactive cells that correspond to gonadotrophs. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 15.)

Figure 8-21 (Figure Not Available) Molecular structure of prolactin and its interaction with the dimerized receptor. (From Bole-Feysot C, Goffin V, Edery M, et al. Prolactin (PRL) and its receptors: actions, signal transduction pathways and phenotypes observed in PRL receptor knockout mice. Endocr Rev 1998; 19:225268.)
PRL is not essential for pubertal mammary development, which appears to require GH, whose action is mediated by IGF-I. Studies of mammary development have, for the most part, been carried out in rodents. At birth, the mammary gland consists of a fat pad with small areas of ductal anlagen, which differentiate into pubertal mammary glandular elements under the influence of estrogen, GH, and IGF-I. At puberty, a surge of estrogen begins the process. Terminal end buds form and lead the process of mammary development by branching and extending into the substance of the mammary fat pad, leaving a network of ducts that virtually fill the mouse mammary fat pad. Interestingly, estrogen does not affect this process in the absence of GH and IGF-I.

These hormones are also responsible for most of ductal morphogenesis. Thus, GH acts on the mammary stromal compartment to produce IGF-I, which, in turn, elevates PRL levels after delivery. Suckling also increases milk production after parturition and is essential for continued lactation because of its distal effect on pituitary hormone production and because it empties the mammary gland of milk. Milk accumulation further inhibits milk synthesis, explaining why a certain level of nursing activity is necessary for successful breast-feeding. In the absence of suckling, PRL concentrations, which rise throughout gestation, return to normal by 7 postpartum days. Suckling increases serum PRL levels approximately 8.5-fold in actively nursing mothers, and amniotic fluid PRL concentrations are 100 times those of maternal or fetal blood.

Alveolar formation and milk production also require progesterone, and lobular-alveolar formation does not occur in mice lacking the progesterone receptor.

Mechanisms of milk production are similar in all mammals, but milk composition differs. Active lactation is due in part to a fall off in estrogen and progesterone and elevation of PRL levels after delivery. Suckling also increases milk production after parturition and is essential for continued lactation because of its distal effect on pituitary hormone production and because it empties the mammary gland of milk. Milk accumulation further inhibits milk synthesis, explaining why a certain level of nursing activity is necessary for successful breast-feeding. In the absence of suckling, PRL concentrations, which rise throughout gestation, return to normal by 7 postpartum days. Suckling increases serum PRL levels approximately 8.5-fold in actively nursing mothers, and the milk let-down phenomenon is not associated with increased PRL. As nursing continues, PRL concentrations fall, but each suckling episode causes a subsequent episodic rise in serum PRL. Mean serum concentrations were 162 µg/L at 2 to 4 postpartum weeks, 130 µg/L at 5 to 14 weeks, and 77 µg/L at 15 to 24 weeks.

It is unclear why active milk production continues despite progressively lower PRL levels after parturition. Although PRL is essential for milk production, the milk yield does not closely correlate with serum PRL levels. In addition to its effects on PRL, suckling stimulates posterior pituitary oxytocin release. Unlike those of PRL, oxytocin responses to suckling do not decline as nursing continues for up to 6 months. Mothers who breast-fed exclusively had mean stimulated oxytocin levels significantly higher during late lactation than during early lactation. Oxytocin induces myoepithelial cell contraction, thereby causing milk ejection. Oxytocin also has important effects on alveolar proliferation. Mice deficient in oxytocin are unable to nurse their young, and oxytocin replacement permits dams to nurse.

Lactational Amenorrhea

Lactational amenorrhea is a form of contraception that depends on the frequency and duration of breast-feeding. The Kung hunter-gatherer women were suckled approximately four times an hour and at will during the night and bore a mean of 4.7 children during their reproductive years. In contrast, the Hutterites of North America bore a mean of 10.6 children during their lifetimes, presumably because they nursed according to a rigid schedule, used supplemental feedings, and weaned at 1 year. In Edinburgh, resumption of menses, albent anovulatory, occurred in 28 weeks and the first ovulation occurred at a mean of 34 postpartum weeks because of persistently abnormal LH pulsatile secretion.

Immune Function

Several lines of evidence indicate that PRL is a lymphocyte growth factor and stimulates immune responsiveness. PRL levels change in concert with immune disease, as seen in patients with lupus erythematosus. In immunosuppressed mice, PRL stimulated immune cell functions. Although PRL has been suggested as an immunomodulatory hormone, there is evidence that PRL may not be important for immune function because innate immunity was not altered in mice that lacked either the PRL receptor (PRLR) or the PRL gene (PRL).
levels. In male subjects with hyperprolactinemia, LH and FSH pulsatility is attenuated, testosterone levels are suppressed, and sperm counts and motility are low.

**Prolactin Assays**

The PRL radioimmunoassay (RIA) is highly specific and clearly distinguishes PRL from GH. PRL measurements are standardized using reference preparations provided by the National Institute for Biological Standards and Control in London and the National Hormone and Pituitary Program. Improvements in assay efficiency and turnaround time, reproducibility, and sensitivity have been achieved by immunoradiometric assay (IRMA) and chemiluminescent PRL assays. Because these samples are usually assayed at a single dilution, extremely high PRL concentrations may saturate their ability to detect very high PRL levels, resulting in a falsely low value being reported. This "hook" effect may result in PRL-secreting macroadenomas diagnosed as clinically nonfunctioning adenomas, with "normal" PRL levels reported in about 5% of patients. In patients harboring macroadenomas with clear-cut clinical features of hyperprolactinemia, serum samples should be subjected to at least a 1:100 dilution before assay.

**Prolactin Secretion**

The calculated production rate of PRL ranges from 200 to 536 µg/day/m2, and the metabolic clearance rate ranges from 40 to 71 mL/min/m2. PRL is cleared rapidly with a calculated disappearance half-life ranging from 26 to 47 minutes. PRL secretion occurs episodically in 4 to 14 secretory pulses, each lasting 67 to 76 minutes, over 24 hours. PRL is secreted episodically during the day, with the highest levels achieved during sleep and the lowest occurring between 10 AM and noon. The nocturnal elevation is sleep entrained and a temporal relationship exists between rapid eye movement (REM) and non-REM sleep cycles. PRL and PRL may cause periods of REM. VIP stimulates both REM sleep and PRL, and when VIP was given to rats together with a PRL antiserum, REM sleep was inhibited. PRL levels fall with age in both men and women. In older men, less PRL is produced with each secretory burst than in younger men. Likewise, postmenopausal women have lower mean serum PRL levels and a lower PRL pulse frequency than premenopausal women or men, suggesting a stimulatory effect of estrogen on both of these parameters.

**Hyperprolactinemia**

In the absence of a prolactinoma, hyperprolactinemia may be caused by other pituitary or sellar tumors that inhibit dopamine because of pressure on the pituitary stalk or interruption of the vascular connections between the pituitary and hypothalamus (Table 8-12).

**Idiopathic Hyperprolactinemia**

An elevated circulating PRL level in patients in whom no cause is identified is considered idiopathic, and these patients are relatively resistant to dopamine. The mean serum PRL level in 41 patients with idiopathic hyperprolactinemia was 57 µg/L, with only 3 patients having PRL concentrations over 100 µg/L. Patients were observed for up to 11 years, and 33 had both galactorrhea and amenorrhea or galactorrhea and oligomenorrhea. Hyperprolactinemia ultimately resolved spontaneously in 14 patients.

**Macroprolactinemia**

PRL is a 23-kd single-chain polypeptide but may also be produced in higher molecular mass forms (50 and 150 kd). Macroprolactinemia reflects a predominant larger circulating PRL molecule (particularly the 150-kd variety) with markedly reduced bioactivity, and few of the expected clinical abnormalities usually associated with hyperprolactinemia (sexual dysfunction, galactorrhea, osteoporosis) occur. The high-molecular-weight PRL variant may represent 85% or more of the total PRL, whereas under usual circumstances the 22-kd variety predominates. Screening for macroprolactinemia can be accomplished by polyethylene glycol precipitation of serum samples.

**Other Causes of Hyperprolactinemia**

Mild hyperprolactinemia occurs in up to 30% of women with polycystic ovarian syndrome. No definite cause-and-effect relationship between the two disorders is apparent. Dopamine agonists reduced PRL and LH levels in patients with polycystic ovarian syndrome in the presence or absence of hyperprolactinemia, and indeed a subset of patients with amenorrhea experienced a return of menses after treatment with these drugs. Breast stimulation has only a minimal effect on serum PRL levels. In 18 normal women serum PRL rose from a mean of 10 to 15 µg/L during breast pump stimulation, and no increase was observed in men. Up to 20% of patients with hypothyroidism have elevated PRL levels. Although the cause of this elevation is not known, studies of hypothyroid animals suggest increased pituitary TRH. Treatment of hypothyroidism with thyroid hormone normalizes serum PRL if the hyperprolactinemia is due to thyroid hormone deprivation. PRL is moderately elevated (mean 28 µg/L) in patients with chronic renal failure and those receiving dialysis. The increase is largely a result of an increase in little PRL related in part to a decreased glomerular filtration rate. A specific pituitary defect is also suggested by the observation that TRH failed to evoke PRL in these patients. Sexual dysfunction is common, and reducing PRL with dopamine agonists improved sexual function in men receiving dialysis but did not normalize

Signs and Symptoms Associated with Hyperprolactinemia

Severe head trauma also results in hyperprolactinemia, often accompanied by diabetes insipidus or SIADH and other anterior pituitary hormone deficiencies. Fifty percent of patients experienced moderate hyperprolactinemia after cranial and hypophalamic radiation. A variety of medications cause minimal or moderate PRL elevations and may cause galactorrhea, amenorrhea, or reduced male sexual function. Neuroleptic drugs elevate PRL because of their dopamine antagonist properties. Chlorpromazine stimulated PRL acutely after an intramuscular injection and chronically during oral administration. Neuroleptics, which act by antagonizing both serotonin and dopamine receptors, including clozapine and olanzapine, weakly induce PRL, whereas others such as risperidone are potent stimulators of PRL.

Treatment of Drug-Induced Hyperprolactinemia

Unless patients exhibit sexual dysfunction, related osteoporosis, or troublesome galactorrhea, no treatment may be advised. It should not always be assumed that hyperprolactinemia in patients receiving drugs known to elevate PRL is due to those medications. Prolactinoma, other pituitary or hypothalamic lesions, hypothyroidism, or renal failure should be considered. In patients taking neuroleptic medications, if the clinical situation permits, temporary drug withdrawal might be considered to determine whether PRL levels become normal. If not, pituitary MRI should be performed. When neuroleptics elevate PRL, olanzapine may be tried because it does not elevate PRL. In determining to discontinue a drug or use an alternative medication, the benefits should be weighed against the risks of drug replacement or cessation. Although combined use of dopamine antagonists and dopamine agonists is not usually advised because of the increased risk of side effects, such as postural hypotension and worsening of psychosis, some advocate the use of both simultaneously.

Galactorrhea

The Talmud describes a man who nursed his baby after his wife's untimely death, probably representing the first recorded case of male galactorrhea. Galactorrhea and amenorrhea were reported in the 19th century by Chiari, and only in the 1950s did Argonz and Forbes and their colleagues associate galactorrhea and amenorrhea with pituitary tumors and PRL. Galactorrhea, inappropriate secretion of milk-like substances from the nipples of either men or women, may persist after childbirth or discontinuation of nursing for as long as 6 months. Thereafter, continued milk production is considered abnormal and other etiologies for galactorrhea should be investigated.

Galactorrhea can occur either unilaterally or bilaterally, be profuse or sparse, and vary in color and thickness. If blood is present in the galactorrhea fluid, it could be the harbinger of an underlying pathologic process, such as a ductal papilloma or carcinoma, and mammography or sonography is indicated. Blood may also appear in galactorrhea fluid with no underlying tumor, such as during pregnancy. Conversely, the absence of blood does not rule out an underlying tumor, particularly when galactorrhea is unilateral and the fluid emanates from a single duct.

The most common cause of galactorrhea is hyperprolactinemia (Fig. 8-23). It is likely that most patients with so-called idiopathic galactorrhea with amenorrhea harbor microprolactinomas. Fifty percent of patients with acromegaly also have hyperprolactinemia. Even in the absence of hyperprolactinemia, human GH is a potent lactogen and can cause galactorrhea when elevated. Twenty-nine of 48 patients with pituitary tumors and galactorrhea had PRL concentrations less than 200 µg/L, suggesting that they had pituitary tumors other than prolactinomas on the basis of stalk compression.

Idiopathic Galactorrhea with Regular Menses

This diagnosis represents the largest single cause of galactorrhea. In two thirds of patients, galactorrhea begins after parturition persists, despite the resumption of menses, and probably does not represent a pathologic entity. Normal PRL levels may still permit milk production because treatment of such patients with dopamine agonists alleviates galactorrhea.

Chiari-Frommel Syndrome

The syndrome, first described by Chiari and later in the 19th century by Frommel, consists of postpartum galactorrhea, amenorrhea, and "uterine-ovarian atrophy" in patients not nursing. Eighteen such patients had galactorrhea and amenorrhea for up to 11 years after parturition. The mean PRL level was 45 µg/L. This disorder is usually self-limiting, and patients eventually become spontaneously fertile, sometimes without having had an intervening menstrual period. Individual patients with postpartum amenorrhea, hyperprolactinemia, and

Serotonin and dopamine receptors, including clozapine and olanzapine, weakly induce PRL, whereas others such as risperidone are potent stimulators of PRL.
Decreased libido, impotence, premature ejaculation, erectile dysfunction, oligospermia.

Osteoporosis.

The most frequent ophthalmic complaint in a series of 1000 patients with tumors was loss of vision.

Prolactinomas may be found as a result of tumor size or invasiveness, or both. Microadenomas range from entirely asymptomatic tumors as small as 2 to 3 mm in size to compressive effects on visual structures.

PRL also directly inhibits ovarian and testicular function. Increased opioid LH inhibition has also been implicated as a cause of amenorrhea in hyperprolactinemic patients.

PRL levels and tumor size generally remain stable when followed prospectively. Although most men present with no symptoms, symptoms may become apparent after a latency period of 2 to 3 years.

Management of Galactorrhea

Galactorrhea can be overlooked unless actively elicited. Bone density may decrease in both men and women as a result of hyperprolactinemia. In oophorectomized rats, high PRL decreased LH pulse frequency and amplitude.

Pathology and Pathogenesis

Although more than 99% of prolactinomas are benign and often sharply demarcated without evidence of invasion, about half invade local structures. Invasion into adjacent dura, bone, or venous structures may represent an intermediate form of prolactinoma between the sharply demarcated benign variety and the exceedingly rare malignant tumor. Invasive tumors that do not metastasize are considered benign. Immunostaining for PRL confirms the diagnosis of prolactinoma, which is usually distinct from the adjacent normal pituitary but is not truly encapsulated.

Patients with both large and small PRL-secreting tumors can present with signs and symptoms of hyperprolactinemia. Menstrual irregularities, sexual dysfunction, galactorrhea, osteopenia are attributable to elevated PRL levels. Elevated PRL causes sexual dysfunction through a short-loop feedback effect on gonadotropin pulsatility, presumably inhibiting GnRH (see Fig. 8-22) . In oophorectomized rats, high PRL decreased LH pulse frequency and amplitude.

High PRL also directly inhibits ovarian and testicular function. Increased opioid LH inhibition has also been implicated as a cause of amenorrhea in hyperprolactinemic patients.

Pathologic examination of pituitary tumors reveals a cellular proliferation with minimal nuclear atypia and minimal mitotic activity. Immunochemical studies for PRL and other pituitary hormones confirm the diagnosis of prolactinoma.

Prolactinomas are the most common pituitary tumors associated with MEN-1, occurring in approximately 20% of a large kindred.

Invasive tumors may have higher mitotic activity and are more cellular and pleomorphic. Invasion into adjacent dura, bone, or venous structures may represent an intermediate form of prolactinoma between the sharply demarcated benign variety and the exceedingly rare malignant tumor. Invasive tumors that do not metastasize are considered benign. Immunostaining for PRL confirms the diagnosis of prolactinoma, which is usually distinct from the adjacent normal pituitary but is not truly encapsulated. These tumors have a "pseudocapsule" composed of compressed adenohypophyseal cells and a reticulin fiber network.

To consider a prolactinoma malignant, a distant extracranial metastasis must be demonstrated.

For the most part, prolactinomas grow slowly, arise sporadically, usually occur singly, and are monoclonal. Infrequently, more than one prolactinoma arises within the gland. Prolactinomas are the most common pituitary tumors associated with MEN-1, occurring in approximately 20% of a large kindred, although the occurrence of prolactinomas is not evenly distributed. Familial prolactinomas have been described with no other features of MEN-1.

Clinical Features

Prolactinomas are the most common pituitary tumors associated with MEN-1, occurring in approximately 20% of a large kindred. Although more than 99% of prolactinomas are benign and often sharply demarcated without evidence of invasion, about half invade local structures.

Pathology and Pathogenesis

Although more than 99% of prolactinomas are benign and often sharply demarcated without evidence of invasion, about half invade local structures. Invasion into adjacent dura, bone, or venous structures may represent an intermediate form of prolactinoma between the sharply demarcated benign variety and the exceedingly rare malignant tumor. Invasive tumors that do not metastasize are considered benign. Immunostaining for PRL confirms the diagnosis of prolactinoma, which is usually distinct from the adjacent normal pituitary but is not truly encapsulated. These tumors have a "pseudocapsule" composed of compressed adenohypophyseal cells and a reticulin fiber network.

To consider a prolactinoma malignant, a distant extracranial metastasis must be demonstrated.

For the most part, prolactinomas grow slowly, arise sporadically, usually occur singly, and are monoclonal. Infrequently, more than one prolactinoma arises within the gland. Prolactinomas are the most common pituitary tumors associated with MEN-1, occurring in approximately 20% of a large kindred, although the occurrence of prolactinomas is not evenly distributed. Familial prolactinomas have been described with no other features of MEN-1.

Hyperprolactinemia

Patients with both large and small PRL-secreting tumors can present with signs and symptoms of hyperprolactinemia. Menstrual irregularities, sexual dysfunction, galactorrhea, and osteopenia are attributable to elevated PRL levels. Elevated PRL causes sexual dysfunction through a short-loop feedback effect on gonadotropin pulsatility, presumably inhibiting GnRH (see Fig. 8-22) . In oophorectomized rats, high PRL decreased LH pulse frequency and amplitude.

High PRL also directly inhibits ovarian and testicular function. Increased opioid LH inhibition has also been implicated as a cause of amenorrhea in hyperprolactinemic patients.

Women with prolactinomas may present with primary or secondary amenorrhea, oligomenorrhea, menorrhagia, delayed menarche, or regular menses with a short luteal phase that may cause infertility. Patients may also report changes in libido and vaginal dryness. Sexual dysfunction in men is usually manifest as loss of or decrease in libido, impotence, premature ejaculation, or loss of erection. If men have oligospermia or azoospermia as a result of hyperprolactinemia, it usually occurs only after many years.

Up to 50% of women and 35% of men with prolactinomas have galactorrhea. This gender difference may occur because male mammary tissue is less susceptible to the lactogenic effects of hyperprolactinemia. Galactorrhea can be overlooked unless actively elicited. Bone density may decrease in both men and women as a result of hyperprolactinemia-induced sex steroid deficiency.

Tumor Mass Effects

Prolactinomas may be found as a result of tumor size or invasiveness, or both. Microadenomas range from entirely asymptomatic tumors as small as 2 to 3 mm in diameter found at autopsy to larger ones that are still less than 10 mm in diameter. These tumors can be invasive despite their small size. The incidence of headaches in patients with a microadenoma is twice that of normal control subjects. In contrast, macroadenomas range in size from noninvasive or diffuse tumors approximately 1 cm in diameter to huge tumors that may impinge on paraseptal structures. Signs and symptoms caused by large or invasive tumors are often related to compressive effects on visual structures.

The most frequent ophthalmic complaint in a series of 1000 patients with tumors was loss of vision. The most frequent objective findings were bitemporal hemianopsia, superior bitemporal defects, and decreased visual acuity. Headaches are common, but seizures (a result of extension into the temporal lobe) and hydrocephalus are rare, as is unilateral exophthalmos. Interestingly, many tumors invade the cavernous sinuses and yet cranial nerve palsies are rarely encountered. A sudden insult, such as pituitary apoplexy, is the more common cause of such palsies and may be a presenting symptom. Prolactinomas can also be found inadvertently by MRI or CT performed for another purpose.
Bromocriptine shrinks prolactinomas by reducing tumor cell size, including cytoplasmic, nuclear, and nucleolar areas. An agonist has been reported to normalize PRL further in some cases, although these patients have impressive tumor shrinkage and sometimes improved sexual function. Although higher doses or a change in the form of dopamine agonist (such as bromocriptine) binding to dopamine receptors on cell membranes. Despite high doses of bromocriptine, some patients are entirely or partially resistant to its effects. In bromocriptine-resistant patients, there is reduced bromocriptine elevation. Bromocriptine lowers PRL despite continued tumor expansion, do not become larger after drug withdrawal. Not infrequently, it is difficult to normalize PRL levels completely in patients with initially very high levels, although when tumors grow during dopamine agonist therapy there is usually a simultaneous PRL elevation. Despite high doses of bromocriptine, some patients are entirely or partially resistant to its effects. In bromocriptine-resistant patients, there is reduced bromocriptine elevation. Therefore, serum IGF-I should be measured. Elevated PRL levels are occasionally encountered in patients with TSH-secreting tumors. Other pituitary hormone functions should be ascertained to determine the presence of hypopituitarism. MRI is required to make a definitive diagnosis of a prolactinoma.

**Treatment**

Optimal outcomes of treatment for a prolactinoma include normalization of PRL levels (and associated signs and symptoms) and complete tumor removal or shrinkage with a reversal of tumor mass effects (Table 8-14). Specifically, previously abnormal sexual function and fertility should be restored, galactorrhea stopped, impaired bone density improved, tumor eliminated or reduced in size without impairing pituitary or hypothalamic function, and vision normalized, if impaired.

**Medical Management**

Medical management of prolactinomas with dopamine agonist drugs has been widely recommended as the treatment of choice.

**Bromocriptine.**

Bromocriptine, a semisynthetic ergot alkaloid dopamine agonist, lowers elevated PRL levels, restores abnormal menstrual function in 80% to 90% of patients, and shrinks prolactinomas, restores impaired sexual function, and improves galactorrhea. Improvement in visual field abnormalities occurs in approximately 90% of affected patients. Drug withdrawal can result in rapid tumor expansion. In contrast, occasional tumors that have shrunk during bromocriptine therapy do not become larger after drug withdrawal. In a subset of patients, hyperprolactinemia disappeared spontaneously after long-term observation. Occasionally, bromocriptine lowers PRL despite continued tumor expansion, although when tumors grow during dopamine agonist therapy there is usually a simultaneous PRL elevation.

**Histologic sections appear quite dense as a result of the small cell size and clumping of nuclei** (Fig. 8-25). PRL mRNA and synthesis is inhibited, exocytoses are reduced, PRL secretory.
granules decrease, and rough endoplasmic reticulum and Golgi apparatus involute. The net effect is reduced cell volume. Tumor necrosis may also occur.

Perivascular fibrosis was noted in prolactinomas derived from patients treated with bromocriptine and it was proposed that this led to difficulty in tumor removal. However, others found no effect of prior treatment with bromocriptine on surgical success rates. In contrast, bromocriptine was a helpful adjunct to transphenoidal microsurgery for macroadenomas. Even the largest tumors or those with the highest PRL levels respond well to treatment with 2.5 mg of bromocriptine three times daily. Higher doses are often not more effective. When positive effects on tumor size and amenorrhea and galactorrhea are established, some patients can be satisfactorily maintained with smaller doses but rarely without medication.

CABERGOLINE

CABERGOLINE has a longer duration of action than other available dopamine agonists and is usually administered once or twice weekly. Since its introduction, it has surpassed bromocriptine as the first-line therapeutic choice for most patients. The long half-life of cabergoline is a result of its high affinity for D2 receptors on lactotrophs and a greater propensity of the drug to remain in pituitary tissue.

In pharmacokinetic studies, cabergoline lowered PRL in a dose-related manner. PRL levels were normalized in 83% of 459 women with hyperprolactinemia treated with cabergoline (0.5 to 1 mg twice weekly) and in 52% of women receiving bromocriptine (2.5 to 5 mg twice daily). Cabergoline was also more effective than bromocriptine in restoring ovulatory cycles and fertility (72% versus 52%, P < 0.001), was better tolerated than bromocriptine, and caused fewer but similar side effects (Fig. 8-26) and as evidenced by the success of pergolide in patients intolerant of bromocriptine. Intravaginal bromocriptine administration has been used with some success in patients who are intolerant of bromocriptine but cannot tolerate cabergoline.

PERGOLIDE MESYLATE

Pergolide, a long-acting ergot derivative with dopamine agonist properties, has an estimated potency 100 times that of bromocriptine. Pergolide is administered at an initial dose of 25 µg/day, and then at 50 µg/day with gradual dose escalation depending on the extent of serum PRL normalization. Menses resumed in 76% of women and serum testosterone increased in 10 of 14 men not receiving testosterone, and tumor size decreased in 10 of 13 patients with macroadenomas. In 22 patients with macroadenomas, pergolide lowered PRL from a mean of 2938 to 59 ng/mL. PRL became normal in 15 of 22 patients, and tumor shrinkage was observed in 95% of patients. Nine patients were resistant to cabergoline despite doses of up to 7 mg/week. Despite the continued experience that a subset of hyperprolactinemic patients are resistant to most or all dopamine agonists, a report indicated that cabergoline normalized PRL in 15 of 19 patients with macroadenomas previously resistant to other dopamine agonists.

QUINAGOLIDE

This nonergot dopamine agonist (CV 205502), administered once daily (mean daily dose of 0.09 mg), normalized PRL in 5 of 10 patients previously intolerant of or resistant to bromocriptine. Side effects, principally nausea, occurred in 6 of 10 women. In 26 patients similarly evaluated, quinagolide normalized PRL levels in 13 but the post-treatment mean remained above normal (30 ng/mL). Thirteen had a return of menses, and galactorrhea was reduced in 12 of 15 women. The effect of this medication on tumor shrinkage is similar to that of other dopamine agonists, but it is not available in the United States.

Administration

Attention to administration of dopamine agonists helps avoid or minimize potential adverse effects. Usual starting doses are 1.25 mg of bromocriptine (daily), 0.025 mg of pergolide (daily), and 0.25 mg of cabergoline (weekly). Doses of medication are either increased gradually as tolerated or decreased depending on tolerability, and treatment should be initiated with a small dose with food before bedtime. Patients should initially avoid activities that cause peripheral vasodilatation (e.g., hot showers or baths), thereby decreasing the risk of postural hypotension. If side effects are troublesome, the next dose should be halved and doses subsequently increased gradually to reach effective levels. Switching from one medication to another may be beneficial as evidenced by the success of pergolide in patients intolerant of bromocriptine. Intravaginal bromocriptine administration has been used with some success to reduce adverse events.

Adverse Events of Dopamine Agonists

Side effects of dopamine agonists are common. Nausea occurs in 31% to 50% of patients; nasal stuffiness, depression, and digital vasospasm also occur, the latter more frequently with higher doses, as in patients with Parkinson’s disease. The most serious side effect, postural hypotension, which can cause loss of consciousness, occurs infrequently and can often be avoided by careful dosing. Signs and symptoms of psychosis or exacerbation of preexisting psychosis can be
encountered in up to 1.3% of patients taking bromocriptine. \textsuperscript{[360]} Psychosis also occurs with other dopamine agonists, including cabergoline (personal experience).\textsuperscript{[361]}

A history of present or past psychotic symptoms should raise concerns about using these medications. If psychosis occurs in a patient in whom dopamine agonists are clearly the treatment of choice, a judicious combination of the agent and antipsychotic medication can be effective. A neuroleptic that is not a potent PRL stimulator, such as olanzapine, is preferred. The combined use of dopamine agonists and antagonists may increase the occurrence of side effects, particularly postural hypotension. Other rarely reported serious side effects include CSF rhinorrhea, \textsuperscript{[362]} hepatic dysfunction, \textsuperscript{[363]} and cardiac arrhythmias. \textsuperscript{[364]} Retroperitoneal fibrosis, pleural effusions, and thickening have been reported in patients taking high doses of bromocriptine. \textsuperscript{[365]}

\subsection*{Radiation Therapy}

Linear accelerator radiotherapy is effective in controlling or reducing the size of prolactinomas. \textsuperscript{[366]} \textsuperscript{[367]} However, this therapy takes years to achieve its maximal effect. The usual recommended radiation dose is 4500 to 4600 cGy, and higher doses are associated with a greater complication rate. \textsuperscript{[368]} Normalization of PRL was achieved in 7 of 12 patients during 3 to 8 years after radiotherapy\textsuperscript{[369]} and in 18 of 36 patients at a mean of 7.3 years after treatment in another study. \textsuperscript{[370]}

Hypopituitarism is a side effect of radiation. Of 165 patients after radiotherapy (3750 to 4250 cGy), \textsuperscript{[371]} all patients were GH-deficient, 91% were gonadotropin-deficient, 77% were

\begin{center}
212
\end{center}

ACTH-deficient, and 42% were TSH-deficient by 5 years. Of 36 patients with prolactinomas, 83% of whom had normal GH responses to insulin-induced hypoglycemia before therapy, 34 were GH-deficient 9 to 12 years after radiotherapy. \textsuperscript{[372]} The incidence of other forms of hypopituitarism was lower.

Thus, although radiotherapy is useful in the control of tumor growth, it is not nearly as effective as dopamine agonists on endocrine function. Stereotactic conformal radiotherapy with a linear accelerator can provide greater tumor focus and a smaller radiation field. \textsuperscript{[373]} There are as yet no reports on large-scale studies of treatment of prolactinomas with gamma knife radiotherapy.

\subsection*{Surgery}

Surgical removal of prolactinomas by the transphenoidal route was repopularized in the early 1970s. \textsuperscript{[374]} As with other functioning pituitary tumors, the success rate of surgery correlates inversely with tumor size and serum PRL concentrations. \textsuperscript{[375]} \textsuperscript{[376]} In a compilation of results in 31 published surgical series, serum PRL was normalized in 71% of 1224 patients with microprolactinomas. \textsuperscript{[377]} Although surgical cure rates for microprolactinomas are high, the rate of hyperprolactinemia recurrence is also relatively high. \textsuperscript{[378]} now estimated to be 17% in patients initially considered cured. \textsuperscript{[379]} In contrast, complete removal of macroprolactinomas, especially large invasive ones, is difficult to achieve; postoperative serum PRL was normalized in only 32% of patients with macroadenomas, with a recurrence rate of 19%. The experience of the surgeon is of major importance, as the cure rate is not nearly as favorable for neurosurgeons who perform a limited number of procedures.\textsuperscript{[380]}

Although results of medical therapy are better than those of surgery, there remains a role for surgery in these patients. Patients with prolactinomas who are resistant to dopamine agonist therapy are particularly well suited for surgery. If tumor removal is only partial, adjunctive radiation therapy should be considered. Prophylactic transphenoidal surgery should also be considered in women whose prolactinomas are large enough to be a potential threat to vision during pregnancy. A subset of patients cannot tolerate available dopamine agonists, and others prefer surgery and refuse medication \textsuperscript{[Fig. 8-27]}.

\subsection*{Pregnancy}

The normal pituitary gland enlarges during pregnancy and by the end of pregnancy may increase in size by 136%. \textsuperscript{[381]} Prolactinomas may also increase in size during pregnancy.\textsuperscript{[382]} Pregnancy-associated tumor enlargement, as determined by the development of abnormal visual fields, has been estimated to occur in 1.4% of women with microadenomas and 16% of women with macroadenomas.\textsuperscript{[383]} In other reports, the risk of macroadenoma enlargement has been estimated to be as high as 36%. In a prospective analysis in which 57 patients with microprolactinomas were observed by formal visual field examinations during pregnancy, none experienced visual disturbances. In contrast, six of eight primiparous women with macroadenomas had visual loss.\textsuperscript{[384]} The results for patients with macroadenomas are probably skewed because these patients were recommended for surgery before pregnancy.

Although dopamine agonists have been used during pregnancy to prevent tumor growth \textsuperscript{[Fig. 8-28]}, \textsuperscript{[385]} \textsuperscript{[386]} it seems prudent to reduce fetal exposure to medication if possible. It is recommended that menstrual periods be allowed to occur naturally for a period of time (3 to 4 months) long enough to predict that a missed period might be a result of pregnancy (Table 8-15). Barrier contraception is recommended during this period. Within several days to a week of obtaining a positive hCG test, medication should be discontinued. In 6239 pregnancies of patients managed in this manner, bromocriptine therapy was not associated with increased abortions or terminations, prematurity, multiple births, or infant malformations above those expected in the control population.\textsuperscript{[387]} There is no evidence that other dopamine agonists are less safe, but exposure to the other agonist forms in pregnancy is less comprehensively documented. Treatment options for patients harboring prolactinomas whose vision becomes impaired during pregnancy include bromocriptine, high-dose steroids, and surgery. \textsuperscript{[388]} \textsuperscript{[389]} One study reported that for 53 pregnant women receiving bromocriptine, mean offspring birth weight was normal, congenital abnormalities occurred in four babies, and the physical and intellectual development of the children was normal for up to 9 years.\textsuperscript{[390]}

To avoid neurologic complications of tumor enlargement during pregnancy, it is recommended that women with prolactinomas be tested for sensitivity to dopamine agonists before proceeding with a pregnancy. If tumors are insensitive to dopamine agonist-related tumor shrinkage, prophylactic surgery would be appropriate. If the tumor is a macroadenoma approximating the optic chiasm, the likelihood of visual difficulties is greater and therefore surgery would be prudent before pregnancy. \textsuperscript{[391]}
PHYSIOLOGY AND DISORDERS OF PITUITARY HORMONE AXES (Continued)

Gonadotropins

Gonadotroph cells secreting FSH and LH constitute about 10% to 15% of the functional anterior pituitary cells. Two classes of electrodense secretory granules are evident; large 350- to 450-nm and smaller 150- to 250-nm granules are packaged in vesicles (Fig. 8-29 (Figure Not Available) and Fig. 8-30 (Figure Not Available) ). They contain large, round cell bodies with prominent rough endoplasmic reticulum and Golgi apparatus. LH secretory granules often accumulate peripherally, and their Golgi may be less prominent. SF-1 and DAX-1 orphan nuclear receptors determine gonadotroph-specific gene expression.

Biasynthesis

In concert with peripheral hormones and paracrine soluble factors, FSH and LH function to regulate gonadal steroid hormone biosynthesis and initiate and maintain germ cell development. The four glycoprotein hormones LH, FSH, TSH, and hCG share structural homology, having evolved from a common ancestral gene. Although the homologous LH and FSH molecules are cosecreted by the single gonadotroph cell, their regulatory mechanisms are not uniformly concordant. The and subunits are encoded by different genes located on chromosomes 6, 11, and 19 (Fig. 8-4) (Figure Not Available) . The heterodimeric structure of the common and unique subunit is essential for their biologic activity. Disulfide linkages maintain noncovalent subunit linkages, which also determine the ultrastructure of the mature folded molecule (Fig. 8-31). After processing of hormonal protein precursors, glycosylation occurs by transferring oligosaccharide complexes to asparaginyl residues. Post-translational processing of carbohydrate side chains is critical for hormone signaling and may be species specific and not uniformly similar for both human LH and FSH.

The complex human LH-gene cluster comprises seven CG-like genes, one of which encodes LH-7 whose promoter and transcriptional start site differ from those of hCG. The three exons and two introns encode a 24-amino-acid leader peptide and a 121-amino-acid mature protein. Unlike -LH, hCG is present only in primate and equine species, and the hCG peptide product contains a 24-amino-acid carboxyterminal extension. Cell-specific LH gene expression and GnRH responsiveness of LH are subverted by different transcriptional mechanisms. GnRH induces LH-transcription, as does SF-1. The rat LH-promoter contains an estrogen-responsive motif and a nuclear factor Y binding site, which appears to be important for basal but not GnRH-mediated transcription. The FSH-gene comprises three exons and two introns located on chromosome 11. The gene promoter is dissimilar to that of LH, and structure-function mechanisms for transcriptional regulation of the human gene by GnRH and sex steroids are not well clarified.

Gonadotropin Assays

Because of the high homology of the glycoprotein hormones, development of highly specific assays, especially to distinguish free subunit from intact hormones, has been challenging. Heterogeneity of circulating LH and FSH molecules, insufficient assay sensitivity especially for measurements in normal healthy individuals, and lack of rigorously pure reference preparations have hampered assay development. Immunofluorometric assays detect LH with a sensitivity of 0.1 mIU/mL. Differences in carbohydrate moieties result in isoelectric charge heterogeneity for LH, accounting for some of the disparities in biologic and immunoreactive LH ratios observed with GnRH agonist treatment, acute critical illness, or aging.

LH bioassays include assessing testosterone generation by cell cultures, and FSH bioassays include measuring granulosa cell or Sertoli cell aromatase generation. Because only intact molecules, but not free or subunits, are biologically active, these cumbersome assays are nevertheless useful for measuring bioactive hormone without potential cross-reaction with free subunits.

Subunit Secreton

Both GnRH and TRH increase circulating levels of free subunit derived from either gonadotrophs or thyrotrophs, especially in patients with hypothyroidism, after castration, and during the menopause. GnRH agonist treatment, TSH-secreting tumors, or nonfunctioning pituitary adenomas may result in discordant ratios of free subunit from intact LH dimer secretion.

Regulation of FSH and LH Secretion

FSH and LH secretion patterns reflect the integration of sensitive complex hypothalamic, pituitary, and peripheral signals. Both GnRH pulse amplitude and frequency determine the physiologic patterns of LH and FSH secretion (Fig. 8-32). In patients with hypothalamic GnRH deficiency, intravenous GnRH injections (25 ng/kg) that achieve GnRH levels similar to those present in primate hypophysial-portal

---

The magnitude of the LH response exceeds that of FSH. Decreasing GnRH pulse frequency enhances LH pulse amplitudes, whereas increasing GnRH pulse frequency to more than every 2 hours down-regulates the subsequent LH response. The interpulse LH secretory interval is 55 minutes, and the pulse amplitude is approximately 40% of basal tonic secretion. Changes in gonadotropin secretion during infancy, childhood, puberty, and aging are described in Chapter 21 and Chapter 25 (Fig. 8-33). A log-linear relationship is evident between GnRH dose and the amounts of LH, FSH, and free subunit pituitary secretion.

Blood and hypothalamic targets for testosterone signals mediate FSH and LH regulation, and testosterone attenuates gonadotropin secretion in males. Thus, after castration, elevated gonadotropin levels can be partially overcome by testosterone replacement. The mechanisms involved are complex, as testosterone also exerts a stimulatory effect on FSH- mRNA levels. Although estrogen administration decreases LH pulse amplitude in normal and GnRH-deficient male subjects, depending on the clinical situation, estrogen may either stimulate or inhibit pituitary gonadotropin synthesis and secretion and also inhibit GnRH synthesis and or action. This pattern is manifest in the cyclic control of gonadotropin secretion during the menstrual cycle and during puberty.

LH, FSH, free subunit, and testosterone pulses are usually concordant in male subjects (Bhasin 2002). Deconvolution pulse analysis allows estimation of "real-time" hormone secretion rates, with an assumed disappearance rate constant. The characteristic secretory episodes characterized for LH and FSH indicate daily production rates of 1000 and 200 IU, respectively, and a disappearance half-life of 90 and 500 minutes for the respective subunits.

**Gonadal Peptides**

Pituitary gonadotropin secretion is regulated by gonadal peptides including inhibin A, an :A heterodimer, and inhibin B, an :B heterodimer, and follistatin peptides. The activin A (A) and activin AB (B) homodimers stimulate in vitro FSH secretion. These proteins, related to transforming growth factor and müllerian-inhibiting factor, are fully described in Chapter 16.

Female

Luteal cell LH receptors signal to enhance cAMP levels and induce cholesterol availability for ovarian steroidogenesis (Fig. 8-34). The steroidogenic acute regular (STAR) protein is induced by LH and mediates cholesterol delivery to the inner membrane. LH enhances cytochrome P450-linked enzyme activity to synthesize pregnenolone and induces 3-hydroxysteroid dehydrogenase, 17-hydroxylase, and 17,20-ylase synthesis. The FSH receptor, a G protein-linked molecule with seven transmembrane domains shares 50% extracellular domain and 80% transmembrane homology with the LH receptor. FSH regulates ovarian estrogen synthesis by inducing 17-hydroxysteroid dehydrogenase and aromatase and also induces follicular growth. Estrogens are also permissive for FSH action and enhance FSH-induced cAMP levels.

Mole

Leydig cell LH receptor signaling induces intratesticular testosterone synthesis mediated by enhanced cAMP production. FSH function in male subjects is not readily apparent but probably mediates spermatogenesis from spermatids in concert with testosterone, especially as failed spermatogenesis leads to elevated FSH levels.

**Gonadotropin-Releasing Hormone Stimulation Test**

A single bolus of GnRH (25 to 100 µg) dose dependently evokes serum LH and FSH levels within 20 to 30 minutes. LH rises more abundantly than FSH, and peak values range from 8 to 34 mIU/mL. Patients with low testosterone levels exhibit more exuberant responses. In contrast, patients with hypogonadotropic hypogonadism and no demonstrable hypothalamic-pituitary lesion have blunted LH responses and reversal of the LH/FSH ratio. The test, however, cannot adequately distinguish hypothalamic from pituitary lesions, and similar...
patterns are observed in patients with anorexia nervosa. Repetitive GnRH pulses may, in fact, normalize responses, as would be expected from an intact hypothalamic-pituitary unit. GnRH responses may vary during the stages of puberty, reflecting altered pituitary sensitivity.

Gonadotropin Deficiency

Gonadotropin deficiency causes hypogonadism with decreased sex steroid production of varying degree, depending on the severity of the insult (Table 8-16). This disorder may occur at any stage of life. In its complete form (e.g., panhypopituitarism, Kallmann's syndrome), primary amenorrhea or total failure of male sexual development may occur. Later in life a varying spectrum of sexual dysfunction develops, ranging from luteal abnormalities or oligomenorrhea to amenorrhea in women and absence of libido, potency, and fertility in men. Women exhibit secondary amenorrhea, vaginal dryness, hot flushes, decreased bone density, decreased breast tissue, and infertility. Men have impotence, testicular hypoplasia or atrophy, decreased libido, low energy, infertility, loss of secondary sexual characteristics, decreased muscle strength and mass, decreased bone mass, decreased body hair growth, and fine facial wrinkling.

In both men and women, serum gonadotropin levels are inappropriately low in the presence of decreased sex steroids and sexual dysfunction. In women with amenorrhea or oligomenorrhea, serum LH, FSH, and estradiol levels should be measured. A vaginal cytologic study is helpful in determining the adequacy of gonadotropin function. Endogenous estrogen

sufficiency can also be assessed by the response to a progesterone challenge (100 mg intramuscularly or 10 mg medroxyprogesterone [Provera] orally daily for 5 days). Men should have serum gonadotropin and testosterone levels measured.

Hypogonadotropic hypogonadism may result from hypothalamic or pituitary defects. Hypothalamic damage including Kallmann’s syndrome, radiation, anosmia, or sexual stress may result in deficient GnRH secretion and action. Pituitary damage from tumors, infarction, or hyperprolactinemia may directly or indirectly attenuate FSH and LH secretion patterns. These acquired causes of central hypogonadism are considered fully in Chapter 16 and Chapter 18 , and genetic causes are listed in Table 8-17 .

Because FSH is required for quantitatively normal spermatogenesis, isolated FSH deficiency is associated with oligospermia or azoospermia in normally androgenized men in the presence of normal testosterone and LH levels. Isolated LH deficiency may be manifest by eunuchoidal body proportions and low testosterone levels. Low LH levels in these patients lead to low intratesticular testosterone concentrations with resultant decreased spermatogenesis. Serum testosterone levels are restored in this “fertile eunuch” syndrome by HCG administration. Isolated hypogonadotropic hypogonadism occurring after apparently normal puberty is manifest with relatively mature secondary sex characteristics or even secondary infertility. These patients have abundant gonadotropin responses to pulsatile GnRH therapy, which restores reproductive function and fertility.

Evaluation

In evaluating hypogonadal patients in the absence of an obvious pituitary or gonadal disorder, the primary diagnostic challenge is to distinguish constitutional pubertal delay from other causes of hypogonadotropism. When puberty is delayed beyond 14 years of age, a primary developmental disorder, hypogonadotropic hypogonadism, or acquired disorders of reproductive function should be considered. The presence of midline defects, a pituitary mass lesion, anosmia, a history of radiation or pituitary damage, drug ingestion, or other systemic illness should be excluded. Patients with chronic liver disease or sickle cell disease may present with impaired pubertal reserve as well as primary testicular dysfunction.

No single test clearly distinguishes constitutional delayed puberty and true hypogonadotropic hypogonadism, and expectant follow-up is often helpful as many patients enter puberty spontaneously. To provide androgenization, testosterone replacement should be intermittently provided until age 18 with periodic interruptions to unmask physiologic pubertal advance. In adults presenting with features of hypogonadotropic hypogonadism, hyperprolactinemia, hemochromatosis, and sarcoidosis should also be excluded before the diagnosis of the idiopathic variety. Pituitary MRI, GH, TSH, and ACTH reserve testing should be performed selectively.

Management

Sex steroid replacement therapy is required to induce and maintain primary and secondary sexual functions, minimize cardiovascular risk factors, and maintain normal body composition and integrity of bone mineral density and muscle mass. For patients not desirous of fertility, sex steroid therapy is warranted to correct central hypogonadism. However, monitoring of LH and FSH responses does not accurately reflect adequate steroid hormonal replacement because basal gonadotropin levels are already low or undetectable.

For women, estrogens are administered as a tablet, patch, gel, or implant. For premenopausal women with pituitary deficiency, a combined oral contraceptive (20 to 35 µg ethynyl estradiol) may be used. Conjugated equine estrogen (0.625 mg) and estradiol valerate (2 mg) provide relatively physiologic steroid replenishment. Estrogen patches or transcutaneous gels usually enable daily absorption of 50 to 100 µg of estradiol. Concomitant cycloprogesterone therapy is indicated for women with an intact uterus to prevent unopposed endometrial proliferation and bleeding.

Although early replacement lowers the risk of developing osteoporosis, effects of estrogen replacement on cardiovascular function are unresolved. In patients with hypopituitarism, estrogen replacement should be maintained at least until the age of 50, after which continuation should be determined on an individual basis by assessing risks and benefits especially in terms of bone mineral integrity, cardiovascular function, and cancer risk. In women with ovarian deficiency, combined estrogen and testosterone replacement may improve libido and sexual function. Estrogen treatment may be associated with thromboembolic disease, breast tenderness, and possibly an enhanced risk of breast cancer.

For males not desiring fertility, intramuscular injection of testosterone 17-hydroxy esters (testosterone enanthate and testosterone cypionate) at 200 mg intramuscularly every 2 or 3 weeks is effective but may be associated with fluctuations in

sexual potency, energy level, and mood reflecting dynamic changes in circulating testosterone concentrations. Administration of lower doses more frequently (e.g., 100 mg weekly or 150 mg every 14 days) may stabilize hormone fluctuations. Elderly men require lower doses, as do boys with delayed puberty. Scrotal and nonscrotal transdermal testosterone patch systems deliver 4 to 6 mg and sustain testosterone profiles. These preparations require adequate shaved scrotal skin for application. Nonscrotal patch sites may develop skin irritation, blisters, and vesicles in about 25% of patients. Some patients require combined patches or low-dose injection to maintain adequate potency and energy levels. There is no apparent cost-benefit advantage of patch delivery over intramuscular injection. Oral androgen replacement therapy with 17-hydroxy ester testosterone undecanoate requires frequent dosing (two to four times daily) and, because absorption is not uniform, testosterone levels may not be adequately maintained. Oral 17-methyltestosterone is associated with hepatotoxicity and not recommended. Testosterone may cause acne, gynecomastia, rarely urine retention related to prostatic obstruction, and polycythemia. Although there is no compelling evidence that testosterone replacement causes prostate cancer, benign prostatic hypertrophy may be exacerbated, especially in elderly patients. Testosterone replacement should not be administered to men with diagnosed prostate cancer.

In patients with hypogonadotropic hypogonadism, fertility may be achieved with gonadotropin or GnRH therapy. In males, coexistence of primary testicular dysfunction precludes the success of direct gonadotropin replacement or GnRH, although the relatively low sperm counts induced may be adequate for impregnation when fertility is induced by gonadotropin or GnRH. Because testosterone therapy may suppress spermatogenesis, the steroid should be discontinued prior to initiating treatment. To induce spermatogenesis, NCG is administered subcutaneously or intramuscularly (500 to 2000 IU two to three times weekly). Lower doses may also be effective. If necessary, after 6 months, human menopausal gonadotropin or purified FSH (75 IU three times weekly) should be added to improve sperm quantity, and doses may be doubled after a further 6 months. If testosterone levels are increased, subsequent conversion to estradiol may be enhanced, resulting in

but are not often associated with specific endocrine syndromes. High serum FSH, usually with low LH levels, is usually the only sign that a pituitary tumor secretes FSH. Paradoxically, these patients may present with hypogonadism related to gonadal down-regulation. Female patients with such tumors may present with pelvic pain caused by ovarian hyperstimulation. High gonadotropin levels associated with menopause or testicular failure may complicate interpretation of gonadotropin levels, but both LH and FSH are high in primary gonadal failure. LH-producing tumors are exceedingly rare and in males cause elevations of serum testosterone with acne and skin oiliness.

**Evaluation**

MRI, visual field examination, and pituitary hormone evaluation should be performed, the last not only to detect hypopituitarism but also to exclude hormone overproduction that may not be clinically apparent. LH, FSH, subunit, PRL, T4, triiodothyronine (T3), TSH, cortisol, and IGF-I levels should be measured. A 24-hour urinary free cortisol measurement by RIA is useful to exclude inapparent ACTH hypersecretion. The extent of hormonal evaluation requires clinical judgment. When LH or FSH is elevated, the values must be interpreted in light of the patient's physiologic state.

**Treatment**

Clinical judgment should be used in determining appropriate therapy including surgery, surgery followed by radiotherapy, radiotherapy alone, or expectant observation. Unfortunately, no reliable tumor marker is predictive of mass growth or recurrence (Fig. 8-35).

If tumors threaten vision or are macroadenomas whose size threatens vital structures, transphenoidal surgery is recommended. Vision improved in approximately 75% of patients whose vision was impaired. Of 100 patients undergoing transphenoidal surgery, 72 had visual disturbances, 81 hypopituitarism, and 36 headache. Vision improved in 53 of 72 patients after surgery, and headache improved in all. Of 50 patients who underwent surgery followed by radiotherapy, 9 had tumor recurrences at a mean of 73 months after radiotherapy and there were 5 recurrences in 42 patients who did not receive radiotherapy. An expectant follow-up of 65 patients after pituitary surgery for nonfunctioning adenomas showed that 32% of tumors grew during a mean follow-up period of 76 months. In a retrospective comparison of 126 patients undergoing surgery alone or surgery with radiation, early postoperative radiotherapy (within 12 months) significantly reduced the risk of tumor regrowth by about 15% at 10 years. Despite the relatively high incidence of postoperative tumor regrowth, even after apparently complete resection, most neurosurgeons avoid routine postoperative radiation therapy. Radiation can be offered if the tumor mass reexpands.

This approach requires advising careful
follow-up with periodic annual MRI studies and visual evaluations. Because patients experience tumor regrowth even after
radiation therapy, all should undergo periodic post-treatment MRI, although less frequently.

**Expectant Observation.**

For nonfunctioning microadenomas or small macroadenomas (incidentalomas), patients may be observed expectantly. Some tumors do not grow over years or even decades. However, regular follow-up with MRI is necessary because these tumors may grow insidiously and are usually asymptomatic until they are large enough to affect vision. Periodic but less frequent endocrine evaluation is also suggested according to the clinical situation. Microadenomas rarely impair vision during pregnancy, whereas macroadenomas do so with greater frequency. Because macroadenomas do not respond to medical therapy, the risks of visual impairment arising during a pregnancy must be weighed carefully and resection prior to pregnancy may be indicated.

**Medications.**

Medications are not effective in reducing tumor size and visual compromise. Although dopamine agonists, GnRH antagonists, and somatostatin analogues modestly reduce tumor size in a few patients, they are not sufficiently effective to be recommended as therapy.
Growth Hormone

Somatotroph Cells

Mammosomatotroph cells expressing both PRL and GH arise from the acidophilic stem cell and immunostain mainly for PRL. Somatotrophs are located predominantly in the lateral wings of the anterior pituitary gland and constitute 35% to 45% of pituitary cells (Fig. 8-36) (Figure Not Available). These ovoid cells contain prominent secretory granules up to 700 µm in diameter. Juxtanuclear Golgi is particularly prominent with secretory granules

Figure 8-36 (Figure Not Available) Normal somatotroph. A somatotroph in the nontumorous pituitary is large, round to ovoid, and contains numerous electron-dense secretory granules whose diameter ranges from 250 to 700 µm. Short profiles of rough endoplasmic reticulum are scattered throughout the cytoplasm. The prominent juxtanuclear Golgi complex harbors forming secretory granules. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 14.)

in formation. The gland contains a total of 5 to 15 mg of GH.

Growth Hormone Biosynthesis

The human GH (hGH) genome locus spans approximately 66 kb and contains a cluster of five highly conserved genes located on the long arm of human chromosome 17q22-24. These are hGH-N, hCS-L, hCS-A, hGH-V, and hCS-B all of which consist of five exons separated by four introns. The hGH-V gene is selectively transcribed in pituitary somatotrophs and encodes a 22-kd (191-amino-acid) protein. The hCS-A and hCS-B genes are expressed in placental trophoblasts. Approximately 10% of pituitary GH is a 20-kd variant lacking amino acid residues 32 to 46. hGH-V, expressed in placental sycloctrophoblasts, encodes a 22-kd protein detected in the maternal circulation from midpregnancy and a minor form, IGH-V2. Elevated maternal IGH-V serum concentrations are accompanied by a decline in hGH-N, suggesting feedback regulation of the maternal hypothalamic-pituitary axis. After childbirth, circulating GH-V levels drop rapidly and are undetectable after 1 hour.

The hGH promoter region contains cis elements that mediate both pituitary-specific and hormone-specific signaling. The POUF1 transcription factor confers tissue-specific GH expression, and a second, ubiquitous factor binds to a distal Pit-1 site containing a consensus sequence for the Sp1 transcription factor. Pit-1 and Sp1 both contribute to GH promoter activation because mutation of the Sp1 binding site attenuates promoter activity. Deoxyribonucleosine hypersensitive sites of a locus control region of the hGH gene determine somatotroph and lactotroph GH expression, which involves regulation of a chromatin domain in these pituitary cells.

GH synthesis and release are under control of a variety of hormonal agents, including GHRH, somatostatin, ghrelin, IGF-I, thyroid hormone, and glucocorticoids. GH stimulates GH synthesis and release mediated by cAMP, CREB binding protein is phosphorylated by protein kinase A and is a cofactor for Pit-1-dependent human GH activation. IGF-I attenuates basal and stimulated GH gene expression.

The GH molecule, a single-chain polypeptide hormone consisting of 191 amino acids, is synthesized, stored, and secreted by somatotroph cells. The crystal structure of human GH reveals four alpha helices. Circulating GH molecules comprise several heterogeneous forms: 22- and 20-kd monomers, acetylated 22K, and two des-amino GH molecules. The 22-kd peptide is the major physiologic GH component, accounting for 75% of pituitary GH secretion. Amino acids 32 to 46 are deleted by alternative splicing of the gene to yield 20-kd GH, accounting for about 10% of pituitary GH. The 20-kd GH has slower metabolic clearance, accounting for the 20-kd/22-kd ratio being higher in plasma than in the pituitary gland. The 22-kd peptide retains growth-promoting activity but lacks diabetogenic effects, which are more pronounced with the 20-kd form.

GHRH and SRIF Interaction in Regulating Growth Hormone Secretion

The somatotroph cell expresses specific receptors for GHRH, GH secretagogues, and SRIF receptor subtypes 2 and 5 that mediate GH secretion. Hypothalamic SRIF and GHRH are secreted in independent waves and interact together with additional GH secretagogues to generate pulsatile GH release. GHRH selectively induces GH gene transcription and hormone release and does not induce other anterior pituitary or gut hormones. SRIF suppresses both basal and GHRH-stimulated GH pulse amplitude and frequency but does not affect GH biosynthesis. GH stimulation to normal adults elicits a prompt rise in serum GH levels, with higher levels occurring in female subjects. Although mature GH comprises 44 amino acids, GH-releasing activity resides in shorter proteolyzed forms involving amino acids 1 to 37 and 1 to 40 and the N-terminus. GH also is a determinant of somatotroph mitotic activity.

The rat hypothalamus releases GHRH and SRIF 180 degrees of out phase every 3 to 4 hours, resulting in pulsatile GH levels. SRIF antibody administration elevates GH levels, with intact intervening GH pulses, implying that hypothalamic SRIF secretion generates GH troughs. Similarly, GHRHR antibodies eliminate spontaneous GH surges. In humans, GH pulsatility persists when GH is tonically elevated as with ectopic tumor GHRH production or during GHRIH infusion, suggesting that hypothalamic SRIF is largely responsible for GH pulsatility. Preexposure to SRIF enhances somatotroph sensitivity to GHRH stimulation. Hence, during a normal GH trough period, the high SRIF level probably primes the somatotroph to respond maximally to a subsequent GHRH pulse, thus optimizing GH release. SRIF also inhibits central GHRIH release through direct synaptic connections with hypothalamic SRIF-containing neurons.

Chronic GHRH stimulation, by either continuous infusion or repeated bolus administration, eventually desensitizes GH release in vitro and in vivo, possibly through depletion of a GHRH-sensitive pool of GH. GHRH pretreatment also decreases somatotroph GHRIH binding sites. GH stimulation hypothalamic SRIF, GHRH and SRIF autoregulate their own secretion, and GHRIH also stimulates SRIF release. GH secretion is further regulated by its target growth factor, IGF-I, which participates in a hypothalamic-pituitary peripheral regulatory feedback system. GH stimulates IGF-I, which exerts a negative feedback effect on the hypothalamus and pituitary. IGF-I stimulates hypothalamic SRIF release and inhibits pituitary GH gene transcription and secretion.

Growth Hormone Secretagogues and Ghrelin

The isolation of ghrelin indicates a control system in addition to GHRH and SRIF in regulation of GH secretion (see Chapter 23). Ghrelin is a 28-amino-acid peptide that binds the GH secretagogue (GHS) receptor to induce hypothalamic GHRH and pituitary GH. A unique n-octanoylated serine 3 residue confers GH-releasing activity to the molecule. Ghrelin
is synthesized primarily in peripheral tissues, especially gastric mucosal neuroendocrine cells. Ghrelin administration dose dependently evokes GH release and also induces food intake and obesity development. It is thought that ghrelin controls GH secretion and peripheral sources may have additional nutritional effects requiring further elucidation. Current evidence suggests that the dual control of GH secretion postulated for GHRH and SRIF should be expanded to incorporate ghrelin.

Synthetic hexapeptides (artificial GHSs) recognize the GHS receptor, induce potent and reproducible GH release, and are useful for the diagnosis of GHD. GHSs stimulate GH secretion, and GHRH and GHSs act through distinct receptors and different intracellular signaling pathways on somatotroph subpopulations. GHSs require the presence of a functional hypothalamus to evoke GH, as evidenced in patients with an intact pituitary but disordered hypothalamic function, in whom GHS does not induce GH. GHSs potentiate GH release in response to a maximal stimulating dose of exogenous GHRH, and after a saturating dose of GHRH, when subsequent GHRH administration is ineffective, GHSs remain fully effective.

Functional GHS receptors are expressed in the human fetal pituitary by the fifth week of gestation. GHS-mediated GH release is demonstrable at birth, continues through infancy, increases at puberty, and decreases thereafter. Estradiol and testosterone increase GH-mediated GH release in childhood. Because GHS-evoked GH secretion is minimally altered by age, sex, or adiposity and is devoid of potential side effects (unlike insulin-induced hypoglycemia), GHSs may become a useful diagnostic tool in the diagnosis of adult GHD. Slight PRL and ACTH or cortisol increases have been reported with some GHSs, leading to the development of novel GHSs with more selective somatotroph actions.

Regulation of Growth Hormone Secretion

Multiple factors regulate the integrated secretion of GH. In some patients with acromegaly or chronic depression, CRH modestly increases GH. GnRH stimulates GH secretion in about one third of patients with GH responses to TRH are evoked in patients with liver disease, renal disease, ectopic GHRH-releasing carcinoid tumors, anorexia nervosa, and depression. Intravenous CRH modestly increases GH in some patients with acromegaly or chronic depression. GnRH stimulates GH secretion in about one third of patients with acromegaly.

Other Hormones Facilitating Growth Hormone Secretion

Acute glucocorticoid administration stimulates GH secretion, whereas chronic steroid treatment inhibits GH. Three hours after acute glucocorticoid administration, GH levels rose and remained elevated for 2 hours. However, supraphysiologic glucocorticoid exposure retarded growth, and Cushings disease was also associated with growth retardation, decreased serum GH, and decreased pituitary content surrounding the adenoma. Glucocorticoids administered to normal subjects do not inhibit GHRH-stimulated GH secretion in a manner similar to that seen in Cushing's syndrome. Furthermore, cortisol antagonizes peripheral GH action.

GH levels are decreased in hyperthyroid patients but become normal when patients are rendered euthyroid, suggesting that thyroid hormone suppresses GH secretion. Elevated circulating gonadal steroids observed during puberty may also account for higher pubertal GH levels. Estradiol stimulates GH secretory rates, and testosterone increases GH secretory mass per pulse with resultant IGF-I induction. Elevated circulating gonadal steroids may also account for higher pubertal GH levels. Estradiol stimulates GH secretory rates, and testosterone increases GH secretory mass per pulse with resultant IGF-I induction. Higher pubertal GH levels are associated with elevated GH pulse frequency and amplitude.

Neuropeptides, neurotransmitters, and opiate impinge on the hypothalamus and modulate GHRH and somatostatin (SRIF) release. Integrated effects of these complex neurogenic influences determine the final secretory pattern of GH. Apomorphine, a central dopamine receptor agonist, stimulates GH release. As does levodopa treatment. Oral levodopa administration evokes a brisk serum GH response within an hour in healthy young subjects. Norepinephrine increases GH secretion through -adrenergic pathways and inhibits GH release through -adrenergic pathways. Insulin-induced hypoglycemia, clonidine, arginine administration, exercise, levodopa, and arginine vasopressin facilitate GH release through -adrenergic effects. -Adrenergic blockade increases GHRH-induced GH release, possibly by a direct pituitary action or by decreasing hypothalamic somatostatin release. Endorphins and enkephalins stimulate GH and may account for GH release during severe physical stress and extreme exercise. Galanin, a 29-amino-acid neuropeptide, induces GH release and responses to GHRH. Cholinergic and serotoninergic neurons and several neuropeptides stimulate GH, including neuropeptide Y and somatostatin reverse starvation-induced GH release. In GH-deficient hypopituitary adults, elevated concentrations are higher than would be expected from their body fat mass.

Neuropeptides, neurotransmitters, and opiate impinge on the hypothalamus and modulate GHRH and somatostatin (SRIF) release. Integrated effects of these complex neurogenic influences determine the final secretory pattern of GH. Apomorphine, a central dopamine receptor agonist, stimulates GH release. GHRH is synthesized primarily in peripheral tissues, especially gastric mucosal neuroendocrine cells. Ghrelin administration dose dependently evokes GH release and also induces food intake and obesity development. It is thought that ghrelin controls GH secretion and peripheral sources may have additional nutritional effects requiring further elucidation. Current evidence suggests that the dual control of GH secretion postulated for GHRH and SRIF should be expanded to incorporate ghrelin.

Synthetic hexapeptides (artificial GHSs) recognize the GHS receptor, induce potent and reproducible GH release, and are useful for the diagnosis of GHD. GHSs stimulate GH secretion, and GHRH and GHSs act through distinct receptors and different intracellular signaling pathways on somatotroph subpopulations. GHSs require the presence of a functional hypothalamus to evoke GH, as evidenced in patients with an intact pituitary but disordered hypothalamic function, in whom GHS does not induce GH. GHSs potentiate GH release in response to a maximal stimulating dose of exogenous GHRH, and after a saturating dose of GHRH, when subsequent GHRH administration is ineffective, GHSs remain fully effective.

Functional GHS receptors are expressed in the human fetal pituitary by the fifth week of gestation. GHS-mediated GH release is demonstrable at birth, continues through infancy, increases at puberty, and decreases thereafter. Estradiol and testosterone increase GH-mediated GH release in childhood. Because GHS-evoked GH secretion is minimally altered by age, sex, or adiposity and is devoid of potential side effects (unlike insulin-induced hypoglycemia), GHSs may become a useful diagnostic tool in the diagnosis of adult GHD. Slight PRL and ACTH or cortisol increases have been reported with some GHSs, leading to the development of novel GHSs with more selective somatotroph actions.

Regulation of Growth Hormone Secretion

Multiple factors regulate the integrated secretion of GH. In some patients with acromegaly or chronic depression, CRH modestly increases GH. GnRH stimulates GH secretion in about one third of patients with GH responses to TRH are evoked in patients with liver disease, renal disease, ectopic GHRH-releasing carcinoid tumors, anorexia nervosa, and depression. Intravenous CRH modestly increases GH in some patients with acromegaly or chronic depression. GnRH stimulates GH secretion in about one third of patients with acromegaly.

Other Hormones Facilitating Growth Hormone Secretion

Acute glucocorticoid administration stimulates GH secretion, whereas chronic steroid treatment inhibits GH. Three hours after acute glucocorticoid administration, GH levels rose and remained elevated for 2 hours. However, supraphysiologic glucocorticoid exposure retarded growth, and Cushings disease was also associated with growth retardation, decreased serum GH, and decreased pituitary content surrounding the adenoma. Glucocorticoids administered to normal subjects do not inhibit GHRH-stimulated GH secretion in a manner similar to that seen in Cushing's syndrome. Furthermore, cortisol antagonizes peripheral GH action.

GH levels are decreased in hyperthyroid patients but become normal when patients are rendered euthyroid, suggesting that thyroid hormone suppresses GH secretion. Elevated circulating gonadal steroids observed during puberty may also account for higher pubertal GH levels. Estradiol stimulates GH secretory rates, and testosterone increases GH secretory mass per pulse with resultant IGF-I induction. GH responses to TRH are evoked in patients with liver disease, renal disease, ectopic GHRH-releasing carcinoid tumors, anorexia nervosa, and depression. Intravenous CRH modestly increases GH in some patients with acromegaly or chronic depression. GnRH stimulates GH secretion in about one third of patients with acromegaly.

Growth Hormone Binding Proteins

Circulating GH binding proteins (GHBPs) include a 20-kd low-affinity BP and a 60-kd high-affinity BP, which corresponds to the extracellular domain of the hepatic GH receptor and binds half of the circulating 22-kd GH form. The 20-kd GH binds preferentially to the low-affinity BP, which is unrelated to the GH receptor. The GHBPs function to damp acute oscillations in serum GH levels associated with pulsatile pituitary GH secretion, and the plasma half-life of GH is prolonged by...
decreased renal clearance of bound GH. The high-affinity BP also prevents GH binding to surface GH receptors by competing for the GH ligand. Patients with hypopituitarism or acromegaly have normal BP concentrations. GH resistance, as demonstrated in malnutrition, chronic liver disease, short stature, Laron dwarfism, and some African pygmies, is characterized by decreased BP levels in plasma. High BP levels are encountered in obese or pregnant subjects or those receiving estrogens or undergoing refeeding.

**Peripheral Growth Hormone Action**

GH acts to mediate growth and metabolic functions (Fig. 8-40). GH elicits intracellular signaling though a peripheral receptor and initiates a phosphorylation cascade involving the JAK/STAT pathway. The liver contains abundant GH receptors, and several peripheral tissues also express modest amounts of receptor, including muscle and fat (Fig. 8-41). The GH receptor is a 620-amino-acid, 70-kd protein of the class I cytokine-hematopoietin receptor superfamily consisting of an extracellular ligand-binding domain, a single membrane-spanning domain, and a cytoplasmic signaling domain. The GH receptor superfamily is homologous with receptors for PRL, interleukins 2 to 7, erythropoietin, interferon, and colony-stimulating factor.

GH complexes with two GH receptor components leading to receptor dimerization critical for subsequent GH signaling. Dimerization is followed by rapid JAK2 tyrosine kinase activation leading to phosphorylation of intracellular signaling molecules, including the signal-transducing activators of transcription proteins (STATs 1, 3, and 5), critical signaling components.

**IGF-I, a critical growth factor induced by GH, is probably responsible for most growth-promoting activities of GH** and also directly regulates GH receptor function. Paracrine IGF-I produced in extrathoracic tissues appears critical for growth because growth persists even when hepatic IGF-I is depleted in mice. GH receptor mutations are associated with partial or complete GH insensitivity and growth failure. These syndromes are associated with normal or high circulating levels, decreased circulating GHB levels, and low levels of circulating IGF-I. Multiple homozygous or heterozygous exonic and intronic GHR mutations have been described. Tissue responses to GH signaling are determined by the pattern of GH secretion in addition to the absolute amount of circulating hormone. Gender-specific patterns of GH secretion profiles determine sex-specific expression of cytokrome P450 enzymes. In turn, circulating steroids regulate neuroendocrine release of GH. SRIF, by suppressing interpulse GH levels, serves to masculinize the ultradian GH rhythm. In mice harboring a disrupted SRIF gene, plasma GH secretory patterns were elevated and liver enzyme induction lost its gender-specific dimorphism but the animals retained sexually dimorphic growth patterns.

Linear growth patterns and GH dose induction are phenotypically gender-specific because of higher GH pulse frequency rates and also show gender-specific STAT5b activity. Sexually dimorphic patterns of GH secretion and tissue targeting appear to be determined by STAT5b, which is sensitive to repeated pulses of injected GH, whereas other GH-induced responses are desensitized by repeated administration. Disruption of STAT5b in transgenic mice caused impaired male-pattern body growth associated with female-pattern IGF-I and testosterone levels. Appropriate GH pulsatility is also required to determine body growth mediated by STAT5b but not for metabolic effects of GH on carbohydrate metabolism.

Intracellular GH signaling is abrogated by suppression of cytokine signaling (SOCS) proteins, which disrupt the JAK/STAT pathway and thus disrupt GH action. In transgenic mice with deletion of SOCS-2, gigantism develops, presumably because of unrestrained GH action. Because SOCS proteins are also induced by proinflammatory cytokines, critically ill patients or those with renal failure may experience GH resistance related to cytokine-induced SOCS proteins. Unraveling STAT-SOCS regulation in syndromes associated with disordered GH signaling should yield mechanistic insights into dysregulated GH action. The impact of GH on growth is fully reviewed in Chapter 23. Extrapolitarily GH and GH secretagogues may complement the classical endocrine action between the GH-releasing factors, GH, and target tissues. Although GH immunoreactivity and mRNA expression have been documented in placenta, mammary gland, muscle, spleen, and lymphocytes, their physiologic role is not yet apparent.
**GH** is anabolic and causes urinary nitrogen retention, decreased plasma urea levels, and increased muscle mass. GH increases fat mobilization, decreases fat deposition, and activates hormone-sensitive lipase, resulting in increased triglyceride hydrolysis to free fatty acids and glycerol (lipolysis) and also decreased fatty acid reesterification. Replacement of GH in GH-deficient adults leads to decreased body fat and decreased adipocyte size and lipid content. As GH is degraded in the kidney, GH levels are elevated in patients with chronic renal failure and GH rises paradoxically in response to a glucose load in these patients.

**Growth Hormone Secretion Patterns**

Frequent serum sampling for measurements of GH concentrations has revealed a pattern of pulsatile secretion separated by troughs, during which GH is undetectable (<0.4 µg/L) (Table 8-19). Using currently available assays, random GH levels are undetectable in 50% of samples obtained from healthy subjects. GH secretion is high in the fetal circulation, peaking at about 150 µg/L during midgestation. Neonatal levels are lower (30 µg/L), possibly reflecting negative feedback control by rising levels of circulating IGF. GH levels during childhood (up to 7 µg/L) are characterized by enhanced pubertal GH pulse amplitude and mass with unchanged GH pulse frequency. GH pulse amplitudes decline inexorably with age, and GH levels in middle age are about 15% of pubertal levels. Healthy adult males produce GH at about 0.25 to 0.52 mg/m² per 24 hours. Obesity is associated with decreased GH pulse frequency and blunted evoked GH responses to secretagogues. In contrast, fasting is associated with enhanced GH pulse frequency and amplitude, possibly reflecting altered feedback regulation by nutritionally mediated changes in IGF binding protein concentrations and free IGF-I availability.

**Measurement of Spontaneous Growth Hormone Secretion**

Because pituitary GH secretion occurs episodically, accurate quantification of integrated GH secretion requires continuous measurement of secretion over 24 hours. This procedure requires insertion of a continuous withdrawal pump or patent indwelling catheter with unrestricted food intake and physical activity. Increasing sampling frequencies from every 20 minutes to 5-minute or 30-second sampling intervals enhances the threshold for detecting more pulses per hour. Although cumbersome and expensive, this method eliminates the error of isolated peak or trough measurements that might otherwise be obtained by single or multiple random GH samplings.

The discriminating power of continuous 24-hour GH measurement in the diagnosis of GHD in children has been disputed. With no clear diagnostic advantage over GH stimulation tests, integrated GH levels in young healthy subjects may overlap those of patients with organic hypopituitary disorders, which limits the utility of the measurement in the diagnosis of acquired adult GHD. However, fasted subjects may exhibit a clear distinction of deficient integrated GH levels measured over 8 hours.

**Urinary Growth Hormone Measurement**

Immunoassay methods for urinary GH measurement do not reliably reflect pharmacologic GH testing or adequately discriminate between normal and abnormal GH secretion. Clinical utility of urinary GH measurements requires rigorous agematched and gender-matched control subjects and standardized expression of GH concentrations relative to body weight or creatinine excretion.

**Variability of Growth Hormone Assays**

Plasma GH is measured by RIA (polyclonal or monoclonal) or by IRMA (dual monoclonal), but comparative GH measurements obtained using 11 commercial immunoassays varied by a factor of 3. Measured GH concentrations are antibody-dependent, and different antibodies bind to a heterogeneous spectrum of GH isoforms. Furthermore, GH isoform patterns vary between individuals and not all circulating GH forms are routinely detectable in GH assays adding further variation to comparison of results from different GH immunoassays. Monomeric 22-kd GH, the most abundant circulating form, is the only GH standard of sufficient purity and quantity and is used as the basis for GH measurement; however, it accounts for only about 25% of circulating immunoreactivity. Other GH forms are recognized to varying and largely unknown degrees. Polyclonal antibodies used in earlier RIAs recognized several molecular forms of GH as compared with newer immunometric assays employing highly specific monoclonal antibodies.

GH standards also affect comparison of GH values. In 1994, the first World Health Organization international standard for somatotropin, IRP 88/624, used recombinant technology, whereas previous standards were prepared from pituitary extracts. GHBPs may also interfere because approximately 50% of GH is bound by GHBP, spuriously high GH values may be reported. The heterogeneity of GH immunoassay results poses a challenge in the definition of accepted standards for diagnosis of GHD. However, the RIA is now infrequently used and clinicians should be aware of the nature of the GH assay employed and how values compare with those previously obtained by polyclonal RIA. New GH assays based on measuring GH bioactivity have been developed, including the eluted stain assay (ESTA) and the immunofunctional assay (IFA). The 22-kd exclusion assay (GHEA) also measures circulating GH isoforms.

**Growth Hormone Deficiency**

GHD in adults is recognized as a distinct adult syndrome (Table 8-20). GH is the most frequently deficient of the pituitary hormones in patients with pituitary disease, and GH has negative effects on body composition, cardiovascular risk factors, and quality of life. Life expectancy is reduced in hypopituitary patients with GHD and largely as a consequence of cardiovascular and cerebrovascular events, especially in female subjects. Although neither estrogen nor thyroid deficiency accounts for these risk factors and reduced survival, it has not yet been rigorously confirmed that the observed increased mortality and morbidity are solely a result of GHD.

**Pathophysiology**

Adult GHD is most frequently encountered in patients with pituitary or hypothalamic disease. Although pituitary tumors and craniopharyngiomas are associated with GHD, these patients may also experience GHD as a result of head or neck radiotherapy. GHD in children is typically isolated GHD or results from rare genetic causes (see Chapter 23) or other central structural abnormalities. Isolated GHD may be complete or partial, and up to 67% of children initially diagnosed with “idiopathic” GHD had normal GH responses when retested for GHD after cessation of GH treatment as adults. Children with GHD should be retested before GH treatment is continued into adulthood unless they have clearly documented panhypopituitarism or a defined genetic or developmental abnormality that causes complete and irreversible GHD. Mutations in the GH and GHRH receptor genes and GH insensitivity as a result of primary GH receptor dysfunction result in GHD. Other

specific GH secretagogues. The insulin tolerance test (ITT) has remained the "gold standard" test for GHD. Although some GH secretagogues reliably differentiate normal GH reserve from GHD, others are not as effective in clearly distinguishing between normal and deficient because of overlapping GH values (Table 8-21).

Differences in published responses can also be accounted for by gender, weight, or possibly age. For example, the mean peak GH response to arginine plus GHRH, GHRH plus hexarelin, or GHRH plus GH-releasing peptide 6 was administered than when insulin-induced hypoglycemia was employed. Although a GH response of less than 3 µg/L has been considered consistent with GHD according to a current consensus, the recommended cutoff points below which adult patients should be considered to have GHD vary according to the test employed (Fig. 8-42). Not unexpectedly, patients with pituitary disease with no or one pituitary hormone deficiency have a lower incidence of GHD than patients with multiple hormone deficiencies. When 3 or more pituitary hormones are deficient, or if patients had pituitary disease with no or one pituitary hormone deficiency, a GH stimulation test may not be required to diagnose adult GHD.

Use of ghrelin, an endogenous ligand for the GH-releasing peptide receptor, may also be proposed as a test for GHD because ghrelin is a potent GH secretagogue. The requirement to test patients with proven panhypopituitarism has been questioned because virtually all patients with more than two trophic hormone deficiencies are also GH-deficient. Although mean serum IGF-I levels are low in adults with GHD and very low IGF-I levels may indicate GHD, IGF-I is not useful in a screening test in adults because about 60% of GH-deficient adults have normal IGF-I levels for their age and gender. Forty percent of patients older than 60 years with GHD had IGF-I concentrations that were normal for their age and gender. Measurement of IGF-BP3 is also not a reliable screening procedure for adult GHD.

Symptoms of GHD are nonspecific and may include fatigue, lack of energy, social isolation, poor concentration, and memory loss. Signs include increased fat mass (especially abdominal and visceral), decreased lean body mass, decreased body water, and decreased bone density, particularly in patients with more severe GHD and long-standing childhood-onset GHD. Other features include hyperlipidemia, reduced exercise capacity, and an increase in cardiovascular

As GH is secreted in a pulsatile manner, the diagnosis of GHD requires tests of evoked GH sufficiency in response to
risk factors including abdominal adiposity, insulin resistance, and increased carotid intimal thickness. GHD may also be associated with heart abnormalities including reduced left ventricular mass. Cardiovascular parameters of GHD are often more pronounced in adults who had childhood-onset GHD than in those who acquired the deficiency during adulthood, who have more pronounced disorders involving quality of life, lipids, and body composition.

Many symptoms of GHD are nonspecific, and clinical judgment should be exercised in selecting patients for testing. Patients with pituitary or hypothalamic disease should be considered for diagnosis of GHD and replacement with GH even in the absence of other pituitary hormone deficiencies. Deficiencies in sex hormones also lead to body composition changes similar to those observed in GHD. For example, testosterone deficiency causes decreased lean body mass and increased fat mass, each of which can be partially improved when testosterone is administered. That GH has additional positive effects on body composition is suggested by observations that many patients with GHD whose body composition parameters improved after GH replacement were already receiving sex steroids. A study of healthy volunteers also demonstrated inhibition of catabolic effects when hGH was given along with prednisone.

**Growth Hormone Replacement Therapy**

See Table 8-20. Treatment of GH-deficient adults with recombinant hGH for 4 to 6 months increased lean body mass and decreased fat mass (Fig. 8-43 and Fig. 8-44). In a review of nine placebo-controlled trials, hGH (in doses ranging from 2.6 to 26 µg/kg/day) increased lean body mass by a mean of 3.4 kg and reduced fat mass by 4.4%. GH also increased bone density and parameters of both bone formation and bone resorption. The GH-induced reduction in abdominal and visceral fat suggests an associated improvement in cardiovascular risk factors.

* Results from two studies on the effects of insulin-induced hypoglycemia and the combination of arginine and GHRH illustrate the effect of body weight on GH responses.

The effect of hGH replacement on lipid abnormalities is variable. The hGH had a significant effect on raising high-density lipoprotein cholesterol and overall the most consistent change was an improvement in the ratio of cholesterol to high-density lipoprotein cholesterol. Some have reported increases in cardiac output, reduction in intima media thickness, and improved energy, mood, and quality of life, but not all investigators concur. Improved quality of life, including a significant reduction in sick days, hospitalization length, and physician visits, has been reported in some studies. There may be a latency period up to 3 months before patients recognize the benefits of hGH replacement, which are most obvious in those with the most profound symptoms and signs of GHD. Beneficial effects...
of GH replacement persist for at least 10 years. 

GH Administration.

GH is administered by nightly subcutaneous injection, the recommended dose for adults is much lower than for children, and children experience fewer side effects of GH than adults. Men, particularly older ones, are more sensitive to GH and require lower GH doses than women. The maintenance dose of hGH in 665 adult patients with GHD was 0.43 mg/day for men and 0.53 mg/day for women. Women with GHD require higher doses of hGH with oral than with transdermal estrogen (Fig. 8-45). It is recommended that replacement be initiated with relatively low doses. Most adults tolerate a starting dose of 300 µg/day or lower, which is then titrated according to serum IGF-I concentrations and side effects of the medication. If side effects occur, the dose should be reduced. If no side effects are reported, the therapeutic goal is to maintain IGF-I levels in the normal range for age and gender while avoiding levels in the upper quintile.

Precautions and Caveats of Treating with Human Growth Hormone

The most common side effects of hGH are edema, arthralgias, and myalgias which occurred in up to one third of patients when the drug was administered at a weight-based dosage. Using total daily doses titrated for IGF-I levels, the incidence of side effects is much lower. Patients with active malignancies should not be treated with GH, nor should patients with active carpal tunnel syndrome or other fluid retention disorders. The possibility that hGH might initiate new cancers or stimulate growth of preexisting benign tumors is an important theoretical issue. An epidemiologic association between higher, albeit normal, IGF-I levels and later risk of development of prostate cancer, breast cancer in premenopausal women, and colon and lung cancer has been reported. In contrast, patients with acromegaly, who have very high serum levels of IGF-I, do not have an increased incidence of either breast or prostate cancer or cancer in general. In fact, the overall risk for cancer in acromegaly is lower than expected. However, these patients have significantly increased mortality from colon cancer.

The possibility that hGH treatment might cause new or recurrent malignancies has been best examined in children in whom GHD developed as a result of treatment. When the relative risk of brain tumor recurrence in 180 children treated with hGH versus 891 who did not receive hGH was analyzed, the risk of recurrence after a mean of 6.4 years was lower in the treated group than those not receiving hGH. Nevertheless, long-term surveillance with adequate control groups and avoidance of high IGF-I levels in adults being treated for GHD are required to ensure that GH replacement in adults does not increase the incidence of new cancers or growth of existing benign tumors. Blood glucose levels should also be monitored carefully, especially in patients also being treated for diabetes.

Growth Hormone Treatment of Catabolic States

The well-recognized anabolic actions of GH have prompted use of GH in catabolic states including those associated with surgery, trauma, burns, parenteral nutrition, and organ failure. These potential indications for GH are not approved in the United States. The negative nitrogen balance in critically ill patients is partly attributable to GH resistance as well as to decreased IGF-I production and action. GH administered to postsurgical patients as well as to normal subjects receiving hypocaloric intravenous alimentation results in reversion to positive nitrogen balance.

Beneficial effects of GH have been reported in patients with extensive burns, chronic high-dose glucocorticoid treatment, chronic obstructive pulmonary disease, cancer, and cardiac failure. Nevertheless, published end points for these studies have not been definitive. When GH was administered to elderly malnourished patients, it was found to be an effective adjuvant for dietary augmentation. A study in which critically ill patients...

received very high doses of GH (up to 7 mg/day) was prematurely terminated because of unexplained increased mortality. It was suggested that GH may have had an adverse effect on acute phase protein synthesis in these patients.

Growth Hormone Treatment for Osteoporosis

As declining GH secretion has been implicated in the pathogenesis of osteoporosis, GH was administered to otherwise healthy subjects with idiopathic osteoporosis in an attempt to decrease bone loss. GH increased indices of bone formation and resorption, but a modest increase in spine bone mineral density was observed only in male subjects. A longer study in osteoporotic female subjects showed that GH together with calcitonin increased spine and total hip bone mineral density after 2 years of treatment, although the response was less marked than that observed with estrogen or bisphosphonate therapy. Limited proven efficacy, unclear side effects, and lack of comparative studies with other beneficial therapies for osteoporosis indicate a need for further study of the potential use of GH in treating osteoporosis.

Growth Hormone Treatment in Human Immunodeficiency Virus Infection

GH is approved by the Food and Drug Administration for administration to adult patients with human immunodeficiency virus (HIV) associated cachexia. The GH treatment resulted in positive nitrogen balance, increased lean body mass, decreased body fat, and improved work output. Ten HIV-infected subjects with fat redistribution syndrome associated with protease inhibitor therapy received GH at 6 mg/day subcutaneously for 12 weeks and showed decreased weight/hip ratios and enhanced mid thigh circumference. However, long-term beneficial effects of GH on survival and quality of life in HIV infection have not yet been reported.

Growth Hormone Use in Competitive Sports

The public policy issues of GH abuse in competitive sports have received much attention. GH has been used by athletes to enhance muscle mass. Whether persistent GH use is accompanied by increased muscle strength is unclear. Continued use of pharmacologic GH doses by athletes could result in adverse effects of acromegaly, which would decrease performance.

Decreased Insulin-like Growth Factor I Levels

Short-term fasted normal healthy subjects have moderately elevated basal GH levels, and protein-calorie malnutrition, starvation, and anorexia nervosa are associated with low IGF-I and markedly elevated GH levels. This observation may reflect uncoupling of IGF-I feedback regulation of GH secretion. Low IGF-I levels in normal fasting subjects are normalized by caloric refeeding to a greater degree than by protein intake alone.
Acromegaly

In 1866 Pierre Marie published the first clinical description of disordered somatic growth and proportion and proposed the name acromegaly. He also recognized cases previously described by others. When the relation of this syndrome to a pituitary tumor was later recognized, Benda showed in 1900 that these tumors comprise mainly adenohypophyseal eosinophilic cells, which he proposed to be hyperfunctioning. Cushing, Davidoff, and Bailey documented the clinicopathologic features of acromegaly and demonstrated clinical remission of soft tissue signs after adenoma resection. Evans and Long induced gigantism in rats injected with anterior pituitary extracts, confirming the association of a pituitary factor with somatic growth. Establishment of the unequivocal pathophysiologic link between hyperfunctioning adenoma and acromegaly represented the earliest example of a pituitary disorder being clinically and pathologically recognized and appropriately managed by surgical excision of a hypersecreting source.

Incidence

The prevalence of acromegaly is estimated to range from 38 to 69 cases per million, and the annual incidence of new patients is 3 to 4 cases per million. On the basis of these largely Western European studies, it is estimated that over 1000 new cases of acromegaly are diagnosed annually in the United States.

Pathogenesis

GH and IGF-I act both independently and dependently in inducing features of hypersonsomatotropism. Acromegaly is caused by pituitary tumors secreting GH or rarely by extrapituitary disorders (Fig. 8-47) (Figure Not Available). Regardless of the etiology, the disease is characterized by elevated levels of GH and IGF-I with resultant signs and symptoms of hypersonsomatotropism.

Pituitary Acromegaly

More than 95% of patients with acromegaly harbor a GH-secreting pituitary adenoma (Table 8-23). Pure GH cell adenomas contain either densely or sparsely staining cytoplasmic GH granules, and these two variants grow slowly (densely granulated) or rapidly (sparsely granulated). The former arise insidiously and occur during or after middle age, whereas the latter arise in younger subjects with more florid disease. Mixed GH cell and PRL cell adenomas are composed of distinct somatotrophs expressing GH and lactotrophs expressing PRL. Monomorphic acidophilic stem cell adenomas arise from the common GH and PRL stem cell and also often contain giant mitochondria and misplaced GH granule exocytosis. They grow rapidly, are invasive, and arise with predominant features of hyperprolactinemia. Monomorphic mammomatosomatotroph cell adenomas express both GH and PRL from a single cell, and plurihormonal tumors may express GH with any combination of PRL, TSH, ACTH, or subunit. These patients present with clinical features of acromegaly as well as hyperprolactinemia, Cushing's disease, or rarely hyperthyroxinemia.

Somatotroph hyperplasia is difficult to distinguish from a GH cell adenoma, and silver staining displays a well-preserved reticulin network without a surrounding pseudocapsule. The rigorous morphologic diagnosis of GH cell hyperplasia is usually associated with stimulation by ectopic GHRH derived from an extrapituitary tumor causing acromegaly. Silent somatotroph adenomas immunostain positively for GH and are apparently clinically nonfunctional, although GH or PRL levels, or both, may be modestly elevated in over 50% of these patients.

Pathogenesis of Somatotroph Cell Adenomas

Both pituitary and hypothalamic factors influence pituitary tumor pathogenesis. Even when exhibiting marked nuclear pleomorphism, mitotic activity, and invasiveness, these tumors are usually benign.

Disordered GHRH Secretion or Action.

Adenomas express receptors for GHRH, ghrelin, and SRIF, but activating mutations of the GHRH or SRIF receptor have not been reported. GHRH directly stimulates GH gene expression and also induces somatotroph mitotic activity. Transgenic GHRH expression causes somatotroph hyperplasia and ultimately adenoma. Clinically, GHRH production by hypothalamic, abdominal or chest neuroendocrine tumors causes somatotroph hyperplasia and occasionally adenoma with resultant unrestrained GH secretion and acromegaly. However, histologic examination of most pituitary GH cell adenoma tissue specimens does not show hyperplastic somatotroph tissue surrounding the adenoma, implying no generalized hypothalamic overstimulation. Failure to down-regulate GH secretion during prolonged GHRH stimulation also points to a role for GHRH in maintaining persistent GH hypersecretion. Expression of intra-adenomatous GHRH correlates with tumor size and activity, implying a paracrine role for GHRH in mediating adenoma pathogenesis. GH modestly stimulates PRL secretion, and up to 40% of patients with acromegaly also have hyperprolactinemia.

Complete surgical resection of well-defined GH-secreting microadenomas usually results in a definitive cure of excess hormone secretion with low postoperative tumor recurrence rates, strongly suggestive of intact hypothalamic function in these patients. Although basal GH levels are usually high in acromegaly, the episodic pulsatile pattern of GH release is intact and the nocturnal GH surge usually preserved. Patients treated with SRIF analogues also retain GH pulsatility, and GH pulse amplitude and sensitivity to GHRH appear intact.

Disordered Somatotroph Cell Function.

A somatotroph mutation may be a prerequisite for the abnormal growth response to disordered GH secretion or action. The monoclonal origin of somatotroph adenomas was determined by X-chromosome inactivation analysis of somatotroph tumor DNA. An altered Gs protein identified in a subset of GH-secreting pituitary adenomas led to high levels of intracellular cAMP and GH hypersecretion. Point mutations in two critical sites, Arg201, the site for adenosine diphosphate ribosylation, and Gly227, the guanosine triphosphate binding domain of Gs proteins, prevent guanosine triphosphatase activity and result in constitutive adenyl cyclase activation. This dominant gain mutant mimics GHRH effects, results in elevated cAMP levels, and is present in about 30% of GH-secreting tumors. Loss of heterozygosity has been observed for chromosomes 11, 13, and 9, especially in larger, more invasive macroadenomas. However, no defined tumor suppressor gene has been isolated for these sporadic nonfamilial tumors. An activating pituitary tumor transforming gene (PTTG) isolated from pituitary tumors is overexpressed in GH-secreting tumors, and its abundance correlates with tumor size and invasiveness. PTTG participates as a securin protein, regulating sister chromatid separation during the cell cycle, and its overexpression may lead to cell aneuploidy.

The sequence of events leading to somatotroph clonal expansion appears multifactorial. An activated oncogene may be required for initiating tumorigenesis, and promotion of tumor growth may require GHRH and other growth factor stimulation. The cellular mutation may not by itself be sufficient to provide a growth advantage for a GH-secreting adenoma without additional disordered hypothalamic or paracrine growth factor signaling.

Extrapituitary Acromegaly

Microadenomas usually result in a definitive cure of excess hormone secretion with low postoperative tumor recurrence rates, strongly suggestive of intact hypothalamic function in these patients. Although basal GH levels are usually high in acromegaly, the episodic pulsatile pattern of GH release is intact and the nocturnal GH surge usually preserved. Patients treated with SRIF analogues also retain GH pulsatility, and GH pulse amplitude and sensitivity to GHRH appear intact.
Excess GH secretion in acromegaly may not necessarily be pituitary in origin. Because management of ectopic acromegaly differs from that of pituitary GH hypersecretion, rigorous clinical and biochemical criteria should be fulfilled to confirm the diagnosis of ectopic acromegaly. These criteria include demonstration of elevated circulating GHRH or GH levels in the absence of a primary pituitary lesion, a significant arteriovenous hormone gradient across the ectopic tumor source, biochemical and clinical cure of acromegaly after resection of the ectopic hormone-producing tumor, and normalization of the GHRH-GH-IGF-I axis. Finally, GHRH or GH gene product expression should be shown. Patients with inconclusive imaging, biochemical, or clinical features of pituitary acromegaly may inadvertently be diagnosed as harboring a nonpituitary source of excess GH secretion and be inappropriately treated.

**GHRH Hypersecretion.**

Hypothalamic tumors, including hamartomas, choristomas, gliomas, and gangliocytomas, may produce GHRH with subsequent somatotroph hyperplasia or even a pituitary GH cell adenoma and resultant acromegaly. Primary mammosomatotroph hyperplasia with no evidence for pituitary adenoma or an extrapituitary tumor source of GHRH has been described in gigantism. The structure of hypothalamic GHRH was, in fact, elucidated from material extracted from pancreatic GHRH-secreting tumors in patients with acromegaly.

</tbody>
</table>

GHRH immunoreactivity is detectable in about 25% of carcinoid tumor samples. Acromegaly in these patients is uncommon, however. In a retrospective survey of 177 patients with acromegaly, only a single patient was identified with elevated plasma GHRH levels. Bronchial carcinoids make up most tumors associated with ectopic GHRH secretion. Pancreatic cell tumors, small cell lung cancers, adrenal adenoma, pheochromocytoma, and medullary thyroid, endometrioid, and breast cancers have rarely been described to express GHRH and cause acromegaly. Surgical resection of the tumor secreting ectopic GHRH should reverse the GH hypersecretion, and pituitary surgery is not required in these patients. Carcinoid syndrome with ectopic GHRH secretion can also be managed with somatostatin analogues, which lower GH and IGF-I levels and suppress ectopic tumor elaboration of GHRH.

**Ectopic Pituitary Adenomas.**

GH-secreting adenomas may arise from ectopic pituitary remnants in the sphenoid sinus, petrous temporal bone, or nasopharyngeal cavity. Rarely, pituitary carcinoma may spread to the meninges, CSF, or cervical lymph nodes, resulting in functional GH-secreting metastases that may be diagnosed by radiolabeled octreotide imaging (indium In 111 pentetreotide [OctreoScan]).
Peripheral GH-Secreting Tumors.

Lung adenocarcinoma, breast cancer, and ovarian tissues contain immunoreactive GH without clinical evidence of acromegaly. Rarely, a GH-secreting intramesenteric pancreatic islet cell tumor causes acromegaly; these patients present with an intra-abdominal mass, a normal-sized or small pituitary gland on MRI, no GH response to TRH injection, and normal levels of circulating plasma GHRH.

Acromegolism.

Rarely, conditions exhibiting soft tissue and skin changes usually associated with acromegaly and normal baseline and dynamic GH and IGF-I with no demonstrable pituitary or extrapituitary tumor have been termed acromegolism. Pachydermoperiostosis should be considered in the differential diagnosis. Insulin resistance and defective IGF-I binding have been demonstrated in cells derived from some patients with acanthosis nigricans, and treatment is symptomatic.

McCune-Albright Syndrome.

This rare hypersecretory syndrome consists of polyostotic fibrous dysplasia, cutaneous pigmentation, sexual precocity, hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly. Although few patients have definitive evidence of a pituitary adenoma, Gs mutations have been detected in both endocrine and nonendocrine tissues. GH hypersecretion can be controlled by somatostatin analogues or pituitary irradiation.

Multiple Endocrine Neoplasia.

GH cell pituitary adenoma is a well-documented component of the autosomal dominant MEN-1 syndrome, which also includes parathyroid and pancreatic tumors (see Chapter 36). MEN-1, associated with germ cell inactivation of the MENIN tumor suppressor gene located on chromosome 11q13, appears intact in sporadic GH cell adenomas. Rarely, functional pancreatic tumors in patients with MEN-1 also express GHRH.

Familial Acromegaly.

Familial acromegaly may occur in association with the Carney complex, which maps to chromosome 2p. Several families with isolated familial acromegaly comprise related cases of acromegaly and gigantism and harbor loss of heterozygosity in chromosome 11q13, distinct from MENIN (see Table 8-4).

Clinical Features

Manifestations of acromegaly are caused by either central pressure effects of the pituitary mass or peripheral actions of excess GH and IGF-I. Central features of the expanding pituitary mass are common to all pituitary masses and have already been described. In acromegaly, headache is often severe and debilitating. Local signs are especially important presenting features because a preponderance of macroadenomas (>65%) is encountered in acromegaly, compared with mostly microadenomas for PRL-secreting tumors.

Gigantism

Tall stature may be caused by a GH-secreting pituitary tumor or hyperplasia. About 20% of patients have the McCune-Albright syndrome with somatotroph hyperplasia or rarely pituitary adenomas. Somatotroph hyperplasia and acidophilic stem cell adenomas may cause gigantism in infancy or early childhood, suggesting early hypersecretion of GHRH or disordered pituicyte cell differentiation. Pituitary gigantism should be considered in children who are more than 3 standard deviations (SD) above normal mean height for age or more than 2 SD above their adjusted mean parental height.

The biochemical diagnosis is similar to that for acromegaly; that is, GH levels are in excess of 1 µg/L after a glucose load and serum IGF-I concentrations are elevated. In children undergoing pubertal growth spurts, GH responses to glucose may vary. A summary of the clinical presentation of acromegaly is shown in Table 8-24.

be paradoxical and serum IGFl concentrations are often physiologically elevated. Thus, the diagnosis requires clear-cut MRI evidence for a pituitary lesion. The differential diagnosis includes familial tall stature, redundancy of Y chromosomes, Marfan's syndrome, and homocystinuria.

**Clinical Features of Acromegaly**

Effects of hypersomatotropism on acral and soft tissue growth and metabolic function occur insidiously over several years ([Table 8-24; Fig. 8-48 and Fig. 8-49]). The slow onset and elusive symptoms often result in a delay in diagnosis ranging from 6.6 to 10.2 years, with a mean delay of almost 9 years. Patients may seek care for dental, orthopedic, rheumatologic, or cardiac disorders. Only 13% of 256 patients diagnosed during a 20-year period presented with primary symptoms of altered facial appearance or enlarged extremities.

In a review of several hundred patients presenting with acromegaly worldwide, 98% had acral enlargement and hyperhidrosis was prominent in 70%.

When patients present early, facial and peripheral features are usually not obvious and a serial review of old photographs often reveals the progress of subtle physical changes. Characteristic features include large fleshy lips and nose, spade-like hands, frontal skull bossing, and cranial ridges. Enlarged tongue, bones, salivary glands, thyroid, heart, liver, and spleen are the effects of generalized visceromegaly. Clinically apparent hepatosplenomegaly, however, is rare. Increases in shoe, ring, or hat size are commonly reported. Progressive acral changes may lead to facial and skeletal disfigurement, especially if excess GH secretion begins prior to epiphyseal closure. These include mandibular overgrowth with prognathism, maxillary widening, teeth separation, jaw malocclusion and overbite, and nasal bone hypertrophy. Sonorous voice deepening occurs in association with laryngeal hypertrophy and enlarged panarosal sinuses.

Up to half of the patients may experience joint symptoms severe enough to limit daily activities. Arthropathy occurs in about 70% of patients, most of whom exhibit joint swelling, hypermobility, and cartilaginous thickening. Local periarticular fibrous tissue thickening may cause joint stiffening or deformities and nerve entrapment. Knees, hips, shoulders, lumbosacral joints, elbows, and ankles are affected with monoartricular or polyartricular arthritides, but joint effusions rarely develop. Spinal involvement includes osteophytes, disc space widening, and increased anteroposterior vertebral length, which may result in dorsal kyphosis.

Neural enlargement and wrist tissue swelling may lead to carpal tunnel syndrome in up to half of all patients. Chondrocyte proliferation with an increased joint space occurs early, and ulcerations and fissures of weight-bearing cartilage areas are often accompanied by new bone formation. Debulking osteoarthritides may result in bone remodeling, osteophyte formation, subchondral cysts, narrowed joint spaces, and lax periarticular ligaments. Osteophytes commonly occur at the phalangeal tufts and over the anterior aspects of spinal vertebrae. Ligaments may ossify, and periarticular calcium pyrophosphate deposition occurs. Although the duration of hypersomatotropism correlates with clinical severity of the joint changes, it is unclear whether higher GH levels correlate with increased articular disease activity. Therapeutic responses usually depend on the degree of irreversible bone changes already in place.

Hyperhidrosis and malodorous oily skin are common early signs, occurring in up to 70% of patients. Facial wrinkles, nasolabial folds, and heel pads thicken and body hair may become coarse. Hyperhidrosis and malodorous oily skin are common early signs, occurring in up to 70% of patients. Facial wrinkles, nasolabial folds, and heel pads thicken and body hair may become coarse. Hyperhidrosis and malodorous oily skin are common early signs, occurring in up to 70% of patients. Facial wrinkles, nasolabial folds, and heel pads thicken and body hair may become coarse.

Symptomatic cardiac disease is present in about 20% of patients and is a major cause of morbidity and mortality. Hypertension is present in about 50% of patients with active acromegaly. Left ventricular hypertrophy is also observed in about half of normotensive patients with acromegaly. Asymmetric septal hypertrophy is common, and cardiac failure may occur with early or mild cardiomegaly. Subclinical left ventricular diastolic dysfunction is due to myocardial hypertrophy, interstitial fibrosis, and lymphocytic myocardial infiltrates. Resting electrocardiograms are abnormal in about 50% of patients, with S-T segment depression, T-wave abnormalities, conduction defects, and arrhythmias. Plasma renin levels are suppressed, and endogenous plasma digitalis-like activity with chronic volume expansion has been identified in acromegaly. Cardiovascular disease accounts for approximately 60% of deaths in patients with acromegaly, and the presence of cardiovascular disease at the time of diagnosis portends high mortality rates despite improved cardiac function after effective GH and IGF-I control.

Prognathism, thick lips, macrognathia, and hypertrophied nasal structures may obstruct airways. Irregular laryngeal mucosa, cartilage hypertrophy, tracheal calcification, and cricoarytenoid joint arthropathy lead to unilateral or bilateral vocal cord fixation or laryngeal stenosis with voice changes and upper airway obstruction or stridor. Tracheal intubation may be particularly difficult in patients undergoing anesthesia, and tracheostomy may be required. Both central respiratory obstruction and airway obstruction lead to paroxysmal daytime sleep (narcolepsy), sleep apnea, and habitual excessive snoring. Obstructive sleep apnea, characterized by excessive daytime sleepiness with at least five episodes of apnea per hour of sleep, causes daytime somnolence, especially in men with acromegaly, who may also have a ventilation-perfusion defect with hypoxemia. Sleep apnea may also be central in origin and associated with higher GH and IGF-I levels.

Synovial edema leads to hyperplastic wrist ligaments and tendons that contribute to painful median nerve compression. Chondrocyte proliferation with an increased joint space and the presence of cardiovascular disease at the time of diagnosis portends high mortality rates despite improved cardiac function after effective GH and IGF-I control. Synovial edema leads to hyperplastic wrist ligaments and tendons that contribute to painful median nerve compression. Chondrocyte proliferation with an increased joint space and the presence of cardiovascular disease at the time of diagnosis portends high mortality rates despite improved cardiac function after effective GH and IGF-I control.
tags in patients older than 50 years may be peripheral markers for the presence of adenomatous colon polyps, unrelated to GH or IGF-I serum levels. Hypertrophic mucosal folds and colonic hypertrophy are commonly present; colonoscopy is warranted every 3 to 5 years after diagnosis, depending on the presence of other risk factors. Mortality from colon cancer is largely related to GH levels rather than the enhanced incidence of the disease in acromegaly (Table 8-26).

Analysis of nine retrospective reports (1956 to 1998) encompassing 21,470 person-years of risk yielded no significant increase in cancer incidence. Cancer incidence was, in fact, lower than expected in 1362 patients with acromegaly in the United Kingdom, and the enhanced colon cancer mortality observed in this study correlated with GH levels. Thus, although disordered cell proliferation and increased risk for promotion of coexisting neoplasms could be anticipated, there is little evidence for an increased cancer incidence in acromegaly (Table 8-27). Although elevated IGF-I levels may correlate with colon polyph prevalence when patients are retested, a controlled prospective study showed no increased colon polyp incidence in acromegaly. Patients are now living longer with improved biochemical control, and long-term prospective controlled studies are required to resolve this question in an aging population.

Endocrine Complications

About 30% of patients exhibit elevated serum PRL levels (up to 100 µg/L or more) with or without galactorrhea. Functional pituitary stalk compression by a pituitary mass prevents lactotroph access of hypothalamic dopamine, releasing the cell from tonic hypothalamic inhibition. GH-secreting adenoma subtypes may also concomitantly secrete PRL. Because GH behaves as an agonist for breast PRL binding sites, the

Repeated colonoscopy.

tumor may cause galactorrhea in the presence of normal PRL levels. Tumor mass compressing surrounding normal pituitary tissue may also cause hypopituitarism. Over half of all patients have amenorrhea or impotence, and secondary thyroid or adrenal failure are common in about 20% of patients. Gonadal dysfunction may result in reduced bone.

The direct anti-insulin effects of GH cause carbohydrate intolerance, and insulin-requiring diabetes mellitus may also develop. Carbohydrate intolerance and insulin requirements improve rapidly with lowering of GH after surgery or somatostatin analogue therapy. Hypertriglyceridemia (type IV), hypercalciuria, and hypercalcemia also occur. Thyroid dysfunction in acromegaly may be caused by diffuse or nodular toxic or nontoxic goiter or Graves’ disease, especially as IGF-I is a major determinant of thyroid cell growth. Associated MEN-1 features may be present in affected individuals, including hypercalcemia with hyperparathyroidism or pancreatic tumors. Benign prostatic hypertrophy has been documented in acromegaly with no apparent increase in prostate cancer rates.

Mortality and Mortality

Cardiovascular disease, respiratory disorders, diabetes, and malignancy account for the threefold enhanced mortality in acromegaly. In a retrospective study reported in 1966, cardiovascular disease was the leading cause of

*Post-treatment GH levels correlate with mortality in acromegaly. Standardized mortality ratios are depicted for overall mortality and for cancer-related mortality.

death and 50% of patients died before the age of 50. Life expectancy was reduced in 194 patients with acromegaly, with cardiovascular disorders accounting for 24% of deaths followed by respiratory (18%) and cerebrovascular (14%) disease. Diabetes mellitus, occurring in 20% of patients, was associated with 2.5 times the predicted mortality, and hypertension was present in about 50% of all patients. The most significant mortality determinants are GH levels and the presence of coexisting cardiac disease. Moreover, control of GH levels to less than 2.5 µg/L after surgery or medical treatments significantly reduces both morbidity and mortality (Fig. 8-50).
The diagnosis of acromegaly requires measurement of a random GH higher than 0.4 µg/L or a GH nadir greater than 1 µg/L during an oral glucose tolerance test. In healthy subjects, serum GH levels initially fall after oral glucose and subsequently increase as plasma glucose declines. However, in patients with acromegaly, oral glucose fails to suppress GH; GH levels may increase, remain unchanged, or fall modestly in approximately one third of patients. Basal morning (**) and random GH levels are usually elevated in acromegaly. Because of the episodic nature of GH secretion, however, serum concentrations may normally fluctuate from undetectable up to 30 µg/L. In contrast to the largely undetectable nadir GH levels in normal subjects, detectable levels of GH (>2 µg/L) were found in those with acromegaly sampled over 24 hours. (**)

Elevated IGF-I levels are also encountered during pregnancy and late puberty. A high IGF-I level is thus highly specific for acromegaly and correlates with clinical indices of disease activity. IGF-BP3 levels are also elevated but provide little added diagnostic information. GH-secreting adenomas exhibit discordant GHI responses to TRH and GnRH administration in up to 50% of patients, but these adjunctive tests are rarely required to confirm the diagnosis.

Differential Diagnosis of Acromegaly

The overwhelming majority of patients with acromegaly harbor a GH cell pituitary adenoma; rarely, extrapituitary acromegaly should be considered. Nevertheless, distinguishing between pituitary and extrapituitary acromegaly is important for planning effective management. Regardless of the cause of unrestrained GH secretion, IGF-I levels are invariably elevated and GH levels are not suppressed (<1 µg/L) after an oral glucose load. When clinical features of acromegaly are associated with normal GH and IGF-I levels, "burned out" acromegaly associated with an infarcted pituitary adenoma, often with a secondary empty sella, should be considered. About 5% of consecutive patients with proven GH cell adenomas have normal GH and elevated IGF-I levels. It is likely that improved GH assay sensitivity will unmask abnormal GH secretion in these patients.

Dynamic pituitary testing (with TRH, dopamine) does not differentiate patients with pituitary adenomas from those harboring extrapituitary tumors. Plasma GHRH levels are invariably elevated in patients with peripheral GHRH-secreting tumors but are normal or low in patients with pituitary adenomas. GHRH plasma level measurement is precise and cost-effective for diagnosis of ectopic acromegaly. Peripherial GHRH levels are not elevated in patients with hypothalamic GHRH-secreting tumors, presumably because eulotropic hypothalamic GHRH secreted into the hypophyseal portal system does not appreciably enter the systemic circulation.

Unique or unexpected clinical features, including respiratory wheezing or dyspnea, facial flushing, peptic ulcers, or renal stones, sometimes indicate the diagnosis of a nonpituitary endocrine tumor. Hypoglycemia, hyperinsulinemia, hypergastrinemia, and rarely hypercortisolism, all not usually encountered in pituitary acromegaly, should justify an evaluation for an extrapituitary source of GH excess. MRI and CT scanning are employed to localize a pituitary or extrapituitary tumor. Routine abdominal or chest imaging of all patients yields a low incidence of true positive cases of ectopic tumor, and such screening is not recommended as cost-effective.

A normal-sized or small pituitary gland or clinical and biochemical features of other tumors known to be associated with extrapituitary acromegaly and elevated circulating GHRH levels are indications for extrapituitary imaging. An enlarged pituitary is, however, often present in patients with peripheral GHRH-secreting tumors, and the radiologic diagnosis of a pituitary adenoma may be difficult to exclude. The McCune-Albright syndrome should be considered after definitive exclusion of a nonpituitary endocrine tumor. Hypoglycemia, hyperinsulinemia, hypergastrinemia, and rarely hypercortisolism, all not usually encountered in pituitary acromegaly, should justify an evaluation for an extrapituitary source of GH excess. MRI and CT scanning are employed to localize a pituitary or extrapituitary tumor. Routine abdominal or chest imaging of all patients yields a low incidence of true positive cases of ectopic tumor, and such screening is not recommended as cost-effective.

A comprehensive strategy for treating patients with acromegaly should aim to manage the pituitary mass, suppress GH and IGF-I hypersecretion, and prevent long-term clinical sequelae of hypogonadotropism while maintaining normal anterior pituitary function. As elevated GH levels per se are associated with threefold increased morbidity and account for the single most important determinant of mortality, it is important to reverse the mortality rate to that of age-matched healthy subjects by aiming for tight GH control.

GH levels should be suppressed to less than 1 µg/L after an oral glucose load and serum IGF-I levels normalized for age and gender. A patient whose condition is controlled should also have a normal 24-hour integrated secretion of GH (<2.5 µg/L). GH may not be measurable for most of the day, but the tumor may still be hypersecreting as reflected by elevated IGF-I levels. Current therapeutic modes for acromegaly management, including surgery, irradiation, and medical treatment, do not comprehensively fulfill these goals.

**Surgical Management**

Well-circumscribed somatotroph cell adenomas should preferably be resected by transphenoidal surgery. Successful resection alleviates preoperative compression effects and compromised trophic hormone secretion, and the skilled surgeon balances the extent of maximal tumor tissue removal with preserving anterior pituitary function. Within 2 hours of successful resection, metabolic dysfunction and soft tissue swelling start to improve, and GH levels are often controlled within an hour. Surgical outcome correlates well with adenoma size and preoperative serum GH levels and particularly with the experience of the surgeon.

Smaller tumors (less than 5 mm), those totally confined within the sella, and preoperative serum GH levels lower than 40 µg/L portend a favorable surgical outcome. Up to 90% of patients with microadenomas achieved postoperative GH levels less than 2.5 µg/L, and less than 50% of those with all-sized macroadenomas had postoperative GH levels below 2 µg/L after glucose administration (Table 8-16). Less than one third of all patients achieve control after resection of adenomas larger than 10 mm, and about 75% of patients with preoperative GH less than 5 µg/L have normalized IGF-I. Overall, in 17 studies of 1284 patients published between 1995 and 1999, 82% of patients harboring macroadenomas had normalized IGF-I levels compared with less than 50% of those with macroadenomas (Table 8-28).

A review of 2665 patients from a single center showed that 72% of patients with microadenomas and 50% harboring macroadenomas had GH levels below 1.0 µg/L during glucose load and normal serum IGF-I levels. Less than one third of these patients had recurrences after 10 years. Endoscopic transnasal surgery offers promise as a less invasive procedure for resection of pituitary tumors and access to cavernous sinus tumor mass, although long-term comparative results are not yet available. Difficulties in endotracheal intubation related to macroglossia or severe kyphosis, or both, may necessitate tracheostomy for anesthesia.

**Side Effects.**

Although often transient, surgical complications may require lifelong pituitary hormone replacement. New hypopituitarism develops in up to 20% of patients, reflecting operative damage to the surrounding normal pituitary tissue. Permanent diabetes insipidus, CSF leaks, hemorrhage, and meningitis occur in up to 10% of patients (Table 8-10). The extent and prevalence of local complications depend on tumor size and invasiveness. Experienced pituitary surgeons report more favorable postoperative complication rates. Biochemical or anatomic recurrence (7% or 10 years) or postoperative tumor persistence may indicate incomplete resection of adenomatous tissue, surgically inaccessible cavernous sinus tissue, or nesting of functional tumor tissue within the dura.

**Radiation**

Primary or adjuvant radiation of GH-secreting tumors may be achieved by conventional external deep X-ray therapy as well as heavy-particle (proton beam) therapy. Maximal tumor radiation should ideally be attained with minimal soft tissue damage. Precise MRI localization, accurate simulation and isocentral rotational techniques, and high-voltage (6 to 15 MEV) delivery have improved radiation efficacy. Radiation is a highly individual choice, depending on the expertise and experience of the treating radiotherapist as well as the physician's and patient's choice of the benefits of therapy weighed against potential risks.

For radiation treatment, up to 5000 rads are administered in split doses of 180-cGy fractions divided over 6 weeks. Radiation arrests tumor growth, and most pituitary adenomas ultimately shrink. GH levels fall gradually during the first year after treatment, and levels are less than 10 µg/L in 70% of patients after 10 years. The National Institutes of Health experience is that over 90% of patients have GH levels less than 5 µg/L after 20 years (Fig 8-51). When pretreatment GH levels were greater than 100 µg/L, only 60% of patients had GH less than 5 µg/L after 18 years. During the first 7 years after irradiation less than 5% of patients had normal GH <2 µg/L (<4 mU/I) after OGTT and/or normal IGF-I levels. GH <5 µg/L (<10 mU/I) and/or normal IGF-I levels

</table>

IGF-I levels but about 70% of patients exhibited normal IGF-I levels when treated during longer follow-up. Radiotherapy does not normalize GH secretory patterns, probably accounting for persistently elevated IGF-I levels in the presence of apparently controlled GH levels. Thus, during the initial years after irradiation, most patients are still exposed to unacceptably high levels of circulating GH and IGF-I. Promising stereotactic pituitary tumor ablation by the gamma knife has been reported. Long-term outcomes and potential long-term side effects are not yet available.

Side Effects

After 10 years about half of all patients receiving radiotherapy have signs of pituitary trophic hormone disruption, and the prevalence increases annually thereafter, requiring gonadal steroids, thyroid hormone, or cortisone replacement. Side effects of conventional radiation, including hair loss, cranial nerve palsies, tumor necrosis with hemorrhage, and rarely loss of vision or pituitary apoplexy, have been documented in up to 2% of patients. Lethargy, impaired memory, and personality changes may also occur. The incidence and extent of local complications have been markedly diminished by use of highly reproducible simulators, precise rotational isocentric arc capability, and doses less than 5000 cGy. Proton beam therapy (Bragg peak) is contraindicated in patients with suprasellar tumor extension because of unacceptably optic tract exposure to the radiation field. The rare development of second brain tumors in these patients has been reported at a cumulative risk frequency of 1.9% over 20 years.

Radiation therapy effectively shrinks over 95% of GH cell adenomas and lowers GH levels over 20 years in more than 90% of patients. In fact, GHD may result from radiation because of the side effects, radiation therapy should be employed as an adjuvant for patients not controlled by surgery or medical management or for those who refuse these therapies.

Dopamine Agonists

Because dopamine attenuates GH secretion in about one third of patients with acromegaly, D2 receptor agonists, including bromocriptine and cabergoline, have been used as either primary or adjuvant therapy for acromegaly. Bromocriptine may lower GH at a dose of 20 mg/day or more, which is higher than required to suppress PRL in patients harboring prolactinomas. Approximately 15% of patients worldwide have been reported to have suppressed GH levels below 5 µg/L when taking the medication (7.5 to 80 mg/day), and IGF-I became normal in 10% of patients. The drug causes minimal tumor shrinkage, but most patients experience subjective clinical improvement and report reduced perspiration, decreased soft tissue swelling, and improved fatigue and headache despite persistently elevated serum GH or IGF-I levels, or both. Side effects of bromocriptine are more marked, especially as high doses are required. These include gastrointestinal upset, transient nausea and vomiting, headache, transient postural hypotension with dizziness, nasal stuffiness, and rarely cold-induced peripheral vasospasm (see earlier).

Cabergoline, a long-acting dopamine agonist, is highly effective in suppressing PRL hypersecretion and shrinking prolactinomas. The drug has been reported to suppress GH to less than 2 µg/L and to normalize IGF-I in up to a third of patients with acromegaly. Side effects include gastrointestinal symptoms, dizziness, headache, and mood disorders. Patients with hyperprolactinemia and minimal GH elevation may benefit most from dopamine agonist treatment.

Somatostatin Release-Inhibiting Factor Receptor Ligands

Of the five SRIF receptor subtypes, SSTR2 and SSTR5 are preferentially expressed on somatotroph and thyrotroph cell surfaces and mediate suppression of GH and TSH secretion. Several SRIF ligands have been employed as approved or investigational drugs for acromegaly (Fig. 8-52). For over 15 years, these analogues have proved safe and effective for controlling acromegaly.

Octreotide (po-Phe-Cys-Phe-o-Trp-Lys-Thr-Cys-Thr-OH), an octapeptide SRIF analogue, binds predominantly to SSTR2 and SSTR5 and inhibits GH secretion with a potency 45 times greater than that of native SRIF, whereas its potency for inhibiting insulin release is only 1.3-fold that of SRIF. The in vivo half-life of the analogue is prolonged (up to 2 hours) because of its relative resistance to enzymatic degradation. The rebound GH hypersecretion seen after SRIF infusion does not occur after octreotide injection. These properties are highly advantageous for long-term use in acromegaly. A single subcutaneous dose (50 or 100 µg) suppresses GH secretion for up to 5 hours. In patients harboring microadenomas, integrated GH and IGF-I levels almost invariably became normal, but the response in larger tumors was less pronounced. In a double-blind, placebo-controlled trial, octreotide (8-hourly injections) significantly attenuated GH and IGF-I levels overall in over 90% of patients. A combination of octreotide and bromocriptine or cabergoline may provide added efficacy. In an open-label study of 151 patients responsive to octreotide, the analogue suppressed serum GH levels to less than 2.5 µg/L in about 70% of patients. Interestingly, tumor shrinkage was observed after up to 2 years in 12 of 15 patients receiving octreotide LAR as primary treatment, whereas no shrinkage was observed in 4 of 9 patients after surgery. Fifty-nine patients undergoing pituitary surgery were randomly assigned to treatment with or without octreotide, and 22 who received preoperative octreotide for 3 to 6 months demonstrated improved postoperative biochemical control and reduced hospital length of stay.

Effects of SRIF Receptor Ligands on Pituitary Adenomas

Invariably, tumor growth does not occur while patients receive depot preparations of SRIF analogues, and adenomas shrink by 20% to 80% in about one third of patients receiving these analogues. Interestingly, tumor shrinkage was observed after up to 2 years in 12 of 15 patients receiving octreotide LAR as primary treatment, whereas no shrinkage was observed in 4 of 9 patients after surgery. Fifty-nine patients undergoing pituitary surgery were randomly assigned to treatment with or without octreotide, and 22 who received preoperative octreotide for 3 to 6 months demonstrated improved postoperative biochemical control and reduced hospital length of stay. Over 70% of patients experience improved general well-being, and soft tissue swelling dissipates within several days of treatment, reflecting a specific central analgesic effect. Asymptomatic patients experience a significant decrease in acromegaly, usually resolves within minutes of injection,
of blood pressure, heart rate, and left ventricular wall thickness. In patients with cardiac failure, octreotide reversibly reduces systemic arterial resistance, oxygen consumption, and fluid volume and restores functional activity. In 30 patients, an improved left ventricular ejection fraction with unchanged diastolic filling was associated with octreotide-induced GH suppression to less than 2.5 µg/L. Persistently elevated GH levels after a year were associated with increased systolic blood pressure. Control of IGF-I and GH levels is associated with improved left ventricular ejection function; in patients in whom the levels were not controlled, cardiac performance worsened. Joint function and crepitus improve, ultrasonography shows evidence of bone or cartilage repair, and after several months sleep apnea improves.

Side Effects

SRIF receptor ligands are generally safe and well tolerated. Gastrointestinal side effects predominate and include transient loose stools, nausea, mild malabsorption, and flatulence, reported in about one third of patients. Hypoglycemia and hyperglycemia are not commonly encountered, and insulin requirements in diabetic patients with acromegaly are dramatically reduced within hours of receiving octreotide, concomitant with GH lowering. The drug attenuates gallbladder contractility, delays emptying, and leads to reversible sludge formation evidenced by ultrasonography in up to 25% of patients. Frank cholecystitis is rarely reported in these patients. The incidence of gallbladder sludge or stones is geographically variable, with higher rates reported in China, Australia, and the United Kingdom. In the United States, up to 30% of patients have demonstrable evidence of echogenic gallbladder deposits within the first 18 months of treatment. Thereafter, further sludge formation is not usually encountered. Octreotide may interact with several drugs including cyclosporine, enhancing transplant rejection risk. SRIF receptor ligand dose adjustments should be carefully titrated in patients requiring insulin or oral hypoglycemic agents, calcium channel blockers, and α-blockers. Asymptomatic sinus bradycardia has also been recognized.

Growth Hormone Receptor Antagonist

GH action through the surface membrane GH receptor is mediated by ligand-induced GH receptor dimerization and subsequent receptor signaling. The postreceptor GH signal is not elicited if the receptor fails to dimerize. Pegasysom, a GH receptor antagonist, blocks receptor dimerization and subsequent IGF-I generation. The pegylated molecule also binds to the GH receptor dimer and interacts with GHBP. Daily injections (20 mg) of this pegylated GH mutant molecule normalized IGF-I levels in over 90% of patients and dose dependently improved fatigue, decreased soft tissue swelling assessed by ring size, and diminished perspiration. The drug, not yet approved in the United States, may be particularly useful in patients resistant to somatostatin receptor ligand therapy as it effectively normalizes IGF-I levels in these patients. Long-term side effects are not yet known, but the action of the medication increases levels of GH, which are bioinactive because of receptor blockade. Long-term surveillance should also include monitoring of liver function and pituitary adenoma size.

Choice of Therapy

Tight control of GH secretion should be achieved because adverse mortality rates correlate strongly with GH levels. Each treatment modality has respective advantages and disadvantages that should be weighed in order to individualize patients' care. Selective surgical excision of a well-defined pituitary microadenoma is recommended for most patients. Remission rates are unacceptably low for patients with macroadenomas and locally invasive tumors. Attempted medical debulking of the sellar mass prior to surgery would be desirable, although controlled prospective studies are required to confirm the validity of this approach to improve surgical morbidity and possibly enhance subsequent postoperative outcomes, especially for patients with surgically inaccessible tumor tissue and cavernous sinus invasion.

Postoperatively, patients who do not achieve control can be treated with bromocriptine; although the efficacy of this drug is low, it is relatively inexpensive and free of major side effects. An SRIF analogue should be administered, GH and IGF-I measured after 2 hours, and Sandostatin LAR (10, 20, or 30 mg) initiated if patients are shown to be responsive. More frequent dosing rather than increases in total drug dose may be more efficacious and beneficial, and some may benefit by addition of bromocriptine or cabergoline with octreotide.

Maybe permanent control | Sustained long-term efficacy | Good compliance by patients | No hypopituitarism | Sustained efficacy

**Disadvantages**

- New hypopituitarism (10%)
  - Cost of drug and monitoring
  - Ineffective and slow on-set
  - Relatively ineffective
  - Long-term safety unknown
- Diabetes insipidus (23%)
  - Asymptomatic gallstones (25%)
  - Hypopituitarism (70%)
  - Adverse events (30%)
- Local complications (6%)
  - Injections required
  - Visual and CNS dysfunction (2%)
  - High dose required
  - Not yet approved (2002)
- Cranial nerve or CNS damage (1%)
  - Cost of interim medical therapy
- Tumor persistence

**Adapted from Melmed S, Jackson I, Kleinberg D, Klibanski A. Current treatment guidelines for acromegaly. J Clin Endocrinol Metab 1998; 83:2646-2652.**

Ultrasoundography should be performed only in symptomatic patients, and those with demonstrable sludge or gallstones may require prophylactic anticholelithogenic agents or laparoscopic cholecystectomy if symptoms develop.

Primary therapy with SRIF receptor ligands may be offered to patients who refuse surgery or in whom the risks of surgery or anesthesia are unacceptable. Invasive macroadenomas invariably hypersecrete GH postoperatively and require somatostatin analogue treatment. In patients whose pituitary lesion does not compress vital structures, primary medical management may therefore be an appropriate therapeutic option. Radiation should be administered to patients who are resistant to or cannot tolerate the medication, prefer not to receive long-term injections, or cannot afford the medication. After radiation, medications are required for several years until GH levels are effectively controlled.

Tumors that recur despite medical therapy or radiation may rarely require reoperation. Although tight GH control is critical, these patients also require counseling for anxiety engendered by disfigurements and interpretation of laboratory test results. Patients should be observed quarterly until biochemical control is achieved. Thereafter, hormone evaluation is performed semiannually, and for patients who are biochemically in remission and in whom no residual tumor tissue is present, MRI should be repeated every 1 to 2 years. Follow-up evaluation includes documenting and treating new skin tag and lipoma growth; nerve entrapments; jaw overbites; rheumatologic, dental, and cardiac evaluations; and metabolic assessment. Visual field perimetry and pituitary reserve testing should be repeated semiannually and pituitary MRI annually, especially in patients with residual tumor or those requiring hormone replacement or medical treatment. Mammography and colonoscopy should be performed as clinically indicated for patients older than 50 or those harboring polyps. Maximal and sustained long-term GH and IGF-I control should ameliorate the deleterious effects of these hormones by judicious use of available treatment modalities.
Adrenocorticotropic Hormone

Corticotroph Cells

Corticotroph cells constitute about 20% of functional anterior pituitary cells and are the earliest detectable human fetal pituitary cell type, appearing by the eighth week of gestation. Corticotrophs are clustered mainly in the central median pituitary wedge and are readily identified by immunostaining with ACTH or ß-lipotropin antibodies. They are large, irregular cells with ultrastructural features including prominent neurosecretory granules (150 to 400 nm), endoplasmic reticulum, and Golgi bodies (Fig. 8-56 (Figure Not Available) and Fig. 8-57 (Figure Not Available)). These cells produce the POMC gene products including ACTH 1 to 39, ß-lipotropin, and endorphins. Because of the rich carbohydrate moiety of these molecules, the cells are strongly positive for periodic acid-Schiff stain. In the presence of excess glucocorticoid, characteristic hyaline deposits are evident (Fig. 8-58) (Figure Not Available).

Adrenocorticotropic Hormone Biosynthesis

The 8-kb human POMC gene, located on chromosome 2p23, consists of three exons with two intervening introns (Fig. 8-59). The first exon encodes a leader sequence, the second encodes the signal initiation sequence and the N-terminal portion of the POMC peptides, and the third exon encodes most of the mature peptide sequences and the chemokine-like regions and ß-lipotropin.

POMC is the precursor of ACTH, which acts on the adrenal glands to induce synthesis and secretion of adrenal steroids. The primary translation product of POMC is a 266-aminoacid POMC pro-hormone molecule encoding corticotrophic, opioid, and melanotropic peptides. The peptide contains a leader sequence and multiple dibasic proteolytic cleavage sites for glycosylation, acetylation, and amidation. Products of this processing include ACTH 1 to 39 and ß-lipotropin, which in turn give rise to ß-lipotropin and ß-endorphin, also containing met-enkephalin. ACTH itself may also be cleaved to melanocyte-stimulating hormone (1 to 13) and corticotroplike intermediate lobe peptide (CLIP; 18 to 39). The neurointermediate pituitary lobe is not developed in humans and is not normally a source of circulating POMC-derived peptides.

Multiple signals in synergy induce ACTH gene expression. These include CRH, cytokines, arginine vasopressin, catecholamines, and VIP. Glucocorticoids inhibit POMC gene expression. The CRH type 1 receptor is predominantly expressed on the corticotroph, and receptor activation increases cAMP, protein kinase A, and CREB induction of CRHBP binding to the promoter leading to POMC transcription. CRH also activates an AP-1 site within the first exon by a mitogen-activated protein kinase-mediated pathway. In addition to mediating ACTH secretion, this receptor appears critical for fear and anxiety responses, possibly through a related ligand, uricorin. The type 2 CRH receptor is predominantly important for cardiovascular function.

Leukemia inhibitory factor (LIF), a proinflammatory cytokine also expressed in the pituitary and hypothalamus, signals through the JAK/STAT pathway, acts in synergy with CRH, and induces direct STAT3 binding to POMC. Glucocorticoid receptor activation leads to transcriptional suppression through two cooperative binding sites. The intracellular glucocorticoid receptor binds directly to S-regulatory elements to suppress POMC transcription. CRH action is also potentiated by vasopressin (acting through phospholipase C) and ß-adrenergic catecholamines by enhancing POMC mRNA levels, increasing ACTH secretion, or both. The net effects of these intracellular signals are to regulate POMC gene transcription, peptide synthesis, and ACTH secretion for mediating appropriate neuroendocrine responses.

Pro-opiomelanocortin Processing

Several post-translational POMC modification steps are required for ultimate polypeptide hormone secretion (Fig. 8-60). First, the N-terminal signal sequence is removed followed by glycosylation through an O linkage to Thr45 and N linkage to Asn65. Serine phosphorylation then occurs within the Golgi apparatus. After being transported to secretory vesicles, the constituent peptides are cleaved at dibasic amino acid residues and ACTH-related peptides stored in dense secretory granules for ultimate regulated release. Some POMC products also undergo C-terminal amidation mediated by peptidylglycine-aminating monoxygenase and peptidylhydroxyglycine-aminating lase and N-terminal acetylation. POMC proteolytic processing occurs at Lys-Arg or Arg-Arg residues. Prohormone convertase 1 (PC1) or prohormone convertase 2 (PC2), related to the subtilisin-kexin proteinases, exert tissue-specific cleavage.
activities at dibasic sites. PC1 is most abundant in the pituitary and hypothalamus, and PC2 is present in white blood cells. Nevertheless, most circulating ACTH is derived from the anterior pituitary or from neuroendocrine tumor ectopic production. Extrapituitary neuroendocrine tumors associated with ectopic ACTH secretion do not process the prohormone efficiently. As ACTH is synthesized in non-tumorous neuroendocrine cells, "ectopic" tumor hormone production may in fact reflect inappropriate ACTH processing. These patients also exhibit a higher ratio of circulating ACTH precursors as well as smaller peptides, including CLIP.

Adrenocorticotropic Hormone Secretion

The complex control of ACTH secretion patterns is critical for maintenance of adrenal cortex function and reflects the neuroendocrine control of stress homeostasis. Essential metabolic and endocrine functions require a sensitively controlled nonstress pattern of hypothalamic-pituitary-adrenal (HPA) axis function. This baseline pattern allows the axis to mount an appropriate stress response, with a well-buffered reserve capacity to counteract life-threatening insults.

The 4.5-kd ACTH polypeptide consists of 39 amino acids. The highly conserved 12 N-terminal amino acid residues are critical for adrenal gland steroid synthesis. Several variables characterize the central and peripheral control of ACTH secretion. The ACTH circadian rhythm is generated in the suprachiasmatic nucleus, which signals CRH release. The hormone is secreted with both circadian periodicity and ultradian pulsatility, and this centrally controlled pattern is influenced by peripheral corticosteroids. ACTH pulse amplitudes may vary by 40% over 24 hours. The circadian pattern of ACTH secretion typically begins at about 4 AM and peaks before 7 AM, with both ACTH and adrenal steroid levels reaching their nadir between 11 PM and 3 AM. Within this overall diurnal cycle, periodic ACTH secretory bursts occur at a frequency of 40 pulses per 24 hours, with changing pulse amplitudes throughout the day. Each pulse contains an average ACTH level of 24 ng/L.

Pulse amplitude changes, rather than frequency, appear to determine ACTH circadian rhythm. ACTH circadian rhythm is entrained by visual cues and the light-dark cycle and is centrally controlled by CRH and other factors. Although continuous CRH administration desensitizes the ACTH response,

Adrenocorticotropic Hormone Action

The primary action of ACTH is to maintain adrenal gland size, structure, and function; ACTH induces adrenal steroidogenesis by activating ACTH receptors situated on the adrenal cortex cell surface. ACTH signals through adenyl cyclase to regulate P450 enzyme transcription, cortisol aldosterone (10%), 17-hydroxyprogestosterone, and to a lesser extent adrenal androgen synthesis and secretion. ACTH stimulates mitochondrial cholesterol transport and regulates the rate-limiting side-chain cleavage of cholesterol to pregnenolone. Secretory cortisol pulses follow ACTH pulses within 5 to 10 minutes, with a linear dose dependence, especially evident after physiologic CRH stimulation. However, circulating cortisol levels reach a plateau when pharmacologic levels of ACTH are attained by cosyntropin (Cortronesyn; Synacthen) injection.

The adrenal cortisol response to ACTH is sensitive to the background ambient ACTH milieu. In states of chronic ACTH deficiency, adrenal reserve is compromised, whereas during ongoing ACTH hypersecretion the gland is primed so that a given ACTH bolus elicits a higher cortisol response. Both basal ACTH secretion and stimulated (e.g., by CRH) ACTH secretion are blunted by glucocorticoids. Conversely, low or absent circulating glucocorticoids (e.g., after adrenalectomy) result in exaggerated ACTH secretion and corticotroph cell hyperplasia. The HPA axis is inhibited by a low feedback inhibition whereby cortisol rapidly inhibits hypothalamic CRH and pituitary ACTH. These effects may also be delayed by 30 to 60 minutes by inhibition of ACTH release rather than synthesis, especially after a single glucocorticoid bolus. After chronic glucocorticoid exposure (>24 hours), HPA suppression may persist for days or longer. In a short feedback loop, pituitary ACTH inhibits hypothalamic CRH, and in an ultrashort loop it may also suppress the corticotroph itself.

Physiologic Adrenocorticotropic Hormone Regulation

Exercise enhances ACTH and -endorphin levels, especially if it is exhausting and of short duration. Exercising up to 90% of maximum oxygen capacity causes a significant elevation of ACTH, similar to levels observed during surgery or hypoglycemia. Levels may remain elevated for up to 6 minutes after exercise cessation, and lower intensity exercise does not evoke ACTH. Well-trained athletes exhibit hypercortisolism, possibly a result of decreased adrenal ACTH sensitivity. Other causes of elevated ACTH include acute hemorrhage, surgery, and emotional stress. Acute illness is associated with increased ACTH and cortisol levels with loss of diurnal secretory patterns.

Stress Response

Both exogenous and endogenous stress stimuli activate the HPA axis to produce sufficient glucocorticoid in an attempt to counteract the insult. The HPA stress response occurs in the context of a wide variety of peripheral and central adaptors to stress, including vasovagal and catecholamine activation and cytokine secretion and action. A tightly controlled immunoneuroendocrine interface regulates the ACTH response to peripheral stressors, which include pain, infection, inflammation, hypovolemia, trauma, psychologic stress, and hypoglycemia. These signals vary in their ability to generate ACTH secretion and to sensitize the ACTH response to glucocorticoids. In addition to CRH, peripheral and centrally released proinflammatory cytokines potentially induce POMC transcription and ACTH secretion. Sensitive intracellular signals within the corticotroph also serve to override the ACTH response to stress, thus preventing persistent and chronic hypercortisolism.

Cytokines such as interleukin-6 and LIF activate the HPA axis and enhance glucocorticoid production, thus protecting the organism against lethality by constraining the inflammatory response. Thus, mice with inactivated CRH or LIF genes mount an inadequate neuroendocrine response to stress, inflammation, or endotoxins. During stress, glucocorticoid inhibition of ACTH is also prevented by nuclear factor B activation, which interferes with pituitary glucocorticoid receptor function, thus further exaggerating enhanced ACTH secretion.

Integrated Regulation of Adrenocorticotropic Hormone Secretion

As with other anterior pituitary hormones, ACTH regulation is subserved by at least three tiers of control. First, the brain and hypothalamus release regulatory molecules (including CRH, vasopressin, and other peptides) that traverse the portal system and directly signal for corticotroph secretory and mitotic activity. Second, intrapituitary cytokines and growth factors act locally to regulate ACTH either in concert with hypothalamic factors or independently. These paracrine controls often overlap and are redundant, and they have been shown to induce sensitive intracellular molecules that limit the ACTH response and prevent chronic ACTH hypersecretion. Third, peripheral hormones, especially glucocorticoids, maintain potent feedback inhibition control of corticotroph secretion and replication.

Measurement of Adrenocorticotropic Hormone

Both RIA and IRMA employ antisera specifically directed against intact ACTH (1 to 39) or other POMC fragments. Generally, the IRMA is more sensitive, reproducible, and rapid. Most IRMAs have a sensitivity of less than 0.5 ng/L with precise variations of less than 10%. Intact ACTH or POMC precursor peptides are detectable, depending on the sequence specificity of the assay employed. Awareness of the peptide specificity may be especially critical when evaluating ectopic POMC products secreted by lung tumors. ACTH precursors are assessed by a specific IRMA employing unique monoclonal antibodies to ACTH, N-POMC, -lipotropin (-LPH), or -endorphin.

Extrapancreatic Tumor Adrenocorticotropic Hormone Synthesis

Tissue POMC is also expressed in the gonads, lung, gastrointestinal and adrenal medulary neuroendocrine cells, and white blood cells. Nevertheless, most circulating ACTH is derived from the anterior pituitary or from neuroendocrine tumor ectopic production. Extrapancreatic neuroendocrine tumors associated with ectopic ACTH secretion do not process the prohormone efficiently. As ACTH is synthesized in non-tumorous neuroendocrine cells, "ectopic" tumor hormone production may in fact reflect inappropriate ACTH processing. These patients also exhibit a higher ratio of circulating ACTH precursors as well as smaller peptides, including CLIP.
corticotosteroid-binding globulin (CBG) levels and stress may influence measured cortisol values. Random ACTH values do not provide an accurate assessment of HPA function unless concurrent cortisol levels are obtained. Thus, an integrated assessment of both hormone levels is required for interpreting the significance of an appropriately obtained ACTH value. Often, measurement of cortisol levels alone may provide a useful surrogate endpoint for ACTH action and HPA axis integrity. Plasma ACTH levels fluctuate broadly within the same individual and are highly sensitive to stress, time of collection, and gender. Men exhibit greater ACTH pulse frequency and amplitude and pregnant women have higher ambient ACTH levels, possibly related to placental CRH secretion.

Dynamic Testing for Adrenocorticotropic Hormone Reserve

Hypothalamic

Insulin hypoglycemia is a potent endogenous stressor that evokes ACTH secretion. Thus insulin (0.1 to 0.15 U/kg) is injected intravenously after an overnight fast to achieve symptomatic hypoglycemia and a blood glucose level less than 40 mg/dL. This test correlates well with other indices of ACTH reserve. A normal HPA response to this stressor evokes cortisol levels above 20 µg/dL. As hypoglycemia acts centrally, a normal response implies integrity of all three tiers of HPA axis control. Up to 20% of patients may require insulin up to 0.3 U/kg or more to achieve symptoms of glucopenia including sweating, hunger, palpitations, and tremors.

Vencos are sampled at -15, 0, 15, 30, 45, 60, 90, and 120 minutes for measurement of glucose, ACTH, and cortisol levels. GH can also be measured. After the test, oral glucose should be administered. Intraindividual variations in blood glucose levels attained at a given dose of insulin, fluctuations in central sensitivity to glucose, and activation of catecholamines may lead to difficulties in reproducibility. The test is contraindicated in subjects with a history of seizures, those with active coronary or cerebral ischemia, and in pregnancy. If pronounced adrenal insufficiency is likely, insulin injection may provoke an adrenal crisis because of inadequate adrenal reserve, and hydrocortisone (100 mg) should be available for urgent intravenous use if required.

Metyrapone blocks cortisol synthesis by inhibiting adrenal 11-hydroxylase. Thus, the drug releases the HPA axis from negative feedback by cortisol, normally resulting in an ACTH surge and elevated levels of 11-deoxycortisol (compound 5). A single oral dose (2 to 3 g) is given at midnight, and serum levels of ACTH, 11-deoxycortisol, and cortisol are measured at 8 am the next morning. The test is valid only in the presence of documented suppressed cortisol levels less than 10 µg/dL. In normal subjects, peak ACTH values higher than 200 ng/L are achieved. Side effects include nausea, gastrointestinal upset, and insomnia.

False-positive results may be obtained when phenytoin is being administered because the drug prevents adequate enzymatic blockade. This test should be performed under observation in hospital because acute adrenal insufficiency may ensue.

Pituitary Stimulation

Pituitary ACTH secretion may be evoked by injecting either CRH or arginine vasopressin. Ovine or human CRH (100 µg or 1 µg/kg) is administered intravenously, and cortisol and ACTH are measured at -5, -1, 0, 15, 30, 60, 90, and 120 minutes. Normally, maximal ACTH responses (twofold to fourfold above baseline) are evoked at 30 minutes, and cortisol levels peak (over 20 µg/dL) at 60 minutes or increase more than 10 µg/dL above baseline. Although CRH readily induces ACTH secretion and demonstrates ACTH deficiency or ACTH excess, the wide variation of responses observed has limited its utility.

A useful application of the CRH test is in making the diagnosis of Cushing's disease with or without dexamethasone pretreatment and in the context of petrosal venous sampling for diagnosing ACTH-secreting pituitary adenoma. CRH injection allows a sensitive and specific ACTH gradient to be established, which effectively distinguishes peripheral from pituitary sources of excessive ACTH secretion. Because of the suppressive impact of circulating glucocorticoids on pituitary CRH responsiveness, it may be difficult to distinguish a corticotroph adenoma from pseudo-Cushing's disease, as hypercortisolism is associated with both conditions. In these circumstances, combining this test with dexamethasone suppression may be useful.

In the combined dexamethasone-CRH test, dexamethasone is administered at 0.5 mg every 6 hours for 48 hours starting at noon and ending at 6 am then CRH is administered intravenously at 8 am. In normal subjects or those with pseudo-Cushing's disorder, cortisol levels do not rise and are less than 1.4 µg/dL. If cortisol levels elicit at 15 minutes exceed 4 µg/dL, an ACTH-secreting pituitary tumor is invariably present with 100% sensitivity and specificity. CRH responsiveness (at least a 35% cortisol rise) is usually retained in ACTH-secreting adenomas but is not apparent in more than 90% of ectopic ACTH-producing tumors, with which ACTH levels elicited at 15 minutes exceed 4 µg/dL. The test is valid only in the presence of documented suppressed cortisol levels less than 10 µg/dL. In normal subjects, peak ACTH values higher than 200 ng/L are achieved. Side effects include nausea, gastrointestinal upset, and insomnia.

False-positive results may be obtained when phenytoin is being administered because the drug prevents adequate enzymatic blockade. This test should be performed under observation in hospital because acute adrenal insufficiency may ensue.

Adrenal Stimulation

The acute response of the adrenal gland to a bolus ACTH injection reflects ambient ACTH concentrations to which the gland has been exposed. Thus, the cortisol response to an acute ACTH injection is blunted if the subject has had chronic pituitary ACTH hyposecretion with resultant adrenal atrophy and diminished cortisol reserve. Conversely, persistently elevated ACTH levels lead to adrenal hyperthrophy and augmented cortisol responses. The utility of this test in diagnosing a diminished pituitary ACTH reserve has been challenged because the commonly employed dose of Cortrosyn (ACTH 1 to 24, 250 µg) or Synacthen is high and may evoke a "normal" cortisol response in hypopituitary subjects. An unacceptably high false-negative rate (about 85%) has been determined in a large series, although peak cortisol levels at 30 minutes do, in fact, correlate well with peak responses to an ITT.

A normal cortisol response is greater than 20 µg/dL or a doubling of baseline values. Basal cortisol levels correlate inversely with the incremental response to ACTH. Low-dose stimulation with 1 µg of Synacthen evoked maximal serum cortisol levels at 30 minutes, and these correlated well with values observed after insulin or high-dose ACTH administration. A cutoff of greater than 500 nmol/L provides almost 100% sensitivity and a specificity of 80% to 100%. Failure to respond to low-dose ACTH should be corroborated by a standard dose insulin or ACTH test stimulation.

Text.

A 250-µg dose of Cortrosyn (ACTH 1 to 24) is injected intramuscularly or intravenously, and cortisol levels are measured before and 30 and 60 minutes after injection. Cortisol values higher than 20 µg/dL reflect a normal adrenal reserve response.

Interpretation.

Fluctuation of CBG levels may confound interpretation of cortisol values. Thus, ciprofloxacin and hyperthyroidism lower CBG and cortisol levels, whereas estrogens elevate CBG concentrations.

Secondary Adrenal Insufficiency

Ideally, nonstressed resting subjects should have venous blood withdrawn between 6 and 9 AM. Because ACTH is relatively unstable at room temperature and has a propensity to adhere to glass, plasma samples should be separated immediately in iced siliconized glass tubes containing ethylenediaminetetraacetic acid (EDTA) and stored below -20°C for transport. The plasma ACTH levels at 8 AM range from 5 to 25 ng/L as measured by IRMA. Episodic secretion and short plasma half-life result in wide and rapid fluctuation of plasma measurements. Cortisol values at 4 AM are about half of morning levels, and at 11 AM levels are usually less than 5 µg/dL. Altered corticosteroid-binding globulin (CBG) levels and stress may influence measured cortisol values.

Random ACTH values do not provide an accurate assessment of HPA function unless concurrent cortisol levels are obtained. Thus, an integrated assessment of both hormone levels is required for interpreting the significance of an appropriately obtained ACTH value. Often, measurement of cortisol levels alone may provide a useful surrogate endpoint for ACTH action and HPA axis integrity. Plasma ACTH levels fluctuate broadly within the same individual and are highly sensitive to stress, time of collection, and gender. Men exhibit greater ACTH pulse frequency and amplitude and pregnant women have higher ambient ACTH levels, possibly related to placental CRH secretion.
ACTH deficiency is usually reflective of already profound pituitary insufficiency with disordered GH, gonadotropin, and TSH reserve. Rarely, isolated ACTH deficiency is manifest later in life, is more common in males, but may occur after childbirth associated with autoimmune thyroiditis and diabetes mellitus. Two families with recessive mutations in the corticotroph-specific TPIT gene have been described with congenital adrenal insufficiency and ACTH deficiency. Insufficient ACTH secretion leads to attenuated adrenal corticosteroid production, with relative mineralocorticoid preservation.

Patients present with slowly progressive weight and appetite loss, anorexia, and generalized fatigue. Because adrenal mineralocorticoid is largely unpaired, salt wasting, volume contraction, and hyperkalemia, commonly encountered features in Addison's disease, are not present. Furthermore, the hyperpigmentation usually associated with exuberant ACTH-related peptide secretion in the presence of adrenal damage does not occur. Morning serum cortisol levels less than 3 µg/dL suggest ACTH deficiency, and basal morning cortisol levels greater than 18 µg/dL usually indicate a normal ACTH reserve. Patients with ACTH deficiency have low to normal serum cortisol levels and low to normal plasma ACTH levels. Blunted responses to provocative tests such as insulin-induced hypoglycemia or metyrapone are required to document a partial deficiency.

**Treatment.**

Hydrocortisone is used to replace deficient glucocorticoid hormone directly. The normal secretory rate of cortisol is about 20 mg/day, which is the recommended total daily dose for correcting hypoadrenalism and maintaining blood pressure. The plasma circulating half-life of cortisol is less than 2 hours, and twice-daily dosing regimens may result in very low cortisol levels in the late afternoon with impaired quality of life. Hydrocortisone dosing three times daily for a total daily requirement of 20 mg (10 mg in the morning, 5 mg at noon, and 5 mg in the evening) is most effective for starting replacement. Although excessive dosing leads to iatrogenic Cushing's syndrome, doses should be increased during stress or prior to operative procedures. Cortisone acetate is metabolized to cortisol and has a slower onset of action and longer biologic activity than hydrocortisone. Other synthetic glucocorticoids, including prednisolone and dexamethasone, are less useful because they are difficult to monitor biochemically. Even modest cortisol overreplacement may result in bone mineral loss.

Mineralocorticoid replacement is rarely required. Central diabetes insipidus may rarely be unmasked after initial glucocorticoid replacement.

**Adrenocorticotropic HormoneSecreting Tumors**

The evaluation and management of Cushing's disease are described fully in Chapter 14. Briefly, the diagnosis of an ACTH-secreting pituitary tumor is suggested by features of hypercortisolism, elevated 24-hour urinary free cortisol levels, and failure to suppress morning cortisol levels to less than 3 µg/dL after 1 mg of dexamethasone administered at 11 PM. In healthy subjects, glucocorticoid feedback suppresses CRH and ACTH, attenuating cortisol secretion.

Surgical resection of an ACTH-secreting adenoma is the treatment of choice. Because these tumors are usually small, sometimes less than 2 mm in diameter, they may be localized incorrectly, or not at all, by venous sampling for ACTH (see earlier) and sensitive MRI. Therefore, these tumors pose a significant challenge even for the experienced surgeon. Furthermore, the disorder is also characterized by venous hypertension leading to turgid venous sinuses requiring control by the anesthetist.

Bilateral petrosal venous sampling for ACTH levels and cavernous sinus venography should ideally be performed before surgery. However, if sellar venous sinus drainage is predominantly unilateral, left-right ACTH gradients may not reliably lateralize the lesion. Cavernous sinus venography may also outline a filling defect representing the tumor. If an ACTH gradient is indeed detected with normal venous drainage patterns, hemihypophysectomy may be curative in 80% of such patients with clearly defined biochemical features of ACTH-dependent Cushing's disease. Metliculous surgical exploration of both anterior and posterior lobes is required for these tiny tumors, which are often off-white and speckled by petechiae and may be inadvertently suctioned. Unfortunately, even carefully performed preoperative lateralization is not infallible and the so-called normal side should also be carefully explored.

**Assessment of Surgical Outcome**

Transsphenoidal adenoma resection is the preferred treatment for these adenomas. After selective adenomectomy of a clearly identifiable adenoma, remission was achieved in 75% of 295 patients. However, partial hypophysectomy performed in 31 patients in whom an adenoma could not be identified resulted in biochemical remission in only 10 patients. On the third postoperative day, 1 mg of dexamethasone can be given at 10 PM and cortisol levels measured the following morning, prior to initiating hydrocortisone therapy. If the immediate postoperative cortisol level is less than 3 µg/dL, a 95% 5-year remission rate can be expected. In 21 of 27 patients tested prior to glucocorticoid administration, postoperative cortisol levels below 10 mg/dL or less than those obtained with preoperative midnight sampling were predictive of remission.

**Silent Corticotroph Adenoma**

These basophilic tumors are generally nonfunctional and yet exhibit POMC, -lipotropin, and -endorphin immunoreactivity. ACTH secretion is apparently unaltered, with no associated clinical or biochemical features of hypercortisolism, although these tumors are morphologically indistinguishable from adenomas associated with Cushing's disease. They may represent up to 7% of all surgically removed adenomas and are usually hemorrhagic and invariably macroadenomas. Unlike Cushing's disease, they have a 2:1 male preponderance, often occur with mass effects, and about one third have preoperative evidence of pituitary insufficiency. About half exhibit cavernous sinus or bone invasion, hemorrhage, necrosis, and cyst formation. These tumors often recur, and postoperative radiation and reoperation are required to eradicate tumor regrowth or residual mass. Unless appropriate immunostaining is performed, many of these tumors remain undiagnosed and are classified as recurrent nonfunctioning macroadenomas.
Thyroid-Stimulating Hormone

Thyrotroph cells constitute about 5% of the functional anterior pituitary cells and are situated predominantly in the anteromedial areas of the gland. They are smaller than the other cell types and are irregularly shaped with flattened nuclei and relatively small secretory granules ranging from 120 to 150 µm (Fig. 8-61 (Figure Not Available) and Fig. 8-62 (Figure Not Available)).

Figure 8-61 (Figure Not Available) Normal thyrotrophs have angular cell bodies with elongated processes. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 19.)

Figure 8-62 (Figure Not Available) Electron micrograph of normal thyrotrophs showing angular cell bodies with elongated processes. (From Asa SL. In Tumors of the Pituitary Gland. Atlas of Tumor Pathology. Washington, DC, Armed Forces Institute of Pathology, 1997, p 19.)

Thyrotroph cells constitute about 5% of the functional anterior pituitary cells and are situated predominantly in the anteromedial areas of the gland. They are smaller than the other cell types and are irregularly shaped with flattened nuclei and relatively small secretory granules ranging from 120 to 150 µm (Fig. 8-61 (Figure Not Available) and Fig. 8-62 (Figure Not Available)).

Thyroid-Stimulating Hormone Biosynthesis

TSH is a glycoprotein hormone that is a heterodimer of two noncovalently linked and subunits. The subunit is common to TSH, LH, FSH, and hCG, but the subunit is unique and confers specificity of action. The subunit is the earliest hormone gene expressed embryonically; activation of the subunit gene occurs later under the influence of GATA-2 and Pit-1. The 13.5-kb subunit gene is located on chromosome 6 and comprises four exons and three introns. Although the subunit gene is expressed in thyrotroph, gonadotroph, and placental cells, its regulation is uniquely cell-specific. The downstream promoter region (-200 and below) is required for placental expression, intermediate sequences are required for gonadotroph expression, and upstream promoter elements are required for thyrotroph-specific expression. The subunit transcript is inhibited by T3 at regions close to the transcriptional initiation site, in concert with other nuclear corepressors. The 4.9-kb TSH subunit gene located on chromosome 1 comprises three exons and two introns. Pit-1 binds directly to the gene promoter to confer tissue-specific expression. TSH gene transcription is suppressed by the thyroid hormone receptor acting directly on exon 1.

This potent suppression is evident within 30 minutes of T3 exposure and is a critical determinant of TSH synthesis and ultimate secretion. Transcription of both TSH subunit genes is induced by TRH, and depletion of CAMP by dopamine leads to suppressed gene transcription. Intrapituitary TSH is stored in secretory granules, and the mature hormone (28 kd) is released into the venous circulation primarily in response to hypothalamic TRH. The predicted structural model of the TSH molecule is that of a cystine knot growth factor. The tertiary TSH structure comprises three hairpin loops separated by central disulfide bonds, with the longer loop straddling one side. Production of the mature heterodimeric TSH molecule requires complex cotranslational glycosylation and folding of nascent and subunits. After subunit translation and signal peptide cleavage, glycosylation occurs at asparagine 23 on the subunit and at two asparagine residues, 52 and 78, on the subunit. Appropriate glycosylation is required for accurate molecular folding and subsequent combination of and subunits within the rough endoplasmic reticulum and Golgi apparatus. Both TRH and T3 regulate TSH glycosylation, albeit in opposite directions. TRH administration or T3 deprivation, such as occurs in hypothyroidism or T3 resistance, enhances oligosaccharide addition to the TSH molecule.

Thyroid-Stimulating Hormone Secretion

The TSH production rate is normally 100 to 400 mU/day, with a calculated circulating half-life of about 50 minutes. Secretion rates are enhanced up to 15-fold in hypothyroid subjects and are suppressed in states of hyperthyroidism. The degree of TSH glycosylation determines the metabolic clearance rate as well as bioactivity, and in hypothyroidism the molecule appears highly sialylated. Immunoactive fetal pituitary TSH is detectable by 12 weeks. Immediately after full-term birth, there is a brisk rise in TSH, which remains elevated for up to 5 days before stabilizing at adult levels.

Although TSH secretion is pulsatile, the low pulse amplitudes and long TSH half-life result in modest circulating variances. Secretory pulses every 2 to 3 hours are interspersed with periods of tonic, nonpulsatile TSH secretion. Circadian TSH secretion peaks between 11 PM and 5 AM, mainly because of increased pulse amplitude, which does not appear to be sleep-entrained. Pulsatile and circadian TSH secretory patterns are largely determined by ambient thyroid hormone levels, TRH release, dopamine, and cortisol. Primary hypothyroidism is associated with enhanced TSH pulse amplitudes occurring throughout the day, and nocturnal TSH surges are abrogated in patients with critical illness.

Thyrotropin-Releasing Hormone and Thyroid Hormone Regulation

Because feedback control of TSH secretion by peripheral thyroid hormones is so sensitive, most thyrotroph disorders can be diagnosed by measuring basal TSH and thyroid hormone levels. However, evoked dynamic TSH measurements may be required to assess fully the integrity of the hypothalamic-pituitary-thyroid axis. TRH (200 to 500 µg) is administered intravenously, and TSH levels are measured at -15, 0, 15, 30, 60, and 120 minutes.

In euthyroid subjects, peak TSH levels (up to 22-fold higher than basal) are observed after 30 minutes. Because feedback suppression of TSH by elevated thyroid hormone levels overrides positive hypothalamic signals, hyperthyroid subjects have undetectable basal TSH levels that do not respond to TRH. In subjects with primary thyroid failure, the TSH response is exuberant, but in those with secondary thyroid failure related to pituitary disease TSH levels do not change in response to TRH.

Sustained TRH infusions for up to 4 hours result in biphasic TSH increases, reflecting early release of preformed TSH, followed later by newly synthesized hormone. Further prolonged TRH infusions elevate thyroid hormone levels, which subsequently suppress pituitary TSH synthesis and release. Within hours of T3 administration, basal TSH levels are suppressed and TRH-evoked TSH levels are attenuated. Thyroid hormones suppress tonic TSH secretion and pulse amplitude but do not appear to regulate TSH pulse frequency. T3 also suppresses hypothalamic TRH synthesis and decreases pituitary TRH receptor number, thus further limiting TSH biosynthesis.

Other Factors

SRIF inhibits TSH pulse amplitude, blocks the nocturnal TSH surge directly at the pituitary level, and may also suppress TRH release and possibly TRH receptor abundance. Although SRIF analogues are used to treat TSH-secreting pituitary adenomas (see later), long-term SRIF treatment for acromegaly does not lead to hypothyroidism in adult subjects although T3 levels may be lowered within the normal range. Dopamine inhibits TSH subunit gene expression, and dopamine infusions suppress TSH pulse amplitude by 70% and abrogate the nocturnal TSH surge. Prolonged use of dopamine agonists, however, does not result in hypothyroidism.

Glucocorticoids suppress TSH secretion, and in patients with adrenal failure without autoimmune thyroid damage, TSH levels may be elevated. Sex steroids and cytokines alter TSH secretion in animal models, but their contribution to human TSH physiology is unclear. Nonsteroidal anti-inflammatory agents, especially...
meclomenamate and fenclofenac, decrease serum TSH levels, albeit still within the normal range. The mechanism may involve displacement of thyroid hormone ligands from their binding proteins or direct inhibition of pituitary TSH.

Thyroid-Stimulating Hormone Action

TSH acts on the thyroid gland to induce thyroid hormone synthesis and release and to maintain trophic thyroid cell integrity. The TSH G protein-coupled (GPC) receptor is located on the thyrocyte plasma membrane and is encoded by a gene on chromosome 11q31. Its regulation is comprehensively described in Chapter 10.

Thyroid-Stimulating Hormone Assays

The challenge for a clinically compelling robust TSH assay is to differentiate circulating TSH levels in euthyroid subjects from those in both hyperthyroid and hypothyroid patients. The development of immunoradiometric TSH assays has provided high specificity with little or no cross-reactivity with other glycoprotein hormones. These assays detect quantifiable TSH levels in euthyroid control subjects with no overlap with the low values associated with hyperthyroidism. The most sensitive commercially available third-generation assays have a functional sensitivity of 0.01 to 0.02 mIU/L, and newer fourth-generation assays should have greatly enhanced sensitivity (0.001 to 0.002 mIU/L). Levels of free subunit (normal range 0.1 to 1.6 μg/L) are elevated in patients harboring TSH-secreting or nonfunctional pituitary adenomas, choriocarcinomas, and several malignancies.

TSH deficiency results in childhood mental or growth retardation, or both, and hypothyroidism in adults is associated with a broad spectrum of clinical features including hypothemia, fluid retention, voice and skin changes, and ultimately frank myxedema and death. Pituitary damage may result in functional TSH deficiency, often without a clearly demonstrable reduction in serum TSH levels. Although impractical to measure, nocturnal TSH pulse amplitudes may be attenuated in patients with pituitary dysfunction. TSH deficiency should be diagnosed by measuring free T levels because TSH measurements are not helpful in diagnosing central hypothyroidism. In fact, only about one third of patients with secondary hypothyroidism have abnormally low basal TSH levels. TSH deficiency is thus associated with low T levels concomitant with low, normal, or even minimally elevated TSH levels. This biochemical profile may also be encountered in critically ill patients with low TSH and T levels without evidence of pituitary disease.

Treatment

L-Thyroxine is used for replacement therapy, and dosing variables are similar to those required for treating primary hypothyroidism. Hypothyroid features are effectively ameliorated by T (0.05 to 0.25 mg/day). The molecule is converted peripherally into the active T and has a 7-day half-life with stable blood levels. The dose of levothyroxine in hypopituitary patients is titrated to achieve midnormal clinically euthyroid serum free T levels because serum TSH levels are low or undetectable in patients with damaged pituitary function.

Measurement of TSH levels is not useful in determining thyroid hormone replacement because the damaged thyrotroph is unlikely to reflect appropriate feedback suppression. Many women with pituitary failure also receive estrogen replacement, and measuring free T levels is required because of increased TBG levels. TSH overdosing may also lead to osteopenia and cardiac arrhythmias. Some patients may have associated ACTH deficiency, and thyroid hormone replacement should not be initiated until adrenal reserve has been evaluated and, if necessary, treated. Thyroid hormone replacement may also accelerate cortisol metabolism or requirements, or both, and may therefore exacerbate primary hypoadrenalism or precipitate adrenal crisis in patients with perturbed adrenal function.

Thyrotropin-Secreting Tumors

TSH-producing pituitary tumors are rare. Most older series indicate that they represent less than 1% of pituitary tumors. From 1979 to 1992, Mindermann and Wilson analyzed tumor type by immunohistochemistry and found that the overall prevalence of TSH-secreting tumors was 19 in

2225 (0.85%). Between 1989 and 1991, they found a prevalence of 2.8%. It is not clear whether the incidence of this tumor type is increasing or whether tumors are now more readily recognized. Enhanced recognition may be a result of the development of high-sensitivity TSH assays that distinguish between normal TSH levels that are, in fact, inappropriately elevated for thyroid hormone levels in some patients with TSH-producing tumors and frankly low ones. TSH-secreting tumors can also cosecrete other hormones including GH, PRL, and rarely ACTH.

Pathology

These tumors are invasive, but for the most part benign, and distant metastases are extremely rare. The secretory pattern is determined by a panel of antibodies to TSH, subunit, GH, PRL, and ACTH. TSH-secreting tumors exhibit positive immunostaining for subunit and TSH in 20% to 75% of cells and for Pit-1.

Presentation

Patients with TSH-secreting tumors present with symptoms related to tumor size (e.g., visual field abnormalities, cranial nerve palsies or headache) or to hormone overproduction. Signs and symptoms of hyperthyroidism, including palpitations, arrhythmias, weight loss, tremor, and nervousness, or a goiter are common. A case of periodic paralysis has been reported. Serum TSH is often but not invariably elevated, and the combination of abnormally high thyroid hormone and TSH within the normal range points to a TSH-producing pituitary tumor. A relatively long period of hyperthyroidism, initially thought to represent Graves’ disease and treated accordingly, often predates the realization that the hyperthyroidism is a result of a TSH-secreting pituitary tumor. Alternatively, thyroid hormone insensitivity can exist with similar laboratory profiles.

TSH-secreting tumors are usually large. A review of six reports indicates that 80% of TSH-secreting tumors are macroadenomas and 12% microadenomas. Over 60% are also locally invasive. From an analysis of 10 reports on a total of 153 patients, we estimate that TSH is frankly elevated in 58% of patients, with the remainder having normal although inappropriately elevated levels. Patients previously treated with radioactive iodine for presumed Graves’ disease present with significantly higher TSH levels than patients not previously radioablated (mean of 56 and 9 mIU/L, respectively). An ecotropic TSH-producing tumor has also been reported. Serum TSH is high in the majority of patients, as is the glycoprotein hormone subunit. Approximately two thirds of patients with TSH-producing pituitary tumors have a goiter with elevated radioactive iodine uptakes. Signs or symptoms of acromegaly or hyperprolactinemia may also be present in controls.

Evaluation

The T, T, TSH (by high-sensitivity assay), and subunit should be measured. The combination of high T, T, and subunit; high or inappropriately normal TSH; and a pituitary tumor strongly confirms the diagnosis of a TSH-producing pituitary adenoma. TRH stimulation distinguishes between TSH overproduction by a TSH-secreting tumor and thyroid hormone insensitivity. With TSH-secreting tumors, the TSH response to TRH is blunted. In contrast, TSH usually rises in response to TRH in thyroid hormone insensitivity and in normal subjects. Concomitant measurement of subunit at each point during the TRH test is helpful because the molar ratio of subunit to TRH is high (>1) in almost 85% of patients with TSH-secreting tumors. Ratios greater than 1 can also be seen in normal subjects.

A T suppression test is helpful in that complete inhibition of TSH does not occur in patients with TSH-secreting tumors. This test can also differentiate subclinical hyperthyroidism in a patient treated with radioactive iodine for hyperthyroidism in the past but found to have an incidental pituitary tumor. TSH elevation may also result from inadequate thyroid hormone replacement. Pituitary MRI should be performed and IGF-I and PRL levels determined to exclude acromegaly or hyperprolactinemia. The presence of other pituitary hormones in immunostained histologic sections does not necessarily imply that their levels are elevated.

The degree of hyperthyroidism should be assessed to determine whether control of these signs and symptoms should be undertaken prior to further evaluation or treatment of the pituitary tumor. One report characterized the hyperthyroidism in this condition as being severe in 14 of 25 patients and having been present in most patients for years before the diagnosis was made. Perioperative deaths in patients with TSH-secreting tumors have been reported, which might be attributed to

251
poorly controlled hyperthyroidism.

Management

Surgery

Surgery is recommended as the first-line treatment, but surgical cures occur in no more than 40% of patients (Table 8-30). However, the rarity of this tumor type has precluded large controlled studies. Fourteen of 22 patients had cavernous or sphenoid sinus invasion and tumors were fibrous and unusually hard. Eight patients were considered cured after surgery. In another study, surgery resulted in normalization of T₄ in 15 and of parameters of cure in 7 of 17 patients. Over half of the patients, when assessed by MRI 6 months after surgery, exhibited evidence of residual tumor.

Radiation Therapy

There are no large series reporting treatment of TSH-secreting tumors with radiotherapy alone. Radiation has mostly been employed as adjunctive therapy to surgery, especially when the latter was not curative.

Somatostatin Analogues

Octreotide, used as either primary or adjunctive treatment, normalized T₄ and T₃ and reduced TSH levels by half in 25 patients treated with octreotide (100 to 500 µg/day) for up to 61 months, 84% had controlled thyroid function. However, tachyphylaxis developed in five patients, and three escaped the effect of the drug. Overall, tumor shrinkage occurs in about a third of patients. In 18 patients with TSH-secreting adenomas, lanreotide (30 mg every 10 or 14 days), significantly decreased TSH levels from 2.72 to 1.89 mU/L, decreased T₄ levels, but did not shrink tumors. Responsiveness to octreotide LAR (up to 30 mg monthly) appeared similar to that observed for the subcutaneous preparation in seven patients.

Unless vision is threatened, patients should be evaluated to determine whether the clinical signs of hyperthyroidism warrant immediate treatment (Fig. 8-63). Propranolol, radioactive iodine thyroid ablation, thyroidectomy, antithyroid medications including methimazole (Tapazole) and propylthiouracil, and somatostatin analogues are employed. Both radioactive iodine and antithyroid medications are targeted to the thyroid gland rather than the pituitary seat of the disorder. Both also

inhibit the remaining negative feedback of T₃ on TSH and lead to increased tumor TSH production. 

Surgery and somatostatin analogues simultaneously treat hyperthyroidism and tumor TSH hypersecretion. Propranolol is important for inhibiting peripheral hyperthyroid manifestations. Somatostatin analogues lower TSH, subunit, and T₄ and are recommended as first-line drugs in the initial control of hyperthyroidism related to TSH-secreting tumors because they act more rapidly than other therapeutic approaches and tumor shrinkage occurs in up to 40% of patients. If these drugs are ineffective or only partially effective, other therapeutic modalities should be used. Thus, no single treatment is expected to cure patients with TSH-secreting adenomas. Surgery is curative in only a minority of patients, and although tumor bulk removal may normalize thyroid function when invasive tumor tissue persists, patients continue to have abnormal TSH responses to TRH and require somatostatin analogue therapy.
PITUITARY FAILURE

Impaired synthesis of one or more anterior pituitary hormones may result from heritable genetic factors, acquired anatomic insults, inflammation, or vascular damage. Because of its close anatomic contiguity, impaired hypothalamic hormone synthesis or secretion may also occur as a component of the pituitary gland insult, especially after external radiation. Furthermore, distinct hypothalamic lesions may result in diminished pituitary hormone secretion by abrogating hypothalamic hypophysiotropic signals.

Developmental and Genetic Causes of Pituitary Failure

Developmental Pituitary Dysfunction

Congenital pituitary gland absence (aplasia), partial hypoplasia, or ectopic tissue rudiments are rarely encountered. Pituitary development follows midline cell migration from Rathke’s pouch, and impaired midline anomalies including failed forebrain cleavage and anterior commissure and corpus callosum defects lead to structural pituitary anomalies. Craniofacial developmental anomalies including anencephaly result in cleft lip and palate, basal encephalocele, hypertelorism, and optic nerve hypoplasia with varying degrees of pituitary dysplasia and aplasia. If these infants survive, appropriate lifelong pituitary hormone replacement is required. Children with mild forms of midline anomalies are also more susceptible to GH deficiencies.

With sensitive MRI techniques for pituitary visualization, several anatomic features characteristic of hypopituitarism are now apparent. Evidence for acquired pituitary gland damage or destruction is often clearly visible on MRI, and patients presenting with hypopituitarism of undetermined etiology may exhibit decreased gland volume, partial or complete empty sella, disturbed sella turcica architecture, absent or transected pituitary stalk, and an absent or ectopic posterior pituitary bright intensity signal. An absent infundibulum noted on MRI is associated with pituitary hormone deficits, and about 25% of patients with GHD of unclear cause show imaging evidence of mild stalk defects, reflecting a midline developmental anomaly. Congenital basal encephalocele may result in the pituitary herniating through the sphenoid sinus roof, resulting in pituitary failure and diabetes insipidus.

Heritable Disorders of Pituitary Failure

Mutations of transcription factors that determine anterior pituitary development may lead to pituitary deficiency syndromes. Patients heretofore diagnosed with idiopathic isolated or polyhormonal pituitary failure may, in fact, harbor such a mutation. As the genetic control of pituitary development has been clarified, increasing numbers of mutant genes have become apparent.

PROP1

PROP1 (Online Mendelian Inheritance in Man [OMIM] 601538) gene expression is required for subsequent Pit-1 activation. The gene, located on chromosome 5q, encodes a 223-amino-acid protein expressed in cells secreting GH, PRL, and TSH. The Ames dwarf mouse harbors a missense PROP1 mutation (Ser83Pro) and exhibits a hypoplastic pituitary gland with combined GH, PRL, and TSH deficiency. This mutation abrogates Pit-1 activation and results in failed development of Pit-1-dependent cell lineages. At least eight human mutations have been associated with GH, PRL, TSH, and gonadotropin deficiencies. The most commonly encountered mutation is a 2-bp deletion at position 296 (301-302delAG), resulting in early translation termination and a nonfunctional protein.

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone. Functional defects include missense or frameshifts leading to truncated or deleted protein, DNA binding abnormality, inactivated protein, or impaired coactivation. *POU1F1* mutations result in varying phenotype of early growth failure with or without hypothyroidism. *PROP1* mutations may be fully manifest only in adulthood. *HESX1* is critical for corpus development and associated with structural brain defects.

protein product. The clinical spectrum of combined pituitary hormone deficiency associated with *PROP1* mutations varies with both the type of mutation and the age of the patient. 798

Human *PROP1* mutations are associated with deficiencies in Pit-1-dependent lineages (GH, PRL, and TSH) as well as impaired FSH, LH, and ACTH reserve function. 517 Because the development and mature function of the latter cell types are not Pit-1-dependent, it appears that additional critical developmental factors are disrupted in these patients, leading to the clinical phenotype. Over 50 patients with *PROP1* mutations leading to combined pituitary hormone deficiency have been described since the original report in 1996, 799 and this disorder appears to be the most common heritable cause of combined pituitary hormone deficiency.

**Molecular Analysis**

Modes of inheritance of *PROP1* mutations usually reflect autosomal recessive patterns. Thus, patients are usually homozygous for either deletion or missense frameshift mutations leading to truncated *PROP1* protein products devoid of functional activity. *PROP1* has been identified at a GA repeat in exon 2. Combination of a GA or AG deletion in this repeat results in a coding frameshift and premature termination at codon 109. Nonafflicted siblings are heterozygous or bear a normal *PROP1* sequence on both alleles.

**Clinical Features**

The frequency of PRO1 gene mutations in patients with combined pituitary hormone deficiency is high, the mutations occurring in approximately 50% of affected subjects. However, in families with multiple affected subjects, PRO1 mutations account for virtually all affected individuals. Patients harboring PRO1 mutations exhibit a predominantly hypogonadal phenotype. Puberty is often delayed or absent, with markedly attenuated LH and FSH responses to GnRH stimulation. Some patients enter puberty spontaneously and develop subsequent...
features of central hypogonadism, akin to an acquired presentation. Although the pituitary gland is small or normal in size, patients have been described with grossly hypoplastic anterior pituitary glands with cystic changes and development of a secondary empty sella. Slowing of linear growth usually becomes apparent after the age of 3 years, and these patients usually do not enter puberty. Height SDs may be severely impaired and may range to -10 with eunuchoidal proportions and reduced upper body/lower body ratios. Affected adults are short and have infanteile external genitilia. The onset of clinically evident pituitary failure is usually characterized by GHD (80%) and thyroid failure (TSH deficiency, 20%), followed by hypogonadism and later subclinical or overt adrenal insufficiency.

Features of PROP1 excess have been described in a mouse model. These animals have hypothyroidism, hypogonadism, and persistent Rathke's cleft cysts and, after 1 year, develop pituitary adenomas.

**Evaluation**

Combined hypothalamic hormone stimulation (GnRH, TRH, CRH, and GHRH) or insulin-evoked hypoglycemia reveals blunted responses consistent with varying degrees of pituitary hormone deficiencies. Serum IGF-I and IGFBP3 levels are usually low, and peripheral thyroid hormone levels are low or at the lower limits of normal ranges. In the presence of low or absent TSH responses, these findings are consistent with secondary hypothyroidism. Most older patients also exhibit blunted cortisol responses to CRH or ACTH or insulin stimulation.

**Pituitary Size**

Heterogeneous changes in pituitary size may reflect a combination of adaptive signals for the Pit-1 lineage, compensatory cystic expansion of nonaffected pituitary cell types with subsequent autolaminction, and the absence of other unknown factors required for mature pituitary function.

**POU1F1**

The POU1F1 gene (Pit-1) is located on chromosome 3p11 (OMIM 173110) and encodes a 290-amino-acid protein. The N-terminal POU-specific domain activates gene transcription, and two DNA-binding domains recognize a TATNCAT consensus sequence present in the GH, PRL, and TSH genes and the GHRH receptor gene. The Pit-1 nuclear protein activates transcription of the GH, PRL, and TSH genes and the GHRH receptor gene and also interacts with coactivators including thyroid hormone, estrogen, and retinoic acid receptors as well as other transcription factors including CREB, P-Lim, Ptx-1, HESX-1, and Zn-15. Pit-1 autoregulates its own expression and is therefore critical for maintaining appropriate Pit-1 expression. Because of the absolute requirement of Pit-1 for GH, PRL, and TSH cell development and specific gene expression, inactivating mutations of the gene result in a spectrum of pituitary hormone deficiencies. Two dwarf mouse strains harboring POU1F1 gene mutations. The Snell dwarf mouse harbors a tryptophan cystine missense mutation (Trp261Cys). The Jackson mouse, also a dwarf, harbors a truncated POU1F1 protein with defective DNA binding.

Several POU1F1 mutations have been described, each of which is associated with a characteristic clinical phenotype. Arg172Tyr mutants are associated with neonatal hypothyroidism and GH and PRL deficiency. Both sporadic patients and multiplex families with multiple pituitary hormone defects have been described, and at least 10 recessive and 3 dominant Pit-1 mutations have been identified so far. Recessive mutations result in a varied spectrum of loss of DNA binding or transcriptional activation of TSH, GH, and PRL. Impaired retinoic acid activation of the Pit-1 distal enhancer has been described for a Pit-1 Lys261Glu mutation. This mutant protein also behaves as a dominant negative inhibitor of Pit-1 activation. A sporadic mutation (Arg271Try) results in a protein that binds to DNA but dominantly inhibits Pit-1 transcription with severe combined GH, PRL, and TSH deficiencies.

**Hesx1**

Hesx1 (Rpx) is an early transcriptional marker of the primitive pituitary, with expression restricted to Rathke's pouch. Coincidentally with the appearance of specific pituitary cell types, Hesx1 expression declines and is extinguished in the mature anterior pituitary.

The gene is located on chromosome 3p212, encodes a 1214-amino-acid protein, and competes with PROP1 protein for DNA binding. The heterogeneous syndrome of septo-optic dysplasia (hypoplastic optic nerves, absent corpus callosum and septum pellucidum, and hypopituitarism) is associated with a homozygous Arg53Cys homeodomain mutation. Although the mutant molecule exhibits reduced DNA binding, no specific hormonal target gene is yet apparent, and hypopituitarism may be secondary to the

**LHX3**

Missense and deletion mutations of LHX3 are associated with hypopituitarism except for intact ACTH reserve. These patients also exhibit defective neck rotation because of a rigid cervical spine. PX2 Rieger's syndrome (anterior eye, teeth, and umbilical maldevelopment) may be associated with GHD and haploinsufficiency of the RIEG (POX2) homeobox gene.

The frequency of heritable combined pituitary hormone deficiencies is rare. Nevertheless, within this cohort of patients, PROP1 mutations appear to be the most prevalent, accounting for well over 50% of retrospective reports and over 90% of patients with more than one affected sibling. Pit-1 mutations are less commonly encountered. Patients with a family history of pituitary dysfunction and those who exhibit blunted hormonal responses to TRH, GHRH, or GnRH stimulation should be subjected to molecular screening for PROP1 or Pit-1 defects. The pronounced clinical phenotype of Hesx-1 mutations determines the need for further molecular analysis.

**Lawrence-Moon-Biedl Syndrome**

This autosomal recessive disorder is characterized by hypogonadotrophic hypogonadism, mental retardation, obesity, retinitis pigmentosa, hexadactyly, brachydactyly, or syndactyly. By age 30, most patients are blind. Although most patients have evidence of GnRH deficiency, about 25% of affected males may have primary testicular failure.

**Prader-Willi Syndrome**

These patients have marked hyperphagia and obesity with retarded mental development, muscle hypotonia, and diabetes mellitus. Related conditions include
micrognathia, absent auricular cartilage, and acromesia. The condition has been ascribed to deletion or translocation of chromosome 15. In hypogonadal patients, bilateral cryptorchidism and absent scrotal folds are accompanied by evidence for attenuated GnRH secretion. LH and FSH levels have been restored in some patients with chronic GnRH treatment. Defective oxytocin and vasopressin synthesis has also been reported.

Kallmann's Syndrome

Kallmann's syndrome consists of defective GnRH synthesis with olfactory nerve agenesis or hypoplasia and variable anosmia. Associated developmental disorders include optic atrophy, color blindness, eighth-nerve deafness, cleft palate, renal agenesis, cryptorchidism, and movement disorders. This X-linked recessive disorder has been ascribed to a defective KAL gene located on chromosome Xp22.3. The KAL protein mediates hypothalamic migration of GnRH cells from the primitive olfactory placode, and its absence leads to defective GnRH synthesis and anosmia. Both autosomal recessive and dominant forms of the disorder have been described, indicating the involvement of additional genetic factors in the pathogenesis of the disorder.

Clinical Features

These patients are exposed to low or absent sex steroids from birth. Consequently, females are tall and present with primary amenorrhea and absent secondary sexual development and males have delayed puberty and micropenis.

Laboratory

Absent GnRH secretory pulses result in characteristically low LH and FSH levels in the presence of very low concentrations of estradiol or testosterone. Because the nonprimed normal pituitary may not respond initially to GnRH stimulation (25 to 100 µg intravenously), this test is of little value in distinguishing the hypothalamic defect. In some patients, repetitive GnRH priming may elicit normal pituitary LH and FSH responses, indicating a hypothalamic defect in GnRH secretion.

The differential diagnosis of congenital hypogonadotropic hypogonadism includes Kallmann's syndrome (KAL gene mutation), congenital adrenal hypoplasia (DAX1 mutation), GnRH receptor mutations, leptin and leptin receptor mutations, PROPT gene mutations, and mutations of the LH or FSH molecules themselves. These conditions are characterized by absent or low GnRH-mediated LH secretory patterns in the presence of a structurally normal pituitary gland. The cause of hypogonadotropic hypogonadism still remains elusive in over 80% of patients (see earlier). In the absence of a structural pituitary defect, genetic evaluation of these patients should be undertaken.
Acquired Pituitary Failure

Causes

In the absence of demonstrable hypothalamic-pituitary anatomic damage and after excluding genetic and syndromic causes of pituitary insufficiencies, acquired, often transient, causes of pituitary failure should be considered (Table 8-32). Causes of pituitary insufficiency including pituitary tumors, parasellar masses, hypophysectomy, aneurysms, and pituitary apoplexy have already been discussed. Hypophysitis, diabetes insipidus, diabetes mellitus, and vocal cord paralysis are all relatively common causes of pituitary hormone insufficiency. Following external radiotherapy for pituitary tumors in adults, hypopituitarism is a frequent complication. Growth hormone (GH) deficiency is the most common endocrine disorder seen in irradiated patients, but other anterior pituitary hormones are also affected. In about 50% of irradiated patients, symptoms and signs of pituitary hormone insufficiency develop over a period ranging from a few weeks to several decades. Seventy-five percent of patients with post-traumatic pituitary failure are men younger than 40 years who were involved in a motor vehicle accident within a year of diagnosis. Virtually all patients with subsequent pituitary failure have a history of loss of consciousness after the insult, and half of all such patients have documented skull fracture. One third of these patients have demonstrable signs of hypothalamic or posterior pituitary dysfunction caused by birth trauma, cranial hemorrhage, or death at birth. Although hypopituitarism after head trauma is usually manifest within a year after the insult, some patients may have overtly manifest signs of pituitary failure only after several decades. Seventy-five percent of patients with post-traumatic pituitary failure are men younger than 40 years who were involved in a motor vehicle accident within a year of diagnosis. Virtually all patients with subsequent pituitary failure have a history of loss of consciousness after trauma, and half of all such patients have documented skull fracture. One third of these patients have demonstrable signs of hypothalamic or posterior pituitary hemorrhage or anterior lobe infarction on MRI. Diabetes insipidus is the most common endocrine disorder, encountered in about 30% of these patients. Gonadotropin deficiency, amenorrhea, and hyperprolactinemia occur in children receiving 27 to 32 Gy or 35 Gy of cranial irradiation for a brain tumor in relation to time from irradiation (dxt). This illustrates that the speed at which individual pituitary hormone deficits develop is dose-dependent; the higher the radiation dose, the earlier GH deficiency occurs. The acquired immunedeficiency syndrome (AIDS) is associated with suppressed pituitary function independent of other associated infections. Drugs such as estrogens, which suppress FSH and LH, and GnRH analogues used for treating prostate cancer inhibit gonadotropin action. In addition to pituitary apoplexy, other vascular accidents such as aneurysms, strokes, cavernous sinus thrombosis, and arteritis can cause pituitary hormone insufficiency. Isolated pituitary hormone deficiencies may also occur as a manifestation of vascular abnormalities including arteritis.

Head Trauma

The pituitary gland may be partially or totally damaged by birth trauma, cranial hemorrhage, fetal asphyxia, or breech delivery. Head trauma may lead to direct pituitary damage by a sella turcica fracture, pituitary stalk section, trauma-induced vasospasm, or ischemic infarction after blunt trauma. The most common traumatic cause of compromised pituitary function in the adult is iatrogenic neurosurgical trauma. Adherent or inadvertent pituitary manipulation or damage during surgery leads to transient or permanent diabetes insipidus and varying degrees of anterior pituitary dysfunction.

Although hypopituitarism after head trauma is usually manifest within a year after the insult, some patients may have overtly manifest signs of pituitary failure only after several decades. Seventy-five percent of patients with post-traumatic pituitary failure are men younger than 40 years who were involved in a motor vehicle accident within a year of diagnosis. Virtually all patients with subsequent pituitary failure have a history of loss of consciousness after trauma, and half of all such patients have documented skull fracture. One third of these patients have demonstrable signs of hypothalamic or posterior pituitary hemorrhage or anterior lobe infarction on MRI. Diabetes insipidus is the most common endocrine disorder, encountered in about 30% of these patients. Gonadotropin deficiency, amenorrhea, and hyperprolactinemia may occur in the months following trauma or even years later. Pituitary testing performed within the first 48 hours of hospital admission shows that about 75% of patients have evidence of hypopituitarism, and the degree of pituitary failure correlates with the severity of head trauma.

Radiation

Pituitary radiation, usually indicated as therapy for pituitary adenoma, directly causes atrophy of the gland in addition to the damaging impact of radiation on hypothalamic synthesis of hypothalamic hormones. Pituitary function in children and adolescents is particularly sensitive to head and neck therapeutic radiation. Radiation dose exposure, time interval after completion of radiotherapy, and distance of the pituitary or hypothalamus from the central energy field correlate with the development of pituitary hormone deficits (Fig. 8-64 and Fig. 8-65).

After a median dose of 5000 rads directed at the skull base, nasopharynx, or cranium, up to 75% of patients experience pituitary insufficiency within 10 years. Later manifestations of pituitary failure usually reflect hypothalamic damage rather than atrophy of irradiated pituitary cells. Although the degree of hormone loss after radiation is variable, the pattern of loss usually occurs sequentially with GH before FSH and LH followed by ACTH and TSH. Thus, evidence for secondary thyroid or adrenal failure usually implies that the GH and gonadotropin axes are also compromised. Previously irradiated patients should therefore undergo lifelong periodic anterior pituitary hormone testing. Ideally, rigorous long-term screening should unmask incipient pituitary failure before the onset of morbidity.

Empty Sella Syndrome

Damage to the sellar diaphragm may lead to arachnoid hernaition into the sellar space. An empty sella may develop as a consequence of a primary congenital weakness of the diaphragm in patients in whom no secondary cause is evident. Up to 50% of patients with primary empty sella have associated benign intracranial hypertension. A secondary empty sella may develop after infarction of a pituitary adenoma or surgical or radiation-induced damage to the sellar diaphragm. MRI usually exhibits demonstrable pituitary tissue compressed against the sellar floor with lateral stalk deviation. Although an empty sella is usually an incidental finding, if more than 90% of pituitary tissue is compressed or atrophied, pituitary failure occurs. About 10% of patients may have small adenomas secreting GH or PRL within...
the rim of compressed pituitary tissue.
Clinical Features of Hypopituitarism

The spectrum of clinical features of pituitary insufficiency depends on several factors. In acquired pituitary insufficiency, the clinical spectrum depends on the degree of hormone deficiency, the number of hormones impaired, and the rapidity of onset. In congenital forms, the earlier the age of onset, the greater the severity of thyroid, gonadal, adrenal, growth, or water disturbances. Heritable genetic disorders invariably exhibit the most severe phenotypic changes, although later changes may also occur in these disorders, as seen with PROPT mutations.

The resilience of the individual pituitary cell lineages in the presence of compressive, inflammatory, vascular, radiation, and invasive insults also differs. The lactotroph cell is often hyperfunctional as a result of decreased tonic inhibitory signals. PRL deficiency is thus exceedingly rare except for complete pituitary destruction or genetic syndromes. The order of diminished trophic hormone reserve function with pituitary compression usually is GH prior to the other trophic hormones. The corticotroph and thyrotroph cells appear particularly resistant to hypothalamic or pituitary destruction and are usually the last to lose function. The qualitative phenotypic manifestations of pituitary failure are determined by which specific trophic hormones are lost (see the preceding descriptions of individual hormone deficiencies) (Table 8-34).

Adrenocorticotropic Hormone

Clinical symptoms and signs of ACTH deficiency are most profound and life-threatening. With acute pituitary failure, such as may occur with pituitary apoplexy, patients with ACTH deficiency may present with hypotension, shock, hypoglycemia, nausea and vomiting, extreme fatigue and asthenia, and dilutional hyponatremia. Serum potassium is normal because these patients are deficient in glucocorticoids but usually not mineralocorticoids.

When acute ACTH deficiency is suspected clinically, treatment with steroids should not be withheld. Serum cortisol and ACTH should be determined before glucocorticoid administration and would be expected to be low. In an acute setting, such as sudden apoplexy, responses to Synacthen stimulation may be normal and misleading because the blunted response of cortisol usually seen in secondary adrenal insufficiency is due to loss of glucocorticoid-producing cells, which requires at least several weeks after the onset of ACTH deficiency. When ACTH deficiency occurs gradually, features are more insidious and include weight loss, asthenia, weakness, fatigue, nausea, and dilutional hyponatremia. This may be due to corticotroph dysfunction arising as a result of an enlarging pituitary tumor, delayed effects of radiation, damage related to pituitary tumor surgery, or removal of parasellar masses. In these cases, tests for ACTH reserve are likely to be blunted. If unsuspected or untreated, this form of adrenal insufficiency may also lead to death. Caution must be exercised in performing an ITT or metyrapone test because the latter can cause worsening of adrenal insufficiency and the former seizures and nausea. These tests should be done only in a hospital setting under supervision with available intravenous cortisone and glucose.

Steroid replacement doses should be appropriate to the clinical situation. Under conditions of major stress, such as pituitary apoplexy or pituitary surgery, maximal cortisone requirements range from 200 to 300 mg daily. Because the adrenal glands are incapable of increasing cortisol production during stress in the presence of deficient ACTH, an initial intravenous dose of 100 mg of hydrocortisone (Solu-Cortef) in acute adrenal insufficiency or an intravenous infusion of the same dose during pituitary surgery is followed by 50 mg intravenously every 6 hours for the first day. Similar doses are employed for other forms of major stress in patients with established secondary adrenal insufficiency.

Clinical judgment must be used in determining how long patients should be exposed to supraphysiologic doses of steroids. In our view, doses should be lowered to maintenance as soon as clinically feasible without endangering the patient. We employ replacement doses of 10 to 20 mg of hydrocortisone daily, usually 10 mg in the morning and 5 mg in the evening. An additional 5 mg is administered in the afternoon if needed clinically. Because surgical decompression may lead to recovery from hormone deficiencies, a clinical decision should be made postoperatively about whether to wean patients from hormonal replacement therapy and retest them hormone by hormone. Great care must be taken when secondary adrenal insufficiency has been previously documented.

Thyroid-Stimulating Hormone

Because the half-life of serum T₄ is 6.8 days, hypothyroidism may not become apparent for several weeks in patients with acute pituitary insufficiency; therefore, thyroid function should be tested. However, serum T₄ is not elevated in secondary hypothyroidism and it cannot be used to assess the adequacy of thyroid hormone replacement, nor is a TRH test helpful. Severity of symptoms of hypothyroidism depends on the degree of hypothyroidism and length of time it has been present. Even in the absence of symptoms, T₄ should be administered if thyroid function studies are consistent with hypothyroidism. Glucocorticoids should be replaced before thyroid hormone because thyroid hormone in hypothyroid individuals increases the requirement for glucocorticoids in stressful situations.

Gonadotropins

Sexual dysfunction related to gonadotropin deficiency is far more common than hypothyroidism or hypoadrenalism in patients with pituitary disease. Its presence is established by the constellation of abnormal menses or amenorrhea with no elevated LH and FSH levels in women and sexual dysfunction in men with low testosterone and normal or low gonadotropin levels. Because even mild hyperprolactinemia may cause sexual dysfunction, it should be determined whether PRL is causing hypogonadism. Treatment with dopamine agonists may result in normal sexual function without the need to replace sex steroids. A GnRH stimulation test rarely differentiates causes of gonadotropin deficiency and is usually not indicated.

Sex steroid replacement in deficient patients has important effects on body composition in addition to normalizing sexual function. Testosterone replacement may not be as effective in normalizing sexual function in men with long-standing secondary hypogonadism and loss of libido as it is in men whose sexual dysfunction is recent. Osteoporosis is common in women deficient in estrogen and men deficient in testosterone, and replacement improves bone density. Testosterone reduces abdominal and visceral fat and improves muscle mass in testosterone-deficient men. Therefore, sex hormone replacement is important even though sexual function may not be normalized or is not desired.

Growth Hormone

GHD is discussed comprehensively earlier and is invariably present when two or more other trophic hormones are deficient.

Prolactin

PRL deficiency is extremely rare because it occurs only when the anterior pituitary is completely destroyed, as in patients after apoplexy, or in patients with congenital causes of PRL deficiency. When present, PRL deficiency prevents lactation. In fact, PRL is often elevated in most forms of pituitary insufficiency. For example, many patients with preoperative...

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHD, growth hormone deficiency; GHRH, GH-releasing hormone; GnRH, gonadotropin-releasing hormone; PRL, prolactin; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyrotropin. PRL hypersecretion is diagnosed by single serum measurement.

*Not a good screening test for secondary or tertiary hypothyroidism.*

Hyperprolactinemia related to tumor pressure on stalk structures continue to have hyperprolactinemia even after tumors are surgically debulked. Likewise, hyperprolactinemia occurs in 50% of patients treated with whole-brain radiation, the most common endocrine disturbance.

**Posterior Pituitary**

Diabetes insipidus occurs frequently after pituitary surgery. Hyponatremia may also develop as the second of three phases of postoperative diabetes insipidus or may develop without evidence of diabetes insipidus after surgery. This subject is comprehensively covered in Chapter 9.
Screening for Pituitary Failure

The onset of hypopituitarism may be extremely slow, and subclinical pituitary failure is often not apparent to the patient or physician. Screening for pituitary dysfunction should be undertaken in patients with hypothalamic or pituitary mass lesions, developmental craniofacial abnormalities, inflammatory disorders, brain granulomatous disease, prior head or neck radiation, head trauma, prior skull base surgery, and newly discovered empty sella and in those who previously experienced pregnancy-associated hemorrhage or blood pressure changes.

Because hypopituitarism may develop insidiously and is often not readily clinically apparent, screening of appropriate patients is important to prevent long-term morbidity. Therefore, all patients harboring hypothalamic or pituitary masses should be screened for hypopituitarism. PRL should be measured because many patients with hypopituitarism also present with secondary hyperprolactinemia. Up to two thirds of patients harboring pituitary macroadenomas, craniopharyngiomas, and other parasellar lesions have compromised pituitary reserve function. Less commonly, patients with intrasellar aneurysms, pituitary metastases, parasellar meningiomas, optic gliomas, and hypothalamic astrocytomas also have pituitary failure. Although about a third of patients with hypopituitarism undergoing pituitary surgery recover function after decompression, about 25% of patients experience further loss of pituitary function after surgery and therefore should be screened annually. Treatment of pituitary failure was described fully earlier.

Chapter 9 - Posterior Pituitary Gland

Alan G. Robinson
Joseph G. Verbalis

ANATOMY

Normal Anatomy

The posterior pituitary gland is neural tissue and consists only of the distal axons of the hypothalamic magnocellular neurons that make up the neurohypophysis. The perikarya (cell bodies) of these axons are located in the paired supraoptic nuclei and the paired paraventricular nuclei of the hypothalamus.

During embryogenesis, neuroepithelial cells of the lining of the third ventricle mature into magnocellular neurons while migrating laterally to and above the optic chiasm to form the supraoptic nuclei (SON) and to the walls of the third ventricle to form the paraventricular nuclei (PVN). The axon tracts in the hypothalamus are shown in Figure 9-1. In the posterior pituitary gland, the axon terminals of the magnocellular neurons contain neurosecretory granules, membrane-bound packets of hormones stored for subsequent release. The blood supply for the anterior pituitary is through the hypothalamic-pituitary portal system but the posterior pituitary blood supply is directly from the inferior hypophyseal arteries, which are branches of the posterior communicating and internal carotid arteries. The drainage is into the cavernous sinus and internal jugular vein.

The hormones of the posterior pituitary gland oxytocin and vasopressin are synthesized in individual hormone-specific magnocellular neurons. In addition, the magnocellular neurons that synthesize vasopressin and oxytocin, respectively, are clustered into subdivisions of the supraoptic and paraventricular nuclei. The synthesis of oxytocin and vasopressin in separate neurons and the organization of the magnocellular neurons into clusters of oxytocinergic and vasopressinergic cells are compatible with the idea that the secretion and function of each hormone are distinct and individually controlled. Virtually all of the oxytocinergic neurons and vasopressinergic neurons in the supraoptic nucleus project their axons to the posterior pituitary. The organization of the paraventricular nucleus, however, is much more complex and varies among species. In addition to at least three distinct magnocellular divisions consisting of oxytocinergic neurons and vasopressinergic neurons, parvicellular (smaller cells) divisions synthesize other peptides (e.g., corticotropin-releasing hormone, thyrotropin-releasing hormone, somatostatin) and opioids. The parvicellular neurons project to the median eminence, brain stem, and spinal cord, where they play a role in a variety of neuroendocrine autonomic functions. The supraoptic nucleus is a more discrete nucleus, but there are concentrations of oxytocin-containing cells in its dorsal portion and vasopressin-containing cells in its ventral portion.

Dorsally and laterally, the supraoptic nucleus is surrounded by a cell-poor, fiber-rich area (the perinuclear zone). This zone contains GABAergic (γ-aminobutyric acid)-secreting neurons that project outside the general area and to the supraoptic nucleus, where they are reported to have an inhibitory function. Another nucleus that contains many vasopressin but not oxytocin neurons is the suprachiasmatic nucleus located in the midline at the base of and anterior to the third ventricle. The suprachiasmatic nucleus controls circadian as well as seasonal rhythms.
Ectopic Posterior Pituitary

With the development of magnetic resonance imaging (MRI) scans of the brain, it was discovered that T1-weighted MR images showed a bright signal in the posterior pituitary. This new diagnostic imaging technology (see later) allowed the identification of a group of patients in whom there was abnormal anatomy of the posterior pituitary, and the bright spot was recognized in the base of the hypothalamus. These cases are referred to as ectopic posterior pituitary. Most of these cases are recognized in children with growth retardation and anterior pituitary deficiency rather than posterior pituitary deficiency. Although most of these patients do not have clinically apparent diabetes insipidus, when specifically and systematically tested for quantitative abnormalities of thirst or vasopressin secretion, subnormal responses have been noted.

The degree of anterior pituitary deficit depends on the persistence of a pituitary stalk and a retained portal vasculature from the hypothalamus to the anterior pituitary. Most authors believe that this condition is not a traumatic but a congenital abnormality with an undescended posterior pituitary that may be at any level along the pituitary stalk.
SYNTHESIS AND RELEASE OF NEUROHYPOPHYSIAL HORMONES

Vasopressin and oxytocin are nonapeptides consisting of a six-amino-acid ring with a cysteine-to-cysteine bridge and a three-amino-acid tail (Fig. 9-2). All mammals have arginine vasopressin and oxytocin (see Fig. 9-2) with the exception of the pig. In the pig, a lysine is substituted for arginine in position 8 of vasopressin, producing lysine vasopressin. Both genes are found on chromosome 20, although they are situated in a tail-to-tail position and transcribed in opposite directions. The cellular anatomy and biochemistry of synthesis are illustrated in Figure 9-3. For oxytocin, the peptide products are the nonapeptide and a neurophysin but with no glycopeptide. The neurophysin is distinct for each hormone but with high homology.

When a stimulus for secretion of vasopressin or oxytocin acts on the appropriate magnocellular cell body, an action potential is generated and propagates down the long axon to the posterior pituitary. The action potential causes an influx of calcium, which induces a movement of neurosecretory granules to fuse with the cell membrane and extrude the entire contents of the neurosecretory granule into the perivascular space and subsequently into the capillary system of the posterior pituitary. At the physiologic pH of plasma, there is no binding of hormones (vasopressin and oxytocin) to their respective neurophysins and each peptide circulates independently in the bloodstream.

The control of hormone synthesis resides at the level of transcription. Stimuli for secretion of vasopressin or oxytocin also stimulate transcription and increase the messenger ribonucleic acid (mRNA) content in the magnocellular neurons. This has been studied in most detail in rats, in which dehydration accelerates transcription and increases the levels of vasopressin (and oxytocin) mRNA and hypo-osmolality produces a decrease in the content of vasopressin mRNA. The transport of neurosecretory vesicles from the site of synthesis to the posterior pituitary along microtubule tracks is also regulated. When synthesis is turned off, transport stops, and when synthesis is increased transport is up-regulated. Thus, there is coordination of stimulated release of hormone, transport of hormone, and synthesis of new hormone. There is, however, asynchronous in the timing of these events. The asynchrony is demonstrated by changes in the content of vasopressin stored in the posterior pituitary. The absolute content varies considerably among species but is quite a remarkable store, generally equivalent to the amount of hormone required to sustain basal release for 30 to 50 days or maximum release for 5 to 10 days.

In animals, prolonged and intense stimulation of vasopressin release, such as dehydration or salt loading, produces a depletion of stored hormone in the posterior pituitary. There is then a gradual recovery of pituitary content back to baseline (or above) 7 to 14 days after animals are returned to normal water intake. This phenomenon has been modeled by Fitzsimmons and colleagues, who provided experimental evidence that a long half-life of the vasopressin message, approximately 2 days, is (from a minimalist point of view) a plausible explanation for the events. When a strong or sustained stimulus releases vasopressin, there is an immediate stimulus to the synthesis of new mRNA. However, because it requires several days for the peak level of mRNA to be reached, synthesis increases slowly. When the stimulus is removed, the elevated mRNA synthesizes hormone to replete the store in the posterior pituitary. The mRNA slowly declines to the previous baseline, and synthesis of vasopressin returns to a basal rate.

The magnocellular neurons specific for oxytocin and vasopressin have intrinsic individual characteristic electrical firing patterns. These patterns are modulated by the paracrine and autocrine action of hormone released by the dendrites into the extracellular space surrounding the magnocellular neurons in the supraoptic nucleus and paraventricular nuclei. Oxytocin neurons develop a pattern of high-amplitude bursting activity (hormone release) followed by long pauses, a pattern that may facilitate the pumping action of muscular contraction of myoepithelial cells in the breast. For vasopressin, weakly active neurons and highly active neurons are brought to a medium level of alternate phasic firing and resting that facilitates optimal secretion of vasopressin.

Structural plasticity also enhances secretion. When stimulated to secrete, the neurons retract dendrites to become more compact, which may allow more efficient propagation of inputs and decrease nonspecific synaptic inputs. Retraction of glia around the magnocellular perikarya increases juxtaposition of like neurons to enhance recruitment of neighboring neurons and to synchronize firing. At the level of the posterior pituitary, retraction of pericytes surrounding axon terminals removes an immediate barrier between the axons and the perivascular space and facilitates diffusion of peptides into capillaries.
PHYSIOLOGY OF SECRETION OF VASOPRESSIN AND THIRST

The physiologic regulation of vasopressin synthesis and secretion involves two systems: osmotic and pressure-volume. (Fig. 9-4). The functions of these two systems are so distinct that historically it was thought there were two homologous antidiuretic hormone and a vasopressor hormone. Hence, the two names that are used interchangeably for (8-arginine) vasopressin.

There are separate systems at the level of the receptors on the end organs of response. V1 receptors on blood vessels are distinct from V2 receptors on renal collecting duct epithelia. A third receptor, V3, is responsible for the nontraditional biologic action of vasopressin to stimulate adenocorticotropic hormone (ACTH) secretion from the anterior pituitary, and V2 receptors regulate the nontraditional action of vasopressin to stimulate factor VIII production.

Vasopressin is the main hormone involved in regulation of water in humans, and all mammals control water to regulate osmolality. On the other hand, the main hormones involved in pressure-volume in humans are renin, angiotensin, and aldosterone; and controlling serum sodium concentration (Na"^+) largely regulates pressure-volume. Therefore, the pathology of disorders of the neurohypophysis is expressed primarily as abnormalities of osmolality produced by abnormal excretion or retention of water. In the case of osmoreceptors, the magnicellular neurons are chronically under some mild input to stimulate release of vasopressin, and the regulation of vasopressin in response to osmolality is relatively uncomplicated, with small decreases in osmolality causing a parallel decrease in

Figure 9-3 Vasopressin synthesis in a magnicellular neuron. A. The vasopressin gene is located on the short arm of chromosome 20. In the nucleus, the gene is transcribed to heteronuclear ribonucleic acid (RNA). B. The introns are then excised, and the three exons are spliced to form mature RNA, which consists of exon A, exon B, and exon C. The mature RNA exits the nucleus to the cytoplasm. It is targeted to the endoplasmic reticulum, where it is attached to ribosomes. C and D, There is translation of the three exons into pre-provasopressin. Exon A is translated to the 19-amino-acid signal peptide (SP), the nonpeptide arginine-vasopressin (AVP), and the amino-terminal portion of the 93- to 95-amino-acid neurophysin (NP). Exon B encodes the highly conserved middle region of neurophysin. Exon C encodes the variable carboxyl terminal of neurophysin and a 39-amino-acid glycopeptide (GP). The pre-provasopressin is transferred across the endoplasmic reticulum, the glycopeptide is glycosylated, and the signal peptide is cleaved (D). E. Provasopressin enters the Golgi apparatus, where the entire provasopressin complex is packaged into neurosecretory granules. The neurosecretory granules attach to microtubules and are transported along the microtubules to the posterior pituitary, where the neurosecretory granules are stored. F. During transport, enzymes in the acidic granules cleave the prohormone to vasopressin (which is amidated), to neurophysin, and to the glycopeptide. Neurophysins form dimers and, subsequently, tetramers with one vasopressin attached to each neurophysin. There is an auxiliary fifth binding site for vasopressin, which spans the four neurophysin molecules of the tetramer. G. When there is an action potential signaling release, a neurosecretory granule fuses with the axon membrane and the vasopressin, neurophysin, and glycopeptide are secreted into the extracellular space and, hence, into plasma, where they circulate independently of each other. Figure 9-4 Comparison in humans of the release of vasopressin in response to percentage changes of osmolality (increase) and pressure or volume (decrease). Note: To increase plasma vasopressin, the change in osmolality is much more sensitive, responding to as little as a 1% increase in osmolality, whereas volume and pressure require greater than a 10% to 15% change to stimulate release of vasopressin. (Redrawn from Robertson GL, Bier T. Water metabolism. In Brenner BM, Rector FC Jr [eds]: The Kidney, vol 1, 3rd ed. Philadelphia, WB Saunders, 1986, p 385.)

vasopressin and small increases in osmolality a parallel increase in vasopressin.

The regulation of volume and blood pressure is complicated (see Thrasher[0]), and experimental models of vasopressin and baroreceptor regulation in animals often involve inhibiting or measuring other concurrent sympathetic inputs to the system in order to determine any direct effect of a stimulus on secretion of vasopressin (see Fig. 9-4). Other influences on secretion of vasopressin, such as the inhibiting influence of glucocorticoids and the potent stimulus of nausea and vomiting, are less important as physiologic regulators of vasopressin but may be important in the differential diagnosis of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), discussed later.

Volume and Pressure Regulation

High-pressure arterial baroreceptors are located in the carotid sinus and aortic arch and low-pressure volume receptors in the atria and pulmonary venous system. [2][1] The afferent signals from these receptors are carried from the chest to the brain stem through cranial nerves IX and X. Interruption of the vagal input by vagotomy or vagal cold block[2][3][4] in dogs and destruction of the A1 area of the medulla, which receives input from IX and X, [1][2][3][4] in rabbits leads to an increase in vasopressin secretion.

These and other data led to the concept that baroreceptors and volume receptors normally inhibit the magnicellular neurons and that decreases in this tonic inhibition result in release of vasopressin. Arterial and venous constriction induced by vasopressin action on V1 receptors causes the vessels around the existing plasma volume to contract and effectively increase plasma volume and reestablish the inhibition of secretion of vasopressin. Although the action of vasopressin at the kidney to retain water helps to replace volume, the major hormonal regulation to control volume actually involves the renin-angiotensin system, which stimulates sodium reabsorption in the kidney (see Chapter 15).

The concept of tonic inhibition of vasopressin by baroreceptors has been questioned,[1][2][3] but most agree that the volume receptor and baroreceptor responses leading to an increase in vasopressin in humans are much less sensitive than are the osmoreceptor responses (see Fig. 9-4). It has been interpreted that the lesser response occurs because changes in volume and central venous pressure have little effect to increase vasopressin in humans as long as arterial pressure is maintained by sympathetic reflexes.[3][4] When hypovolemia is sufficient to cause a decrease in blood pressure, there is a sudden and exponential increase in the level of vasopressin in plasma (see Fig. 9-4). [1][2][4][5]

It is also agreed that changes in volume or pressure that are insufficient to cause increases in vasopressin nonetheless modify the response of the vasopressin system to osmoregulation.[3][4] Increases in pressure and central volume decrease the secretion of vasopressin, [3][4] but, again, the response of the renin-angiotensin system to cause sodium excretion is much more sensitive to increases of pressure and volume than the response to decrease secretion of vasopressin.[3][4] Thus, both excitatory and inhibitory influences exist from the brain stem to the magnicellular neurons, with the dominant influence depending on the physiologic circumstances.
Osmonic Regulation

The primary receptors for sensing changes in osmolality are located in the brain. Most of the brain is within the blood-brain barrier, which is impermeable to polar solutes. Because the osmostat is insensitive to urea and glucose, which readily cross cellular membranes (but not the blood-brain barrier), the osmoreceptors must be outside the blood-brain barrier.

Studies of experimental brain lesions in animals strongly suggest that cells in the organum vasculosum of the lamina terminalis (OVLT) and in areas of the adjacent anterior hypothalamus near the anterior wall of the third cerebral ventricle are osmoreceptors. These organs are perfused by fenestrated capillaries and are thus outside the blood-brain barrier. Surgical destruction of the OVLT abolishes vasopressin secretion and thirst responses to hyperosmolality but not responses to other stimuli such as hypovolemia. 

Essentially the same conclusion was drawn from clinical observations of human subjects with brain damage that destroyed the region around the OVLT, who are often unable to maintain normal plasma osmolalities even under basal conditions. In contrast, destruction of the macrocellular neurons of the supraoptic nucleus and paraventricular nuclei eliminates dehydration-induced secretion of vasopressin but does not alter thirst, clearly indicating that osmotically stimulated thirst must be generated proximal to the macrocellular cells.

Extracellular fluid (ECF) osmolality (determined predominantly by sodium concentration) in normal subjects varies from 280 to 295 mOsm/kg but in any individual is maintained in a narrow range. The ability to maintain this narrow range depends on (1) the sensitive response of plasma vasopressin to changes in plasma osmolality, (2) the sensitive response of urine osmolality to changes in plasma vasopressin, and (3) the gain in the system by the response of urine volume to changes in plasma vasopressin (Fig. 9-5). Basal plasma vasopressin is in the range of 0.5 to 2 pg/μL. As little as a 1% increase or decrease in plasma osmolality causes a rapid increase in plasma vasopressin by release of vasopressin from the store of hormone in the posterior pituitary. For levels of vasopressin in plasma to decrease rapidly requires rapid metabolism of vasopressin, and this is also characteristic of the hormone, which circulates freely in plasma and has a half-life of approximately 15 minutes. Thus, small increases in osmolality produce a concentrated urine and small decreases in osmolality produce a water diuresis.

Figure 9-5 illustrates the linear relationship between plasma osmolality and plasma vasopressin that has been described in humans. The linear relationship exists for osmolalities well above the normal excursion of osmolalities, as demonstrated when the increase is induced by infusion of hypertonic saline or is observed during dehydration of patients with nephrogenic diabetes insipidus. Similarly, Figure 9-5 shows the presence of a sensitive and linear relationship between the level of vasopressin in plasma and the induced osmolality of the urine. In this case, however, although plasma vasopressin may increase out of the normal physiologic range, the urine osmolality levels off at approximately 1000 to 1200 mOsm/kg. This occurs because the maximum concentration reached by the fluid in the collecting duct is determined by the osmolality of the inner medulla.

Figure 9-5 also shows the relationship of plasma vasopressin to urine volume. This relationship is calculated on the basis of the urine volume necessary to excrete a fixed quantity of osmoles (800 mOsm) at the urine osmolality produced by the change in plasma vasopressin. These graphs demonstrate the gain in the system when the changes in urine volume relative to plasma vasopressin are considered. With a decrease of plasma vasopressin, for example, from 5 to 1 pg/μL, urine volume is maintained at less than 4 L/day; however, urine volume increases dramatically to 18 to 20 L/day when plasma vasopressin is decreased further.

In the kidney, water is conserved by the combined functions of the loop of Henle and the collecting duct. The loop of Henle generates a high osmolality in the renal medulla through the countercurrent multiplier system. Vasopressin acts in the collecting duct to increase water permeability, thereby allowing osmotic equilibration between the urine and the hypertonic medullary interstitium. The net effect of this process is to extract water from the urine into the medullary interstitial blood vessels (vasa recta), resulting in increased urine concentration and decreased urine volume (antidiuresis). Vasopressin produces antidiuresis by its effects on the epithelial principal cells of the collecting tubule, which have vasopressin receptors of the V2 type.

The intracellular organelles responsible for water reabsorption across the collecting duct cells are called aquaporins, a widely expressed family of water channels that mediate rapid water transport across some cell membranes. Aquaporin-2 is regulated by vasopressin and mediates water transport across the apical plasma membrane of the principal cells of the collecting ducts. In contrast, aquaporin-3 and aquaporin-4 are expressed at high levels in the basolateral plasma membranes of principal cells and are responsible for the constitutively high water permeability of the basolateral plasma membrane.

Vasopressin binding to the V2 receptor increases intracellular cyclic adenosine monophosphate (cAMP) levels by activating adenylate cyclase. The cAMP induces a fusion of aquaporin-2 containing intracytoplasmic vesicles with the apical plasma membranes of the principal cells, a process that increases apical water permeability by markedly increasing the number of water-conducting pores in the apical plasma membrane. Dissociation of vasopressin from the V2 receptor allows intracellular cAMP levels to decrease, and the water channels are reinternalized into the intracytoplasmic vesicles, thereby terminating the increased water permeability.

The aquaporin-containing vesicles remain just below the apical membrane and can be quickly "shuttled" into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism therefore allows minute-to-minute regulation of renal water excretion through changes in ambient levels of vasopressin in plasma. There is also long-term regulation of collect duct water permeability in response to prolonged high levels of circulating vasopressin. This response requires at least 24 hours to elicit and is not as rapidly reversible. The long-term effect is due to the ability of vasopressin to induce large increases in the abundance of aquaporin-2 and aquaporin-3 water channels in the collecting duct principal cells.
Thirst

Urine volume can be reduced to a minimum but not eliminated, and insensible water loss is a continuous process. To maintain water balance, one must consume water to replace the obligate urinary and insensible fluid losses, and this consumption is regulated by thirst. Thirst represents the body’s defense mechanism to increase water consumption in response to perceived deficits of body fluids.

Like vasopressin, thirst can be stimulated by increases in osmolality of the ECF or by decreases in intravascular volume. Furthermore, there is evidence that the receptors are similar, that is, osmoreceptors in the anterior hypothalamus and low-pressure or high-pressure, or both, baroreceptors (with a likely contribution from circulating angiotensin II during more severe degrees of intravascular hypovolemia and hypotension). Studies in animals have consistently reported thresholds for osmotically induced drinking ranging from 1% to 4% increases in plasma osmolality above basal levels, and analogous studies in humans using quantitative estimates of subjective symptoms of thirst have confirmed that increases in plasma osmolality of 2% to 3% are necessary to produce an unequivocal sensation described as thirst.

As with vasopressin, the threshold for producing thirst by hypovolemia is significantly higher. Studies in multiple species have shown that sustained decreases in plasma volume or blood pressure of at least 4% to 8%, and in some species 10% to 15%, are necessary to stimulate drinking consistently. In humans, it is difficult to demonstrate an effect of mild to moderate hypovolemia to stimulate thirst independently of osmotic changes occurring with dehydration. This blunted sensitivity to changes in ECF volume or blood pressure in humans probably represents an adaptation that occurred as a result of the erect posture of primates, which predisposes them to wider fluctuations in blood and atrial filling pressures as a result of orthostatic pooling of blood in the lower body. Stimulation of thirst (and secretion of vasopressin) by transient postural changes in blood pressure may lead to overdrinking and inappropriate antidiuresis in situations in which the ECF volume was actually normal but transiently maldistributed.

Although osmotic changes clearly are effective stimulants of thirst, it is not likely that changes in plasma osmolality are responsible for the major part of day-to-day fluid intakes. Most humans consume the bulk of their ingested water as a result of the relatively unregulated components of fluid intake, such as the consumption of beverages in association with food intake, for reasons of palatability or desired secondary effects (e.g., caffeine), or for social or habitual reasons (e.g., sodas or alcoholic beverages). As a result, both animals and humans generally ingest volumes in excess of what can be considered to be an actual need for fluid.

Consistent with this observation is the fact that, under most conditions, plasma osmolalities in humans remain within 1% to 2% of basal levels, and these relatively small changes in plasma osmolality are generally below the threshold levels that have been found to stimulate thirst. This suggests that despite the obvious vital importance of thirst during pathologic situations of hyperosmolality and hypovolemia, under normal physiologic conditions water balance in humans is accomplished more by free water excretion regulated by vasopressin than by water intake regulated by thirst. This also demonstrates why water intake must be consciously restricted in cases of persistent unregulated secretion of vasopressin.
Clinical Consequences of Osmotic and Volume Regulation

In most physiologic situations, there is concurrence and synergy between the effects of increased osmolality and decreased volume to stimulate release of vasopressin. For example, with dehydration, osmolality increases and volume decreases and each stimulates the release of vasopressin. Furthermore, there is good evidence that a decrease in volume shifts the plasma vasopressin/plasma osmolality response curve to the left, resulting in a greater release of vasopressin at a given osmolality. Similarly, excess of fluid produces a decrease in osmolality and an increase in volume, and both cause a decrease in vasopressin secretion.

The physiology underlying the relationships between plasma osmolality, plasma vasopressin, and especially urine volume determines some of the pathophysiology of decreased or increased secretion of vasopressin. In Figure 9-5, we see that a regular loss of vasopressin neurons, which may decrease the secretory capacity of the neurohypophysis from that able to produce a blood vasopressin level of 10 to 20 pg/mL down to a secretory capacity sufficient only to maintain a blood level of 5 pg/mL, may produce no change in the ability to attain a maximum urine osmolality. Below 5 pg/mL, there is a linear decrease in the ability to concentrate the urine maximally. However, from the volume curve we see that this results in only a modest increase in urine volume because of the logarithmic relationship of urine volume to urine osmolality and plasma vasopressin. Then, when the last few vasopressinergic neurons are lost and the maximum vasopressin level drops from 1 to 0.5 pg/mL, there might be a great increase in urine volume.

These responses might be viewed as protective, allowing water conservation, even with minimal ability to secrete vasopressin. This may be why even in idiopathic hypothalamic diabetes insipidus there is often a sudden onset of symptoms. The same physiologic considerations may explain why patients with diabetes insipidus that has persisted for a relatively long period of time (e.g., after surgery or head injury) may eventually be able to discontinue vasopressin treatment. The number of vasopressinergic neurons that need to recover to maintain an asymptomatic urine volume is small. The same pathophysiology is important in regard to SIADH. In this situation, however, one might consider the consequences of an inability to suppress vasopressin to less than 1 pg/mL. Note that the maximum urine volume with a standard osmolar load at 1 pg/mL can be as little as 2 L/day. If a patient's fluid intake is greater than that which can be excreted with the fixed level of vasopressin of 1 pg/mL, the extra fluid is retained and the sequence of events that causes hyponatremia in SIADH is initiated.

A synthesis of what is known about the regulation of thirst and secretion of vasopressin in humans contributes to our understanding of this simple but elegant system to maintain water balance. Under normal physiologic conditions, the sensitivity of the osmoregulatory system for secretion of vasopressin accounts for maintenance of plasma osmolality within narrow limits by adjusting renal water excretion to small changes in osmolality. Stimulated thirst does not represent a major regulatory mechanism under these conditions, and unregulated fluid ingestion and water from metabolized food supply water in excess of true need. Excess water is then excreted using osmoregulated secretion of vasopressin. However, when unregulated water intake does not supply body needs, even with plasma levels of vasopressin sufficient to produce maximal antidiuresis, plasma osmolality rises to levels that stimulate thirst and produce water intake proportional to the elevation of osmolality. Thirst thus represents a backup mechanism that is called into play when pituitary and renal mechanisms are insufficient to maintain plasma osmolality within a few percentage points of basal levels.

This arrangement has the advantage of freeing animals and humans from frequent episodes of thirst that would require a diversion of activities toward behavior oriented to seeking water when the water deficiency is sufficiently mild to be compensated for by renal water conservation, but it does stimulate water ingestion when water deficiency reaches a potentially harmful level. This system of differential effective thresholds for thirst and secretion of vasopressin therefore nicely complements the excess unregulated, or need-free, drinking in both humans and animals demonstrated in many studies.
Reset Osmostat during Pregnancy

During pregnancy, major shifts of fluid produce a decreased plasma osmolality of about 10 mmol/kg and an increase in plasma volume.\(^81\)\(^82\) This decrease in osmolality is a normal consequence of pregnancy and is probably the best example of a true resetting of the osmostat. A true resetting of the osmostat must regulate both increases and decreases of secretion of vasopressin at a lower than normal plasma osmolality. These criteria are met in pregnant women, and there is a resetting of the osmostat for thirst in parallel with the resetting of the osmostat for release of vasopressin.\(^83\)

Figure 9-6 shows the relationship of plasma vasopressin to plasma osmolality in normal and pregnant women. In pregnant women, as in nonpregnant women, the plasma vasopressin level is increased with as little as a 1% increase in plasma osmolality, but the entire curve with a normal slope is shifted to the left.\(^81\) The shift in osmotic threshold appears at about 5 to 8 weeks of gestation and persists throughout pregnancy, returning to normal by 2 weeks after delivery.\(^81\) Although the osmotic threshold is constant throughout pregnancy, there is a change in sensitivity at about 28 to 33 weeks of gestation. At this time, the threshold to release vasopressin occurs at the same plasma osmolality; however, the slope changes, so that for increases in osmolality, there is less vasopressin (see Fig. 9-6, slope C).

The physiology of the reset osmostat has been considered in relation to the expanded plasma volume. Total body water in pregnant women is also increased by 7 to 8 L as a result of profound vasodilatation.\(^84\) This volume is sensed as normal, and vasopressin responds normally to decreases and increases of volume.\(^81\)\(^84\)\(^85\)\(^86\) Both the changes in volume and the changes in regulation of osmolality have been reproduced by infusion of relaxin (a normal hormone of pregnancy that is a member of the insulin-like growth factor family) into virgin female and normal rats\(^87\)\(^88\) and reversed in pregnant rats by immunoneutralization of relaxin; therefore, relaxin is a proposed mediator of the effect.

In women, the placenta produces an enzyme, cysteine aminopeptidase, that is released into the plasma and is known as oxytocinase.\(^81\)\(^82\) This enzyme is as potent in degrading vasopressin as in degrading oxytocin and in making vasopressin biologically inactive. The activity of vasopressinase increases markedly around 20 weeks of gestation and increases further to 40 weeks, returning slowly to normal over a few weeks after delivery.\(^81\) The data are consistent with the supposition that the change in the sensitivity of the plasma vasopressin-plasma osmolality response in late pregnancy (see Fig. 9-6, line C) may be due to accelerated degradation of vasopressin.
Aging

Many physiologic processes are compromised in aging humans, and numerous studies have reported that elderly people are at risk for both hypernatremia and hyponatremia. In many older subjects, there is a decrease in glomerular filtration rate (GFR) and the collecting duct in the aged kidney may be less sensitive to vasopressin, limiting the ability to excrete free water. Many other abnormalities of fluid and electrolyte balance in elderly people are due to co-morbid conditions or to the numerous pharmacologic agents to which these patients are often exposed. Studies of responses to dehydration, osmolar stimulation, or volume stimulation in older people are complicated by the fact that by age 75 to 80 years the total body water level declines to 50% of the level in normal young adults.

Although some have reported altered morphology of the neurohypophyseal system in aged humans, there appears to be no change in the number of magnocellular neurons in normal elderly people or in patients with Alzheimer's disease. There is a greater range of normal levels of vasopressin and a less direct correlation of plasma vasopressin with plasma osmolality, but changes in levels of vasopressin in response to acute increases in serum sodium are either normal or increased. An increased response of vasopressin to changes in plasma osmolality has been ascribed to a decreased ability of vasopressin to stimulate levels of aquaporin-2 in the kidney. The decrease in renal sensitivity has also been interpreted as causing a chronic increase in secretion of vasopressin and a depletion of hormone stores in the posterior pituitary. This may be why elderly patients demonstrate a decreased incidence of visualization of the bright spot on T1-weighted MRI scans; in more than 70% of elderly subjects, the spot was not observed.

A number of studies have indicated that elderly people have decreased thirst with dehydration and less fluid intake to return their volume to normal during recovery from dehydration. At the other end of the spectrum, elderly patients have been found to excrete a water load less well than younger subjects and at least part of this is due to decreased suppression of vasopressin. Elderly people are also reported to have a decreased ability to shut off vasopressin in response to drinking and stimulation of oral-pharyngeal receptors.

In summary, there are age-related changes in body volumes and renal function that probably predispose elderly people to abnormalities in water and electrolyte balance. Diseases that are more common in elderly persons exacerbate this and, in addition to therapy for these diseases, affect water balance. Healthy older humans probably have at least a normal ability to secrete vasopressin but a decreased appreciation for thirst and a decreased ability to achieve either a maximum concentration of urine to retain water or a maximum dilution of urine to excrete water. Thus, it is necessary to pay attention to fluid balance problems in older people as undetected hypernatremia or hyponatremia can lead to increased morbidity and mortality.
DIABETES INSIPIDUS

Diabetes insipidus is a disorder in which there is a large volume of urine (diabetes) that is hypotonic, dilute, and tasteless (insipid). This is in contrast to the hypertonic and sweet urine of diabetes mellitus (honey). Four pathophysiologic mechanisms related to vasopressin produce large volumes of dilute urine and polydipsia, resulting from the following conditions:

1. Hypothalamic (central or neurohypophyseal) diabetes insipidus, with inability to secrete and usually to synthesize vasopressin in the neurohypophyseal system.
2. Nephrogenic diabetes insipidus, in which there is an inappropriate renal response to vasopressin.
3. Transient diabetes insipidus of pregnancy, produced by the accelerated metabolism of vasopressin.
4. Primary polydipsia, in which the initial pathophysiology involves the ingestion of fluid rather than the excretion of fluid.

Differential Diagnosis

To determine whether there is a large volume of urine, one can measure a 24-hour urine collection or the patient can keep a diary for 24 hours, recording the volume and the time of each voided urine. Simultaneously, it must be determined whether polyuria is due to an osmotic agent, such as glucose, or to intrinsic renal disease. Usually, routine laboratory studies and the clinical setting distinguish these diseases or disorders from consideration of diabetes insipidus. If the thirst mechanism is intact, most patients are ambulatory with normal serum sodium levels and no evidence of dehydration. All agree that the diagnosis of diabetes insipidus is confirmed by the presence of some dehydration to stimulate the normal release of vasopressin and then by the absence of the ability to concentrate the urine.

The test most commonly used clinically is a dehydration test in a controlled environment, followed by a response to administered vasopressin or to the analogue desmopressin. If the patient has mild polyuria, the test may begin in the evening with the majority of dehydration taking place overnight. If the patient gives a history of large volumes of urine during the night, it is best to perform the test during the day when the patient can be observed.

The patient is weighed at the beginning of test in attire that can be worn throughout the study and on a clinical quality scale that can be used for all repeated weighings. The patient voids, and the starting weight is recorded. A serum sodium level is obtained, and nothing is allowed by mouth (certainly no fluid) during the test. Each voided urine is then recorded and urine osmolality measured. The patient is weighed after each liter of urine is excreted.

When two consecutive measures of urine osmolality differ by no more than 10% and the patient has lost 2% of the body weight, plasma is drawn for Na⁺, osmolality, and vasopressin determinations. The patient is given 2 µg of desmopressin intravenously or intramuscularly (or 5 units of aqueous vasopressin subcutaneously), and urine output and osmolality are recorded hourly for an additional 2 hours. The test is discontinued if the patient loses more than 3% of the body weight or at any time that serum Na⁺ is elevated above the normal range. The duration of the test varies; patients with complete diabetes insipidus reach a maximum but very low urine osmolality within a few hours; patients with other disorders reach a maximum in up to 18 hours.

There is no difficulty in determining the diagnosis of severe hypothalamic or severe nephrogenic diabetes insipidus. In the former, urine has minimal concentration despite dehydration and there is a marked increase in urine osmolality in response to administered desmopressin, at least 50% but often a 200% to 400% increase. At the end of the test, these patients have undetectable vasopressin in plasma. In patients with nephrogenic diabetes insipidus, there is also little concentration of the urine despite achieving dehydration, but the urine osmolality also shows little or no response to the administered desmopressin. These patients are unequivocally distinguished from those with hypothalamic diabetes insipidus by high levels of vasopressin in plasma, often greater than 5 pg/ml, at the end of the dehydration phase.

The difficulty is in differentiating partial hypothalamic diabetes insipidus from primary polydipsia. In both disorders, the urine shows some concentration (often above plasma osmolality) with dehydration but the urine osmolality does not approach the 800 to 1000 mOsm/kg characteristic of normal subjects. In response to the administered desmopressin, patients with partial hypothalamic diabetes insipidus usually show a further concentration of the urine of at least 10%, whereas patients with primary polydipsia show no further increase. The reliability of the response to desmopressin is debated. Some patients with primary polydipsia may achieve a plateau level in urine osmolality before reaching their maximum attainable urine osmolality and hence respond to desmopressin. Alternatively, some patients with partial hypothalamic diabetes insipidus may, with severe dehydration, secrete sufficient vasopressin to achieve the maximum attainable urine osmolality and do not respond with a further increase to administered desmopressin.

Investigators who have a highly sensitive radioimmunoassay for vasopressin are able to distinguish between partial hypothalamic diabetes insipidus and primary polydipsia by the measurement of vasopressin at the end of the dehydration phase and further report that one of these disorders may be inappropriately diagnosed using the standard dehydration test. However, a longitudinal clinical study of patients with autoimmune hypothalamic diabetes insipidus reported good correlation between results of the dehydration test and measured vasopressin to diagnose partial diabetes insipidus occurring over time.

There is concern about making the diagnosis of partial diabetes insipidus in patients with primary polydipsia because patients given desmopressin may experience symptomatic hyponatremia as they continue to drink fluid despite desmopressin-induced water conservation. Therefore, when the diagnosis is in doubt, patients should have adequate follow-up to ensure that a good therapeutic response is obtained and that hyponatremia does not develop. This clinical follow-up and response have been considered a continuation of the diagnosis with the trial of desmopressin as a test agent. If a standard dose of desmopressin produces a decrease in polyuria, a decrease in thirst, and no reduction of sodium, the patient almost certainly has partial hypothalamic diabetes insipidus. If polydipsia does not improve and hyponatremia develops, the patient has some abnormality of thirst, and the diagnosis may be primary polydipsia.

The clinical presentation is often helpful in the differential diagnosis. In a patient with no previous history of polyuria or polydipsia who is found to have these symptoms immediately after surgery in the hypothalamic-pituitary area or after head trauma (especially with skull fracture and loss of consciousness), the diagnosis of hypothalamic diabetes insipidus is highly probable. Sometimes diuresis after surgery is the result of water retention during the procedure. Vasopressin is released during surgical procedures, and administered fluid may be retained. As the stress of surgery abates, the vasopressin level falls and administered fluid is excreted. If an attempt is made to match the urine output with further fluid infusion, persistent polyuria occurs and may be mistaken for diabetes insipidus.

Because these patients may be unconscious and may be unable to sense thirst, it is crucial that the diagnosis be established and that patients be treated appropriately to prevent severe dehydration. Because these patients do not sense thirst, it is easy to withhold fluids until there is a modest increase in sodium and then to measure urine osmolality and determine the response to administered desmopressin. If urine output decreases and the serum sodium level remains normal, the response was excretion of physiologically retained fluid. If the serum sodium begins to rise, a response to desmopressin should be determined and the diagnosis of diabetes insipidus established.

Patients with hypothalamic diabetes insipidus often experience a sudden onset of symptoms and persistent thirst throughout the day and night, whereas patients with renal disease experience a more gradual onset of disease and patients with primary polydipsia may have decreased thirst and urination during the night. Hypothalamic diabetes insipidus is associated more with a desire for cold liquids, probably because of dehydration. Patients with diabetes insipidus often have serum sodium levels in the high range of normal, whereas patients with primary polydipsia have serum sodium levels in the low range of normal. Blood urea nitrogen (BUN) concentration is often low in both hypothalamic diabetes insipidus and primary polydipsia because of the high renal clearance, but there is a difference in serum uric acid concentrations.
Serum uric acid is elevated in hypothalamic diabetes insipidus because of modest volume contraction and because vasopressin acts on V1 receptors in the kidney to increase urate clearance. Therefore, in patients with no vasopressin, the uric acid level is high; a value greater than 5 µg/dL has been reported to separate hypothalamic diabetes insipidus from primary polydipsia. Presumably, in patients with primary polydipsia, there is modest volume expansion and intermittent secretion of vasopressin to act on V1 receptors to clear serum urate. Urine volume greater than 18 L suggests primary polydipsia because the volume exceeds the amount of urine delivered to the collecting duct. In fact, most patients with hypothalamic diabetes insipidus have modest dehydration, have a decreased GFR, and excrete urine volumes in the range of 6 to 12 L/day.
Imaging of the Neurohypophysis

When MRI began to be used to evaluate the pituitary gland and hypothalamus, a bright spot in the sella was reported on T1-weighted images. The bright spot is due to stored hormone in neurosecretory granules in the posterior pituitary. The interest in the posterior pituitary bright spot as a diagnostic tool was heightened by reports that the bright spot was absent in patients with diabetes insipidus.

Many studies using small numbers of normal subjects have demonstrated this bright spot in all normal subjects; when larger numbers were evaluated, however, the bright spot was not seen in some normal subjects. In one study of 500 normal subjects, it was calculated that the bright spot would be present in 84% of normal youth. Although it had been suggested that the intensity of this bright spot might vary with the physiologic state of water balance in humans, this would occur only with a prolonged stimulus.

Absence of the bright spot is characteristic of diabetes insipidus, but some studies have reported the presence of a bright spot in patients with clinical evidence of diabetes insipidus. This may be of most interest in patients with familial hypothalamic diabetes insipidus (see later). In these cases, the posterior pituitary bright spot may be seen early in the disease (especially when the diabetes insipidus is partial) but usually disappears over time with increasing severity of the diabetes insipidus.

The role of stored oxytocin as a source of the pituitary bright spot has been largely ignored. Oxytocin is synthesized in the same nuclear groups and is transported and stored in the posterior pituitary in a manner similar to that with vasopressin. In humans, secretion of oxytocin is less responsive to changes in hydration. Therefore, it is possible that a persistent bright spot in patients with diabetes insipidus might be due to the pituitary content of oxytocin. Furthermore, oxytocinergic neurons are more resistant to destruction by trauma compared with vasopressinergic neurons in rats and humans.

The presence of a positive posterior pituitary bright spot has been variably reported in other polyuric disorders considered in the differential diagnosis of diabetes insipidus. The bright spot is usually seen in patients with primary polydipsia. This observation is consistent with studies in animals, in which even prolonged lack of secretion of vasopressin caused by hypotension did not produce a decreased content of hormone in the posterior pituitary. In nephrogenic diabetes insipidus, the bright spot has been reported to be absent in some patients but present in others. Because these patients have high levels of vasopressin in plasma and are chronically dehydrated, the posterior pituitary might be depleted of vasopressin and the bright spot might be absent.

Imaging of the hypothalamus is also an important diagnostic tool for diseases of the neurohypophysis. As noted earlier, the hormones of the neurohypophysis are synthesized in the paired paraventricular nuclei, located bilaterally in the walls of the third ventricle, and in the supraoptic nuclei, located at the extremes of the optic chiasm. When this anatomic information is coupled with the knowledge that 90% of the vasopressinergic neurons must be destroyed to produce symptomatic diabetes insipidus, it is apparent that for a mass lesion or a destructive lesion to produce diabetes insipidus, it either must destroy a large area of the hypothalamus or must be specifically located where the tracks converge in the base of the hypothalamus at the origin of the pituitary stalk. Furthermore, the hormones are synthesized in cell bodies quite distant from the site of release in the posterior lobe, and with section or damage of the axons at the level of the posterior lobe there is a reaccumulation of neurosecretory material and regeneration of a posterior lobe above the site of injury. Thus, tumors confined to the sella do not cause diabetes insipidus, and the area of interest is the discrete area immediately above the diaphragm sella at the base of the hypothalamus.

The pituitary stalk can also be readily identified by MRI and has been an additional tool in the differential diagnosis of diseases of the neurohypophysis. Enlargement of the stalk beyond 2 to 3 mm has been reported as pathologic. Metastatic tumors may be seen as enlargements of the pituitary stalk, probably related to seating of metastases in the long portal capillary system. Infiltrative diseases of the neurohypophysis, such as Langerhans cell histiocytosis, Wegener’s granulomatosis, and lymphocytic infundibulohypophysis, may enlarge the stalk. Sarcoidosis and tuberculosis are infiltrative lesions that can cause widening of the stalk. Even cases that remain idiopathic may involve enlargement of the stalk.

When the etiologic diagnosis of diabetes insipidus is in doubt and MRI reveals thickening of the stalk, especially with absence of the posterior pituitary bright spot, a search for systemic diseases is indicated. This search may result in a diagnosis of Langerhans cell histiocytosis, sarcoidosis, or tuberculosis. Further evaluation of cerebrospinal fluid (CSF) and plasma for secretion of human chorionic gonadotropin (hCG) and -fetoprotein may indicate suprasellar germinoma.

When a diagnosis is still in doubt, MRI should be repeated every 3 to 6 months, especially in children, in whom enlargement may indicate a germinoma. Decrease in size of the stalk with follow-up is more likely indicative of lymphocytic infundibulohypophysis or idiopathic diabetes insipidus (but many of these cases may be infundibulitis), although it may also occur with specific treatment of infiltrative diseases.

Finally, MRI may show formation of a new “posterior pituitary” after stalk transection. It has been known for many years that section of the neurohypophyseal stalk at a low level may produce transient diabetes insipidus with eventual return of function. Reaccumulation of neurosecretory material above the transection has been noted histologically. Indeed, the accumulation of neurosecretory products above the site of section was early evidence proving that neurosecretory material was transported along axons. Postoperative patients with diabetes insipidus or patients in whom the posterior pituitary was destroyed by compression of an adjacent anterior pituitary adenoma may “lose” the bright spot on MRI but may demonstrate reappearance of a bright spot at the level of the remaining stalk.
Clinical Syndromes of Hypothalamic Diabetes Insipidus

Hereditary Hypothalamic Diabetes Insipidus

Hereditary hypothalamic (central or neurohypophyseal) diabetes insipidus is characterized by the onset of classic diabetes insipidus, thirst, polydipsia, and polyuria in childhood, but during infancy those who carry the genetic defect may be asymptomatic. In contrast, in cases of familial nephrogenic diabetes insipidus, the defect is expressed as a polyuria disease at birth (see later). The relatively late onset of hereditary hypothalamic diabetes insipidus is also supported by MRI findings, which, although variable, have shown a positive bright spot suggesting vasopressin stores early in the disease but a loss of the bright spot (or a greatly diminished one) late in the disease.

More than 30 different families with autosomal dominant hypothalamic (neurohypophyseal) diabetes insipidus have been studied and the genetic defect identified. Only one defect has been described in the vasopressin gene itself, which was reported as an autosomal recessive with heterozygotic parents and late onset of the disease related to a biologically less active mutated vasopressin hormone. A number of families have been described with a genetic abnormality in the signal peptide of the pre-prohormone, most commonly at the extreme carboxyl terminus at the site of cleavage of the signal peptide from vasopressin (see Fig. 9-3). Disruption of the cleavage is thought to cause the disease. Except for the rare mutants involving the vasopressin hormone, all of the other defects have been in the neurophysin molecule. None have been reported for the glycopeptide.

Most authors have suggested that abnormalities of the folding of neurophysin might be toxic to the magnecellular neurons and that over time (consistent with the late onset of an autosomal dominant disease) may cause neuronal cell death. Of the few postmortem studies, some findings have been consistent with degeneration of magnecellular neurons but others have shown normal neurons with decreased expression of vasopressin or no hypothalamic abnormality.

The mutant deoxyribonucleic acid (DNA) of the vasopressin neurophysin precursor has been expressed in neurogenic cell lines, all showed abnormal trafficking and accumulation of mutant prohormone in the endoplasmic reticulum with difficulty with packaging into neurosecretory granules (see Fig. 9-3). The mechanism whereby this may lead to cell death has not been defined, but cell death may not be necessary to decrease available vasopressin.

Normally, proteins retained in the endoplasmic reticulum are selectively degraded, but if excess mutant is produced and the selective normal degradative process is overwhelmed, an alternative nonselective degradative system (autophagy) is activated. As more and more mutant precursor builds up in the endoplasmic reticulum, the normal wild type is trapped with the mutant protein and degraded by the activated nonspecific degradative system. By this mechanism, the amount of vasopressin that matures and is packaged is markedly reduced. This explanation is consistent with the cases in which little pathology is found in the magnecellular neurons and also with cases of diabetes insipidus in which some small amount of vasopressin can be detected.

Diabetes Insipidus Produced by Solid Tumors or Hematologic Malignancies

Some tumors such as craniopharyngioma and suprasellar germinoma or pinealoma characteristically occur in a suprasellar basal hypothalamic area and are regularly associated with diabetes insipidus. The latter are often diagnosed by accompanying precocious puberty or serum markers such as hCG or -fetoprotein in spinal fluid or plasma. It is not uncommon with pinealomas and suprasellar germinomas for diabetes insipidus to be the presenting complaint, although other evidence of hypopituitarism may be present. MRI may not demonstrate a mass in the suprasellar area for a few months.

Metastatic disease involving the pituitary is usually found in association with widespread metastatic disease and is reported at autopsy but is often not symptomatic during life. Metastases are twice as likely to involve the posterior pituitary as the anterior pituitary, which is thought to be due to a more direct arterial blood supply to the posterior pituitary. It is also possible that any potential metastases to the anterior pituitary lodge in the portal system and occur as hypothalamic tumors. In either case, with metastatic tumors, diabetes insipidus is more common than is deficiency of anterior pituitary hormones.

The diagnosis is usually made in a patient who is known to have primary cancer with metastases elsewhere. MRI of the brain usually demonstrates the pituitary metastasis, often with other metastases in the brain or skull. Occasionally, only micrometastases are found at autopsy and enlargement of the stalk may be the presenting finding. Most primary tumors in the hypothalamic-pituitary area that cause diabetes insipidus grow relatively slowly, and any tumor in this area that shows rapid growth in a short period of time should be considered a possible metastatic tumor. Carcinoma of the breast is the most common primary cancer in women, and carcinoma of the lung is the most common primary tumor in men. Other tumors that have been reported in the area include adenocarcinoma of the stomach, pancreas, uterus, thyroid, and bladder.

Diabetes insipidus has been reported with lymphomas in the hypothalamic-pituitary area. Usually, lymphoma is recognized elsewhere, but rarely it is a primary central nervous system (CNS) lymphoma. There may be an increased incidence of lymphoma with diabetes insipidus because of the increased incidence of lymphoproliferative disease with human immunodeficiency virus (HIV) and hepatitis C infection.

Diabetes insipidus is also associated with leukemia. The mechanism is thought to be infiltration of the hypothalamus, thrombosis, or infection. Although acute lymphocytic leukemia is as common as nonlymphocytic leukemia and is well known to involve the CNS, diabetes insipidus is distinctly more common with nonlymphocytic leukemia. As many as 75% of the cases of diabetes insipidus with leukemia involve nonlymphocytic leukemia. There is also a suggested association with monosomy 7, although a mechanism has not been defined. MRI results in leukemia may show infiltration or an infundibular mass but are often normal even when leukemic cells are found in CSF. In other cases, the CSF has no leukocytes and thrombosis of small vessels in the hypothalamus might be a more likely cause of the diabetes insipidus. Posterior pituitary deficiency may be associated with panhypopituitarism, and the diabetes insipidus may not be apparent because of coexisting adrenal insufficiency and hypothyroidism. Indeed, in some patients symptomatic diabetes insipidus occurs only when prednisone therapy is initiated as treatment for the leukemia.

Response of the Neurohypophyseal System to Surgery or Trauma

Although diabetes insipidus is well known to occur after hypothalamic-pituitary surgery, this diagnosis should be made with caution. Vasopressin is normally secreted in the stress of surgery, and fluid may be retained and then normally excreted after surgery (see "Differential Diagnosis"). The stress of surgery may also induce insulin resistance and may exacerbate diabetes mellitus, producing an osmotic diuresis resulting from glucose. The patterns of diabetes insipidus after surgery have been described in detail. As many as 50% to 60% of patients have some transient diabetes insipidus within 24 hours of pituitary surgery that usually resolves, especially with transphenoidal surgery in which the resection of a tumor is confined to the sella.

If there is a complete section of the stalk, patients may exhibit a pattern known as triphasic diabetes insipidus (Fig. 9-7):
The second (antidiuretic) phase, although originally described as a normal interphase, is not normal and is thought to be due to unregulated release of vasopressin from the store of hormone in the axons of the posterior pituitary as these axons degenerate. Because the release of vasopressin in this phase is unregulated, excess administration of fluids produces hyponatremia as in other forms of SIADH.

The third phase, the return of diabetes insipidus, occurs when all of the hormone has been released from the posterior pituitary. The course of diabetes insipidus may be permanent or may subsequently resolve to partial or clinically inapparent disease.

Magnicellular neurons are unique in that, after the axons are sectioned, the neurons survive and there is outgrowth of dendrites and regeneration of new axons. A factor contributing to the ability of magnicellular neurons to regenerate is the close association of these neurons with specialized glial cells. The glial cells in the area of magnicellular neurons and the median eminence synthesize and release growth factors that may stimulate nerve growth. The newly formed axons grow along fixed glial cells (tanycytes) that span the median eminence from the third ventricle to the external zone of the median eminence. Thus, the regenerating axons and spraying axons create neurosecretory processes in the CSF of the third ventricle as well as in the perivascular region of the external zone of the median eminence. The transected neurosecretory axons may promote capillary sprouting, but its importance in the return of function is uncertain. These newly formed capillaries may have tight interendothelial junctions similar to those elsewhere in the brain, whereas the capillaries that are already present in the external zone of the median eminence are fenestrated capillaries capable of receiving secreted peptides. Several studies have shown that oxytocin neurons survive better than vasopressin neurons after transection of the pituitary stalk. In studies in the rat, the activity of the magnicellular vasopressin neurons had a dramatic effect on recovery. After stalk compression in the rat, if synthesis of vasopressin was inhibited, fewer vasopressin neurons survived, and if vasopressin synthesis was stimulated, more vasopressin neurons survived. However, because the magnitude and duration of both the hyponatremia and the hypotension in the rat studies exceeded those seen in patients, the application of the findings to clinical medicine is uncertain.

An important observation is that the second phase of the triphasic response—uncontrolled release of vasopressin related to axon trauma—may occur without preceding or subsequent diabetes insipidus. This has been observed clinically and has been produced experimentally in the rat by unilateral lesion of the supraoptichypophyseal tract. The interpretation is that if the trauma is only to some of the axons coursing to the posterior pituitary, the remaining intact axons have sufficient vasopressin function to avoid clinically apparent diabetes insipidus characteristic of the first and third phases of the triphasic response. However, the store of hormone in the posterior pituitary is sufficiently large that regeneration and nerosis of even a fraction of these vasopressin neurons causes enough uncontrolled release of vasopressin to produce hyponatremia if excess fluid is administered. The hyponatremia becomes apparent because it is often symptomatic with new-onset headache, nausea, and emesis. When all the vasopressin from the damaged neurons has been secreted, the stimulus for water retention resolves and the retained water is excreted, resulting in recovery from the hyponatremia. Thus, the clinical picture is one of hyponatremia occurring about 7 days after pituitary surgery, persisting for a few days, and then returning to normal. This syndrome of transient hyponatremia has been referred to as an isolated second phase to emphasize the pathophysiologic etiology. In one series, isolated hyponatremia occurred in as many as 25% of patients after pituitary surgery. The hyponatremia was associated with lack of suppression of vasopressin, inability to excrete a water load, and inappropriate natriuresis and was observed in spite of normal levels of cortisol or glucocorticoid replacement. In larger series, including various sizes and etiologic mechanisms of tumors, isolated hyponatremia was reported in about 10%, with only 2% symptomatic.

The same patterns of diabetes insipidus that occur after surgery can be seen in patients after closed-head trauma. Seventy-five percent of these cases are due to factors that do not involve the vasopressin neurons[219] and there is a great preponderance of male patients, usually young men with a mean age in the 20s. More than 90% of patients experience coma and a high percentage have associated skull fracture. Computed tomography (CT) or MRI in a large group of patients with post-traumatic hypopituitarism including diabetes insipidus showed hemorrhage in the hypothalamus or posterior pituitary in 55% and stalk resection or infarction of the posterior pituitary in approximately 6%.

Several important clinical points should be emphasized concerning diabetes insipidus induced by head trauma:

1. These patients are virtually always unconscious and do not have the normal ability to sense thirst.
2. In this situation, large volumes of fluid may be given because of blood loss or other volume deficits; this fluid loss or stress may induce diabetes mellitus and an osmotic diuresis (see “Differential Diagnosis”).
3. There may be a greater risk if the second phase is unrecognized because hyponatremia may produce cerebral edema and worsen any edema related to trauma. Therefore, in administering desmopressin, the effect of one dose should be allowed to wane before another dose is administered in order to ensure that the patient has not entered the second phase.
4. There is a high incidence of anterior pituitary deficiency in association with diabetes insipidus induced by head trauma.

The possibility of cortisol deficiency should be considered immediately, as it may be life-threatening in these patients. It is also well known that anterior pituitary deficiency and, especially, decreased ACTH and adrenal function interfere with the ability to dilute the urine maximally. Cortisol deficiency should also be considered subsequently if diabetes insipidus appears to improve because of a decrease of water excretion in the absence of an administered antidiuretic agent.

Finally, in the long-term follow-up of these patients, the possibility of late development of anterior pituitary deficiency should be kept in mind as well as the possible return of sufficient vasopressin function that the patient no longer has symptomatic diabetes insipidus.

Granulomatous Diseases
Langerhans Cell Histiocytosis

The term Langerhans cell histiocytosis is now applied to a spectrum of diseases from the severe fulminant visceral Letterer-Siwe disease to the multifocal Hand-Schüller-Christian disease to benign eosinophilic granuloma. The etiology is unknown, but the condition is characterized by proliferation of monoclonal Langerhans cells. It may have an acute fulminant course or be marked by spontaneous remission and recurring disease.

In patients with Langerhans cell histiocytosis, diabetes insipidus occurs as a manifestation of CNS involvement and usually in association with other involvements of the head, including cranial bones, oral mucosa, or other areas of the brain. Diabetes insipidus is also more common when there is systemic disease, especially involving the lung, but occasionally diabetes insipidus may be the only systemic manifestation other than diffuse involvement of the skin and may even precede the diagnosis of Langerhans cell histiocytosis. A variety of disorders of water balance may be produced, including complete hypothalamic diabetes insipidus (the most common), partial hypothalamic diabetes insipidus, abnormalities of thirst, and the disorder of essential hypernatremia.

The reported frequency of diabetes insipidus with Langerhans cell histiocytosis depends on whether it is routinely sought by endocrine tests and MRI of the brain or noted only on the basis of the diagnosis in retrospective series. Higher incidences were reported in earlier papers, possibly because the new definition of Langerhans...
diabetes insipidus is due solely to oxytocinase. Instead, these patients must be evaluated to establish an etiologic diagnosis. Because of the accelerated metabolic clearance of vasopressin in pregnancy, symptomatic diabetes insipidus may also develop in patients with borderline

obvious cause of diabetes insipidus have been monitored and have shown regression of the thickened pituitary stalk and tumor-like appearance.

patients underwent operations because of a suspicion of a pituitary tumor. When hypophysal diabetes insipidus is found, MRI usually demonstrates absence of the pituitary bright spot and widening of the stalk. As with other disorders, the degree of involvement is better demonstrated with the administration of contrast agents but occasionally the MRI is completely normal and the pathology is thought to be a vasculitis that is not apparent on imaging studies.

A number of cases have shown complete resolution of diabetes insipidus with appropriate therapy and response of Wegener’s granulomatosis; others have demonstrated persistent diabetes insipidus in spite of response of peripheral manifestations of the disease and even decreased granulomatous lesions in the hypothalamic. Other less specifically defined granulomatous diseases of the periphery have also rarely been reported with hypophysal diabetes insipidus; however, when diabetes insipidus and abnormalities of the pituitary stalk and posterior pituitary are the only findings, these nonspecific inflammatory disorders may be indistinguishable from infundibulohypophysis.

Sarcoidosis

Although only about 5% of patients with sarcoidosis have symptoms of neurosarcoidosis, neurologic symptoms are the presenting complaint in about 50% of those patients, and 25% of the patients with neurosarcoidosis have hypophysal diabetes insipidus. MRI findings may mimic those with other causes of hypophysal diabetes insipidus and consist of a widened stalk with contrast and absence of a posterior pituitary bright spot. Thus, in cases considered as idiopathic diabetes insipidus or infundibuloneurohypophysis, sarcoidosis should be considered and possible systemic manifestations of the disease should be sought. The study would include at a minimum chest radiography, erythrocyte sedimentation rate (ESR), and serum and CSF levels of angiotensin-converting enzyme and serum calcium. Tuberculosis should also be considered and a PPD test done.

Because early treatment of neurosarcoidosis is recommended, it is desirable to make the diagnosis. Although hypophysal diabetes insipidus is the most common water balance problem in sarcoidosis, disordered regulation of thirst and nephrogenic diabetes insipidus related to the disease or hypercalcemia have also been noted. Whereas neurosarcoidosis may be treated with a variety of mechanisms leading to remission of the disease, diabetes insipidus, once established, is usually permanent.

Lymphocytic Infundibulohypophysitis

When obvious causes of diabetes insipidus are not present, most cases of diabetes insipidus are idiopathic. As in other endocrine systems in which loss of function is not associated with a specific etiology, the possibility of an autoimmune process has been considered. Vasopressin antibodies have been reported in serum in up to one third of patients with idiopathic diabetes insipidus and in two thirds of those with Langerhans cell histiocytosis but were absent in patients with tumors. Furthermore, a relatively high incidence of other autoimmune diseases have been reported. In one study, 878 patients with autoimmune endocrine diseases, but without hypophysal diabetes insipidus, were screened for vasopressin antibodies and 9 patients were found to have them. With careful testing, four of these patients were found to have partial diabetes insipidus and five were normal. After a 4-year follow-up, though, three of the normal subjects had experienced partial diabetes insipidus.

A rare but now well-recognized cause of autoimmune diabetes insipidus is lymphocytic infundibulohypophysitis. Lymphocytic infiltration of the anterior pituitary, lymphocytic hypophysitis, has been recognized as a cause of anterior pituitary deficiency for a number of years, but it was not until an autopsy called attention to a similar finding in the posterior pituitary of a patient with diabetes insipidus that this pathology was recognized for the neurohypophysis. Since that report, a number of cases have been described, including cases in the postpartum period, which is characteristic of lymphocytic hypophysitis. Since the advent of MRI, lymphocytic infundibulohypophysitis has been diagnosed on the basis of the appearance of a thickened stalk or enlargement of the posterior pituitary mimicking a pituitary tumor, or both. In these cases, the characteristic bright spot on T1-weighted MRI images is lost.

Enlargement of the stalk so resembled pituitary tumor that before lymphocytic infundibulohypophysitis was known to produce stalk enlargement, some of these patients underwent operations because of a suspicion of a pituitary tumor. Recently, a number of patients with suspected infundibulohypophysitis and no other obvious cause of diabetes insipidus have been monitored and have shown regression of the thickened stalk or tumor-like appearance. Treatment of these patients with prednisone may be associated with a decrease in size of the stalk, but a decrease may also occur spontaneously.

Some cases show coexistence of infundibulohypophysitis and adenohypophysitis. Autoimmune diseases may affect more than one endocrine organ without any specific link to explain the association, such as diabetes insipidus in association with systemic lupus erythematosus or Behçet’s disease.

Diabetes Insipidus in Pregnancy

In rare cases, women with normal regulation of vasopressin have symptoms of diabetes insipidus during pregnancy because of extremely elevated activity of oxytocine aminopeptidase (vasopressinase). This syndrome has been referred to as vasopressinase-resistant diabetes insipidus of pregnancy. Levels of vasopressinase are markedly elevated above levels in normal pregnancy in such patients, and the concurrence of preeclampsia, acute fatty liver, and coagulopathies has been noted. That the excess vasopressinase is due to the condition of the pregnancy (i.e., preeclampsia) is further shown by the report that subsequent pregnancies of these women are uncomplicated by diabetes insipids or acute fatty liver. It has been suggested that the products of vasopressinase degradation produced by vasopressinase might be biologically active in increasing blood pressure, but during testing they were not thought to be causative in the preeclampsia.
insipidus is specifically related to the pregnancy (e.g., as when it occurs with Sheehan's syndrome and infarction of the neurohypophysis). One might anticipate an increased incidence of lymphocytic infundibuloneurohypophysitis in pregnancy because other autoimmune diseases occur during or just after pregnancy. Although such cases have been reported, there does not appear to be a significant association of infundibulohypophysitis with pregnancy.

Desmopressin is clearly the treatment of choice for diabetes insipidus in pregnant women (see "Treatment of Diabetes Insipidus"). In general, labor and parturition proceed normally, and patients have no trouble with lactation. There is a possibility of chronic and severe dehydration when diabetes insipidus is unrecognized, and this may pose a threat in pregnant women. In one case of severe oligohydramnios found to be due to unrecognized diabetes insipidus, the patient responded promptly to therapy with desmopressin.

Essential Hypernatremia

One variant of diabetes insipidus is the syndrome of absent osmostat with intact baroreceptors. Because of the dysfunction of the osmostat, patients do not sense thirst and do not drink water. Unlike the situation with normal subjects, however, as the serum sodium level rises, there is no (or there is a markedly subnormal) release of vasopressin and a hypotonic polyuria continues. Even when patients are made euvoletic with the infusion of normal saline and the serum sodium concentration is allowed to rise to high levels, appropriate secretion of vasopressin is not present. Vasopressin is synthesized and stored, however, because maneuvers to stimulate baroreceptors cause secretion of vasopressin and concentration of the urine.

The proposed pathophysiologic mechanism is that the inadequate water intake and excess water excretion produce a degree of dehydration with hypernatremia. When dehydration is sufficient to stimulate the baroreceptors, vasopressin is released, urine is concentrated, and patients remain in a steady state of hypernatremia with modest dehydration. The increased concentration of sodium per se also causes sodium excretion to help maintain the new steady state.

Infectious Diseases

Infectious granulomatous diseases (tuberculosis, syphilis) are rare causes of diabetes insipidus in the United States. Occasional cases of tuberculosis are still reported, however, and it is important to consider the diagnosis, because a tuberculoma in the suprasellar area may mimic an endocrine tumor or sarcoidosis. It is desirable to make the diagnosis on the basis of peripheral manifestations or CSF findings rather than at surgery.

Diabetes Insipidus and Brain Death

Endocrine failure has been a topic of several clinical reports of brain death. Diabetes insipidus is virtually universal in animal models of brain death. It is extremely common in clinical series, with the incidence ranging from 30% to 80%. higher in series involving only adults than in series including children, and obviously dependent on the rigor with which the diagnosis is sought in patients with diuresis. Important clinical considerations are whether coexistent anterior pituitary deficiency exists, especially whether steroids should be administered, and whether the diabetes insipidus should be treated.

The subject of treatment is controversial. Although there is no firm evidence that treating the diabetes insipidus affects the quality of donor organs, there is also no evidence that treating diabetes insipidus results in any complications. It is important to bear in mind that not all brain death is accompanied by diabetes insipidus and that diabetes insipidus in a comatose patient does not necessarily connote brain death and even severely injured comatose patients may survive (see earlier discussion of diabetes insipidus after head injury). The treatment of diabetes insipidus with brain death is similar to that of acute head injury.
Primary Polydipsia

Primary polydipsia and subsequent polyuria must be differentiated from diabetes insipidus and may also contribute to SIADH. Primary polydipsia may be induced by an organic structural lesion in the hypothalamus identical to that in any of the disorders described as causes of diabetes insipidus and may be especially associated with sarcoidosis of the hypothalamus. It may also be produced by drugs that cause a dry mouth or by any peripheral disorder causing an elevation of renin or angiotensin, or both. If the pathologic etiology is not identifiable, the disorder may be habitual throughout a lifetime or, more commonly, may be associated with psychiatric syndromes.

Series involving patients with polydipsia in psychiatric hospitals have shown an incidence as high as 42% of patients with some form of polydipsia, and for more than 50% of these, the cause of the polydipsia remained unexplained. In some cases, the unexplained presence of polydipsia represented a resetting of the osmotic threshold for thirst independent of the osmotic threshold for vasopressin and these patients responded to administered desmopressin producing SIADH and hyponatremia. Usually, the patient’s condition was refractory to attempts to restrict fluid. Propranolol has been used with some success, presumably because of its ability to inhibit the renin-angiotensin system.
Clinical Syndromes of Nephrogenic Diabetes Insipidus

Congenital Nephrogenic Diabetes Insipidus

Babies with nephrogenic diabetes insipidus present with vomiting, constipation, failure to thrive, fever, and polyuria. Symptoms usually occur during the first week of life, and on testing the patients are found to have hyponatremia and a low urine osmolality. Historically, the patients were reported to have mental retardation, complications of urinary tract dilation, and intracranial calcification. An association between intracranial calcification and mental retardation has not been established, and the calcification may be a consequence of hyponatremia rather than of congenital disease.

The diagnosis is established by high levels of vasopressin in the plasma in the presence of hypotonic polyuria and, subsequently, by the absence of a response to administered desmopressin. There are two causes: (1) mutation in the V2 receptor and (2) mutations in the aquaporin-2 water channels; however, the presentation of diabetes insipidus is independent of the genotype. In patients with the aquaporin defect, one can detect other V2 responses (e.g., stimulation of factor VIII secretion).

As genetic testing becomes more widely available, it may be unnecessary to perform extensive clinical testing to establish the diagnosis; instead, treatment may be initiated when the syndrome is suspected and direct genetic testing of the child and of the parents performed.

Nephrogenic Diabetes Insipidus Caused by Mutation of the V2 Receptor

More than 90% of cases of congenital nephrogenic diabetes insipidus are X-linked disorders occurring in males and are caused by one of more than 132 different V2 receptor mutations. Most mutations occur in the part of the receptor that is highly conserved among species or that is conserved among similar receptors (e.g., homology with V1 vasopressin receptors or oxytocin receptors). Mutations at other locations on the gene may cause mild abnormalities of urinary concentration, but mild defects in concentrating ability may not cause polyuria and may escape clinical detection.

Most reported receptor abnormalities produce disruption of protein folding of the V2 receptor, and the receptor is trapped in the endoplasmic reticulum, destroyed in the cell, or improperly inserted into the cell membrane. In a few cases, the receptors reached the cell membrane and were inserted; the defect was due to inhibition of binding of vasopressin to the receptor or to improper signaling of G proteins and subsequent generation of cAMP. When the V2 receptor is inserted in the cell membrane, clotting and expression of the mutant gene in cell culture may show that the receptor responds to high concentrations of vasopressin or desmopressin, yet only a few of these are responsive to physiologic levels of vasopressin to express congenital nephrogenic diabetes insipidus as a partial disorder.

In clinical series, approximately 10% of the V2 receptor defects causing congenital nephrogenic diabetes insipidus are thought to be de novo. This high incidence of de novo cases, coupled with the large number of mutations that have been identified, hinders the clinical use of genetic identification because it is necessary to sequence the entire open reading frame of the receptor gene rather than short sequences of DNA. This degree of sophistication exceeds the level of expertise that is found in most clinical laboratories.

Although most female carriers of the X-linked V2 receptor defect have no clinical disease, some females were reported to have symptomatic nephrogenic diabetes insipidus. Carriers may have a decreased maximum urine osmolality in response to the plasma level of vasopressin that they obtain but are asymptomatic because of normal urine volume. Female carriers respond to desmopressin with an increase in factor VIII, although the response may be only a fraction of the normal response. Some girls have as severe a defect as boys, and this is thought to be due to inactivation of the normal X chromosome.

In some cases, there may be some heterogeneity of X inactivation in various tissues, so that there is symptomatic nephrogenic diabetes insipidus but a normal response to stimulate factor VIII.

Nephrogenic Diabetes Insipidus Caused by Mutation of Aquaporin-2

When the proband is a girl, it is likely that the defect is a mutation of the aquaporin-2 water channel gene on chromosome 12, q1213 producing an autosomal recessive disease. This should be especially considered when consanguinity is known in the family and the family history shows disease expressed in men and women. The phenotype of nephrogenic diabetes insipidus is identical to the receptor defect when the abnormality is in the aquaporin-2 protein. More than 20 different mutations of the aquaporin-2 protein have been described. The patients may be heterozygous for two different recessive mutations or homozygous for the same abnormality from both parents.

The biologic mechanism responsible for the defect in the aquaporin proteins may be related to the site of the mutation. In some mutations, aquaporins are not properly processed in the endoplasmic reticulum or released into the cytoplasm. In other mutations, aquaporins are processed but are not appropriately inserted in the cell membrane. Mutations in the C-terminal portion of the aquaporin-2 protein produce an autosomal dominant nephrogenic diabetes insipidus. A mutant aquaporin-2 protein produces oligomers with the wild-type protein in the Golgi apparatus, and no functional aquaporin-2 proteins are produced. This form is similar to the autosomal dominant form of congenital hypothalamic diabetes insipidus described earlier.

Acquired Nephrogenic Diabetes Insipidus

The ability to produce a concentrated urine depends on maintaining hyperosmolality of the inner medulla of the kidney. The following conditions are necessary to produce and maintain hyperosmolality of the inner medulla:

1. An intact kidney architecture, with an intact tubular structure of the descending limb and ascending limb of the loop of Henle (essential to the development of the countercurrent multiplier) and a normal anatomy of the collecting duct to pass back through the inner medulla.
2. Active sodium transport in the thick ascending limb and functional aquaporins, to allow water transport across membranes.
3. An anatomically intact vascular structure so that the hyperosmolality of the inner medulla is not washed away by normal blood flow.

Acquired nephrogenic diabetes insipidus without the capacity to produce a concentrated urine may be caused by numerous chronic renal diseases that distort the architecture of the kidney (e.g., polycystic kidney disease, renal infacts with neovascularization, such as produced by sickle cell anemia; and infiltrative disease of the kidney). Washout of the medullary gradient may be produced by excessive water intake of primary polydipsia or by forced sodium and water loss related to administration of a diuretic.

A low-protein diet may be associated with reduced medullary urea concentration, causing inability to produce maximum concentration of the urine. Aquaporin is decreased in chronic renal failure, and other more specific disorders of acquired nephrogenic diabetes insipidus are related to abnormalities of aquaporins.

Studies have shown that the polyuria associated with potassium deficiency develops in parallel with decreased expression of renal aquaporin-2. Repletion of potassium reestablished the normal urinary concentrating mechanism and normalized the expression of aquaporin-2. Hypercalcemia was also associated with down-regulation of aquaporin-2. A low-protein diet diminished the ability to concentrate the urine primarily by decreased delivery of urea to the inner medulla, thus decreasing the hypertonicity of the medulla, but rats on a low-protein diet also down-regulated aquaporin-2, which may be an additional component of the decreased ability to concentrate the urine. Bilateral urinary tract obstruction caused inability to produce a maximum concentration of the urine and rat models demonstrated a down-regulation of aquaporin-2 that persisted for several days after release of the obstruction. In addition, the washout of accumulated waste...
products contributed to postobstructive polyuria.

Drug-Induced Nephrogenic Diabetes Insipidus

Administration of lithium to treat psychiatric disorders is the most common cause of drug-induced nephrogenic diabetes insipidus and illustrates the mechanisms. Lithium administration of lithium to treat psychiatric disorders is the most common cause of drug-induced nephrogenic diabetes insipidus and illustrates the mechanisms. Lithium is known to interfere with the production of cAMP, and it has been demonstrated in studies of animals that lithium produces a dramatic reduction in aquaporin-2 levels. The defect is both of aquaporin-2 on the luminal surface of the collecting duct and of aquaporin-3 on the basal lateral membrane, producing a severe defect in aquaporin-2 levels. The defect is both of aquaporin-2 on the luminal surface of the collecting duct and of aquaporin-3 on the basal lateral membrane, producing a severe defect in aquaporin-2 levels. There is as much as a 95% decrease in aquaporin-2 content, and even the 5% of aquaporin-2 that persists is not normally transported to the collecting duct membrane. Sodium transporters either show no change or are up-regulated in an effort to compensate for the water loss. The defect of aquaporins is slow to correct in both experimental animals and humans, may be permanent, and may be associated with glomerular or tubulointerstitial nephropathy. Lithium may also cause nephrogenic diabetes insipidus by inducing hypercalcemia. Other drugs that are known to induce renal concentrating defects or disorders such as nephrotic syndrome may be associated with abnormalities of aquaporin synthesis. Demeclocycline is another drug known to cause nephrogenic diabetes insipidus and is used clinically to treat SIADH (discussed later). See Bendz and Aurell for a list of drugs also known to induce diabetes insipidus.

Deficient Vasopressin

There may be an element of nephrogenic diabetes insipidus associated with severe central diabetes insipidus related to decreased aquaporin-2. Indeed, even physiologic suppression of vasopressin by chronic administration of water may produce down-regulation of aquaporin-2 in the renal collecting duct. As discussed earlier in this chapter, when a dehydration test is followed by administration of desmopressin to differentiate various causes of diabetes insipidus, the ability to concentrate the urine maximally is impaired both for central diabetes insipidus and for primary polydipsia. Although this has long been attributed to washout of the medullary concentration gradient, part of the decreased response to vasopressin is due to the down-regulation of aquaporin-2. In addition, it takes some time to restore normal expression of aquaporin-2, and this may contribute to the long time it takes patients with primary polydipsia and central diabetes insipidus to achieve maximum concentration of urine after water restriction (or treatment) is initiated.
Treatment

Patients with diabetes insipidus and inadequate thirst can rapidly become dehydrated and may experience severe hypernatremia with devastating effects on the CNS. Hypertonic encephalopathy with obtundation, coma, and seizures may be produced by brain shrinkage. A decreased volume of brain in the skull may lead to subarachnoid hemorrhage, intracerebral bleeding, or petechial hemorrhage. Fortunately, these problems associated with severe hypernatremia are not observed in patients with diabetes insipidus who are ambulatory and have an intact thirst mechanism. Furthermore, they are not a part of the syndromes of hypodipsia (e.g., essential hypernatremia) in ambulatory patients, probably because of the chronic and slower onset of hypernatremia in these cases. Thus, although hypernatremia is a commonly observed clinical

event in hospitalized patients. In most cases the dehydration is due to increased insensible water loss or gastrointestinal loss in elderly or young patients at admission (e.g., with fever) rather than diabetes insipidus. Hypernatremic encephalopathy is a risk in patients with diabetes insipidus only when patients cannot respond to thirst because of either age or level of consciousness. Patients with diabetes insipidus should carry a medical card and wear a medical alert tag indicating that they have this disorder; because diabetes insipidus is rare, the name of a physician who is familiar with the disorder and whom one can notify in an emergency should be included.

Most patients with diabetes insipidus have intact thirst and drink sufficient fluid to maintain relatively normal fluid balance. The absence of vasopressin per se does not produce pathology, and a major goal of therapy is to decrease the thirst and polyuria to an acceptable level. The therapeutic regimen should be easy for the patient to accommodate, and the timing and quantity of dosage should be individually prescribed. The safety of the prescribed agent and a regimen that avoids any detrimental effects of overtreatment are primary considerations because of the relatively benign course of diabetes insipidus and the adverse consequences of hyponatremia.

The therapeutic agents used to treat diabetes insipidus are shown in Table 9-1. Water is considered a therapeutic agent for this disease; when water is taken in sufficient quantity, there is no metabolic abnormality. As noted, therapy is designed to reduce the necessary water intake (and polyuria) to an acceptable level, but occasional lapses in pharmacologic therapy are not detrimental, may avoid overtreatment producing hyponatremia, and may allow recognition of any spontaneous recovery.

Chronic Severe Hypothalamic Diabetes Insipidus

In severe diabetes insipidus, there is virtually no vasopressin in the circulation and no ability to concentrate the urine with dehydration. An antidiuretic hormone is required, and the drug of choice is desmopressin. In this synthetic analogue, the substitution of d-arginine markedly reduced pressor activity, and removing the terminal amine increased the half-life. The two changes produced an agent nearly 2000 times more specific for antidiuresis than naturally occurring vasoressin. Most patients prefer the desmopressin tablets (0.1 and 0.2 mg), although many patients continue to be treated successfully with the desmopressin intranasal spray.

Because of the variability among patients, it is desirable to determine the duration of action of individual doses in each

---

patient. First the patient is allowed to be cleared from the effects of any previous medication, and for each voided urine the time can be recorded and the volume and osmolality measured. The patient is allowed to drink fluid ad libitum. A dose is administered; a decrease in urine volume is noted in 1 to 2 hours, and the total duration of action usually ranges from 6 to 18 hours. A satisfactory schedule can usually be determined with a modest dose, and the maximum dose needed is rarely above 0.2 mg orally or 20 µg (two sprays) given two or three times a day (usually two). Tablets allow considerable flexibility in dosage because they can be used either whole or split. For intranasally administered desmopressin, there is less flexibility with the metered spray, which is fixed at 10 µg in 100 µL. If more flexibility is necessary, the patient should be taught to use the nasal catheter (see Robinson and Verbalis for specific directions). When a dose is sufficient to elicit a stable therapeutic response, further increasing the dose (e.g., doubling it) produces only a moderate increase in duration of few hours. Tablets consistent with the half-life of desmopressin in plasma. The medication is expensive, and in many patients a smaller dose given more often is more cost-effective than a larger dose given less often. Rarely is it necessary to resort to parenterally administered desmopressin (2-mL vials, 1-mL ampules, or 10-mL vials of 4 µg/mL) for ambulatory patients. If an intercurrent illness or allergy is observed in patients with diabetes insipidus who are ambulatory and have an intact thirst mechanism. Furthermore, they are not a part of the syndromes of hypodipsia (e.g., essential hypernatremia) in ambulatory patients, probably because of the chronic and slower onset of hypernatremia in these cases. Thus, although hypernatremia is a commonly observed clinical

---

Hyponatremia is a rare complication of desmopressin therapy and occurs only if the patient is continually antidiuretic while maintaining a fluid intake sufficient to become volume-expanded and natriuretic. Thirst may be protective, and most patients with diabetes insipidus receiving standard therapy may not be continuously
maximally antidiuretic. Hyponatremia has been reported in patients with normal thirst and normal vasopressin function after taking desmopressin for treatment of von Willebrand’s disease and in children treated for primary enuresis. Hyponatremia is often indicated first by the onset of convulsions and coma. Hyponatremia in patients with diabetes insipidus who are receiving desmopressin may be avoided by ensuring, either with routine therapy or by occasionally delaying a dose of desmoppressin, that polyuria recurs once or twice a week, so that any excess fluid can be excreted.

Chronic Partial Hypothalamic Diabetes Insipidus

Patients with partial diabetes insipidus have some ability to secrete vasopressin and to concentrate the urine, but the function is inadequate to maintain normal water intake and urine output. These patients are more likely to respond to therapeutic agents such as chlorpropamide or thiazide diuretics because only a modest decrease in urine volume may make them asymptomatic. The major action of chlorpropamide is on the renal tubule to increase the hydro-osmotic action of vasopressin. The agent can also produce significant antidiuresis even in patients with severe hypothalamic diabetes insipidus.

The usual dose is 250 to 500 mg/day, with a response noted in 1 to 2 days and a maximum antidiuresis in 4 days. This is an off-label use of the drug. This agent should not be used in pregnancy and is not recommended for children, especially those with concurrent hypopituitarism, because of the possibility of severe hypoglycemia. These patients also respond to desmopressin; guidelines for initiating and maintaining therapy are essentially the same as those described earlier for patients with severe diabetes insipidus.

Chronic Diabetes Insipidus with Inadequate Thirst

The presence of diabetes insipidus in a patient with inadequate thirst is a difficult management problem because patients with lack of thirst can experience severe hyponatremia and, if given an antidiuretic agent and encouraged to drink, can become hypotensive. Thus, these patients are subject not only to wide swings in osmolality but also, most characteristically, to persistent hyponatremia. The spectrum of disorders includes that described as essential hyponatremia.

The first therapeutic agent to try is chlorpropamide; it has been found useful for treating diabetes insipidus and for increasing the thirst response. Chlorpropamide does not produce adequate control, the appropriate therapy is a fixed dose of desmopressin and a prescribed quantity of water. These patients usually require encouragement to drink. A constant antidiuresis is maintained by a rigid regimen of desmopressin and water intake prescribed for every 6 to 8 hours during a 24-hour period. Regular follow-up with measurement of serum sodium concentrations is essential to prevent development of water intoxication with hyponatremia or recurrent dehydroinfusion with hyponatremia.

Diabetes Insipidus in Pregnancy

Desmopressin is the only therapeutic agent recommended for treatment of diabetes insipidus during pregnancy. Desmopressin has 2% to 25% of the oxytocic activity of lysine vasopressin or arginine vasopressin and can be used with minimal stimulation of the oxytocin receptors in the uterus. This is the only antidiuretic agent recommended for fluid management during pregnancy. The agent can also produce significant antidiuresis even in patients with severe hypothalamic diabetes insipidus.

During delivery, these patients should maintain adequate oral intake and continued administration of desmopressin. Physicians should be cautious about overadministration of fluid parenterally during delivery because these patients are not able to excrete the fluid and may experience water intoxication and hyponatremia.

After delivery, oxytocinase decreases in plasma and, depending on the cause of the diabetes insipidus, the disorder may disappear or the patient may become asymptomatic with regard to fluid intake and urine volume.

Diabetes Insipidus after Hypothalamic or Pituitary Surgery and after Head Injury

Pituitary Surgery

The surgeon often knows how severely the posterior pituitary or stalk has been injured. The difficulty in making the diagnosis in this clinical setting has been discussed under “Differential Diagnosis.” Sometimes the duration of diabetes insipidus is transient, and the surgeon may prefer to treat only with fluid replacement parenterally or orally (if the patient is awake and able to respond to thirst).

To treat diabetes insipidus, desmopressin may be given at 0.5 to 2 μg subcutaneously, intramuscularly, or intravenously. The intravenous route may be preferable because (1) there is no question about absorption and (2) with the lack of pressor activity, desmopressin is safe. Urine output is reduced in 1 to 2 hours, and the duration of effect is 6 to 24 hours. If the patient is alert, thirst is a good guide to fluid replacement. Because diabetes insipidus may be transient and some patients may experience the triphasic pattern described previously, it is desirable to allow polyuria to return before administering subsequent doses of desmopressin.

Head Injury

The treatment of acute diabetes insipidus after blunt trauma to the head, usually from a motor vehicle accident, is similar to that in the postoperative situation, except that the patient with head injury is more likely to be comatose and unable to respond to thirst. Therefore, hypotonic polyuria is more likely to be associated with hyponatremia. Because a comatose patient must be given fluids parenterally, some clinicians prefer to use a continuous infusion of low-dose vasopressin. The vasopressin can either be added directly to the crystalloid solution that is being administered or infused separately to maintain a constant antidiuresis while fluid intake is adjusted appropriately to any persistent polyuria and to cover insensible water loss. Doses of 0.25 to 2.7 mL/kg per hour have been described. With this method, there is a potential to produce hyponatremia, and serum sodium levels must be checked regularly. Furthermore, with continuous replacement, one does not know whether normal function has resumed or whether a patient is entering the second phase of a triphasic pattern.

Nephrogenic Diabetes Insipidus

Adequate water intake should always be maintained; indeed, appropriate water intake may be lifesaving in congenital nephrogenic diabetes insipidus. By definition, these forms of diabetes insipidus do not respond to vasopressin or desmopressin, although there may be rare partial defects with some response to high doses of desmopressin.

Therapy is aimed at reducing symptomatic polyuria by reducing the volume of urine output. The volume is reduced primarily by causing an element of volume contraction. For congenital nephrogenic diabetes insipidus, volume contraction has been produced by a low-sodium diet and a thiazide diuretic. Thiazide diuretics act at the distal convoluted tubule to inhibit sodium chloride absorption, producing sodium (and water) diuresis. The antidiuretic effect has been attributed to ECF volume contraction. For congenital nephrogenic diabetes insipidus, volume contraction has been produced by a low-sodium diet and a thiazide diuretic. Thiazide diuretics act at the distal convoluted tubule to inhibit sodium chloride absorption, producing sodium (and water) diuresis. The antidiuretic effect has been attributed to ECF volume contraction. For congenital nephrogenic diabetes insipidus, volume contraction has been produced by a low-sodium diet and a thiazide diuretic. Thiazide diuretics act at the distal convoluted tubule to inhibit sodium chloride absorption, producing sodium (and water) diuresis. The antidiuretic effect has been attributed to ECF volume contraction.

Addition of amiloride therapy is now recommended because of the absence of duodenal ulcer and gastrointestinal hemorrhage that may be produced by nonsteroidal anti-inflammatory agents. If the condition is recognized early and treated vigorously,
complications such as intracerebral calcification, mental retardation, growth failure, and hydronephrosis are largely preventable. 

Drug-induced nephrogenic diabetes insipidus should be treated by stopping the offending agent if possible. Persistence of nephrogenic diabetes insipidus can be similarly treated by hydrochlorothiazide and amiloride. With the induced volume contraction, the patient should be closely monitored for the development of renal or other toxicity of the drug causing the diabetes insipidus. 

For example, volume contraction produced by thiazide diuretics, when used to treat lithium-induced nephrogenic diabetes insipidus, may decrease lithium excretion and predispose to lithium toxicity. 

Amiloride has the advantage of decreasing lithium entrance into cells in the distal tubule and may have a specific and preferable action for the treatment of lithium-induced nephrogenic diabetes insipidus. 

Indapamide is an antihypertensive diuretic agent with a structure similar to that of hydrochlorothiazides and chlorpropamide. It has been reported to reduce urine volume in patients with hypothalamic diabetes insipidus.

Diabetes Insipidus in Association with Other Therapeutic Decisions

Routine Surgical Procedures

In most routine surgical procedures, the patient is not unconscious long enough to require anything more than administration of the usual dose of desmopressin and careful monitoring of fluids during the surgery to avoid overhydration. If the patient has been taking desmopressin orally and is to be given nothing by mouth, a nasal or a parenteral dose can be administered before the procedure.

Panhypopituitarism

Because hypothyroidism and adrenal insufficiency act directly on the kidney to inhibit the ability to excrete water, any patient who has anterior pituitary deficiency in association with diabetes insipidus is at risk for hypernatremia if treatment for diabetes insipidus is continued but treatment with thyroid hormone and (more dramatically) hydrocortisone is stopped. For such patients, it is important to maintain treatment of all anterior and posterior pituitary deficiencies continuously as the balance of these replacements is essential.

Promoting a Saline Diuresis

In some clinical situations, such as chemotherapy or use of some contrast agents, diuresis is desirable to minimize renal toxicity. Continuing desmopressin while giving a large volume of normal saline induces a prompt natriuresis and hypernatremia. Withholding desmopressin and replacing with 5% dextrose in water may lead to hyperglycemia, and replacing with normal saline may lead to hyponatremia. It has been reported that continuous intravenous administration of low-dose vasopressin in a manner similar to that described earlier for comatose patients can be used. In this case, the dose of vasopressin is even lower (e.g., 0.08 to 0.1 mU/kg per hour) to allow a moderate and controlled diuresis. As with any situation in which vasopressin is given continuously, serum sodium levels must be checked regularly and the amount of fluids infused monitored carefully.

Hypertonic Encephalopathy

Conditions other than diabetes insipidus are the more common causes of hypernatremia with coma and hypertonic encephalopathy. These conditions often affect older patients with concurrent renal problems or who are receiving treatment with diuretics, in whom total body sodium may be decreased despite hypernatremia, or children with insensible loss or diarrhea.

and who are taking sodium-containing fluids. In patients with severe hypernatremia and hypertonic encephalopathy, overaggressive treatment of the hypernatremia may cause cerebral edema and may worsen the neurologic condition. Sodium is mainly an extracellular cation, and hypernatremia invariably leads to movement of water out of cells and to cellular dehydration.

In the brain, idiogenic osmoles are generated intracellularly, and the degree of cell shrinkage is less than would be expected on the basis of the degree of hypernatremia. The idiogenic osmoles are in three organic classes: (1) polyols, (2) trimethylamines, and (3) amino acids and their derivatives. The increase in these organic osmoles has occurred within 1 to 2 hours in experimental animals but may be somewhat slower in humans. The important clinical observation is that when fluid is replaced, these organic osmoles decrease much more slowly intracellularly than the decrease in osmolality of the ECF. This asynchrony increases the potential for cerebral edema and worsening of the neurologic condition with overzealous treatment of hypernatremia.

In most cases of diabetes insipidus that are seen immediately after surgery or that are identified promptly after head injury, the diagnosis is made within a few hours and therapy is instituted promptly. When the duration of the hypernatremia is not known, the degree of correction of hypernatremia should not exceed 0.5 mEq/L per hour to prevent cerebral edema and convulsions.

Organ Donors

As noted earlier, diabetes insipidus is commonly associated with brain death. Because the patient may be a candidate for organ donation, regulating fluid homeostasis is thought to be desirable for maintaining the health of the organs. Although this is controversial, some degree of treatment of diabetes insipidus is not unreasonable. This may be a situation in which continuous administration of vasopressin in a low dose is easier than maintaining antidiuresis with intermittent doses of desmopressin.
Severe hypo-osmolality (serum Na$^+$) is almost always a consequence of pathological conditions. Even relatively mild hypo-osmolality can quickly progress to more dangerous levels during the therapeutic management of other disorders. Overly rapid correction of hyponatremia can itself cause severe neurologic morbidity and mortality. If the calculated effective plasma osmolality is less than 275 mOsm/kg H$_2$O, the patient usually has true osmotic diuresis and underlying diseases that could reverse the hypo-osmolality. However, in most cases, the calculated effective plasma osmolality is normally based on the calculated serum sodium concentration and glucose elevation; traditionally, the correction factor has been 1.6 mEq/L for each 100 mg/dL increase in serum glucose concentration above normal levels, but later studies showed a more complex relation between serum glucose and serum Na$^+$. The calculated effective plasma osmolality is less than 275 mOsm/kg H$_2$O or if the corrected serum Na$^+$ is less than 135 mEq/L, significant hypo-osmolality exists, provided that large concentrations of unmeasured solutes or pseudohyponatremia secondary to hyperglycemia or hyperproteinemia is not present. To eliminate the latter possibilities, plasma osmolality should also be measured directly when the hyponatremia cannot be accounted for by elevated serum glucose levels. The absence of a discrepancy between the calculated and measured total plasma osmolalities (<10 mOsm/kg H$_2$O) confirms the absence of

**THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION**

SIADH is produced when plasma levels of arginine vasopressin are elevated at times during which the physiologic secretion of vasopressin from the posterior pituitary would normally be suppressed. Because the clinical abnormality is in the osmotic pressure of body fluids, the hallmark of SIADH is hypo-osmolality. In 1957, this finding led to the identification of the first well-described cases of this disorder; it is thus necessary to summarize general issues concerning hypoosmolality and hyponatremia before we present details specific to SIADH.

**Hypo-osmolality and Hyponatremia**

**Incidence**

Hypo-osmolality is one of the most common disorders of fluid and electrolyte balance in hospitalized patients. The incidence and prevalence of hypo-osmolar disorders depend on the nature of the population of patients studied as well as the laboratory methods and criteria used to diagnose hyponatremia. Most investigators have used serum sodium as a screening test to determine the clinical incidence of hypo-osmolality. When hyponatremia was defined as a serum Na$^+$ less than 135 mEq/L, incidences as high as 15% to 30% were observed in studies of both acutely and chronically hospitalized patients. However, incidences decreased to the range of 1% to 4% when only patients with serum Na$^+$ under 130 to 131 mEq/L were included, which represents a more appropriate level at which to define the occurrence of clinically significant cases of this disorder. Even when these more stringent criteria have been used, incidences from 7% to 53% have been reported in institutionalized geriatric patients.

All studies to date have noted a high proportion of iatrogenic or hospital-acquired hyponatremia, which has accounted for as many as 40% to 75% of all patients studied. Therefore, although hyponatremia and hypo-osmolality are quite common, most cases are relatively mild and most are acquired during the course of hospitalization. Nonetheless, hyponatremia is important clinically because:

1. Severe hypo-osmolality (serum Na$^+$ < 120 mEq/L) is associated with substantial morbidity and mortality.
2. Even relatively mild hypo-osmolality can quickly progress to more dangerous levels during the therapeutic management of other disorders.
3. Overly rapid correction of hyponatremia can itself cause severe neurologic morbidity and mortality.
4. Mortality rates are much higher (threelfold to 80-fold higher) in patients with even asymptomatic degrees of hypoosmolality compared with normonatremic patients.

In many but not all cases, hypo-osmolality is more an indicator of the severity of underlying illnesses than an independent factor contributing to mortality.

**Osmolarity, Toxicity, and Serum Sodium**

As discussed previously, the osmolarity of body fluid is normally maintained within narrow limits by osmotically regulated vasopressin secretion and thirst. Although basal plasma osmolarity can vary appreciably among individuals, the range in the general population under conditions of normal hydration is between 280 and 295 mOsm/kg H$_2$O. Plasma osmolarity can be determined directly by measuring the freezing-point depression or the vapor pressure of plasma. Alternatively, it can be calculated indirectly from the concentrations of the three major solutes in plasma:

$$\text{plasma osmolality} = 2 \times \text{Na}^+ \text{ (mEq/L)} + \text{glucose (mg/dL)} / 18 + \text{BUN (mg/dL)} / 2.8$$

Both methods produce comparable results under most conditions. Although either method produces valid measures of total osmolality, this is not always equivalent to the effective osmolality, commonly referred to as the tonicity of the plasma. Only cell solutes such as Na$^+$ and Cl$^-$ that cannot permeate the cell membrane and remain relatively compartmentalized within the ECF space are effective solutes because they create osmotic gradients across cell membranes and regulate the osmotic movement of water between the intracellular fluid (ICF) compartment and the ECF compartment. Solutes that readily permeate cell membranes (e.g., urea, ethanol, methanol) are not effective solutes. Therefore, only the concentrations of effective solutes in plasma should be used to ascertain whether clinically significant hyperosmolality or hypo-osmolality is present.

Because sodium and its accompanying anions are the major effective plasma solutes, hyponatremia and hypo-osmolality are usually synonymous. However, there are two situations in which hyponatremia does not reflect true hypo-osmolality:

1. **Pseudohyponatremia**, produced by marked elevations of either lipids or proteins in plasma. When Na$^+$ is measured by flame photometry, the concentration of Na$^+$ per liter of plasma is artificially decreased because of the larger relative proportion of plasma volume that is occupied by the excess lipids or proteins. However, because the increased protein or lipid does not appreciably change the total number of solute particles in solution, the directly measured plasma osmolality is not significantly affected. Measurement of serum Na$^+$ by ion-specific electrodes, now commonly performed by most clinical laboratories, is less influenced by high concentrations of lipids or proteins than is measurement of serum Na$^+$ by flame photometry.

2. **Presence of high concentrations of effective solutes other than Na$^+$ in plasma**. The initial hyperosmolality produced by the additional solute causes an osmotic shift of water from ICF to ECF, which in turn produces a dilutional decrease in serum Na$^+$. When equilibrium between both fluid compartments is achieved, the total effective osmolality remains relatively unchanged. This situation most commonly occurs with hyperglycemia and is a frequent cause of hyponatremia in hospitalized patients, accounting for up to 10% to 20% of all cases.

Misdagnosis of true hypo-osmolality in such cases can be avoided by measuring plasma osmolality directly or by correcting the measured serum Na$^+$ for the glucose elevation; traditionally, the correction factor has been 1.6 mEq/L for each 100 mg/dL increase in serum glucose concentration above normal levels, but later studies showed a more complex relation between hyperglycemia and serum Na$^+$. The initial hyperosmolality produced by the additional solute causes an osmotic shift of water from ICF to ECF, which in turn produces a dilutional decrease in serum Na$^+$. When equilibrium between both fluid compartments is achieved, the total effective osmolality remains relatively unchanged. This situation most commonly occurs with hyperglycemia and is a frequent cause of hyponatremia in hospitalized patients, accounting for up to 10% to 20% of all cases. Therefore, only the concentrations of effective solutes in plasma should be used to ascertain whether clinically significant hyperosmolality or hypo-osmolality is present.

**Because of these potential confounders, determining whether true hypo-osmolality is present can sometimes be difficult. A straightforward and relatively simple approach is as follows:**

1. The effective plasma osmolality should be calculated from the measured serum Na$^+$ and glucose concentration (2 × [Na$^+$] + glucose/18); alternatively, the measured serum Na$^+$ can simply be corrected by 1.6 to 2.4 mEq/L for each 100 mg/dL increase in serum glucose concentration above normal levels (100 mg/dL).
2. If the calculated effective plasma osmolality is less than 275 mOsm/kg H$_2$O or if the corrected serum Na$^+$ is less than 135 mEq/L, significant hypo-osmolality exists, provided that large concentrations of unmeasured solutes or pseudohyponatremia secondary to hyperglycemia or hyperproteinemia is not present.
3. To eliminate the latter possibilities, plasma osmolality should also be measured directly when the hyponatremia cannot be accounted for by elevated serum glucose levels. The absence of a discrepancy between the calculated and measured total plasma osmalities (<10 mOsm/kg H$_2$O) confirms the absence of
significant amounts of unmeasured solutes; if a significant discrepancy between these measures is found (an osmolar gap), appropriate tests must be conducted to rule out pseudohyponatremia or to identify possible unmeasured plasma solutes.

**Pathogenesis of hypo-osmolality**

Because water moves freely between ICF and ECF, osmolality is always equivalent in both of these fluid compartments. Because the bulk of body solute consists of electrolytes, namely the exchangeable Na⁺ (Na⁺ₑ) in ECF and the exchangeable K⁺ (K⁺ₑ) in ICF along with their associated anions, total body osmolality is largely a function of these two components:

\[
\text{Total body osmolality} = (2 \times \text{Na}⁺ + 2 \times \text{K}⁺ + \text{nonelectrolyte solute})/\text{body water}
\]

According to this definition, the presence of plasma hypo-osmolality indicates a relative excess of water to solute in the ECF. The excess can be produced either by an excess of body water, resulting in dilution of remaining body solute, or by a depletion of body solute, either Na⁺ or K⁺, relative to body water. This classification is an oversimplification because most hypo-osmolar states involve significant components of both solute depletion and water retention. Nonetheless, it is conceptually useful for understanding the underpinnings of hypo-osmolality and as a framework for therapy of hypo-osmolar disorders.

**Solute Depletion**

Depletion of body solute can result from any significant losses of ECF. Body fluid losses by themselves rarely cause hypo-osmolality because excreted or secreted body fluids are usually isotonic or hypertonic relative to plasma and therefore tend to increase plasma osmolality. When hypo-osmolality accompanies ECF losses, it is the result of replacement of body fluid losses by more hypotonic solutions either by drinking or by infusion, thereby diluting the remaining body solutes. If the solute losses are marked, these patients show signs of volume depletion (e.g., Addisonian crisis). However, such patients often have a more deceptive clinical presentation because the volume deficits were partially replaced. Moreover, they may not manifest signs or symptoms of cellular dehydration because osmotic gradients draw water into the relatively hypertonic ICF.

Therefore, clinical evidence of hypovolemia strongly supports solute depletion as the cause of plasma hypo-osmolality, but absence of clinically evident hypovolemia never completely eliminates this as a possibility. Although ECF solute losses are responsible for most cases of depletion-induced hypo-osmolality, ICF solute loss can also cause hypo-osmolality as a result of osmotic water shifts from the ICF into the ECF. This mechanism probably contributes to some cases of diuretic-induced hypo-osmolality, in which depletion of total body K⁺ often occurs.

**Water Retention**

Despite the importance of solute depletion in some patients, most cases of clinically significant hypo-osmolality are caused by increases in total body water rather than by primary losses of extracellular solute. Such increases can occur because of either impaired renal free water excretion or excessive free water intake. However, the former accounts for most hypo-osmolar disorders because normal kidneys have sufficient diluting capacity to allow excretion of free water up to approximately 18 L/day. Intakes of this magnitude are occasionally seen in some psychiatric patients but not in most patients with SIADH, in whom fluid intakes average only 2 to 3 L/day. Consequently, dilutional hypo-osmolality is usually the result of an abnormality of renal free water excretion. The renal mechanisms responsible for impairments in free water excretion can be sub grouped according to whether the major impairment in free water excretion occurs in proximal or distal parts of the nephron, or both.

Any disorder that leads to a decrease in GFR causes increased reabsorption of both Na⁺ and water in the proximal tubule. As a result, the ability to excrete free water is limited because of decreased delivery of tubular fluid to the distal nephron. Disorders causing solute depletion through nonrenal mechanisms (e.g., gastrointestinal fluid losses) also produce this effect. Disorders that cause a decreased GFR in the absence of significant ECF fluid losses are, for the most part, edema forming states associated with decreased effective arterial blood volume (EABV) and secondary hyperaldosteronism.

Even though these conditions are characterized by increased proximal reabsorption of both Na⁺ and fluid, water retention also results from increased distal reabsorption caused by non-osmotic baroreceptor-mediated stimulated increases in plasma vasopressin levels. Distal nephron impairments in free water excretion are characterized by inability to dilute tubular fluid maximally. These disorders are usually associated with abnormalities in the secretion of vasopressin from the posterior pituitary. However, just as depletion-induced hypo-osmolar disorders usually include an important component of secondary impairments of free water excretion, most dilution-induced hypo-osmolar disorders involve significant degrees of secondary solute depletion. This is described later with SIADH.

Some dilutional disorders do not fit well into either category, specifically the hyponatremia that sometimes occurs in patients who ingest large volumes of beer with little food intake for prolonged periods, called beer potomania. Even though the volume of fluid ingested may not seem sufficiently excessive to overwhelm renal diluting mechanisms, free water excretion is limited by low urine solute excretion, thereby causing water retention and dilutional hyponatremia. A case in which hyponatremia occurred in an ovulotovaguetarian with a very low protein intake but no beer ingestion is consistent with this pathophysiology.

**Adaptation to Hyponatremia: Intracellular Fluid and Extracellular Fluid Volume Regulation**

Many past studies have indicated that the combined effects of water retention and urinary solute excretion cannot adequately explain the degree of plasma hypo-osmolality observed in patients. This observation led to the theory of cellular inactivation of solute. The theory suggested that as ECF osmolality falls, water moves into cells along osmotic gradients, causing the cells to swell. At some point during this volume expansion, the cells osmotically inactivate some of their intracellular solutes as a defense mechanism to prevent continued cellular swelling and detrimental effects on cell function and survival. This inactivation decreases the intracellular osmolality and water shifts back out of the ICF into the ECF, further worsening the dilution-induced hypo-osmolality. Despite the appeal of this theory, its validity has never been demonstrated conclusively in either human or animal studies.

An appealing alternative theory is that cell volume is maintained under hypo-osmolar conditions by extrusion of potassium. Whole-brain volume regulation through electrolyte losses was first described by Yannet and has long been recognized as the mechanism by which the brain is able to adapt to hyponatremia and limit brain edema to sublethal levels. After the recognition that low-molecular-weight organic compounds (called organic osmolytes) are a significant osmotic component of a wide variety of cell types, studies demonstrated accumulation of these compounds in response to hyperosmolality in both kidney and brain tissue (see hyperosmotic encephalopathy earlier). Conversely, the brain loses organic osmolytes in addition to electrolytes during volume regulation to hypo-osmolar conditions in experimental animals and human patients. These losses occur relatively quickly (within 24 to 48 hours in rats) and can account for as much as one third of the brain solute losses during hyponatremia. Such coordinate losses of both electrolytes (K⁺) and organic osmolytes from brain tissue allow effective regulation of brain volume during chronic hyponatremia. Consequently, it is now clear that cellular volume regulation in brain tissue occurs predominantly through depletion of a variety of intracellular solutes rather than intracellular osmotic inactivation.

Although contemporary studies of volume regulation during hyponatremia have focused on the brain, all cells regulate volume by cellular losses of both electrolytes and organic solutes to varying degrees. However, volume regulatory processes are not limited to cells. In most cases of hyponatremia induced by stimulated antidiuresis and water retention, natriuresis also regulates the volumes of the ECF and intravascular spaces.

Many experimental and clinical observations are consistent with ECF volume regulation through secondary solute losses, as described next.

First, the concentrations of most blood constituents other than Na⁺ and Cl⁻ are not decreased in patients with SIADH; this suggests that plasma volume is not nearly as expanded as would be predicted simply by the measured decreases in serum [Na⁺].

Second, an increased incidence of hypertension has never been observed in patients with SIADH; again, this is evidence against significant expansion of the arterial bed.
blood volume.

Third, results of animal studies in both dogs and rats have indicated that a significant component of chronic hyponatremia is attributable to secondary Na⁺ losses rather than water retention. The relative contributions of water retention and sodium loss vary with the duration and severity of the hyponatremia: water retention was found to be the major cause of decreased serum [Na⁺] in the first 24 hours of induced hyponatremia in rats, but Na⁺ depletion became the predominant etiologic factor after longer periods (7 to 14 days) of sustained hyponatremia, particularly at low (<115 mEq/L) serum Na⁺ levels.\(^\text{424}\)

Finally, multiple studies of body fluid compartment volumes in hyponatremic patients have not shown either plasma or ECF expansion. For example, a report of body fluid space measurements using isotope dilution techniques in hyponatremic and normonatremic patients with small cell lung carcinoma showed no differences between the two groups with regard to exchangeable sodium space, ECF volume determined by\(^\text{35}\) SO₄ distribution, or total body water.\(^\text{425}\)

Such results have generally been explained by the relative insensitivity of isotope dilution techniques for measurement of body fluid compartment spaces, but an equally plausible possibility is that body fluid compartments have regulated back toward normal through a combination of extracellular (predominantly electrolyte) and intracellular (electrolyte and organic osmolyte) solute losses.\(^\text{442}\) Figure 9-8 (Figure Not Available) schematically illustrates some of the volume regulatory processes that probably occur in response to water retention induced by inappropriate anti-diuresis. The degree to which solute losses versus water retention contribute to the resulting hyponatremia depends on many different factors, including:

1. The cause of the hyponatremia.

2. The rapidity of hyponatremia development.
3. The chronicity of the hyponatremia.
4. The volume of daily water loading and subsequent volume expansion.
5. Undoubtedly, some degree of individual variability as well.

Figure 9-8 (Figure Not Available) Schematic illustration of potential changes in whole-body fluid compartment volumes at various times during adaptation to hyponatremia. A, Under basal conditions the concentrations of effective solutes in the extracellular fluid ([S]\text{ECF}) and the intracellular fluid ([S]\text{ICF}) are in osmotic balance. B, During the first phase of water retention resulting from inappropriate antidiuresis, the excess water distributes across total body water, causing expansion of both ECF and ICF volumes (dashed lines) with equivalent dilutional decreases in [S]\text{ECF} and [S]\text{ICF}. C, In response to the volume expansion, compensatory volume regulatory decreases (VRD) occur to reduce the effective solute content of both the ECF (through pressure diuresis and natriuretic factors) and ICF (through increased electrolyte and osmolyte extraction mediated by stretch-activated channels and down-regulation of synthesis of osmolytes and osmolyte uptake transporters). D and E, If both processes go to completion, such as under conditions of fluid restriction, a final steady state can be reached in which ICF and ECF volumes have returned to normal levels but [S]\text{ECF} and [S]\text{ICF} remain low (B). In most cases, this final steady state is not reached and moderate degrees of ECF and ICF expansion persist but are significantly less than would be predicted from the decrease in body osmolality (D). Consequently, the degree to which hyponatremia is due to dilution from water retention versus solute depletion from volume regulatory processes can vary markedly depending on which phase of adaptation the patient is in and also on the relative rates at which the different compensatory processes occur (e.g., delayed ICF VRD can worsen hyponatremia related to shifts of intracellular water into the ECF as intracellular organic osmolytes are extruded and subsequently metabolized, probably accounting for some component of the hyponatremia unexplained by the combination of water retention and sodium excretion in previous clinical studies). (From Verbalis JG. Hyponatremia: epidemiology, pathophysiology, and therapy. Curr Opin Nephrol Hypertens 1993; 2:63652.)

Differential Diagnosis of Hyponatremia and Hypo-osmolality

Because of the multiplicity of disorders causing hypo-osmolality and the fact that many involve more than one pathologic mechanism, a definitive diagnosis is not always possible at the time of initial presentation. Nonetheless, an approach based on clinical parameters of ECF volume status and urinary sodium concentration generally allows sufficient categorization for appropriate decisions regarding initial therapy and further evaluation (Table 9-2).

CHF, congestive heart failure; ECF, extracellular fluid; Gl, gastrointestinal; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

*Urinary [Na⁺] values <30 mEq/L are generally considered to be low and values 30 mEq/L to be high, based on studies of responses of hyponatremic patients to infusions of isotonic saline.

Decompressed Extracellular Fluid Volume

Clinically detectable hypovolemia always signifies total body solute depletion. A low urinary [Na⁺] indicates a nonrenal cause and an appropriate renal response. A high urinary [Na⁺] indicates that renal causes of solute depletion are more likely. Therapy with thiazide diuretics is the most common cause of renal solute losses, particularly in elderly people, but mineralocorticoid deficiency as a result of adrenal insufficiency or mineralocorticoid resistance must be considered as well as (less commonly) renal solute losses related to salt-wasting nephropathy (e.g., polycyclic kidney disease), interstitial nephritis, or chemotherapy.

Reexpanded Extracellular Fluid Volume

Clinically detectable hypervolemia always signifies total body Na⁺ excess. In these patients, hypo-osmolality results from an even greater expansion of total body water caused by a marked reduction in the rate of water excretion (and sometimes an increased rate of water ingestion). The impairment in water excretion is secondary to a decreased effective arterial blood volume, which increases the reabsorption of glomerular filtrate not only in the proximal nephron but also in the distal and collecting tubules by stimulated secretion of vasopressin. These patients generally have a low urinary [Na⁺] because of secondary hyperaldosteronism. Under certain conditions, however, urinary [Na⁺] may be elevated if there is concurrent diuretic therapy or a solute diuresis (e.g., glucosuria in diabetic patients) or after successful treatment of the underlying disease (e.g., isotropic therapy in patients with congestive heart failure).
An additional disorder that can produce hypo-osmolality and hypervolemia is acute or chronic renal failure with fluid overload (although in early stages of renal failure polyuria resulting from vasopressin resistance is more likely). Urinary [Na⁺] in these cases is usually elevated, but it can be variable, depending on the stage of renal failure. It is important to remember that primary polydipsia is not accompanied by signs of hypervolemia because water ingestion alone, in the absence of Na⁺ retention, does not produce clinically apparent degrees of ECF volume expansion.

**Normal Extracellular Fluid Volume**

Many different hypo-osmolar disorders occur with euvolementia, and measurement of urinary [Na⁺] is an especially important first step. A high urinary [Na⁺] usually implies a distally mediated, dilution-induced hypo-osmolality such as that in SIADH. However, glucocorticoid deficiency can mimic SIADH so closely that these two disorders are often indistinguishable in terms of water balance. Hyponatremia resulting from diuretic use can also occur without clinically evident hypovolemia, and urinary [Na⁺] is usually elevated. A low urinary [Na⁺] suggests a depletion-induced hypo-osmolality resulting from ECF losses with subsequent volume replacement by water or other hypotonic fluids. The solute loss is often nonrenal, but an important exception is recent cessation of diuretic therapy because urinary [Na⁺] can decrease to low values within 12 to 24 hours after discontinuation of the drug.

The presence of low serum [K⁺] is an important clue to diuretic use. Low urinary [Na⁺] can also be seen in some cases of hypothyroidism, in the early stages of decreased effective arterial blood volume before the development of clinically apparent salt retention and fluid overload, or during the recovery phase of SIADH. Hence, a low urinary [Na⁺] is less meaningful diagnostically than a high value.
Clinical Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is the most common cause of euvoletic hypo-osmolality; it is also the single most common cause of hypo-osmolality of all etiologic mechanisms encountered in clinical practice, with prevalence rates from 20% to 40% among all hypo-osmolar patients. The clinical criteria necessary to diagnose SIADH remain basically as set forth by Bartter and Schwartz in 1967:

1. Decreased effective osmolality of the ECF (plasma osmolality < 275 mOsm/kg H₂O). Pseudohipernatraemia or hypoglycemia alone must be excluded.
2. Inappropriate urinary concentration (urine osmolality > 100 mOsm/kg H₂O with normal renal function) at some level of hypo-osmolality. This does not mean that urine osmolality is greater than plasma osmolality; rather, the urine is less than maximally dilute (i.e., urine osmolality > 100 mOsm/kg H₂O). Also, urine osmolality need not be elevated inappropriately at all levels of plasma osmolality because in the reset osmostat variant form of SIADH, vasopressin secretion can be suppressed with resultant maximal urinary dilution if plasma osmolality is decreased to sufficiently low levels.
3. Clinical euvoletic as defined by the absence of signs of hypovolemia (orthostasis, tachycardia, decreased skin turgor, dry mucous membranes) or hypervolemia (subcutaneous edema, ascites). Hypovolemia or hypervolemia strongly suggests different causes of hypo-osmolality. Patients with SIADH can become hypovolemic or hypervolemic for other reasons, but in such cases it is impossible to diagnose the underlying inappropriate antidiuresis until the patient is rendered euvoletic and is found to have persistent hypo-osmolality.
4. Elevated urinary sodium excretion with a normal salt and water intake. This criterion is included because of its utility in differentiating between hypo-osmolality caused by a decreased effective arterial blood volume, in which case renal Na⁺ conservation occurs, and distal dilution-induced disorders, in which urinary Na⁺ excretion is normal or increased secondary to ECF volume expansion. Patients with SIADH can have low urinary Na⁺ excretion if they subsequently become hypovolemic or solute-depleted, conditions that sometimes follow severe salt and water restriction. Consequently, high urinary Na⁺ excretion is the rule in most patients with SIADH, its presence does not guarantee this diagnosis, and its absence does not rule out the diagnosis.
5. Absence of other potential causes of euvoletic hypo-osmolality: hypothyroidism, hypercorticism (Addison's disease or pituitary ACTH insufficiency), and diuretic use.

Several other criteria support, but are not essential for, a diagnosis of SIADH. Because volume expansion and vasopressin acting on V₁ receptors in the kidney increase the clearance of uric acid, hypouricemia is found with SIADH. In hyponatraemic patients, values of uric acid have been less than 4 mg/dl (<0.24 mmol/L). A water-loading test is of value when there is uncertainty about the etiology of modest degrees of hypo-osmolality in euvoletic patients, but it does not add useful information if the plasma osmolality is already less than 275 mOsm/kg H₂O.

Inability to excrete a standard water load normally (with normal excretion defined as a cumulative urinary output of at least 90% of the administered water load within 4 hours to suppress urine osmolality to <100 mOsm/kg H₂O) confirms the presence of an underlying defect in free water excretion. However, water excretion is abnormal in almost all disorders that cause hypo-osmolality, whether dilutional or depletion-induced with secondary impairments in free water excretion. Two exceptions are primary hydropenia, in which hypo-osmolality can rarely be secondary to excessive water intake alone, and the reset osmostat variant of SIADH, in which normal excretion of a water load can occur when plasma osmolality falls below the new set-point for vasopressin secretion.

The water load test may also be used to assess water excretion after treatment of an underlying disorder thought to be causing SIADH. For example, after discontinuation of a drug associated with SIADH, a normal water load test can confirm the absence of persistent inappropriate antidiuresis. Despite its limitations as a diagnostic clinical test, water loading remains an extremely useful tool in clinical research for quantitating changes in free water excretion in response to physiologic or pharmacologic manipulations.

A second supportive criterion is an inappropriately elevated plasma vasopressin level in relation to plasma osmolality. With the development of sensitive vasopressin radioimmunoassays capable of detecting the small physiologic concentrations of this peptide that circulate in plasma, it had been hoped that measurement of plasma vasopressin levels might become the definitive test for diagnosis of SIADH. This has not occurred for several reasons:

First, although plasma vasopressin levels are elevated in most patients with this syndrome, the elevations generally remain within the normal physiologic range and are abnormal only in relation to plasma osmolality.

Second, 10% to 20% of patients with SIADH do not have measurably elevated plasma vasopressin levels, and the levels are at the limits of detection by radioimmunoassay.

Third, most disorders causing solute and volume depletion or decreased effective arterial blood volume are associated with elevations of plasma vasopressin levels secondary to nonosmotic hemodynamic stimuli.

Finally, the response to fluid restriction or volume expansion can be helpful in distinguishing between causes of hyponatraemia. Infusion of isotonic sodium chloride (NaCl) in patients with SIADH provokes a natriuresis with little correction of osmolality, whereas fluid restriction allows gradual achievement of solute and water balance through insensible free water losses. By contrast, isotonic saline is the treatment of choice in disorders of solute depletion; when volume deficits are corrected, the stimulus to continued secretion of vasopressin and free water retention is eliminated. The diagnostic value of this therapeutic response is limited somewhat by the fact that patients with proximal types of dilution-induced disorders may show a response similar to that found in patients with SIADH.

Etiology

Although the list of disorders associated with SIADH is long, they can be divided into four major etiologic groups: tumors, CNS disorders, drugs, and pulmonary disorders.

Tumors

The most common association of SIADH is with tumors. Although many different types of tumors have been associated with SIADH, bronchogenic carcinoma of the lung has been uniquely associated with SIADH since the first description of this disorder in 1957. In virtually all cases, the bronchogenic carcinomas causing this syndrome have been of the small cell (or oat cell) variety. Incidences of hyponatraemia as high as 11% of all patients with small cell carcinoma or 33% of those with more extensive disease have been reported.

The unusually high incidence of small cell carcinoma of the lung, together with the relatively favorable therapeutic response of this type of tumor, makes it imperative that all adult patients presenting with an otherwise unexplained SIADH be investigated thoroughly and aggressively for a possible lung tumor. The evaluation should include a chest CT scan or MRI study and bronchoscopy with cytologic analysis of bronchial washings even if the results of routine chest radiography are normal, because several studies have reported hypo-osmolality that predated radiographic abnormality by 3 to 12 months. Head and neck cancers are another group of malignancies associated with relatively higher incidences of SIADH and some of these tumors have been shown to synthesize vasopressin. A report from a large cancer hospital showed an incidence of hyponatraemia for all malignancies combined of 3.7%, with approximately one third of these related to SIADH.
A large number of CNS disorders are associated with SIADH; no common denominator links them. This is not surprising when one considers the neuroanatomy described earlier. Magnocellular

- AVP, arginine vasopressin; COPD, chronic obstructive pulmonary disease; dDAVP, 1-deamino(8-arginine) vasopressin.

Vasopressin neurons receive excitatory inputs from osmoreceptive cells in the anterior hypothalamus but also a major innervation from brain stem cardiovascular regulatory and emetic centers. Although various components of these pathways have yet to be elucidated fully, many of them appear to have inhibitory as well as excitatory components. Consequently, any diffuse CNS disorder can potentially cause vasopressin hypersecretion either by nonspecifically exciting these pathways through irritative foci or by disrupting them and thereby decreasing the level of inhibition. The wide variety of CNS processes that can potentially cause SIADH stands in contrast to CNS causes of diabetes insipidus, which are limited to lesions of the suprasellar hypothalamus.

### Drugs

Drug-induced hyponatremia is a common cause of hypo-osmolality. Table 9-3 lists some of the agents that have been associated with SIADH, but new drugs are added continually. Pharmacologic agents may stimulate secretion of vasopressin, activate V2 receptor sites, or potentiate the antidiuretic effect of vasopressin. Not all of the drug effects are fully understood, however, and many appear to work through a combination of mechanisms.

A particularly interesting and clinically important class of agents is the selective serotonin reuptake inhibitors (SSRIs). In studies in rats, serotoninergic agents increased secretion of vasopressin but more directly oxytocin. In humans, SSRIs have generally not had significant effects on secretion of vasopressin. However, hyponatremia after SSRI administration has been reported almost exclusively in elderly persons, with rates as high as 22% to 25%, although in larger series the incidence was closer to 1 in 200. Elderly patients are uniquely hypersensitive to serotonin stimulation of vasopressin secretion. A similar effect is probably also responsible for the severe fatal hyponatremia caused by use of the recreational drug 3,4-methylenedioxymethamphetamine, Ecstasy. which has substantial serotoninergic activity and activated hypothalamic magnocellular neurons in rats.

### Pulmonary Disorders

Various pulmonary disorders have been associated with SIADH; other than tuberculosis, acute pneumonia, and advanced chronic obstructive lung disease, however, the occurrence of hypo-osmolality has been noted only sporadically. One reported case of pulmonary tuberculosis suggested that tuberculous lung tissue might synthesize vasopressin, but reports of the reset osmostat with advanced pulmonary tuberculosis and others indicated nonsomotic stimulation of secretion of vasopressin. Hypoxia stimulated secretion of vasopressin in animals, but in humans hypercarbia was more associated with abnormal water retention.

Elevated vasopressin levels may be limited to the initial days of hospitalization, when respiratory failure is most marked. Therefore, with SIADH in nonmalignant pulmonary disease, pulmonary disease is obvious with severe dyspnea or extensive radiographically evident infiltrates and the inappropriate antidiuresis is usually limited to the period of respiratory failure. Mechanical ventilation can cause inappropriate secretion of vasopressin and can worsen SIADH caused by other factors. The mechanism is thought to be decreased venous return.

### Other Causes

In patients with acquired immunodeficiency syndrome (AIDS) or AIDS-related complex and human immunodeficiency virus (HIV) infection, the incidence of hyponatremia has been reported to be as high as 30% to 38% in adults and children. Although there are many potential etiologic mechanisms, including dehydration, adrenal insufficiency, and pneumonitis, 12% to 68% of AIDS patients with hyponatremia appear to meet criteria for a diagnosis of SIADH. Not unexpectedly, some of the medications used to treat these patients may cause the hyponatremia through direct renal tubular toxicity or induced SIADH.

Elderly patients sometimes experience SIADH without any apparent underlying etiologic factor, and the incidence of hyponatremia in geriatric patients suggests that the normal aging process may be accompanied by abnormalities of regulation of secretion of vasopressin. Such an effect may potentially account for the fact that drug-induced hyponatremia occurs much more frequently in older patients. In a series of 50 consecutive elderly patients meeting criteria for SIADH, 60% remained idiopathic despite rigorous evaluation, leading the authors to conclude that extensive diagnostic procedures were not warranted in such elderly patients if routine history, physical examination, and laboratory evaluation failed to suggest an underlying cause.

Some well-known stimuli for vasopressin secretion are notable primarily because of their exclusion from Table 9-3. Despite unequivocal stimulation of vasopressin secretion by nicotine, cigarette smoking has been associated with SIADH rarely and primarily in psychiatric patients who have several other potential causes of inappropriate vasopressin secretion.
Random hypersecretion of vasopressin. Low or even undetectable plasma vasopressin levels despite classic clinical characteristics of SIADH. A reset osmostat system whereby vasopressin is secreted at an abnormally low threshold of plasma osmolality but otherwise displays a normal response to normal or low but nonsuppressible levels of vasopressin can cause sufficient impairment of free water excretion to produce hypo-osmolality, depending on the volume expansion produced as a result of water retention was unequivocally shown by Leaf and co-workers since the original cases studied by Bartter and Schwartz.

Contribution of Natriuresis to the Hyponatremia of SIADH

It is surprising that no correlation has been found between any of these patterns of secretion of vasopressin and the various causes of SIADH.

The best physiologic example of a reset osmostat is pregnancy, as discussed earlier. Perhaps the most perplexing aspect of the reset osmostat pattern is its occurrence in patients with tumors, which suggests that in some of these cases a tumor-related mechanism may affect pituitary vasopressin secretion. The pattern of SIADH that occurs without measurable vasopressin secretion is not yet well understood, but the positive response of one such patient to a vasopressin V2 receptor antagonist suggests that it may represent increased renal sensitivity to low circulating levels of vasopressin.

It is surprising that no correlation has been found between any of these patterns of secretion of vasopressin and the various causes of SIADH. It seems likely that in many cases a heterogeneous group of CNS processes are involved, including osmotic and nonosmotic and stimulatory and inhibitory pathways, rather than a single dominant cause.

**Pathophysiology**

**Sources of Vasopressin Secretion**

Elevated plasma levels of vasopressin can be broadly divided into those associated with paraneoplastic (ectopic) secretion of vasopressin and those associated with pituitary hypersecretion of vasopressin. There is substantial cumulative evidence that tumor tissue can synthesize vasopressin, but it is not certain whether all tumors associated with SIADH do so, because only about half of small cell carcinomas have been found to contain vasopressin immunoreactivity and many of the tumors listed in Table 9-3 have not been so studied.

**Pituitary Vasopressin Secretion: Inappropriate versus Appropriate**

In most cases of SIADH, vasopressin secretion originates from the posterior pituitary. This is also true of more than 90% of all cases of hyponatremia, including hypovolemic and hypervolemic hyponatremia. This raises the question: What is inappropriate secretion of vasopressin?

Secretion of vasopressin in response to a hypovolemic stimulus is clearly physiologically appropriate, but when it leads to symptomatic hyponatremia it can be considered inappropriate for the osmolality. Despite these semantic difficulties, the diagnosis of SIADH should rest on the original criteria and should specifically exclude other clinical conditions known to cause impairments in free water excretion even when these are mediated by secondary stimulation of vasopressin. Without maintaining these distinctions, arguable as some may be, the definition of SIADH becomes too broad to retain any practical clinical utility.

In most cases of SIADH, plasma levels of vasopressin are within normal physiologic ranges and abnormal only relative to the osmolality (Fig. 9-9). This is important for two main reasons:

1. Because the well-known vasoconstrictive effects of vasopressin do not come into play until much higher plasma levels are achieved (see "Physiology of Secretion of Vasopressin and Thirst"), hyponatremia can be ascribed to vasopressor effects of vasopressin.
2. Normal or low but nonsuppressible levels of vasopressin can cause sufficient impairment of free water excretion to produce hypo-osmolality, depending on exogenous fluid intake, as in psychiatric patients with polydipsia.

**Patterns of Vasopressin Secretion**

Studies of plasma vasopressin levels in patients with SIADH during graded increases in plasma osmolality produced by hypertonic saline administration have defined four patterns of secretion (Fig. 9-10):

1. Random hypersecretion of vasopressin.
2. Inappropriate nonsuppressible basal vasopressin release but normal secretion in response to osmoregular changes above basal plasma osmolality.
3. A reset osmostat system whereby vasopressin is secreted at an abnormally low threshold of plasma osmolality but otherwise displays a normal response to relative changes in osmolality.
4. Low or even undetectable plasma vasopressin levels despite classic clinical characteristics of SIADH.

The first pattern, unregulated vasopressin secretion, is often observed in patients with paraneoplastic vasopressin production. Resetting of the osmotic threshold for vasopressin secretion has been well described with volume depletion and edema-forming states with effective arterial blood volume, but most patients with a resetting osmostat are clinically euolemic and may have SIADH. It has been suggested that chronic hypo-osmolality itself may over time reset the intracellular threshold for osmoreceptor firing, but in animals chronic hyponatremia did not significantly alter the osmotic threshold for vasopressin secretion.

The best physiologic example of a reset osmostat is pregnancy, as discussed earlier. Perhaps the most perplexing aspect of the reset osmostat pattern is its occurrence in patients with tumors, which suggests that in some of these cases a tumor-related
Although a negative sodium balance occurs during the development of hyponatremia in patients with SIADH, eventually urinary sodium excretion simply reflects daily sodium intake.\textsuperscript{122} Thus, renal sodium wasting is excretion of sodium despite hyponatremia, but in reality there is a new steady state in which there is a neutral sodium balance.

Studies of long-term antidiuretic-induced hyponatremia in dogs and rats indicated that a large proportion of the hyponatremia was attributable to secondary Na\textsuperscript{+} losses rather than to water retention.\textsuperscript{123,124} However, the natriuresis did not actually worsen the hyponatremia; rather, it allowed volume regulation of ECF. Because of the secondary natriuresis in patients with SIADH, expanded plasma or ECF volumes are not found with tracer dilution techniques.\textsuperscript{125} Intrinsic renal mechanisms produced both diuresis and natriuresis in response to increases in renal perfusion pressures (so-called pressure diuresis) when vasopressin-infused animals were continually fluid loaded.\textsuperscript{126} However, it has not yet been proved that this mechanism is sensitive enough to detect the relatively mild degrees of volume expansion that accompany diuretic hyponatremias.

Another possibility is that natriuresis is mediated through increases in circulating natriuretic peptides such as atrial natriuretic peptide (ANP), which are elevated in SIADH into ranges capable of promoting renal sodium excretion.\textsuperscript{127} These possibilities are not mutually exclusive.

The degree to which hyponatremia may occur primarily as a result of natriuresis is controversial. Cerebral salt-wasting syndrome was first proposed by Peters and colleagues in 1950,\textsuperscript{128} as an explanation for the natriuresis and hyponatremia that sometimes accompany intracranial disease, particularly subarachnoid hemorrhage (SAH), in which up to one third of patients experience hyponatremia. After the description of SIADH in 1957, such patients were generally assumed to have hyponatremia secondary to vasopressin hypersecretion with a secondary natriuresis.\textsuperscript{129} However, clinical and experimental data have suggested that some patients with SAH and other intracranial diseases indeed have a primary natriuresis leading to volume contraction rather than SIADH.\textsuperscript{130,131,132} and the elevated plasma vasopressin levels may be physiologically appropriate for the degree of volume contraction. Some studies indicate that there is insufficient evidence of hypovolemia despite ongoing natriuresis,\textsuperscript{133,134} whereas others argue that the combined measures used to estimate ECF volume do support hypovolemia.\textsuperscript{135}

With regard to the potential mechanisms of natriuresis, both plasma and CSF ANP levels are elevated in many patients with SAH\textsuperscript{117} and have been found to correlate variably with hyponatremia in patients with intracranial diseases.\textsuperscript{136,137} However, because SIADH is also frequently associated with elevated plasma ANP levels, this finding does not prove causality. In other disorders of hyponatremia related to Na\textsuperscript{+} wasting (e.g., Addison's disease) and diuretic-induced hyponatremia, infusion of saline restores normal ECF volume and plasma tonicity by shutting off the secondary vasopressin secretion. In SAH, however, large volumes of isotonic saline sufficient to maintain plasma volume did not change the incidence of hyponatremia.\textsuperscript{138} In contrast, mineralocorticoid therapy to inhibit natriuresis reduced the incidence of hyponatremia in patients with SAH,\textsuperscript{139} but elderly patients with SIADH responded similarly to mineralocorticoid therapy.\textsuperscript{140} It seems most likely that SAH and other intracranial disorders represent a mixed disorder in which some patients have both exaggerated natriuresis and inappropriate vasopressin secretion; which effect predominates in the clinical presentation depends on their relative intensities as well as the effects of concomitant therapy.

The possibility that ANP-induced natriuresis may exacerbate hyponatremia is not confined to intracranial diseases, and it has been suggested that ectopic ANP production may contribute to or even cause the hyponatremia accompanying some small cell lung cancers.\textsuperscript{141} In several studies, small cell lung carcinoma was reported to produce ANP in addition to, or in some cases instead of, vasopressin.\textsuperscript{142} However, hyponatremia appeared to correlate more with plasma vasopressin levels than plasma ANP levels.\textsuperscript{143} Consequently, such cases may represent a mixture of inappropriate secretion of both hormones, and the ANP may further exacerbate the secondary natriuresis produced primarily by vasopressin-induced water retention.

**Renal Adaptation**

In addition to excretion of osmoles to bring volumes back toward normal, some adaptations allow excretion of more water. As stated earlier, vasopressin stimulates water retention by increasing the activity and content of aquaporin-2 water channels in the renal collecting duct epithelium. Chronic action of vasopressin in SIADH produces dramatic increases above normal of aquaporin-2 content and insertion into the epithelial cell membranes. This increases the efficiency of water retention and worsens the pathology. However, when vasopressin induces volume expansion and hypotonicity, the volume expansion and hypotonicity per se, by ill-defined mechanisms, act on the tubular cells of the collecting duct to decrease the content and action of aquaporin-2, thus decreasing the amount of water resorbed in spite of high vasopressin. This renal escape is another adaptation (besides natriuresis) that allows a patient with persistent SIADH to achieve a new steady state of Na\textsuperscript{+} and water balance with a low serum sodium level.\textsuperscript{144,145}

### Clinical Manifestations of Hyponatremia Disorders

Regardless of the etiology of hypo-osmolality, most clinical manifestations are similar. Non-neurologic symptoms are relatively uncommon, but a number of cases of rhabdomyolysis have been reported, presumably secondary to osmotically induced swelling of muscle fibers. Hypo-osmolality is primarily associated with a broad spectrum of neurologic manifestations, ranging from mild nonspecific symptoms (e.g., headache, nausea) to more significant disorders (e.g., disorientation, confusion, obtundation, focal neurologic deficits, seizures).\textsuperscript{146} This neurologic symptom complex has been termed hyponatremic encephalopathy\textsuperscript{147} and primarily reflects brain edema resulting from osmotic water shifts into the brain because of decreased effective plasma osmolality.

Significant neurologic symptoms generally do not occur until serum [Na\textsuperscript{+}] falls below 125 mEq/L, and the severity of symptoms is roughly correlated with the degree of hypo-osmolality.\textsuperscript{148,149} Individual variability is marked, however, and for any single patient the level of serum [Na\textsuperscript{+}] at which symptoms appear cannot be predicted. When the brain has volume-adapted through solute losses, thereby reducing brain edema, neurologic symptoms may even be virtually absent.\textsuperscript{150} From animal studies, the rate of serum [Na\textsuperscript{+}] decline is often more strongly correlated with morbidity and mortality than is the actual magnitude of the decrease.\textsuperscript{151} The reason is that the volume-adaptation process takes a finite period of time to complete, and the more rapid the decline in serum [Na\textsuperscript{+}], the more brain edema is accumulated before the brain can volumeregulate.

Thus, there is a much higher incidence of neurologic symptoms as well as a higher mortality rate in patients with acute hyponatremia than in patients with chronic hyponatremia.\textsuperscript{152,153} For example, the most dramatic cases of death related to hyponatremic encephalopathy have generally been reported in postoperative patients in whom hyponatremia developed rapidly as a result of intravenous infusion of hypotonic fluids.\textsuperscript{154,155} In such cases, nausea and vomiting are frequently overlooked as potential early signs of increased intracranial pressure; however, because hypo-osmolality does not have any direct effects on the gastrointestinal tract, unexplained nausea or vomiting in a hypo-osmolal setting should be assessed to have a CNS origin. Similarly, critically ill patients with unexplained seizures should be immediately evaluated for possible hyponatremia, because as many as one third of such patients have [Na\textsuperscript{+}] below 125 mEq/L as the cause of the seizure activity.\textsuperscript{156} Underlying neurologic disease and non-neurologic metabolic disorders (e.g., hypoxia,\textsuperscript{157} acidosis, hypercalcemia) can raise the level of plasma osmolality at which CNS symptoms occur.

In the most severe cases of hyponatremic encephalopathy, death results from respiratory failure after tentorial cerebral herniation and brain stem compression. One quarter of patients with severe postoperative hyponatremic encephalopathy manifested hypoxic/hypoxic respiratory failure, the expected result of brain stem compression, but three quarters had pulmonary edema as the apparent cause of the hypoxia.\textsuperscript{158}

Studies of acute hyponatremia after marathon races have shown hypoxia and pulmonary edema in association with brain edema.\textsuperscript{159} These results therefore suggest that hypoxia resulting from noncardiogenic pulmonary edema may be an early sign of developing cerebral edema even before the brain stem compression and tentorial herniation.

Clinical studies also suggest that menstruating women\textsuperscript{160} and young children\textsuperscript{161} may be particularly susceptible to the development of neurologic morbidity and mortality during hyponatremia, especially in the acute postoperative setting.\textsuperscript{162} However, other studies have failed to corroborate these findings.\textsuperscript{163,164} Consequently, the true clinical incidence and the mechanisms responsible for these sometimes catastrophic cases are not certain.
Therapy of Hypo-osmolar Disorders

Despite some areas of continuing controversy regarding correction of osmolality in hypo-osmolar patients, a relative consensus has evolved concerning the most appropriate treatment of this disorder. The following recommendations are summarized in the diagnostic and therapeutic flow diagram shown in Figure 9-11 (Figure Not Available).

Initial Evaluation

ECF volume status determines treatment of hyponatremia. If volume is expanded, the treatment of the underlying disease should take precedence over correction of plasma osmolality. This treatment often involves diuretic therapy, which should simultaneously improve plasma toxicity by stimulating excretion of hypotonic urine. If hyponatremia is present, the patient must be considered to have depletion-induced hypo-osmolality, in which case volume repletion with isotonic saline (0.9% NaCl) at a rate appropriate for the estimated fluid deficit should be initiated.

If diuretic use is known or suspected, the isotonic saline should be supplemented with potassium (30 to 40 mEq/L) even if serum [K+] is not low because of the propensity for total body potassium depletion to occur in such patients. Although generally the hypo-osmolar patient is clinically euovolemic, if a possibility of depletion-induced, rather than dilution-induced, hypo-osmolality exists, it is then appropriate to treat the patient initially with isotonic saline whether or not signs of hypovolemia are present. Improvement in and eventual correction of the hyponatremia verify solute and volume depletion. If the SIADH rather than solute depletion is present, administration of a limited volume (e.g., 1 to 2 L) of isotonic saline produces Na⁺ and water excretion without significantly changing plasma osmolality.

A patient who meets the essential criteria for SIADH but has a low urine osmolality should be observed with a trial of modest fluid restriction. If the hypo-osmolality is attributable to transient SIADH or severe polydipsia, the urine remains dilute and the plasma osmolality is fully corrected as free water is excreted. If the patient has the reset osmostat form of the disorder, however, the urine becomes concentrated at some point before the plasma osmolality and serum [Na⁺] return to normal ranges.

If either primary or secondary adrenal insufficiency is suspected, glucocorticoid replacement should be initiated immediately after the completion of a rapid ACTH stimulation test. A prompt water diuresis after initiation of glucocorticoid treatment supports a diagnosis of glucocorticoid deficiency, but absence of a quick response does not necessarily negate this diagnosis because several days of glucocorticoid replacement are sometimes required for normalization of plasma osmolality. If hypothyroidism is suspected, thyroid function tests should be performed. Replacement therapy is usually withheld pending these results unless the patient is obviously myxedematous.

If renal failure is present in a patient with hypo-osmolality, a more extensive evaluation of renal function is necessary before a course of treatment is selected.

Acute Treatment

For any significantly hyponatremic patient, one must decide how quickly the plasma osmolality should be increased and to what level. This decision depends on the risks of uncorrected hyponatremia and the risks of the correction. It has become clear that correcting severe hyponatremia too rapidly is dangerous because it is sometimes associated with pontine and extrapontine myelinolysis, a brain demyelinating disease that causes severe neurologic morbidity and mortality.

Consequently, appreciation of the appropriate therapy of this disorder requires understanding this disease as well as the pathophysiology underlying hyponatremic encephalopathy.

Pontine and Extrapontine Myelinolysis

It has become apparent that the demyelinating disease of central pontine myelinolysis (CPM) occurs with a significantly higher incidence in patients with hyponatremia and in both animal and human studies brain demyelination has been associated with the correction of existing hyponatremia. In animal models of chronic hyponatremia, this pathologic disorder is probably precipitated by the brain dehydration that has been demonstrated to occur after correction of serum [Na⁺] toward normal ranges. MRI in animals has shown that chronic hypo-osmolality predisposes to opening of the blood-brain barrier in rats after rapid correction of hyponatremia and that the disruption of the blood-brain barrier is highly correlated with subsequent demyelination. Opening the blood-brain barrier can lead to subsequent myelinolysis through an influx of complement, which is toxic to oligodendrocytes that manufacture and maintain myelin sheaths of neurons.

Although there has been considerable debate in the literature, studies in both patients and experimental animals support the concept that both the rate of correction of hyponatremia and the total magnitude of the correction over the first few days determine the risk of demyelination. In rats, an initial rate of correction of hyponatremia less than 20 mEq/L in 24 hours involved less risk, and clinical data indicate that the initial magnitude of correction represents the major risk factor related to subsequent neurologic morbidity and mortality. Initial reports implicated increases in serum [Na⁺] greater than 25 mEq/L over the first 24 to 48 hours of treatment, but later studies suggested the occurrence of CPM with increases in serum [Na⁺] of more than 12 mEq/L in 24 hours or 18 mEq/hour in 48 hours. Although overcorrection of hyponatremia to supranormal levels is also clearly a risk factor for neurologic deterioration, both clinical and experimental studies have found that demyelination occurred after corrections to serum [Na⁺] levels still below normal ranges. Both experimental studies and clinical reports have demonstrated that demyelination occurs regardless of the method used to correct the hyponatremia.

The susceptibility to demyelination after correction of hyponatremia is strongly influenced by the severity and duration of the preexisting hyponatremia. The more severe and prolonged the hyponatremia, the more solute loss that occurs during the process of brain volume regulation, and the loss of larger amounts of solute impairs the ability of the brain to buffer volume in response to subsequent increases in plasma osmolality. Clinical studies show that CPM rarely occurs in patients with a starting serum [Na⁺] above 120 mEq/L, does not appear to occur in patients with psychogenic polydipsia in whom hyponatremia develops acutely as a result of massive water ingestion, and is corrected rapidly by diuresis of the excess fluid.

Other independent risk factors for the occurrence of CPM are chronic alcoholism and malnutrition. It seems likely that the threshold for increases in serum [Na⁺] that increase the risk for CPM is lower in alcoholic and malnourished patients, and a case report of myelinolysis in a patient with beer potomania in whom the rate of correction stayed within the recommended guidelines supports this likelihood. Interestingly, uremia appears to protect hyponatremic patients from myelinolysis after rapid correction of hyponatremia, purportedly because urea acts as an intracellular osmolyte to stabilize intracellular volume and thereby reduces the degree of
brain dehydration produced after rapid correction of hyponatremia. 

The term central pontine myelinolysis is historically correct but anatomically too limited. Demyelination after correction of hyponatremia frequently occurs in white matter areas of the brain other than thepons. This occurrence led to the term osmotic demyelination syndrome (PMS) but the term pontine and extrapontine myelinolysis (PEM) would be more accurate. Apropos of the widespread nature of the neuropathologic lesions, a much broader range of neurologic disorders is now being reported in patients after correction of hyponatremia, including cognitive, behavioral, and neuropsychiatric disorders, presumably as a result of demyelination in subcortical, corpus callosal, and hippocampal white matter, and movement disorders, as a result of demyelination in the basal ganglia.

The presence of positive MRI findings strongly supports a diagnosis of PEM. But scans often fail to demonstrate the characteristic demyelinating lesions because scans are usually negative until sufficient time has passed (generally 3 to 4 weeks) after correction of hyponatremia and onset of neurologic symptoms. Although most cases of osmotically induced PEM have been reported with rapid correction of hyponatremia, the disorder has also been reported with severe hyponatremia in both animal models and patients. It is clear that one cannot predict with any degree of certainty which patients will develop demyelination. Many patients undergo rapid and large changes of serum Na⁺ without subsequent neurologic complications, which is true of experimental animals as well. Consequently, overly rapid correction of hyponatremia should be viewed as a factor that puts patients at risk for PEM but does not inevitably precipitate this disorder.

**Individualization of Therapy**

From the previous discussions of hyponatremic encephalopathy and PEM, it follows that optimal treatment of hyponatremia must entail balancing the risks of hyponatremia against the risks of correction for each patient individually. Three factors should be considered when one is making a treatment decision for a hypo-osmolar patient: (1) the severity of the hyponatremia, (2) the duration of the hyponatremia, and (3) the patient's neurologic symptoms.

**Acute Hyponatremia**

Cases of acute hyponatremia, arbitrarily defined as 48 hours in duration, are usually symptomatic if the hyponatremia is severe (i.e., < 120 mEq/L). These patients are at greatest risk for neurologic complications from the hyponatremia but rarely have demyelination, presumably because sufficient brain volume regulation has not yet occurred. Consequently, serum Na⁺ in such patients should be corrected relatively quickly.

Figure 9-11 (Figure Not Available) emphasizes that hypo-osmolar patients should always be evaluated quickly for the presence of neurologic symptoms so that appropriate therapy can be initiated, if indicated, even while other results of the diagnostic evaluation are pending. Postoperative patients, and particularly young women and children in some studies, appear to be at somewhat greater risk for rapidly progressing hyponatremic encephalopathy. They should be treated especially promptly, and administration of hypotonic fluids should be avoided in such patients postoperatively.

**Chronic Asymptomatic Hyponatremia**

Conversely, patients with chronic hyponatremia (arbitrarily defined as more than 48 hours in duration) who have minimal neurologic symptoms are at little risk from complications of hyponatremia itself, but demyelination can develop after rapid correction because of greater degrees of brain volume regulation through electrolyte and osmolyte losses. There is no indication to correct the hyponatremia rapidly, regardless of the initial serum Na⁺, and these patients should be treated by slower-acting therapies, such as fluid restriction.

**Chronic Symptomatic Hyponatremia**

Although the first two extremes have clear treatment indications, most hypo-osmolar patients have hyponatremia of indeterminate duration and varying degrees of neurologic symptoms. Such patients should be treated promptly, because of their symptoms, but with methods that allow a controlled and limited increase of hypo-osmolality. Some studies have suggested that correction parameters should consist of a maximal rate of correction of serum Na⁺ in the range of 1 to 2 mEq/L per hour as long as the total magnitude of correction does not exceed 25 mEq/L over the first 48 hours. Others recommend even more conservative parameters, with maximal correction rates of 0.5 mEq/L per hour or less and magnitudes of correction that do not exceed 12 mEq/L in the first 24 hours and 18 mEq/L in the first 48 hours.

A reasonable approach for treatment of individual patients would therefore entail choosing correction parameters within these limits, depending on the symptoms. In patients who are only minimally symptomatic, one should proceed at the lower recommended limits of 0.5 mEq/L per hour or less. In patients with more severe neurologic symptoms, initial correction at a rate of 1 to 2 mEq/L per hour (or even 3 to 5 mEq/L per hour in comatose or seizing patients who are at risk for imminent ventricular herniation and respiratory arrest) would be more appropriate.

Regardless of the initial rate of correction chosen, acute treatment should be interrupted when any of three end-points is reached:

1. The patient's symptoms are abolished.
2. A safe serum Na⁺ (> 120 mEq/L) is achieved.
3. A total magnitude of correction of 20 mEq/L is achieved.

At such a point, the active correction should be stopped and the patient treated with slower-acting therapies (e.g., oral rehydration, fluid restriction), depending on the cause of the hypo-osmolality. From these recommendations, it follows that serum Na⁺ levels must be carefully monitored at frequent intervals (at least every 4 hours) during the active phases of treatment to adjust therapy to keep the correction within these guidelines.

**Interventional (Active) Therapies for Acute Corrections**

Controlled limited corrections can be accomplished with either isosmotic or hypertonic saline infusions, depending on the etiology of the hypo-osmolality. Patients with volume-depletion hypo-osmolality (e.g., clinical hypovolemia, diuretic use, or urine Na⁺ < 30 mEq/L) usually respond well to isosmotic (0.9%) NaCl. However, patients with diuretic-induced hyponatremia are especially susceptible to rapid corrections for several reasons:

1. Such patients are usually only minimally volume-depleted.
2. They are often small, elderly women with correspondingly small plasma volumes.
3. With cessation of diuretic therapy, these patients often have a free water diuresis as their urinary diluting defect dissipates.
4. The hypokalemia that frequently accompanies the hyponatremia in such patients appears to be an additional risk factor for demyelination after correction.

Consequently, in the absence of marked neurologic symptoms, such patients should simply be prescribed a regular sodium diet (4 to 8 g/day) and should discontinue diuretics. If isotonic saline is infused, it should be done so judiciously (e.g., 50 to 75 mL/hour) with potassium replacement. Patients with euovolemic hypo-osmolality (including those with SIADH) generally do not respond to isotonic NaCl and are best treated with hypertonic (3%) NaCl solution given by continuous infusion. An initial infusion rate can be estimated by multiplying the patient's body weight in kilograms by the desired rate of increase in serum Na⁺ by approximately 1 mEq/L per hour and an infusion of 35 mL/hour increases serum Na⁺ by about 0.5 mEq/L per hour.

In patients with known cardiovascular disease, furosemide can be used to treat volume overload. It cannot be emphasized too strongly that it is necessary only to correct plasma osmolality acutely to a safe range rather than completely to normotremia.
Several days of restriction are usually necessary before a significant increase in plasma osmolality occurs. Only fluid, not salt, should be restricted. The degree of restriction required depends on urine output plus insensible fluid loss (generally, discretionary, nonfood fluids should be limited to 500 mL a day rapidly with vasopressin receptor antagonists will still be at risk for PEM, which has already been documented in animals, without measurable vasopressin levels) and should provide better therapy for patients with chronic hyponatremia. Patients whose hyponatremia is corrected too quickly diminish free water diuresis. 

Chronic Treatment

Fluid Restriction

The treatment of chronic SIADH entails a choice among several suboptimal therapeutic regimens. Any drugs known to be associated with SIADH should be discontinued or changed. Continued fluid restriction represents the least toxic treatment choice and is the preferred treatment for most cases of mild to moderate SIADH. Several points should be remembered when this approach is used:

1. All fluids, not only water, must be included in the restriction.
2. The degree of restriction required depends on urine output plus insensible fluid loss (generally, discretionary, nonfood fluids should be limited to 500 mL a day below the average daily urine volume).
3. Several days of restriction are usually necessary before a significant increase in plasma osmolality occurs.
4. Only fluid, not salt, should be restricted.

Because of the ongoing natriuresis, patients with chronic SIADH often have a negative total body [Na⁺] balance and therefore should be maintained with relatively high NaCl intakes unless otherwise contraindicated. Failure to improve after several days of confirmed negative fluid balance prompts reconsideration of other possible causes, including solute depletion and clinically inapparent hypovolemia.

Although it has not been confirmed in humans, in animals the expanded volume and hypotonicity of SIADH decrease the vasopressin-induced increase of aquaporin-2 water channels in the collecting duct and this escape allows more water excretion. 

When hyponatremia is caused primarily by polydipsia, ideally therapy should be directed at reducing fluid intake to normal ranges. Unfortunately, fluid restriction has proved difficult to accomplish in many cases. Patients with a reset thirst threshold are resistant to fluid restriction because of the thirst resulting from stimulation of brain thirst centers at higher plasma osmolalities. In some cases, the use of alternative methods to ameliorate the sensation of thirst (e.g., wetting the mouth with ice chips or using sour candies to increase salivary flow) can help to reduce fluid intake.

Fluid intake in patients with psychogenic causes of polydipsia is driven by psychiatric factors that have responded variably to behavioral modification and pharmacologic therapy. Several reports have suggested potential efficacy of the antipsychotic drug clozapine as an agent to reduce polydipsia and to prevent recurrent hyponatremia in at least a subset of these patients.

Pharmacologic Therapy

Pharmacologic intervention is reserved for refractory cases in which the degree of fluid restriction required to avoid hypo-osmolality is so severe that the patient is unable or unwilling to maintain it. Pharmacologic intervention should also be avoided initially in patients with SIADH that is secondary to tumors because successful treatment of the underlying malignant lesion often eliminates or reduces the inappropriate vasopressin secretion.

When pharmacologic management is necessary, the preferred drug is the tetracycline derivative demeclocycline. 

Pharmacologic intervention is reserved for refractory cases in which the degree of fluid restriction required to avoid hypo-osmolality is so severe that the patient is unable or unwilling to maintain it. Pharmacologic intervention should also be avoided initially in patients with SIADH that is secondary to tumors because successful treatment of the underlying malignant lesion often eliminates or reduces the inappropriate vasopressin secretion.

When pharmacologic management is necessary, the preferred drug is the tetracycline derivative demeclocycline. 

This agent causes nephrogenic diabetes insipidus, thereby decreasing urine concentration even in the presence of high plasma vasopressin levels. Appropriate doses of demeclocycline range from 600 to 1200 mg/day administered in divided doses. Treatment must be continued for several days to achieve maximal diuretic effects; consequently, one should wait 3 to 4 days before deciding to increase the dose. Demeclocycline can cause reversible azotemia and sometimes nephrotoxicity, especially in patients with cirrhosis. Renal function should therefore be monitored on a regular basis in patients receiving demeclocycline, and the medication discontinued if increasing azotemia is noted.

Other agents, such as lithium, have similar renal effects but are less desirable because of inconsistent results and significant side effects. Urea has also been described as an alternative mode of treatment for SIADH as well as other hyponatremic disorders.

Several drugs appear to decrease vasopressin hypersecretion in some cases (e.g., diphenhydantoin, opiates, ethanol), but responses have been erratic and unpredictable. Potential exceptions are agonists selective for kappa opioid receptors, which appeared to be more specific for inhibition of vasopressin hypersecretion in animal studies and in clinical trials successfully produced an aquaresis in patients with cirrhosis.

Vasopressin Antagonists

An antagonist of the kidney vasopressin V2 receptors would be the ideal agent for treatment of dilutional hyponatremia. 

Previous attempts at using peptide vasopressin receptor antagonists in humans were frustrated by species variability with regard to partial agonistic effects of such compounds. Several nonpeptide V2 receptor antagonists have been described that appear to overcome these problems. As of this writing, several of these compounds were already in clinical trials with promising results. It thus appears that we are poised to begin a new era in both the evaluation and treatment of patients with SIADH.

When selective V2 receptor antagonists are eventually approved for clinical use, clinical trials should enable investigators to answer some long-standing questions about the role of vasopressin receptor activation in producing antidiuresis as well as other potential effects in various disease states (e.g., hyponatremic patients without measurable vasopressin levels) and should provide better therapy for patients with chronic hyponatremia. Patients whose hyponatremia is corrected too rapidly with vasopressin receptor antagonists will still be at risk for PEM, which has already been documented in animals, but appropriate dosing and monitoring should allow successful adherence to the same guidelines for limited controlled correction that apply to other methods of treatment.
OXOTOCIN

Synthesis of oxytocin and electrophysiology of oxytocinergic neurons have been described earlier in the chapter. The normal physiologic regulation of oxytocin secretion and action is complicated by the fact that secretion and function of oxytocin vary markedly among different experimental mammals. There are sites of synthesis in the ovary and in various tissues of the uterus that differ among species. Because it is difficult to study pregnant women and human tissue, physiologic regulation of oxytocin secretion and function is less well known in humans than other species. The classic roles of oxytocin are uterine myometrial contraction at parturition and smooth muscle activation promoting milk let-down with nursing. 2, 5

Parturition

The isolation of oxytocin was followed quickly by the description of its ability to stimulate uterine contractions, and this was soon followed by clinical use of oxytocin as a uterotonic agent. Indeed, oxytocin is the most potent known stimulator of myometrial contraction. The uterine myometrial cells have intrinsic contractile activity, and it is necessary during pregnancy to maintain the uterus in a quiet state. In most species, this is accomplished by action of progesterone and by relaxin (produced by the corpus luteum and decidual tissue), which decrease uterine contractility. Late in pregnancy, parturition is initiated by synchronizing the myometrial activity so that contractions become contractions, with softening and dilatation of the cervix and rupture of the fetal membranes. Parturition is then completed by separation of the placenta and involution of the uterus.

Estrogen activates many of the events required to initiate and progress through parturition, whereas progesterone tends to inhibit these events. In several species, progesterone withdrawal may be an initiating factor of parturition. The mechanism of the increase of the estrogen/progesterone ratio, however, may vary considerably among species. In sheep, an increase in corticotropin-releasing hormone and vasopressin in the fetus near term produces a remarkable increase in ACTH and cortisol. The increased cortisol leads to decreased progesterone in the ewe, and this triggers parturition. In mice, the corpus luteum makes progesterone and estradiol throughout pregnancy. There is also a decrease in progesterone at delivery, but the progesterone decrease is not dependent on glucocorticoids.

In some species, such as mice and sheep, the corpus luteum is maintained throughout pregnancy and secretes progesterone. Uterotropism at the time of parturition causes an abrupt fall in progesterone. In humans and nonhuman primates, the corpus luteum is present only during the first trimester and estrogen and progesterone rise throughout pregnancy, although the rate of increase of estrogen is greater than that of progesterone as parturition approaches. A decreasing effect of progesterone and increasing estrogen in humans may be more important at a paracrine level in fetal membranes, where progesterone is inactivated and estrogen synthesis increased. It has also been reported that estrogen receptor increases in human fetal membranes at parturition whereas progesterone receptor remains stable. Thus, the cycle of events that are observed in plasma in some species may be reproduced distally as a paracrine action in primates.

In various species, several other hormones play a role in initiation of or completion of parturition, or both, including prostaglandins, endothelins, adrenergic agonists, glucocorticoids, and cytokines. The role of oxytocin in the complex interplay of these various agents is not well understood in humans.

The importance of prostaglandins is increasingly recognized in numerous species. The predominant prostaglandin, prostaglandin F 

2 (PGF 

2 ), is responsible for uteristoraxation of the corpus luteum in sheep and rodents, causing the decrease in progesterone described earlier. In fetal membranes, cyclooxygenase enzymes that stimulate synthesis of prostaglandins from arachidonic acid are increased at parturition and release prostaglandins from the uterus to act on the ovary to cause luteolysis. Prostaglandins may also help promote a controlled inflammatory response in the cervix to assist in thinning and dilatation.

In nonhuman primates, as parturition approaches, synchronized nocturnal contractions begin but revert to asynchronous contractions during the day. These synchronized nocturnal contractions correlate with plasma oxytocin levels and are blocked by administration of an oxytocin antagonist. Similarly, the response of the uterus to administered oxytocin in the monkey is greater at night than during the day, and fetal dehydroepiandrosterone sulfate (DHEAS) levels are also highest at night. DHEAS secretion by the fetus may be an important source of estrogen because the DHEAS is converted to estradiol by the placenta. Estradiol stimulates oxytocin synthesis in decidua and also stimulates synthesis of PGF 

2 in decidua.

As mentioned earlier, at this time there is an increase in estrogen receptors, which would favor the action of DHEAS to increase the estrogen response. Furthermore, there is a feed-forward mechanism whereby increased PGF 

2 stimulates oxytocin, which in turn stimulates increased production of PGF 

2 . Teleologically, it makes sense that the developing fetus, upon reaching maturity, would be a controlling factor in the initiation of labor. It was previously noted that in the sheep there is an absolute requirement for the hypotalamic-pituitary-adrenal axis to initiate labor, and the interaction of fetal DHEAS, estrogen, oxytocin, and progesterone provides a potential similar mechanism in primates (and humans?).

Although the role of oxytocin in the initiation of parturition is still debated, it is agreed that oxytocin is released explosively in a pulsatile fashion after the initiation of parturition and as parturition continues. This release of oxytocin is brought about by vaginal and cervical dilatation and is known as the Ferguson reflex. In animals with multiple births, the reflex release of oxytocin after one fetus passes the cervicovaginal canal may assist in the delivery of subsequent pups, but in humans this second phase of delivery is usually only to deliver the placenta. and may be more important in stimulating a clamping down of the uterine muscle to decrease blood loss.

Interestingly, studies with mice to "knock out" synthesis of oxytocin have found that in oxytocin-deficient mice parturition is initiated on time and proceeds normally. whereas mice deficient in cyclooxygenase and in prostaglandins have markedly prolonged labor. Administration of PGF 

2 to the deficient animals resulted in delivery of viable pups at the appropriate time.

From this brief review, it is clear that parturition is a complicated cascade of events that interact with each other at parturition and feed forward with cross-stimulation. It is not surprising that physiologic events as important to the species as pregnancy and parturition would have many redundant systems to ensure survival of the species. In addition, the complicated interaction of these various redundant systems and the feedback nature of the responses make it unlikely that interrupting any single hormonal response after parturition is initiated would be sufficient to inhibit completion of delivery.

In all of these discussions, there has been an obvious lack of understanding of the role of cytochrome aminopeptidase (oxytocinase) in the physiology of pregnancy in humans. If this enzyme developed as a protective mechanism, one would assume that oxytocin secretion by the neurohypophysis was increased throughout pregnancy, but the presence of this enzyme and the inability to study the hypothalamus in vivo make this possibility uncertain. However, the presence of the oxytocin-associated neurophysin throughout pregnancy supports this point of view. Furthermore, the presence of circulating cytochrome aminopeptidase provides a teleologic explanation for the development of oxytocin synthesis and secretion in fetal membranes in a manner that serves a paracrine function possibly protected from the degradative activity of the cytochrome aminopeptidase in plasma.
Lactation

The hypothalamic-pituitary hormones critical to lactation are prolactin and oxytocin. Prolactin storage and secretion from the anterior pituitary and its action to promote milk production are described in Chapter 8. Oxytocin is critical for milk secretion through the characteristic milk let-down response. Each of these hormones is influenced and regulated by gonadal steroid hormones. The milk-producing unit of the breast is the alveolar system, with multiple clusters of milk-producing cells surrounded by specialized myoepithelial cells. The alveoli are directly connected to ductules, and the ducts converge and lead to the nipple.

Milk is synthesized in the glandular cells of the alveoli. Oxytocin receptors are localized on glandular cells and oxytocin in the systemic circulation acts on these receptors to cause myoepithelial contraction. Oxytocin also acts on myoepithelial cells along the duct to shorten and widen the ducts, enhancing milk flow through the ducts to the nipple. Interestingly, in humans there are also oxytocin receptors on the epithelium of the gland and ducts, and oxytocin may have other indirect effects that enhance milk transport.

When an infant begins sucking at the breast, an afferent signal is transmitted from the mechanoreceptors or tactile receptors in the breast to the spinal cord and from the spinal cord to the lateral cervical nucleus. These ascending fibers cross in the medulla and eventually ascend to the oxytocinergic magnocellular neurons in the supraoptic and the paraventricular nucleus. Numerous neurotransmitters and neuropeptides are activated by different inputs to stimulate or inhibit the magnocellular neurons. Oxytocin itself is a regulator of oxytocin neurons. Oxytocin released by the dendrites acts on the same magnocellular neuron in an autocrine fashion, and an oxytocin antagonist infused into the hypothalamus decreases milk yield.

Although the exact role of each of these neurotransmitters or neuropeptides and their cooperative and competitive interactions has not been clarified in any animal (especially in humans), it is agreed that the final result is synchronous pulsatile depolarization of oxytocin neurons. The pulsatile release of oxytocin by the posterior pituitary can produce a pumping action on the alveoli, promoting maximal emptying of milk from the alveoli. Complete emptying of the breast is important to increase milk yield and if milk is not released from the breast there is involution of synthetic and secretory capacity.

The importance of oxytocin in maintaining milk secretion has been demonstrated by transgenic mice with a neurophysin construct that inhibited oxytocin synthesis. These animals delivered their young normally and had normal milk production, but there was no milk release despite normal suckling. The pups died of dehydration with no milk in the stomach. Administration of oxytocin to these oxytocin-deficient mice restored the ability to secrete milk and allowed the pups to survive. Similarly, oxytocin may promote successful lactation in women who have difficulty with lactation and milk production.

Whereas in most species suckling must occur for the sequence of events leading to milk let-down and, indeed, let-down may require several minutes of suckling. Suckling is, however, important in women because only suckling causes release of prolactin and suckling causes pulsatile release of oxytocin, whereas artificial massage of the breast produces continuous secretion of oxytocin. In women, if oxytocin is not secreted, only 20% to 30% of stored milk is released during nursing and secretion of oxytocin can be markedly inhibited by stress.

The role of steroids in oxytocin secretion is complex. Estrogen stimulates oxytocin release by dendrites, and progesterone withdrawal in an estrogen-primed animal stimulates oxytocin synthesis. Changes in these steroid hormones at the time of parturition probably modulate the lactation response both by modulating oxytocin synthesis and secretion and by modulating oxytocin receptors. Vaginal delivery and the pulses of oxytocin that are produced during the second phase of labor may enhance the pulses of oxytocin that later occur with suckling and lactation.

As breast-feeding continues in humans, the basal levels of oxytocin decrease but pulses of oxytocin in response to suckling continue and may increase. Women with diabetes insipidus have been able to breast-feed infants, and this has caused some to question the importance of oxytocin in humans. As noted earlier, however, oxytocin secretion may be preserved in the absence of vasopressin in patients with diabetes insipidus, even in those with traumatic section of the stalk.

The literature supports an interaction of oxytocin and prolactin. Receptors for prolactin have been described in the supraoptic nucleus, and prolactin enhances oxytocin release at the level of the pituitary and enhances synthesis of oxytocin when applied to magnocellular neurons. The importance of these findings has been questioned because prolactin probably does not cross the blood-brain barrier. Systemic administration of prolactin has been reported to stimulate release of oxytocin and immunoneutralization of prolactin to eliminate suckling-induced oxytocin release. Oxytocin was also reported to act as a prolactin-releasing factor. There may be a reinforcing interaction of oxytocin to stimulate release of prolactin and prolactin to enhance the release of oxytocin, producing a feedforward interaction.
Behavior

In addition to the actions in the periphery to stimulate milk let-down and uterine contraction during parturition, oxytocin is reported to have numerous actions on the CNS. The separate functions, peripheral and central, are mirrored anatomically by two sets of neurons: the magnocellular neurons and the smaller parvocellular neurons, respectively. Because the role of oxytocin secreted peripherally is to regulate physiologic events of reproduction, most of the emphasis regarding CNS effects has been on various aspects of maternal behavior. Maternal behavior is coincident with parturition and lactation in most mammalian species and is not seen with other physiologic events that produce changes only in gonadal steroid secretion. Therefore, it is likely that something in addition to or in place of gonadal steroids is active in inducing maternal behavior.

The most studied species regarding maternal behavior are sheep and rats. Studies have found that oxytocin is increased in various areas of the brain that are thought to be sites of regulation of maternal behavior, such as the olfactory lobes of rats. In some species, injection of oxytocin into the cerebral ventricles can initiate maternal behavior and injection of oxytocin antagonists can inhibit such behavior. However, the findings regarding oxytocin and reproductive behavior vary markedly among species and among strains within a given species.

Oxytocin has also been reported to play a role in males, but this is much less certain. In rodents, oxytocin administered in the CNS induced arousal and penile erection; in some species, oxytocin has been reported to increase sperm transport.
Other Actions of Oxytocin

In a number of reproductive tissues in a variety of species, oxytocin stimulates prostaglandin production. In several species, oxytocin is produced in peripheral organs rather than in the hypothalamus. There is some evidence for action of oxytocin in the menstrual cycle of humans, although this evidence is not as clear as that for the involvement of oxytocin in the estrous cycle of ruminants. Nonetheless, it is suggested that oxytocin may participate in a paracrine or autocrine fashion between cells in the human corpus luteum to stimulate the synthesis of progesterone.

In addition to accepted and postulated roles of oxytocin in reproductive behavior, numerous other central functions may be affected by central secretion of oxytocin, including the following:

1. Feeding behavior and satiety.
2. Gastric acid secretion.
3. Regulation of autonomic functions such as blood pressure, temperature, and heart rate.
4. Stimulation of glucagon to increase glucose.
5. Gonadotropin secretion.
7. Decreasing stress.
8. Stimulation of contractions of tubules and sperm transfer in the testes.

Some generalizations concerning these various central actions of oxytocin are that many of the purported actions are modulated by gonadal steroids, opioids appear to have a generally suppressive effect on oxytocin action, and there is great variability in the pattern of oxytocin receptors among species and considerable plasticity of the oxytocin receptors that may accompany physiologic changes. Oxytocin may have direct actions on receptors in the brain and may serve as a neurotransmitter or may modulate the response of classic neurotransmitters.

Dysfunction and anatomic abnormalities of the thyroid are among the most common diseases of the endocrine glands. This chapter provides an up-to-date physiologic and biochemical background and describes the various tests for evaluating patients with suspected disease of the thyroid gland.
PHYLOGENY, EMBRYOLOGY, AND ONTOGENY

Phylogeny

The phylogeny, embryogenesis, and certain aspects of thyroid function are closely interlinked with the gastrointestinal (GI) tract. The capacity of the thyroid gland to metabolize iodine and incorporate it into a variety of organic compounds occurs widely throughout the animal and plant kingdoms.

Monoiodotyrosine (3'-monoiodo-L-tyrosine [MIT]) and diiodotyrosine (3,5'-diiodo-L-tyrosine [DIT]) are present in a variety of invertebrate species, including mollusks, crustaceans, coelenterates, annelids, insects, and certain marine algae (Fig. 10-1). In these lower forms, however, no recognizable thyroid tissue is present. Thyroid tissue is confined to and is present in all vertebrates. A close link to the thyroid of higher vertebrates is evident in the ammocoete, the larval form of the lamprey. Here the endostyle is capable of carrying out iodinations, but prior to metamorphosis a protease is expressed in the endostyle that can hydrolyze the iodoprotein formed. Presumably, this permits the endostyle to lose its connection with the pharynx during metamorphosis and to assume its adult function as an endocrine organ that secretes iodothyronines, including 3,5,3',5'-tetraiodo-L-thyronine (thyroxine, T\(_4\)), and 3,5,3'-triiodo-L-thyronine (T\(_3\)) (Fig. 10-1).

The phylogenetic association of the thyroid gland and the GI tract is evident in several functions. The salivary and gastric glands, like the thyroid, are able to concentrate iodide in their secretions, although iodide transport in these sites is not responsive to stimulation by thyrotropin (also called thyroid-stimulating hormone [TSH]). The salivary gland contains enzymes that are capable of iodinating tyrosine in the presence of hydrogen peroxide (H\(_2\)O\(_2\)), although it forms insignificant quantities of iodoproteins under normal circumstances.
Structural Embryology

The human thyroid anlage is first recognizable about 1 month after conception, when the embryo is approximately 3.5 to 4.0 mm in length. The primordium begins as a thickening of epithelium in the pharyngeal floor, which later forms a diverticulum. With continuing development, the median diverticulum is displaced caudad and the primitive stalk connecting the primordium with the pharyngeal floor elongates (thyroglossal duct). During its caudal displacement, the primordium assumes a bilobate shape, coming into contact and fusing with the ventral aspect of the fourth pharyngeal pouch.

Normally, the thyroglossal duct undergoes dissolution and fragmentation by about the second month after conception, leaving at its point of origin a small dimple at the junction of the middle and posterior thirds of the tongue, the foramen caecum. Cells of the lower portion of the duct differentiate into thyroid tissue, forming the pyramidal lobe of the gland. Concomitantly, histologic alterations occur throughout the gland. Complex interconnecting cord-like arrangements of cells interspersed with vascular connective tissue replace the solid epithelial mass and become tubule-like structures at about the third month of fetal life; shortly thereafter, follicular arrangements devoid of colloid appear and eventually the follicles fill with colloid.
Functional Ontogeny

The ontogeny of thyroid function and its regulation in the human fetus are fairly well defined. Future follicular cells acquire the capacity to form thyroglobulin (Tg) as early as the 29th day of gestation, whereas the capacities to concentrate iodide and synthesize T4 are delayed until about the 11th week. Radioactive iodine inadvertently given to the mother would be accumulated by the fetal thyroid soon thereafter.

Because the capacity of the pituitary to synthesize and secrete TSH is not apparent until the 10th to 12th weeks, early growth and development of the thyroid do not seem to be TSH-dependent. Subsequently, rapid changes in pituitary and thyroid function take place. Probably as a consequence of hypothalamic maturation and increasing secretion of thyrotropin-releasing hormone (TRH), the serum TSH concentration increases between 18 and 26 weeks of gestation, after which levels remain higher than those in the mother. The higher levels may reflect a higher set-point of the negative feedback control of TSH secretion during fetal life than at maturity.

Thyroxine-binding globulin (TBG), the major thyroid hormonebinding protein in plasma, is detectable in serum by the 10th gestational week and increases in concentration progressively to term. This increase accounts, in part, for the progressive increase in the serum T4 concentration during the second and third trimesters, but increased secretion of T3 must also play a role because the concentration of unbound, or free, T4 also rises. The peripheral metabolism of T4 in the human fetus differs markedly from that in the adult both quantitatively and qualitatively. Overall, rates of production and degradation of T4 in unit per body mass exceed those in the adult by 10-fold. In addition, the enzymatic pathways by which T4 is metabolized differ from those in the adult, favoring the formation of the inactive 3,3',5'-triiodo-\(^{-}\)-thyronine (reverse T3 [rT3]) at the expense of T3.

From the clinical standpoint, several aspects of thyroid development are notable. In rare circumstances, thyroid tissue may develop from remnants of the thyroglossal duct near the base of the tongue. Such lingual thyroid tissue may be the sole functioning thyroid tissue present, and thus its surgical removal would lead to hypothyroidism. More commonly, elements of the thyroglossal duct may persist and later give rise to thyroglossal duct cysts, or thyroid tissue progenitors may migrate to occupy a place within the mediastinum.
ANATOMY AND HISTOLOGY

The thyroid gland is one of the largest of the endocrine organs, weighing approximately 15 to 20 g in North American adults. Moreover, the potential of the thyroid for growth is tremendous. The enlarged thyroid, commonly termed a goiter, can weigh many hundreds of grams.

The normal thyroid gland is made up of two lobes joined by a thin band of tissue, the isthmus. The latter is approximately 0.5 cm thick, 2 cm wide, and 2 cm high. The individual lobes normally have a pointed superior pole and a poorly defined, blunt inferior pole that merges medially with the isthmus. Each lobe is approximately 2.0 to 2.5 cm in thickness and width at its largest diameter and is approximately 4.0 cm in length. Occasionally, especially when the remainder of the gland is goitrous, a pyramidal lobe is discernible as a finger-like projection directed upward from the isthmus, generally just lateral to the midline, usually on the left. The right lobe is normally more vascular than the left, is often the larger of the two, and tends to enlarge more in disorders associated with a diffuse increase in size.

Two pairs of vessels constitute the major arterial blood supply: (1) the superior thyroid artery, arising from the external carotid artery, and (2) the inferior thyroid artery, arising from the subclavian artery. Estimates of thyroid blood flow range from 4 to 6 mL/minute per g, well in excess of the blood flow to the kidney (3 mL/minute per g). In diffuse toxic goiter due to Graves’ disease, blood flow may exceed 1 L/minute and may be associated with an audible bruit or even a palpable thrill.

The gland is composed of closely packed spherical units (follicles), which are invested with a rich capillary network. The interior of the follicle is filled with the clear, proteinaceous colloid that normally is the major constituent of the total thyroid mass. On cross-section, thyroid tissue appears as closely packed, ring-shaped structures consisting of a single layer of thyroid cells surrounding a lumen. The diameter of the follicles varies considerably, even within a single gland, but averages about 200 µm. The follicular cells vary in height with the degree of glandular stimulation, becoming columnar when active and cuboidal when inactive.

The epithelium rests on a basement membrane that is rich with glycoproteins separating the follicular cells from the surrounding capillaries. From 20 to 40 follicles are demarcated by connective tissue septa to form a lobule supplied by a single artery. The function of a given lobule may vary from that of its neighbors.

Under electron microscopy, the thyroid follicular epithelium has many features in common with other secretory cells and some peculiar to the thyroid. From the apex of the follicular cell, numerous microvilli extend into the colloid. It is at or near this surface of the cell that iodination, exocytosis, and the initial phase of hormone secretion, namely colloid resorption, occur. The nucleus has no distinctive features, and the cytoplasm contains an extensive endoplasmic reticulum laden with microsomes. The endoplasmic reticulum is composed of a network of wide, irregular tubules that contain the precursor of Tg. The carbohydrate component of Tg is added to this precursor in the Golgi apparatus, which is located apically. Lysosomes and mitochondria are scattered throughout the cytoplasm. Stimulation by TSH results in enlargement of the Golgi apparatus, formation of pseudopodia at the apical surface, and the appearance in the apical portion of the cell of many droplets that contain colloid taken up from the follicular lumen.

The thyroid also contains parafollicular cells (C cells) that are the source of the calcium-lowering hormone, calcitonin. These cells arise during embryonic development from the last pair of pharyngeal pouches but ultimately come to rest either among the cells of the follicular epithelium or in the thyroid interstitium. They differ from the cells of the follicular epithelium in never bordering on the follicular lumen and in being rich in mitochondria. The C cells undergo hyperplasia early in the syndrome of familial medullary carcinoma of the thyroid and give rise to this tumor in both its familial and its sporadic forms.
IODINE AND THE SYNTHESIS AND SECRETION OF THYROID HORMONES

Overview

The function of the thyroid gland is to generate the quantity of thyroid hormone necessary to meet the demands of the peripheral tissues. This requires the daily thyroidal uptake of sufficient iodide and its oxidation by thyroid peroxidase (TPO) to allow the synthesis of approximately 110 nmoles (85 µg) of T\(_4\), which is 65% iodine by weight. This requires the synthesis of a 660-kd glycoprotein homodimer, Tg. Tg contains specific tyrosine residues that are then iodinated at the apical portion of the thyroid cell to form mono- and diiodotyrosine (MIT and DIT) (see Fig. 10-2).

TPO-catalyzed coupling of two molecules of DIT, or one of DIT and one of MIT, leads to formation of T\(_4\) and T\(_3\), respectively, which are then stored as colloid, still as part of the Tg molecule. Pinocytosis of stored colloid leads to the formation of phagolysosomes, the colloid droplets in which Tg is digested, releasing T\(_4\), T\(_3\), DIT, and MIT as the droplet is translocated toward the basal portion of the cell. Thyroxine and T\(_3\) exit the cell into the capillaries, and DIT and MIT are deiodinated by an iodothyronine deiodinase to allow recycling of the iodide to iodinate newly synthesized Tg.

The synthesis of thyroid hormones requires the expression of a number of thyroid cellspecific proteins. In addition to Tg and TPO, the TSH receptor is also required to transduce the effects of extracellular TSH for efficient hormone synthesis. Several thyroid cellspecific proteins thyroid transcription factors 1 and 2 (TTF-1 and TTF-2) and PAX-8 stimulate transcription of the Tg and TPO genes. One or more of these proteins may also influence expression of the TSH receptor.

Although the biochemical details of these processes are beyond the scope of this discussion, those aspects with clinical relevance are detailed in the following sections. Excellent detailed reviews of these topics may be found elsewhere.
Dietary Iodine

Formation of normal quantities of thyroid hormone requires the availability of adequate quantities of exogenous iodine to allow thyroidal uptake of about 60 µg daily, taking into account the fecal losses of about 10 to 20 µg iodine of iodothyronines as glucuronides and about 100 to 150 µg as urinary iodine in iodine-sufficient populations. Plasma iodide (I⁻), the form of the element in biologic solutions, is completely filterable with about 60% to 70% of the filtered load reabsorbed passively. At least 100 µg of iodine per day is required to eliminate all signs of iodine deficiency (Table 10-1).

In North America, the daily dietary iodine intake is in the range of 150 to 300 µg daily, largely owing to the iodination of salt; in Japan, where large quantities of foods rich in iodine are consumed, intakes may be as high as several milligrams per day. Notably, iodine intake in the United States is decreasing as a result of a reduction in salt intake, with median urinary iodine of 15 µg/dL but a low urinary iodine (<5 µg/dL) in 12% of the population.¹² ¹³ ¹⁴

The daily dietary intake of iodine varies widely throughout the world, depending on the iodine content of soil and water and on dietary practice (see Table 10-1). Even in a single area, iodine intake varies among different individuals and in the same individual from day to day. Iodine may also enter the body via medications, diagnostic agents, dietary supplements, and food additives.

As detailed later under the heading “Regulation of Thyroid Function,” iodine deficiency is common, especially in mountainous and in formerly glaciated regions of the earth. An estimated 1 billion people live in iodine-deficient areas of the world, and individuals living in such areas often develop TSH-induced compensatory enlargement of the thyroid (endemic goiter). If iodine deficiency is severe during pregnancy, fetal thyroid hormone production falls with irreparable damage to the developing central nervous system (CNS). This is manifested by varying degrees of mental retardation and is termed endemic cretinism. Thus, iodine-deficiency disorders (IDDs), including endemic goiter and cretinism, are the most common thyroid-related human illnesses indeed, the most common endocrine disorders worldwide.

Plasma iodide is partly replenished by that lost from the thyroid gland into the blood and by iodide liberated through deiodination of iodothyronines in peripheral tissues. Ultimately, however, the diet is its most important source. Iodine is ingested in both inorganic and organically bound forms. Iodide is rapidly and efficiently absorbed from the GI tract (within 30 minutes), and little is lost in the stool. In the body, iodide is confined largely to the extracellular fluid; however, it is also found in red blood cells and is concentrated in the intraluminal fluids of the GI tract, notably the saliva and gastric juice, from which it is reabsorbed, thus reentering the extracellular fluid. Iodide is also concentrated in milk.

Until it is oxidized and bound to tyrosyl residues in Tg, iodide entering the thyroid by active transport is in rapid equilibrium with the main iodide pool. The concentration of iodide in the extracellular fluid is normally 10 to 15 µg/L (10⁻⁷ M), and the content of the peripheral pool is approximately 250 µg. The thyroid gland contains the largest pool of body iodine (normally 8000 µg), most of which is in the form of DIT and MIT. Generally, this pool of iodine turns over slowly (1%/day).
Iodide Metabolism by the Thyroid Cell

Because the concentration of iodide in plasma is extremely low, a mechanism is required for the thyroid cell to concentrate the required amounts of this element. This process, called iodide trapping, is accomplished by a membrane protein, the sodium-iodide symporter (NIS). Human NIS is a 643 amino acid protein with 13 membrane-spanning domains.

The transport of iodide is an active process, depending on the presence of sodium gradient across the basolateral membrane of the thyroid cell such that downhill transport of 2 Na⁺ ions results in the entry of one iodide atom against an electrochemical gradient (see Fig. 10-2). In addition to being expressed in the basolateral membrane of the thyroid cell, NIS has also been identified in other iodide concentrating cells, including salivary and mammary glands, choroid plexus, gastric mucosa, and in the cytotrophoblast and syncytiotrophoblast. The iodide transport system generates an iodide gradient of 20 to 40 over the cell membrane and NIS also transports $\text{TCO}_4^-$, $\text{ClO}_4^-$, and SCN⁻, accounting for the utility of radioactive $\text{TCO}_4^-$ as a thyroid scanning tool and the capacity of potassium perchlorate ($\text{KClO}_4$) to block iodide uptake. In fact, these anions have a higher affinity for NIS than does iodide itself. On the other hand, the affinity of NIS for iodide is much higher than it is for the other inorganic anions, such as bromide and chloride, accounting for the selectivity of the thyroid transport mechanism.

It has been known for decades that the iodide-concentrating mechanism is required for normal thyroid function, as its absence is associated with congenital hypothyroidism and goiter unless large quantities of inorganic iodide are provided. A number of families have now been identified in which various mutations in the NIS gene are associated with congenital hypothyroidism and an iodide transport defect. Transcription of the NIS gene is increased by TSH. The mechanism for this has not been completely elucidated, but studies of the rat NIS promoter suggest that there is an NIS upstream enhancer, which confers a cyclic adenosine monophosphate (cAMP) response but also contains binding sites for the thyroid specific transcription factors PAX-8 and TTF-1, as well as a degenerate cAMP response element element. Importantly, several studies have documented decreases in NIS expression in human thyroid adenomas and carcinomas that contribute to the loss of iodine uptake in neoplastic thyroid cells, which thus present as "cold" nodules on radioisotopic imaging.

A second thyroid cell protein involved in iodide metabolism, pendrin, the product of the PDS gene, has now been identified by positional cloning using genomic DNA from families with the autosomal recessive disorder, Pendred's syndrome. This is a long-recognized inherited condition in which sensorineural hearing loss is combined with varying degrees of impaired thyroid hormone synthesis, leading to goiter. Pendrin is a transmembrane protein, a member of the sulfate transport protein family. Initially thought to be a sulfate transporter, it is now recognized to transport chloride, iodide, and bicarbonate ($\text{HCO}_3^-$). Pendrin is expressed in the apical border of the thyroid cell, the inner ear, and the kidney (see Fig. 10-2). Mutations in pendrin cause an inner ear malformation, although not all patients have goiter. It is postulated that pendrin is required for iodide transport across the apical membrane of the thyrocyte into the follicular lumen, where it is then oxidized and coupled to tyrosine in Tg (see Fig. 10-2).

The presence of thyroid dysfunction in Pendred's syndrome can be ascertained by the perchlorate discharge test, which illustrates the physiologic role of pendrin in thyroidal iodine metabolism. In normal individuals, more than 90% of thyroid radiiodine is present as iodotyrosine and iodothyronine within minutes of its entry into the thyroid. It is then no longer in the intracellular iodide pool. In patients with Pendred's syndrome, or with other disorders inhibiting the iodination of tyrosine (see later topics, such as Hashimoto's thyroiditis), this process is delayed, as shown by the exit (discharge) of more than 10% of the thyroidal radioiodine within 2 hours of administration of 500 mg of $\text{KClO}_4$. Perchlorate inhibits NIS function by an as yet unidentified mechanism eliminating the iodide gradient, which is required for maintaining the radiiodide in the gland. This illustrates that both iodide transport by NIS at the basal pole of the thyrocyte and its efflux across the apical membrane by pendrin are required for thyroid hormone synthesis. Deafness in patients with Pendred's syndrome is due to formation of a common cavity in the upper coils of the cochlea with dilatation of the vestibular aqueducts, not to the hypothyroidism per se.

In addition to being brought into the thyroid gland by active transport from the extracellular fluid, thyroidal iodide is generated by the deiodination of iodotyrosines liberated during the hydrolysis of Tg. A portion of this iodide is oxidized and used to iodinate tyrosine, and the remainder is lost from the gland as the iodide leak. This conservation process is interrupted when antithyroid drugs which inhibit iodide oxidation, such as methimazole (MMI), carbimazole (CB) or propylthiouracil (PTU) are given, thus further enhancing the effectiveness of these thyroid peroxidase inhibitors in blocking thyroid hormone synthesis.
Iodide Oxidation and Organification of Iodide

Within the thyroid gland, iodide participates in a series of reactions that lead to the synthesis of the active thyroid hormones. The first of these involves oxidation of iodide and incorporation of the resulting intermediate into the hormonally inactive iodotyrosines MIT and DIT, a process termed organification. Iodide is normally oxidized rapidly, immediately appearing in organic combination in Tg. The iodinations that lead to formation of iodotyrosines occur within Tg rather than on the free amino acids.

Oxidation of thyroidal iodide is mediated by the heme-containing protein TPO. The complementary DNA (cDNA) for human TPO encodes 933 amino acids with a molecular size of 103 kd, 10% of which is due to carbohydrate. The protein contains a membrane spanning region near the COOH terminus, and it is oriented in the apical membrane of the thyroid cell with residues 1 to 844 in the follicular lumen (see Fig. 10-2). TPO is the major thyroid microsomal antigen, and recombinant human TPO is now used for the detection of anti-thyroid microsomal antibodies, commonly present in the serum of patients with Hashimoto’s thyroiditis.

Because TPO is a heme protein, organic iodinations require molecular oxygen and are inhibited by cyanide and azide. In vitro, TPO, in the presence of H₂O₂, iodinates Tg as well as other proteins. The reaction catalyzed by peroxidase in vitro has many properties of the iodination reaction in vivo, including inhibition by PTU and MMI and by high concentrations of iodide (the Wolff-Chaikoff effect). The evanescent product of the peroxidation of iodide (i.e., the active iodinating form) may be free hypoiodous acid, iodine, or iodinium (I⁺). The H₂O₂ that serves as the oxidant of iodide is generated through the auto-oxidation of flavin enzymes acting as NADHand particularly NADPHoxidases. In this way, generation of H₂O₂ is linked to electron transfers due to substrate oxidations within the thyroid. Radioautographic and histochemical evidence suggests that the iodination reactions occur at the cell colloid interface (see Fig. 10-2). Thus mitochondrial systems provide a source of H₂O₂, cell membranes contain TPO, and the cytoplasmic fraction the regulatory inhibitors of organic iodinations.

The rate of organic iodinations depends on the degree of thyroid stimulation by TSH (see later). Iodinations are susceptible to inhibition by a number of pharmacologic agents, including the thiourea derivatives, PTU, MMI, and CB, which are inhibitors of peroxidase and have intrinsic reducing activity. Defects in the organic binding mechanism cause goitrous congenital hypothyroidism or, if less severe, goiter without hypothyroidism. In some families, thyroidal TPO is absent. In others, the defect may reside in inadequate production of H₂O₂ or in abnormalities in Tg that render it less readily iodinated (see Chapter 12).
Iodothyronine Synthesis

The MIT and DIT formed via oxidation and organic binding of iodide are precursors of the hormonally active iodothyronines T₄ and T₃. Because noniodinated thyronine cannot be demonstrated in Tg, T₄ and T₃ must arise from iodinated tyrosine precursors. Synthesis of T₄ from DIT requires the fusion of two DIT molecules to yield a structure with two diiodinated rings linked by an ether bridge and is catalyzed by TPO. Concomitantly, a residual dehydroalanine is formed at the site of the DIT residue contributing the phenolic hydroxyl group (beta or outer ring). This process is termed the coupling reaction.

Efficient synthesis of T₄ and T₃ in the thyroid requires Tg. The large (>260 kb) Tg gene is on chromosome 8. The Tg messenger RNA is 8 to 8.5 kb in length and encodes a 330-kd 12S subunit that is 10% carbohydrate by weight. There are 134 tyrosyl residues in the 660-kd homodimer. Only 25 to 30 of these are iodinated, but only residues 5, 1290, and 2553 form T₄ and residue 2746, T₃. The T₄-forming, readily iodinated, and iodothyronine-forming acceptor residues of Tg from different species are in a Glu/Asp-Tyr or a Thr/Ser-Tyr/Ser sequence, suggesting an important role of primary sequence in these reactions.

There are three to four T₄ molecules in each molecule of human Tg under conditions of normal iodination (25 atoms per Tg molecule, 0.5% iodine by weight), but only about one in five molecules of human Tg contains a T₃ residue. In Tg from patients with untreated Graves’ disease, the content of T₃ residues remains approximately the same, but the number of T₃ residues doubles to an average of 0.4 per molecule. This difference is independent of the iodination state of the Tg and is a consequence of thyroidal stimulation. Because the coupling reaction is catalyzed by TPO, virtually all agents that inhibit organic binding also inhibit coupling.
Storage and Release of Thyroid Hormone

The thyroid gland is unique among the endocrine glands by virtue of the large store of hormone it contains and the low rate at which the hormone turns over (1%/day). This aspect of thyroid hormone economy has homeostatic value, in that the reservoir provides prolonged protection against depletion of circulating hormone should synthesis cease. In normal humans, administration of antithyroid agents for as long as 2 weeks has little effect on the serum $T_4$ concentration. There are approximately 250 µg $T_4$/g wet weight in normal human thyroid or 5000 µg of $T_4$ in a 20-g gland. This is sufficient to maintain a euthyroid state for at least 50 days.

When $T_4$ is released rapidly in an uncontrolled fashion during subacute or painless thyroiditis, this can cause significant transient thyrotoxicosis. $T_g$ is present in the plasma of normal individuals at concentrations up to 50 ng/mL, leaving the thyroid gland through the lymphatics. However, peripheral hydrolysis of $T_g$ does not contribute significantly to the $T_4$ and $T_3$ in the circulation, even during thyroiditis, when large quantities of this protein are released.

The first step in thyroid hormone release is the endocytosis of colloid from the follicular lumen by two processes: macropinocytosis by pseudopods formed at the apical membrane, and micropinocytosis by small coated vesicles that form at the apical surface (see Fig. 10-2). Both processes are stimulated by TSH, but the relative importance of the two pathways varies among species. Micropinocytosis is thought to predominate in humans.

Following endocytosis, endocytotic vesicles fuse with lysosomes, and proteolysis is catalyzed by cathepsin - and ß-like thiol proteases, all of which are active at the acidic pH of the lysosome. The iodotyrosines released from $T_g$ are rapidly deiodinated by an NADPH-dependent iodotyrosine deiodinase, and the released iodine is recycled. The $T_4$ is released from $T_g$, but it is not clear how its transfer into the plasma is regulated. Release is acutely stimulated by TSH, as may be the $5'$-monodeiodination of small amounts of $T_4$ to $T_3$ by the types 1 and 2 iodothyronine deiodinases (D1 and D2), which are both expressed in human thyroid.

Although basal and TSH-stimulated conversion of $T_4$ to $T_3$ is easily demonstrated in the perfused canine thyroid gland, the contribution of thyroidal $T_4$ deiodination to $T_3$ secretion in humans under physiologic conditions is not known. The 15'/1 ratio of $T_4$ to $T_3$ in human $T_g$, as compared with the 10'/1 ratio of the secreted hormones, suggests minor $T_g$ monodeiodination. However, stimulation of D2-catalyzed $T_4$ 5'-deiodination in Graves’ thyroid may enhance that pathway and contribute to the relative increase in the ratio of $T_3$ to $T_4$ production in that condition.

$T_g$ proteolysis and $T_4$ release are inhibited by several agents, the most important of which is iodide. Inhibition of hormone release is responsible for the rapid improvement that iodide induces in hyperthyroid patients. The mechanism by which this effect is mediated is uncertain, but iodide inhibits the stimulation of thyroid adenylate cyclase by TSH and by the stimulatory immunoglobulins of Graves’ disease. Increasing iodination of $T_g$ also increases its resistance to hydrolysis by acid proteases in the lysosomes. Lithium inhibits thyroid hormone release, although its mechanism of action is poorly understood and may differ from that of iodide.
Role and Mechanism of Thyrotropin Effects

All steps in the formation and release of thyroid hormones are stimulated by TSH secreted by the pituitary thyrotrophs (see Chapter 8). Thyroid cells express the TSH receptor (TSHR), a member of the glycoprotein G protein-coupled-receptor family. The deduced amino acid sequence of this protein predicts a large extracellular NH₂-terminal domain, seven membrane-spanning domains, and an intracellular domain that transduces the signal to the Gs (adenyl cyclase) and GqII (phospholipase C [PL-C]) pathways (Table 10-2).¹ The TSHR also binds thyroid-stimulating antibody (TSAb) and thyroid-blocking antibodies (TBAb) (see Chapter 11).² In addition, the closely related luteinizing hormone (LH) and chorionic gonadotropin (CG) also bind to and activate TSHR signaling. CG accounts for the physiologic hyperthyroidism of early pregnancy.²³⁴⁵⁶⁷ Nonetheless, the persistence of a functional TSHR that is not down-regulated by autophosphorylation can explain the hyperthyroidism of Graves’ disease and that associated with TSH-producing thyrotroph tumors.²⁸²⁹ Interestingly, certain “activating mutations,” either germline or somatic, have been identified in the membrane spanning or intracellular portions of the TSHR molecule that cause generalized or nodular hyperfunction.³⁰³¹ Even more subtle changes may occur. In one family, a replacement of lysine 183 with arginine in the extracellular domain increased the activation of TSHR by human chorionic gonadotropin (hCG), causing recurrent gestational hyperthyroidism.³² Curiously, the TSHR may be cleaved into A and B subunits to varying extents, but the physiologic significance of cleaved and uncleaved receptors is unclear.³³

Studies of the rate-limiting intracellular reactions stimulated by TSH are complicated by the fact that the intrathyroidal events are stimulated by protein kinase A (PKA)-related mechanisms in one species or cell model and by PL-C-directed pathways in another [see Table 10-2].³⁴ The effects on

iodide kinetics include both an early stimulation of iodide efflux into the follicular lumen and a later increase in the Vₘ₉₅ for iodide transport. The latter is likely due to enhanced expression of NIS.³⁶³⁷³⁸

Peroxidase generation in human thyrocytes is activated by Ca²⁺ and diacylglycerol, although 10-fold higher concentrations of TSH are required for activation of this limb of the TSHR pathways than for activation of adenylyl cyclase. TSH increases the levels of both TPO messenger RNA (mRNA) and protein, even though no cAMP response element-binding protein (CREB) sequences have been identified in the promoter of this gene.³⁹ The effect on TPO may be secondary to cAMP stimulation of thyroid cell-specific proteins, such as TTF-1, TTF-2, or PAX-8 (see earlier), but this remains to be shown. Similarly, transcription of the Tg gene is also stimulated by cAMP through indirect pathways, perhaps involving the same mechanism.⁴⁰

Interestingly, TSH can increase TSH mRNA in human thyroid cells, although at high TSH concentrations there may be a modest decrease in receptor expression. Nonetheless, the persistence of a functional TSHR that is not down-regulated by autophosphorylation can explain the hyperthyroidism of Graves’ disease and that associated with TSH-producing thyrotroph tumors.⁴¹ TSH, via cAMP, also stimulates the ingestion and hydrolysis of colloid and the release of T₄ (and T₃) from the thyroid cell. Thyroid cell proliferation is stimulated by cAMP, phorbol esters, and epidermal growth factor (EGF) through tyrosine kinases.⁴² However, cAMP causes proliferation while maintaining differentiated function, whereas EGF and phorbol esters lead to dedifferentiation. Similarly, insulin-like growth factor I (IGF-I) and fibroblast growth factor (FGF) stimulate cell division and dedifferentiation, although species differences exist in the effects of these agents.⁴³⁴⁴ In human thyrocytes, the events stimulated by the adenylyl cyclase pathway are probably the most crucial for thyroid growth and explain the goitrous changes associated with prolonged TSH stimulation, such as those occurring during iodine deficiency.
THYROID HORMONES IN PERIPHERAL TISSUES

Plasma Transport

The metabolic transformations of thyroid hormones in peripheral tissues determine their biologic potency and regulate their biologic effects. Consequently, an understanding of thyroid physiopathology requires a knowledge of the pathways of thyroid hormone metabolism.

A wide variety of iodothyronines and their metabolic derivatives exist in plasma. Of these, \( T_4 \) is highest in concentration and the only one that arises solely from direct secretion by the thyroid gland. In normal people, \( T_3 \) is also released from the thyroid but about 80% is derived from the peripheral tissues by the enzymatic removal of a single 5'-iodine atom (outer ring or 5'-monodeiodination) from \( T_4 \). The remaining iodothyronines and their derivatives are generated in the peripheral tissues from \( T_3 \) and \( T_4 \). Principal among them are 3,3',5'-triiodothyronine (T3), 3,3'-diiodothyronine (3,3'-T2), and 3,3',5'-triiodothyronine (3,3',5'-T3). Trace concentrations of other diiodothyronines, moniodothyronines, and conjugates thereof with glucuronic or sulfuric acid are also present.

The major iodothyronines are poorly soluble in water and thus bind reversibly to plasma proteins. The plasma proteins with which \( T_3 \) is mainly associated are TBG and transthyretin (TTR), formerly termed \( T_4 \)-binding prealbumin (TBPA), and albumin (Table 10-3). About 75% to 80% of \( T_3 \) is bound by TBG, with the remainder bound by TTR and albumin.

Thyroxine-Binding Globulin

TBG is a glycoprotein with a molecular mass of about 54 kDa, about 20% of which is carbohydrate. The gene that encodes the protein is on the X chromosome. The protein sequence of TBG resembles that of the SERPIN family of serine antiproteases. Because there is one iodothyronine binding site per TBG molecule, the \( T_4 \) or \( T_3 \) binding capacity of TBG in normal human serum is equivalent to its concentration, approximately 270 nmol/L (21 µg \( T_4 \)/dL). The half-life of the protein in plasma is about 5 days, and the metabolic clearance rate (MCR) is approximately 800 mL/day.

Congenital deficiencies of TBG are common, occurring in 1/5000 newborns, and are associated with the complete absence of the protein in males. Other abnormalities of TBG can alter the susceptibility to heat denaturation or the capacity to bind thyroid hormone. One such variant has been described in Australian aborigines, and a TBG protein with increased heat lability occurs in Africans. All of these abnormalities are inherited in an X-linked fashion.

The glycosylation of TBG influences its clearance from the plasma and its behavior during isoelectric focusing. Four to six bands are present; after exposure to neuraminidase, however, these differences are lost, indicating that they are due to variations in the numbers of sialic acid residues. In estrogen-treated patients, the prevalence of the more acidic bands of TBG is increased. The more highly sialylated TBG, compared with the more positively charged TBG, is cleared more slowly from plasma because increased sialylation inhibits the hepatic uptake of glycoproteins. The sera of pregnant patients, women receiving oral contraceptives, and individuals of aboriginal and African origin have abnormal TBG isoelectric patterns.

Other abnormalities of TBG can alter the susceptibility to heat denaturation or the capacity to bind thyroid hormone. One such variant has been described in Australian aborigines, and a TBG protein with increased heat lability occurs in Africans. All of these abnormalities are inherited in an X-linked fashion.

The metabolic clearance rate of TBG is inversely related to its binding capacity. The serum TBG concentration is highest in children and lowest in pregnant women. TBG concentration is also decreased in patients receiving drugs that induce hepatic enzymes, such as phenobarbital and drugs used to treat tuberculosis. In addition, TBG concentrations are increased in patients with liver disease, malnutrition, and pregnancy. TBG is significantly lower in patients with Congenital TBG deficiencies, occurring in 1/5000 newborns, and are associated with the complete absence of the protein in males. Other abnormalities of TBG can alter the susceptibility to heat denaturation or the capacity to bind thyroid hormone. One such variant has been described in Australian aborigines, and a TBG protein with increased heat lability occurs in Africans. All of these abnormalities are inherited in an X-linked fashion.

Another post-translational modification affecting TBG occurs in patients with sepsis or in patients after cardiopulmonary bypass surgery. TBG is subjected to

TBG excess have normal amounts of highly sialylated TBG, as do men and nonpregnant women. Because TBG is the principal \( T_4 \) - and \( T_3 \) -binding protein, changes in TBG or in its binding are paralleled by changes in total plasma \( T_4 \) and \( T_3 \) even though \( T_4 \) and \( T_3 \) production is little changed.

---

cleavage by a serine protease released from polymorphonuclear leukocytes resulting in the release of a 5-kD COOM terminal loop with a consequent decrease in affinity for T₄. An analogous reaction has been described for CBG that releases cortisol at the site of inflammation. 10 It has been postulated that the released T₄ might play a critical role in the response to injury, perhaps by providing a supply of iodine for antibacterial purposes. 11 12 The cleaved TBG (49 kd) circulates, and because it binds T₄ with lower avidity, this may explain the increased ratio of free T₄ to bound T₄ in acute illness, even when TBG saturation studies or immunoassays indicate a normal TBG concentration (see “Thyroid Function during Fasting or Illness”).

Transthyretin

TTR exists in part as a complex with retinol (vitamin A)-binding protein, hence its name. It consists of four identical polypeptide chains, with a total molecular mass of approximately 55 kDa, and is not glycosylated. Its concentration in plasma is approximately 4 mmol/L (250 µg/mL). Each mole of TTR binds 1 mole of T₃ with high affinity, and a second T₃ molecule is bound with lower affinity at high concentrations of T₄. 59 Binding of T₄ by TTR is independent of the association with retinol-binding protein. Its half-life in plasma is normally about 2 days, but this decreases during illness. 60

TTR is expressed in the choroid plexus and is the major thyroid hormone-binding protein in the cerebrospinal fluid (CSF). 61 Targeted TTR gene disruption in mice shows that aside from the predictable 50% decrease in total plasma T₄ concentration and reciprocal increase in the free T₄ fraction (since TTR is a major T₄-binding protein in mice), the absence of the gene causes no developmental abnormality. There is also no evidence of impaired uptake of T₄ into the brain, leaving the role of TTR in CSF undefined in regard to thyroid physiology. 61 62

Variant forms of TTR are associated with familial amyloidotic polyneuropathy. 63 64 In affected families, the TTR monomer has one of several different point mutations and TTR accumulates in amyloid tissue deposits. Neither thyroid dysfunction nor altered vitamin A metabolism has been reported, although there is altered affinity of some of the mutant proteins for T₄. Families with both high-affinity TTR and a few with increased TTR levels have been reported. 65

Comparison of Thyroxine and Triiodothyronine Binding by Thyroxine-Binding Globulin and Transthyretin

The TBG-binding site has an affinity for T₄ that is about 20-fold less than that for T₃ (see Table 10-3). TBG binds both the dextroisomer of T₄ and the naturally occurring levosomer. Deamination of the iodothyronine molecule reduces binding to TBG and increases the affinity for TTR, the acetic and propionic acid analogues of T₄ and T₃ bind poorly, if at all, to this protein. Binding of T₄ by TBG is inhibited by phenytoin, 65 salicylate, 66 salsalate, 65 67 furosemide, 65 fenofenac, 65 and miltoane. The affinity of these compounds for TBG is much weaker than that of T₄ or T₃ by TBG, but their concentration in plasma may be sufficient to interfere with T₄ and T₃ binding and reduce total hormone levels. Inhibitors of the T₄ TTR interaction include salicylate, saltsalate and some of its congeners, penicillin, and plant flavonoids. 68

Albumin

The affinity of albumin for T₄ and T₃ binding is much lower than that of either TBG or TTR, but the high concentration of this protein results in the binding of 10% of the plasma thyroid hormones (see Table 10-3). Changes in albumin concentration per se have little influence on the total hormone levels unless they are accompanied by alterations in TBG and TTR, all of which are synthesized in the liver. Hepatic failure or nephrotic syndrome leads to a decreased plasma concentration of all three, and the albumin concentration serves as a surrogate for estimating TBG concentrations.

The role of albumin in thyroid physiology becomes chemically important in patients with familial dysalbuminemic hyperthyroxinemia (FDH). 68 69 In this autosomal dominant disorder, the plasma contains high amounts of a usually minor albumin variant that binds T₄ (but not T₃) with increased avidity. This increases total T₄ levels, but free T₄ and total free T₃ levels remain normal in an otherwise euthyroid patient. In one family, the albumin variant was reported to bind T₃, but not T₄, with 40-fold higher affinity, resulting in dysalbuminemic hypothyriodothyroxinemia. 69

Other Plasma Thyroid Hormone-Binding Proteins

Between 3% and 6% of plasma T₄ and T₃ are bound to lipoproteins. 70 The T₄-binding lipoprotein is 27-kDa homodimer with an affinity for T₄ that is lower than that of TBG. This binding is of uncertain physiologic significance but may play a role in targeting T₄ delivery to specific tissues.
Free Thyroid Hormones

Because most of the circulating \( T_4 \) and \( T_3 \) is bound to TBG, its concentration and degree of saturation are the major determinants of the free fraction of \( T_4 \). Binding of the thyroid hormones to the plasma proteins alters their metabolism. The negligible urinary excretion of \( T_3 \) and \( T_4 \) is due to the limited filterability of the hormone-binding protein complexes at the glomerulus. The volume of distribution and rate of turnover of the hormones are also affected by their protein associations.

In vitro, the interaction between the thyroid hormones and their binding proteins conforms to a reversible binding equilibrium that can be expressed by conventional equilibrium equations. For the formulations that follow, \( T_4 \) is used as the prototype, with the understanding that similar interactions apply in the case of \( T_3 \). The interaction between \( T_4 \) and TBG can be expressed as follows:

\[
T_4 + TBG \overset{K}{\rightleftharpoons} T_4 \cdot TBG
\]

where TBG is the unoccupied binding protein, \( K \) is the equilibrium association constant for the interaction, and \( T_4 \) is the concentration of free \( T_4 \).

\( T_4 \) TBG is \( T_4 \) bound to TBG (almost equal to 66% of total \( T_4 \)). This interaction can also be expressed by the mass action relationship, wherein

\[
\frac{T_4 \cdot TBG}{(T_4)(TBG)} = K
\]

Rearranging

\[
\frac{T_4}{T_4 \cdot TBG} = \frac{1}{(TBG)K}
\]

Thus, the free fraction of \( T_4 \) is inversely proportional to the concentration of unoccupied TBG-binding sites. Estimates of the free \( T_4 \) concentration in serum can be generated by direct or indirect assay. For example, with the aid of radiolabeled \( T_4 \), the proportion that is unbound by protein is determined by dialysis, and the concentration of free \( T_4 \) can then be calculated as the product of the total hormone concentration and the fraction that is free. In normal serum, the free \( T_4 \) is approximately 0.02% of the total (20 pmol/L, 1.5 ng/dL). The approximately 20-fold lower affinity of TBG for \( T_4 \) results in a higher proportion of \( T_3 \) free (0.30%).

It is the free hormone that is available to the tissues for intracellular transport and feedback regulation, that induces its metabolic effects, and that undergoes degradation. The bound hormone acts merely as a reservoir. It follows that the concentration of the free hormone is the determinant of the metabolic state, and it is this concentration that is defended by homeostatic mechanisms. If an increase in the overall net binding affinity for \( T_4 \) occurs, the free \( T_4 \) concentration can be maintained at normal levels only if the bound \( T_4 \) increases. This is true whether or not the causative factor is an increase in the concentration of TBG or the presence of abnormal \( T_4 \)-binding proteins.

The plasma concentration of \( T_4 \) is determined by its rate of entry into, and exit from, the plasma. The MCR relates the quantity of \( T_4 \) removed from the plasma per unit time to the quantity available for removal (i.e., its plasma concentration). Thus,

\[
\text{MCR} = \frac{D}{[P]}
\]

where MCR is the metabolic clearance rate (volume/time), \( D \) is the absolute disposal or removal rate (amount/time), and \([P]\) is the plasma concentration (amount/volume). Transposing,

\[
[P] = \frac{D}{\text{MCR}}
\]

However, under steady-state conditions, the production rate (PR) of \( T_4 \) and the disposal rate (D) are equal. Hence,

\[
[P] = \frac{\text{PR}}{\text{MCR}}
\]

Thus, for any level of \( T_4 \) production, be it increased, normal, or decreased, the total plasma \( T_4 \) level varies inversely with its MCR. However, if only the free \( T_4 \) leaves the plasma and enters the cells while the bound \( T_4 \) is confined largely to the intravascular space, changing the fraction of total \( T_4 \) that is free, by changing the fraction that is available to the tissues, changes the MCR in a parallel manner. This explains, in part, why a primary increase in thyroid hormone binding, such as occurs when TBG concentrations are increased during pregnancy or by administration of excess estrogen, transiently reduces the free \( T_4 \) level and its clearance, causing an increase in the plasma total \( T_4 \) concentration.

The transient decrease in free thyroid hormones also reduces the negative feedback on the hypothalamic-pituitary-thyroid axis. This results in an increase in TSH secretion with a consequent increase in thyroid hormone production as an additional compensation. This can explain a portion of the increased levothyroxine (\( L-T_4 \)) requirement in the first trimester of pregnancy and the adaptation of the normal thyroid gland that occurs during estrogen administration.

This formulation is called the free thyroid hormone hypothesis. If it is free hormone that is available for cellular entry, what is the role, if any, of the hormone-binding proteins? These proteins permit distribution of the hydrophobic thyroid hormones throughout the vascular system. For example, if a protein-free solution containing tracer \( T_4 \) is perfused through rat liver via the portal vein, there is a steep concentration gradient with a decreasing quantity of \( T_4 \) in cells as the distance from the center of the portal lobule increases. In fact, virtually all of the \( T_4 \) is taken up by the first cells to be contacted by the bolus. In contrast, if serum albumin is added to the perfusate, the distribution of tracer is uniform throughout the lobule, with only 46% of the tracer removed from the bolus. Both influx and efflux of thyroid hormone from tissues are rapid. Thus, intracellular free \( T_3 \) and \( T_4 \) are in equilibrium with the free hormone pool in plasma. In the steady state, the rate of \( T_3 \) and \( T_4 \) metabolism (not the dissociation rate from plasma proteins) determines the rate of removal of these hormones from the plasma.
Cellular Uptake and Intracellular Binding

Carrier-mediated, energy-dependent transport of thyroid hormones has now been demonstrated in many cell lines. The carrier transport system for T\textsubscript{3} and T\textsubscript{4} is saturable, stereospecific, and requires adenosine triphosphate (ATP), but the two iodothyronines typically do not compete for uptake.

The proteins mediating this transport are the Na\textsuperscript{+}/taurocholate cotransporting polypeptide (NTCP), members of the Na\textsuperscript{+} independent organic anion transporter (OATP) family and the L type amino acid transporters. Information is still available only in preliminary form, but it is likely that there will be a variety of overlapping mechanisms for thyroid hormone transport and that different transporters will be present in different cell types.

In patients receiving a low-calorie diet for 1 week, T\textsubscript{3} and T\textsubscript{4} uptake into both rapidly equilibrating (liver and kidney) and slowly equilibrating pools (muscle) is decreased. Thus, inhibition of T\textsubscript{4} (and rT\textsubscript{3}) transport into these organs may well explain the low production of T\textsubscript{3} and the elevation of rT\textsubscript{3} concentrations in the serum of sick or fasting individuals (see later). The processes regulating efflux of thyroid hormones from cells are less well understood but appear to involve a verapamil-sensitive mechanism.

Cellular-Binding Proteins

Proteins that bind T\textsubscript{4} and T\textsubscript{3} are present in the cytosol, and some studies suggest that the cytosol-binding proteins for T\textsubscript{4} and T\textsubscript{3} are distinct from one another. The intracellular free T\textsubscript{3} concentration can be estimated by evaluating the binding affinity of intracellular and nuclear binding proteins and by measuring the T\textsubscript{3} concentration in cytosol. Such analyses suggest that there is a free hormone gradient of twofold to threefold across the plasma membrane. This concentration gradient, however, is not nearly as high as that calculated for the nuclear/cytosolic ratios in liver, kidney, heart, and brain, which are 50:1 to 250:1.

The mechanisms for maintaining these gradients have not been defined and have not been verified by direct methods. It is surprising that, despite such high ratios for free T\textsubscript{3} between the nucleus and cytoplasm, only 10% of the intracellular T\textsubscript{3} is present in the nucleus except in pituitary cells, where T\textsubscript{3} is equally divided between the nuclear and cytoplasmic compartments.
Thyroid Hormone Activation and Inactivation by the Selenodeiodinases

The most important pathway for \( T_4 \) metabolism is its outer ring (S') monodeiodination to the active thyroid hormone, \( T_3 \). This reaction is catalyzed by type 1 and type 2 deiodinases (D1 and D2) \(^{(1)}\). Inner ring deiodination, catalyzed primarily by type 3 deiodinase (D3), inactivates \( T_4 \) and \( T_3 \) \(^{(2)}\). These reactions can be considered physiologically activating and inactivating pathways that control \( T_4 \) concentrations in peripheral tissues.

The structures of the three human deiodinases are similar to one another and are conserved from tadpoles to humans. All three contain selenocysteine in the active catalytic center and hence are termed selenodeiodinases \(^{(3)}\). Selenocysteine has nucleophilic properties that make it ideal for catalysis of oxidoreductive reactions such as iodothyronine deiodination and the reduction of \( \text{H}_2\text{O}_2 \) by another family of selenoenzymes, the glutathione peroxidases. \(^{(4)}\) Selenium acts as the iodine acceptor during deiodination reactions \(^{(5)}\).

Mutagenesis of selenocysteine in D1 to cysteine (e.g., replacing Se with S) reduces the reaction velocity by 100-fold. \(^{(6)}\) Synthesis of selenoproteins is a complex process because the normal STOP translation function of the UGA codon which encodes selenocysteine must be overridden by the cell. This is accomplished by a combination of a specific structural feature, the SECIS element, in the 3′-untranslated region of the mRNAs encoding these proteins together with a specific group of selenocysteine-incorporating gene products. \(^{(7)}\)

### Comparative Enzymology and Regulation of the Selenodeiodinases

**Type 1 and 2**

Type 1 deiodinase has several characteristics that distinguish it from D2 and D3 \(^{(8)}\). It can catalyze both S- and S'-deiodination of \( T_4 \) to form \( T_3 \) and r\( T_3 \), respectively, but the \( K_m \) for these reactions is about three orders of magnitude greater than that of D2 and D3 for this substrate. In fact, the preferred substrates of D1 are r\( T_3 \) (S'-deiodination) and T\(_3\)SO\(_4\) (S-deiodination). \(^{(9)}\)

Unlike the deiodinations catalyzed by D2 and D3, D1-catalyzed reactions are susceptible to inhibition by PTU \(^{(10)}\). D1 also differs from D2 in being markedly increased by excess thyroid hormone through increased gene transcription, whereas D2 mRNA and protein are reduced during thyrotoxicosis and increased during hypothyroidism. \(^{(11)}\)

D1 and D2 are also expressed in different tissues; D1 is highly expressed in human liver and kidney, but human D2 is widely distributed in skeletal and cardiac muscle, the CNS, skin, and the pituitary gland. \(^{(12)}\) Furthermore, in some cell types, the subcellular location of D1 is the plasma membrane whereas that of D2 is the endoplasmic reticulum. \(^{(13)}\)

It is likely based on its subcellular location that the \( T_3 \) produced by D1 is formed close to the cell surface, whereas that generated by D2 is near the nucleus. This may explain why the \( T_3 \) produced by D1-catalyzed reactions readily enters the plasma whereas that generated by D2 enters the nucleus. \(^{(14)}\)

**Type 3**

Type 3 deiodinase is most highly expressed in placenta and in the gravid uterus in rats; it is also found in the CNS. \(^{(15)}\) The highest expression identified to date in humans is in infantile hemangiomas. In infants with extensive visceral lesions, thyroid hormone inactivation by D3 may overwhelm the secretory capacity of the infant's thyroid, causing hypothyroidism. \(^{(16)}\) D3 expression is increased by thyroid hormone at a transcriptional level thus providing a feedback loop to maintain \( T_3 \) homeostasis.

---

In normal adults, T₄ has a distribution volume of approximately 10 L (Table 10-5). Because the concentration of total T₄ in plasma is approximately 100 nmol/L (8 µg/dL), the extrathyroidal T₄ pool is approximately 1 µmol (about 800 µg). In the adult, the fractional rate of turnover of T₄ in the periphery is about 10%/day (half-life, 6.7 days). Thus, about 1.1 L of the peripheral T₄ distribution space is cleared of hormone daily, a volume containing approximately 110 nmol (85 µg) of T₄.

The kinetics of T₄ metabolism differ from those of T₃, partly because of the 10-fold to 15-fold lower affinity of T₄ for TBG. The volume of distribution of T₄ in the normal adult is about 40 L, about four times that of T₃, and its fractional turnover rate is about 60%/day. Hence, the MCR of T₄ is about 24 L/day. At a mean normal serum T₄ concentration of 1.8 nmol/L (120 ng/dL), 50-fold lower than T₃, the daily production of T₄ is approximately 50 nmol (33 µg), or about 46% of that of T₃ (see Table 10-4). The rapid MCR of reverse T₃ and a low concentration in plasma (0.25 nmol/L, 15 ng/dL) combine to yield daily production rates for rT₃ of about 45 nmol. The turnover of 3,3'-T₂ (see Fig. 10-3) is even more rapid than that of T₄.

About 40% of secreted T₄ is monodeiodinated in the 5'-position to yield T₁, and a similar fraction is deiodinated in the 5-position to yield rT₂, the latter largely by D₃ (see Fig. 10-3). With a normal T₄ production rate of approximately 110 nmol (85 µg)/day, about 44 nmol (28 µg) of T₄ and rT₂ is produced by peripheral deiodination. Thus, 80% to 85% of T₄ and all of rT₂ production in humans can be accounted for by peripheral deiodination of T₄, findings consonant with the high ratio of T₄ to T₃ (15:1) and rT₂ to rT₃ in human Tg.

Of the T₄ generated via T₃-5'-deiodination in euthyroid humans, only 20% to 25% is inhibited by PTU. This suggests that in the euthyroid state, thyroidal T₃ secretion and D₁-catalyzed T₃ production may only account for about 40% of T₃ production. Alternatively, the inhibition by PTU may be incomplete and D₂-generated T₃ thereby underestimated. Whatever the contribution, the remainder of T₃ production is derived from D₂-catalyzed T₄ deiodination, perhaps catalyzed by the large pool of D₂ in skeletal muscle. This is consistent with the increase in fractional T₄ to T₃ conversion in hypothyroid or hypothyroxinemic subjects characteristic of D₂-mediated deiodination.

In contrast, PTU inhibits about 50% of peripheral T₃ production in the hyperthyroid patient consistent with an up-regulation of D₁ and down-regulation of D₂, which would be anticipated under these circumstances.

Although much of the T₄ and rT₂ produced from T₄ in peripheral tissues exits those tissues and enters the blood, an uncertain fraction of both are degraded intracellularly prior to their exit. As discussed later, in some D₂-containing tissues a significant fraction of T₄ in the cell nucleus is derived from intracellular local T₃ generation rather than from the plasma.

Other pathways are also involved in T₄ and T₃ metabolism. T₄ and T₃ undergo glucuronidation of the phenolic hydroxyl by the UDP-glucuronyltransferases (UDPGT) (see Fig. 10-4) (Figure Not Available). This pathway is clinically significant because certain pharmacotherapeutic agents such as phenytoin, rifampin and phenobarbital may enhance glucuronide conjugation, leading to biliary excretion into the intestine. Because T₄-G and T₃-G are not easily reabsorbed from intestinal contents, the significance of this pathway is that therapy with such agents generally increases ¹-iodothyronine requirements. In patients with an intact thyroid, this is not apparent, because internal adjustments increase the thyroid hormone production rate to compensate for the accelerated biliary excretion. In patients with hypothyroidism, however, an increase in ¹-iodothyronine dosage is required. Deamination and decarboxylation reactions that produce tetrac and triac and sulfation of T₄, and T₃ at the phenolic hydroxyl account for an as-yet-unidentified fraction of T₃ and T₄ metabolism in humans (see Fig. 10-4) (Figure Not Available).

T₃ is metabolized mainly by 5'-monodeiodination, either by D₃ orrafter sulfation in the liverby D₁. T₃ is metabolized by 5'-monodeiodination, primarily by D₁ (see Table 10-4). Both pathways yield 3,3'-T₂ (see Fig. 10-3), which is then rapidly degraded to moniodothyronines and thyronine. Thyronine and the iodide which escapes uptake by the thyroid gland are excreted in the urine.

Sources of Intracellular Triiodothyronine

In view of the differential tissue distribution of the various deiodinases, their various Kₗ values, and their differential regulation, it is not surprising that tissues may derive intracellular T₃ via several deiodinative pathways. Because T₃ regulates gene expression, it is especially relevant to analyze the quantity and source of nuclear T₃ in various tissues (Fig. 10-6).

In rat kidney and liver, D₁-expressing tissues, most nuclear T₃ is derived from plasma T₄. In the rat cerebral cortex, pituitary gland, and brown fat, all of which express D₂, half or more of intracellular T₃ is generated locally from T₄ within the tissue. This may be due in part to the differences in the subcellular localization between D₂ and D₁ that were mentioned earlier. In the rat, tissues depending on D₂ for nuclear T₃ are those in which a constant supply of thyroid hormone is crucial for either normal development (cerebral cortex), thyroid function (pituitary), or survival during cold stress (brown adipose tissue). These tissues are also characterized by a high
degree of saturation of the nuclear T3 receptors in comparison with other tissues (liver, kidney) in which nuclear T3 receptor sites are only about 50% occupied at normal serum T3 concentrations (see Fig. 10-6). This arrangement allows multiple levels of regulation of thyroid hormone action.

Intracellular D2-catalyzed T3 production has important implications for thyroid hormone physiology. First, because the T3 produced from T4 occupies a significant fraction of the receptors in those tissues, changes in either serum T4 or T3 can change receptor occupancy. However, because a fall in T4 also increases D2 protein half-life by decreasing the rate of ubiquitination and its proteasomal degradation, a rise in D2 activity mitigates the impact of a reduction of serum T4 in D2-expressing tissues, helping to maintain T3 homeostasis. Second, the requirement for both T3 and T4 for normal saturation of pituitary gland and CNS T3 receptors permits a response of the hypothalamic-pituitary axis to a reduction in plasma T4, which is the earliest manifestation of iodine deficiency or primary hypothyroidism (see "Regulation of Thyroid Function").

Because the D2 gene is positively regulated by cAMP, D2 activity and T3 production increase rapidly in brown adipose tissue under stimulation by the sympathetic nervous system during exposure to cold. This response is critical to adaptive thermogenesis during cold exposure in the human neonate and lifelong in the rodent.

Figure 10-6 Schematic diagram of the origin of the specifically bound nuclear triiodothyronine (T3) in various rat tissues. Data are derived from studies in which double-isotope labeling techniques were used to estimate the sources of specifically bound nuclear T3. In tissues having a receptor saturation significantly greater than 50%, the additional T3 is provided by D2-catalyzed T4 to T3 conversion. T3 in rat plasma is derived from thyroid secretion (40%) with the remainder from D1-and D2-catalyzed T4 to T3 conversion. BAT, brown adipose tissue; PIT, pituitary gland.
Physiologic, Pathologic, and Pharmacologic Influences on Thyroid Hormone Deiodination

There are a number of circumstances in which thyroid hormone activation is either inhibited or the degradation of thyroid hormone is accelerated via deiodination pathways. There are several categories: (1) physiologic, (2) pathologic, and (3) pharmacologic (Table 10-6).

Physiologic Influences

Physiologic activation of T₄ to T₃, particularly by D1, is impaired during fetal life. In experimental animals, however, D3 activity is increased in the fetus, particularly in the skin and in other tissues as well, contributing to a reduced serum T₃ level in the fetal state. In contrast, D2 action is sufficient to provide intracellular T₃ in those tissues, such as the brain, where thyroid hormone is absolutely required for normal development.

Careful chronic activation of D2 or D3 has been demonstrated in several animal models. These include a short-lived burst of D2 activity in the cochlea of the newborn mouse and the increased D3 activity in the retina during metamorphosis in the tadpole. Similar, although not yet documented, events may occur in humans.

Pathologic Influences

Alterations in iodothyronine deiodination occur during fasting and illness. This group of conditions is associated with a marked decrease in T₃, elevated serum rT₃ levels, and a decrease in T₃ clearance. These changes in thyroid hormone metabolism probably reflect both decreased T₄ transport and D1 and D2 actions. Tumor necrosis factor- (TNF-) and interleukin-1 decrease D1 expression in isolated hepatocytes, and TNF- decreases D2 expression in human skeletal muscle cells. TNF and IL might be playing a role in the fasting or illness-induced reductions in T₃ activation. These events are part of the global response that reduces plasma T₃ during illness (see "Thyroid Function during Fasting or Illness").

Selenium deficiency may be due to endemic deficiency (e.g., as in western China) or to the effects of protein-restricted diets. Because of the differential retention of selenium in various organs, selenium deficiency predominantly affects the liver and kidney, organs expressing D1. Under these circumstances, the serum T₄ level and the serum T₃/T₄ ratio are increased, a compensatory response to decreased T₃ production via the D1 pathway during this condition.

In Zaire, where both iodine and selenium are deficient, replenition of selenium prior to replenition of iodine led to a deterioration in overall thyroid function, presumably because of the acceleration of T₂ degradation by D1, and perhaps by D3, in the selenium-deficient subject. Hepatic dysfunction may reduce T₃ activation as a consequence of the decrease in D1-containing cells or because of the effects of the accompanying illness on deiodinase activity. Changes in deiodinase function with altered thyroid states have been reviewed in Table 10-4.

Pharmacologic Influences

A number of commonly used drugs have significant effects on thyroid hormone deiodination. PTU causes a dose-related inhibition of T₃ production, which is most readily seen in the thyrotoxic patient in whom T₄ to T₃ conversion via the D1 pathway is markedly increased. This inhibitory capacity is not shared by methimazole or carbimazole.

</table>

The antiarrhythmic drug amiodarone shares sufficient structural similarity with T₄ that it can inhibit deiodination of T₄ and rT₃ (Fig. 10-7). Patients receiving this agent develop a compensatory increase in plasma T₃ to maintain serum T₃ in the normal range. There is also a corresponding increase in TSH within the first weeks of therapy that gradually returns to normal as the thyroid axis reequilibrates. The T₃ and rT₃ MCRs are reduced by 20% to 25%, with a reduction in the fractional T₃ to T₄ conversion rate of about 50%. There is direct evidence of inhibition of D1 activity in rats given this agent, but no studies have examined its effects on D2. The mechanism is probably due to competitive inhibition either by the drug or by one of its metabolites, but inactivation of D1 and accelerated D2 degradation may also occur. Amiodarone also inhibits the active transport of T₄ and T₃ into hepatocytes, and the drug or one of its products may interfere with T₃ binding to
thyroid hormone receptors.

The effects of amiodarone resemble those observed with the iodoaniline derivatives formerly used for visualization of the gallbladder (see Fig. 10-7). Iopanoic or iopodic acid inhibits the deiodinases by competing with the iodothyronine substrates. This makes these agents useful in the acute treatment of patients with severe hyperthyroidism, in whom they cause a rapid decrease in T3.

High dosages of glucocorticoids (10 times replacement) acutely reduce the T3/T4 ratio in plasma, suggesting that T4 to T3 conversion is blocked. The rT3/T4 ratio increases, suggesting that D3 action is also increased. These effects resolve during chronic therapy such that thyroid function is little affected, and thyroid hormone requirements are not increased by chronic glucocorticoid therapy.

Figure 10-7 Comparison of the chemical structure of thyroxine (T4) with the structures of two agents that block the deiodination of the iodothyronines. The inhibition of T4 to triiodothyronine (T3) conversion, which occurs in patients receiving amiodarone, may be due to the drug itself or to a metabolic product. Iopanoic acid and related iodoanilines are competitive inhibitors of all three iodothyronine deiodinases.

Recombinant growth hormone increases circulating T3 and T4 levels and reduces rT3/T4 ratios. This result is also seen in patients with hypothyroidism who are receiving L-thyroxine, indicating it is a peripheral effect. In the chick, growth hormone reduces D3 activity, suggesting that a similar effect on this enzyme may be the explanation for its effect in humans; however, direct evidence is lacking.
Mechanism of Thyroid Hormone Action

Thyroid hormone acts by binding to a specific nuclear DNA-bound thyroid hormone receptor (TR), usually as a heterodimer with retinoid X receptor (RXR) at specific sequences (thyroid hormone response elements (TREs)) dictated by the DNA binding-site preferences of the RXR-TR complex. The general mechanism by which nuclear receptor-activating ligands, such as T3, produce their effects is discussed in Chapter 4.

T3 has a 15-fold higher binding affinity for TRs than does T4, which explains its function as the active thyroid hormone. In humans, two TR genes (and) are found on different chromosomes (TR on chromosome 17, TR on chromosome 3). Several alternatively spliced gene products from each of these genes form both active and inactive gene products. The active proteins are TR-1 and TRs 1, 2, and 3. The structure of the TRs conforms to a protein with three major functional domains, one binding DNA, one binding ligand, and two major transcriptional activation domains. These activation domains of the TRs and are similar to, but not identical with, the major differences in the amino-terminal portion of the molecule.

There are tissue-specific preferences in expression of the various TRs, suggesting that they subserve different functions in various tissues. In general, TR-2 is down-regulated in the thyroid gland, where regulation of thyroid function occurs. In addition to differences in the amino-terminus between TR-1 and 2, the two proteins are under the regulation of different promoters that can function in tissue-specific patterns.

TR-2 is down-regulated by T3, whereas TR-1 mRNA expression is not affected. TR-2 is also expressed in the cochlea. TR-1 is expressed in all tissues, although its mRNA is especially highly expressed in the kidney, liver, brain, and heart. TR-1 mRNA is also expressed in the brain and at lower levels in skeletal muscle, lungs, and heart. TR-3 mRNA is expressed at very low levels but is more abundant in the liver or kidneys and lungs in comparison with other tissues.

It is instructive to examine the effects of gene targeting of TR and TR in order to understand their different physiologic roles. A disruption of the TR gene (both TR-1 and 2) causes deafness, a marked reduction in feedback sensitivity of hypothalamic-pituitary-thyroid axis, and a decrease in hepatic D1. Thus, in these mice, both TSH and thyroid hormone levels are elevated. However, TSH levels are further increased if thyroid hormone levels are reduced, indicating a feedback suppression of TSH release, albeit attenuated by this genetic manipulation. Phenotypically, thyroid function in these mice resembles that in families with resistance to thyroid hormone (RTH) in which TR mutations markedly reduce its binding affinity for T3. Curiously, the clinical manifestations in these individuals may resemble thyrotoxicosis for reasons discussed in Chapter 12.

Despite evidence of impaired feedback regulation, there is relatively little abnormality in the brain and heart of the TR-deficient mice. The effect of a TR-1 disruption in the mouse is quite different. The predominant phenotypic effects are modest bradycardia and hypothermia. These animals have subtle but significant abnormalities in myocardial function and electrical activity and, despite the basal hypothyroidism, have normal responses to cold exposure.

These studies have led to the generalization that feedback regulation of thyroid hormone effects, along with cochlear development, are functions of TR, whereas cardiac functions and energy metabolism are probably regulated by TR. However, this is a generalized feature, and further experimental studies of these animals, as well as animals with specific mutations in the TR gene analogous to those in families with thyroid hormone resistance, are currently in progress. It is also likely that small differences in the ligand-binding domains of TR and TR will allow design of thyroid hormone analogues selective for one or the other of these receptors.

The binding of T3 to the TR-TRE complex of a gene positively regulated by T3 initiates a conformational change in the TR such that one or more repressors of transcription are dissociated from the receptor and replaced by coactivator proteins. Some of these coactivating proteins induce DNA acetylation, or histone acetyltransferase activity, making the neighboring thyroid hormoneregulated genes dissociate from nucleosomes and available for binding of the transcriptional initiation complex.

Another group of genes, as exemplified by those encoding the TSH subunit, the -glycoprotein subunit, and TRH, are negatively regulated by T3. Negative regulation by thyroid hormone is still poorly understood but may involve specific negative TREs located in the promoter or even the coding regions of target genes. In one scenario, the complexing of T3 with DNA-bound TRs recruits corepressors and histone deacetylases to these binding sites. An example of this mechanism is that regulating the subunit of TSH. In the absence of T3, a gene containing a TR bound to a negative TRE is activated by association of coactivator and histone acetylating activator proteins, which then dissociate as a result of T3. Other mechanisms of negative regulation by T3 have also been suggested, including TR trapping and sequestration of coactivators to prohibit positive regulation of these genes.

Other potential mechanisms of thyroid hormone action by interaction with the membrane are under investigation. The pivotal role of T3 in the activation of thyroid hormone-dependent genes indicates that T3 serves primarily as a prohormone. Because T3 down-regulates D2 and inactivates D1, however, it might be considered an active hormone in the sense that it negatively regulates its own activation.
addition, there is an inverse relationship between the glandular organic iodine level and the rate of hormone formation. Such autoregulatory mechanisms serve to stabilize the rate of hormone synthesis despite fluctuations in the availability of iodine. Stability in hormone production is achieved, in part, because the large intraglandular store of hormone buffers the effect of acute increases or decreases in hormone synthesis. Autoregulatory mechanisms within the gland, in turn, tend to maintain the constancy of the thyroid hormone pool.

Finally, the hypothalamic-pituitary feedback mechanism senses variations in the availability of free thyroid hormones, however small, and acts to correct them. There is a close relationship between the hypothalamus, the anterior pituitary gland, the thyroid gland, and still higher centers in the brain, with the function of the entire complex being modified in a typical negative-feedback manner by the availability of the thyroid hormones. Additional hormones and neuropeptides also influence this axis (see Chapter 7 and Chapter 8).

Thyrotropin-Releasing Hormone Synthesis and Secretion

TRH, a modified tripeptide (pyroglutamyl-histidyl-proline-amide), is derived from a large pre-pro-TRH molecule that contains five progenitor sequences. The TRH peptides are released from the pre-pro molecule by a peptidase that acts at flanking lysine/arginine residues. TRH is expressed in the hypothalamus, the brain, the C cells of the thyroid gland, the beta cells of the pancreas, the myocordium, the reproductive organs (including prostate and testes), and the spinal cord. The parvocellular region of the paraventricular nuclei of the hypothalamus is the source of the TRH that regulates TSH secretion. The 5'-flanking region of the gene encoding TRH has sequences for mediating responses to glucocorticoids and cAMP. In addition, at least two elements in this region of the gene can confer negative regulation of thyroid hormone receptor complexes.

TRH travels in the axons of the peptidergic neurons through the median eminence and is released close to the hypothalamic-pituitary portal plexus. The neuron bodies that produce TRH are innervated by catecholamine, neuroepitopeptide Y, and somatostatin-containing axons, all of which potentially influence the rate of synthesis of the pre-pro-TRH molecule.

A complex series of interactions with neuropeptides involving leptin, agouti-related peptide (AgRP), and melanocyte-stimulating hormone (-MSH) regulates pre-pro-TRH synthesis in the rat. The acute decrease in TRH synthesis that occurs in the starved rodent and leads to central hypothyroidism can be reversed by leptin infusion. Leptin directly increases pro-TRH biosynthesis in rat hypothalamic neurons, as does -MSH, whereas neuroepitopeptide Y and melanocortin-4 receptor (MC4R) suppress TRH synthesis as well. Thus, a fall in leptin, directly and indirectly, can reduce TRH synthesis.

Although leptin and -MSH can also activate the human TRH promoter through MC4R and the leptin receptor (ObRb), there is no acute reduction of TSH in fasted humans despite a decline in leptin levels. In humans, fasting causes a slight decrease in the amplitude of the pulsatile TSH release, which may be due to a decrease in TRH synthesis owing to reduced leptin. In addition, whereas a human leptin geneinactivating mutation causes morbid obesity and hypogonadism, it does not cause central hypothyroidism. Thus, current results suggest that the major role of leptin in regulating thyroid function in rodents in response to fasting is not shared by humans.

T3 suppresses the levels of pre-pro-TRH mRNA by T3 in the hypothalamus but normal feedback regulation of pre-pro-TRH mRNA synthesis by thyroid hormone requires a combination of T3 and T4 in the circulation, with the latter giving rise to T3 via T3 5'-deiodination in the CNS. In rats, there is a dense expression of D2 in the specialized ependymal cells (tanyocytes) in the inferior portion of the third ventricle. These cells have processes extending into the median eminence and arcuate nucleus, where active conversion of T3 to T3 releases T3 in the region of the hypothalamic-pituitary portal system. Thus, part of the negative feedback induced by T3 may be generated both indirectly at the level of the paraventricular nucleus by suppressing TRH and at the median eminence and arcuate nucleus at a point where neuropeptides and T3 enter the pituitary portal system.

TRH binds to a receptor in the thyrotroph membrane, and calcium and cyclic guanosine monophosphate (cGMP) are the second messengers for induction of the thyroid response. The calcium is derived from endoplasmic reticulum, owing to increases in inositol triphosphate (IP₃) secondary to G protein activation of PLC-C. Both phorbol ester and calcium ionophores can stimulate TSH gene transcription. In addition to inhibiting the synthesis of pre-pro-TRH mRNA, thyroid hormone also blocks the capacity of TRH to stimulate TSH release from the thyrotroph. The mechanism for this effect is unknown, but the stimulating effects of both phorbol esters and calcium ionophores are blocked by prior incubation with thyroid hormone.

Exogenous TRH elicits the secretion of prolactin at threshold doses that are the same as those for stimulation of TSH secretion. As with TSH, the prolactin response to TRH is modified by the prevailing levels of thyroid hormones, although not to as marked an extent. The role of TRH as a physiologic modulator of prolactin secretion is uncertain, however. For example, nursing increases the serum prolactin concentration, but the serum TSH concentration is unchanged.

TSH is the major regulator of the morphologic and functional states of the thyroid gland. It is a glycoprotein secreted by thyrotrophs in the anteromedial portion of the adenohypophysis composed of an subunit of 14 kd (92 amino acids) that is common to LH, follicle-stimulating hormone (FSH), and hCG as well as a specific subunit, a 112-amino acid protein synthesized in thyrotrophs. The peptide sequence cysteine-alanine-glycine-tyrosine-cysteine (CACYC) is highly conserved in the subunits of TSH, FSH, LH, and hCG and is required for heterodimerization with the subunit. An an

In normal thyrotrophs and in thyrotroph tumors, synthesis of the subunit is in excess, indicating that the quantity of the subunit is rate-limiting for TSH secretion. TRH
increases and thyroid hormone suppresses the transcription of both subunits; these are the most important influences on TSH synthesis.

The physiologic glycosylation of TSH involves addition of preformed asparagine-linked oligosaccharides in the rough endoplasmic reticulum, modifications in proximal and distal Golgi apparatus, and the appearance of the intact, folded hormone in the secretory granules. The glycosylation of the subunits protects them from intracellular degradation and permits normal folding of the protein chains so that internal disulfide linkages are correctly formed. Glycosylation is also required for full biologic activity, and sialylation protects circulating TSH from interaction with hepatic galactose receptors, thus increasing its half-life. The biologic activity of TSH in the serum of patients with pituitary tumors or hypothalamic disorders is inappropriately low compared with immunologic activity, suggesting the formation of an abnormal product. Long-term administration of TRH can enhance the biologic activity of TSH in patients with hypothalamic hypothyroidism and may lead to increased thyroid hormone levels, suggesting that this is due to TRH deficiency. Thus, in humans, TRH regulates not only TSH subunit synthesis but also post-translational processing.

Levels of subunit in serum range from 0.5 to 5 µg/L but are elevated in postmenopausal women. In normal serum, TSH is present at concentrations between 0.5 and 5 mUL. The level is increased in hypothyroidism and reduced in hyperthyroidism (see later). The plasma TSH half-life is about 30 minutes, and production rates in humans are 40 to 150 mU/day.

Circulating TSH displays two types of variations. Pulsatile variations are characterized by fluctuations at 1- to 2-hour intervals. The magnitude of TSH pulsations is decreased during fasting, illness, or after surgery. Circadian variations are characterized by a nocturnal surge that precedes the onset of sleep and appears to be independent of the cortisol rhythm and fluctuations in serum and in T4 and T3 concentrations. When the onset of sleep is delayed, the nocturnal TSH surge is enhanced and prolonged, and the early onset of sleep results in a surge of lesser magnitude and shorter duration.

The degree of thyroid hypofunction after destruction of the hypothalamus is less severe than that following hypophysectomy, and residual thyroid function in the former circumstance can be altered by raising or lowering the concentration of thyroid hormones in the blood. Thus, thyroid hormones mediate the feedback regulation of TSH secretion, and TRH determines its set-point. The relationship between circulating T4 and TSH and pituitary TSH release is illustrated in Fig. 10-10. The acute inhibition of TSH release by in vivo administration of physiologic quantities of T3 is mediated by the T3 produced by D2 in the pituitary gland (and perhaps the hypothalamus), since it is blocked by a general delodinase inhibitor, but not by PTU, the specific D1 inhibitor. A decrease in either plasma T3 or T4 causes an increase in TSH secretion because both T3 directly, and T4 via intrapituitary and intracerebral T3 to T4 conversion, contribute to T3 in the hypothalamus and pituitary gland (see Fig. 10-10). It follows that exogenous T3 is an effective suppressor of TSH secretion because (1) it is converted to plasma T3 and (2) it serves as the prohormone for T3 in the CNS and the pituitary gland. There is a linear relationship between the serum T3 concentration and the log of the TSH (Fig. 10-11). Thus, the serum T3 concentration is an exquisitely sensitive indicator of the thyroid state of most patients.

Somatostatin (SRIH, or somatotropin release-inhibiting hormone), acting through inhibitory G protein (Gi), decreases TSH secretion in vitro and in vivo, but prolonged treatment with a somatostatin analogue does not cause hypothyroidism. Similar acute effects occur during dopamine infusion and administration of bromocriptine, a dopamine agonist. Both of these agents inhibit adenylyl cyclase. Conversely, blockade of the dopamine receptor by metoclopramide increases the basal serum TSH concentration in both euthyroid and hypothyroid patients. These findings suggest that dopamine is a regulator of TSH secretion, indicating that compensatory mechanisms negate these acute effects. The neuroendocrine regulation of TSH secretion is detailed in Chapter 7.

A number of drugs or hormones can suppress TSH secretion (Table 10-7). Glucocorticoids given in high doses acutely suppress TSH secretion transiently, although prolonged therapy is not associated with central hypothyroidism. Patients with Cushing's disease have subnormal TSH production but with minimal effects on T4 production. Bexarotene, an RXR agonist used for treatment of T cell lymphoma, suppresses TSH sufficiently to cause central hypothyroidism, presumably by reducing TSH gene transcription.
Iodine Deficiency

The response of vertebrates to a deficiency of iodine is designed to conserve this limited resource and to improve the efficiency of its utilization. These adjustments occur at the hypothalamic, pituitary, thyroid, and peripheral tissue levels. Removal of iodine from the diet causes a rapid decrease in serum T\textsubscript{4} concentrations and a simultaneous increase in serum TSH. Interestingly, no detectable decrease in T\textsubscript{3} occurs, suggesting that the signal to increase TSH must derive from a decrease in the T\textsubscript{3} generated intracellularly from T\textsubscript{4} in the pituitary gland, the hypothalamus, or both. TSH increases NIS, Tg, and TPO synthesis and iodine organization and Tg turnover. Because of the decrease in iodide supply and in the DIT/MIT ratio, the T\textsubscript{4}/T\textsubscript{3} ratio in Tg decreases and the rate of thyroidal T\textsubscript{3} secretion is probably increased despite a decline in T\textsubscript{4} secretion.

TSH also stimulates cell division, leading to goiter. In the rat model, the fall in plasma T\textsubscript{4} increases D2 from fivefold to 20-fold in the CNS, hypothalamus, and pituitary gland, increasing the efficiency of T\textsubscript{4} conversion to T\textsubscript{3}. With moderately severe iodine deficiency, D3 in the CNS is also reduced, prolonging the mean residence time of T\textsubscript{3} in that organ. This permits serum T\textsubscript{3} to remain normal and the CNS T\textsubscript{3} to be only moderately reduced even with up to a 10-fold decrease in circulating T\textsubscript{4}.

Despite the TSH elevation and nearly undetectable serum T\textsubscript{4}, growth, oxygen (O\textsubscript{2}) consumption and thermal homeostasis can be maintained. In humans, these compensatory alterations in thyroid function come into operation when total iodine intake falls below 75 µg/day. This situation obtains in many countries in Europe and South America as well as for several hundred million individuals in areas of iodine deficiency in China, India, Indonesia, and Africa.

These changes in serum hormones have been well documented in humans in areas of iodine deficiency and in patients with NIS mutations. The physiologic response to iodine deficiency is similar to that occurring during the development of primary hypothyroidism in humans. It is also reproduced when the efficiency of iodide trapping and organification is reduced in patients with Hashimoto’s disease or in patients with Graves’ disease receiving thiourea drugs. The physiologic rationale for this series of events is clear. T\textsubscript{3} has approximately three times the potency of the prohormone T\textsubscript{4} and contains only three iodine atoms. In terms of metabolic potency, this results in a fourfold more efficient use of iodine. Maintenance of normal circulating T\textsubscript{3} levels provides hormone for tissues in which nuclear T\textsubscript{3} is completely derived from the plasma.
Besides being protected against iodine deficiency, the thyroid gland is protected against an excess of iodine that might otherwise lead to hyperthyroidism. As with the response to iodine deficiency, there are multiple levels of defense against this eventuality. The usual source of excess iodine is pharmaceutical, with angiographic dyes, amiodarone, and povidone-iodine the most common sources (Table 10-8).

Effects of Increased Iodine Intake on Thyroid Hormone Synthesis

The quantity of iodine undergoing organification displays a biphasic response to increasing doses of iodide, at first increasing and then decreasing as a result of a relative blockade of organic binding. This decreasing yield of organic iodine from increasing doses of iodide (the Wolff-Chaikoff effect) results from a high concentration of inorganic iodide within the thyroid cell. The susceptibility to the Wolff-Chaikoff effect can be increased by (1) stimulation of the iodide-trapping mechanism (as in patients with Graves' disease) or during persistent TSH stimulation or (2) in patients with impairment of iodine organification, as may occur during thiourea drug treatment, in Hashimoto's disease, or in thyroid glands previously irradiated by either $^{131}$I or external beam therapy (e.g., for Hodgkin's disease).

In such situations, goiter and hypothyroidism can develop if excess iodide is given for long periods. The mechanism for inhibition of organification may involve the effects of high iodide concentrations on TPO-catalyzed organifications as well as a consequence of the formation of one or more inhibitory iodolipids in the thyroid cells.

Consequently, thyroidal iodide falls to levels insufficient to maintain the full Wolff-Chaikoff effect. This adaptation prevents the development of hypothyroidism, iodide goiter, or myxedema. Of note, it does not occur in the third trimester fetus; thus, chronic high iodine intake during pregnancy must be avoided because it causes fetal hypothyroidism and compensatory, obstructive goiter (Fig. 10-13).

Effects on Thyroid Hormone Release

An important practical effect of pharmacologic doses of iodine is the prompt inhibition of thyroid hormone release. Iodine decreases not only the fractional turnover of thyroidal iodide but also the $T_4$ secretion rate. This effect is the mechanism by which iodine rapidly lowers the serum $T_4$ concentration in patients with diffuse toxic goiter or toxic nodules (see Chapter 11). The mechanism by which iodide inhibits secretion of thyroid hormones is unknown, but the effect is mediated at the thyroid cell level rather than through an action on TSH. Iodine also diminishes the hypervascularity and hyperplasia that characterize the diffuse toxic goiter of Graves' disease. This effect facilitates surgical therapy for the disorder.
Thyroid Function in Pregnancy and in the Fetus and Newborn

Pregnancy affects virtually all aspects of thyroid hormone economy (Table 10-9). Total serum T₄ and T₃ concentrations rise to levels twice those of nonpregnant women owing to the increase in TBG concentration in the first trimester (Fig. 10-14). Free T₄ and T₃ levels also increase slightly during the first trimester but return to normal by about 20 weeks of gestation and remain so until delivery. This increase is due to hCG, which is a weak agonist for the TSH receptor. The slight decrease in serum TSH during the first trimester indicates that the free T₄ and T₃ changes are not dependent on the hypothalamic-pituitary axis. This decrease in serum TSH is all the more surprising, since it coincides with a number of events that act to increase maternal requirements for thyroid hormone.

In addition to an increase in serum TBG, there is also an increased plasma volume as well as accelerated inactivation of T₄ and T₃ by D3 expression in placenta and, perhaps, in the uterus as well. On the basis of changes in requirements for T₃ during gestation in women with primary hypothyroidism, the estimated increase in T₃ production required during this period is approximately 50%.

During pregnancy, the requirement for increased T₄ production increases iodine requirements. This need is compounded by the fact that the increased glomerular filtration rate during pregnancy enhances renal iodide clearance, leading to higher fractional urinary excretion of circulating iodide. In addition, maternal iodine intake must be increased to supply the iodide requirements of the fetal thyroid gland during the second and third trimesters (see Table 10-9). If these increased requirements for iodide are not met, serum T₄ levels fall, TSH levels rise, and goiter ensues. This series of events is well documented in areas of endemic iodine deficiency or a borderline iodine supply, such as in Brussels.

In that city, 70% of pregnant women carefully monitored throughout their pregnancy had a 20% or greater increase in thyroid volume during gestation. This contrasts with the lack of goiter during pregnancy in studies in North America. After delivery, the changes in thyroid hormone gradually return to normal, with serum TBG values reaching their normal levels 6 to 8 weeks post partum.

Pregnancy exerts a number of effects on the immune system. These changes may have striking effects on the natural history of patients with autoimmune thyroid disease, including both Graves' disease and Hashimoto's thyroiditis. In general, thyroid stimulation in women with Graves' disease is exacerbated during the first trimester but then is reduced gradually during the second and third, only to exacerbate again in the first several months post partum. Other than the increase in T₄ requirements in hypothyroid pregnant women, there is no evidence of a clinically significant change in patients with Hashimoto's disease during pregnancy, except that thyroid antibody levels fall. On the other hand, the marked rebound in the immune system occurring in the postpartum period leads to a phase of acute thyroid cell destruction, postpartum thyroid disease (PPTD), in about 30% of these patients (see Chapter 12). The basal metabolic rate (BMR) increases during the second trimester owing to the increase in the total mass of body tissue consequent to the pregnancy. The changes of pregnancy, together with the decreased peripheral vascular resistance, vasodilatation, and modest tachycardia, may suggest thyrotoxicosis (see Table 10-9). It is important that physicians remember that such changes are normal in pregnancy, especially when treating the hyperthyroid pregnant patient.

Fetal Thyroid Function

Fetal thyroid function begins at about the end of the first trimester. Thereafter, there are steady increases in fetal TBG and in total T₄ and T₃. Throughout gestation, serum TSH values are greater than are present in maternal circulation and higher than would be expected in adults with normal thyroid function. This indicates that there is increasing hypothalamic-pituitary resistance to T₄ during fetal development; it is speculated that this may be a consequence of increased TRH secretion.

Circulating T₄ levels remain relatively low, in contrast to the fetal free T₄ concentrations that approximate those in the maternal circulation from gestational age 28 weeks onward. This is explained primarily by the high D3 in fetal tissues, especially the liver.
Maternal-Fetal Interactions

The fetal pituitary-thyroid axis functions as a unit that is essentially independent of the mother. Transplacental passage of TSH from mother to fetus is negligible, but the same is not true of maternal T₄. In infants with congenital hypothyroidism caused by either TPO deficiency or athyreosis, serum concentrations of T₄ in umbilical cord blood are usually one third to one half of normal.

Thus, at least when the maternal-fetal concentration gradient is high, significant transfer of T₄ to the fetal circulation occurs. This transfer may be significant, given the capacity of the fetal brain to increase the efficiency of T₄ to T₃ conversion. Furthermore, T₄ can be found in coelomic and amniotic fluids prior to the onset of thyroid function.

The major factor limiting T₄ and T₃ transport from mother to fetus is the D3 expressed in the placenta. Blocking D3 activity in a perfused human placental lobule markedly increases the quantity of T₄ crossing into the equivalent of the fetal circulation. Placental D3 activity is present throughout gestation, although its activity, expressed per milligram of placental protein, decreases. Nonetheless, the increase in placental size results in progressive increases in total D3 content throughout gestation. This can account, at least in part, for the sudden decrease in maternal -thyroxine requirements that occurs immediately upon delivery.

Thyroid Function in the Newborn

Mean total T₄ levels in cord sera are 150 nmol/L (12 µg/dL). Serum TBG concentrations are elevated, but not as high as in the maternal serum. At term, free T₄ concentrations are slightly lower than those in the mother. Cord serum T₃ concentrations are low (0.8 × 10⁻⁹ M, 50 ng/dL), and rT₃ and T₃, S are elevated. After delivery, the neonate’s serum TSH level increases rapidly to a peak at 30 minutes of extrauterine life, returning to its initial value within 48 hours. This neonatal TSH surge is thought to occur in response to marked reduction in environmental temperature after delivery. Serum T₄, T₃, and Tg concentrations increase rapidly during the first few hours after delivery and are in the hyperthyroid range by 24 hours of life. The TSH surge doubtless contributes to the increase in serum T₃ concentration, but enhancement of extrathyroidal conversion of T₄ to T₃ by D1 or D2 is thought to be a major factor as well. The adrenergic stimulation of D2 in brown adipose tissue may also contribute to the increase in serum T₃.

Serum T₃ concentrations increase during the first 24 hours of postnatal life as a result of the increased T₄ but decrease to normal values by the fifth postnatal day. By the 10th day or so, the serum T₄ and T₃ concentrations are lower but still exceed normal adult values. Serum T₄ levels are slightly higher in the first year of life but gradually fall to the normal adult range.

Premature infants have an immature hypothalamic-pituitary-thyroid axis with low levels of T₄, T₃, and TSH. Serum T₄, TBG, and free T₄ all tend to correlate with gestational age. Preterm infants do have a TSH surge after delivery, but this is attenuated relative to that of full-term infants. In addition, when prematurity is accompanied by complications, such as respiratory distress syndrome or nutritional problems, serum T₄, and especially T₃, may fall to low levels because of a combination of reduced TBG production, immaturity of the thyroid gland, and suppression of the hypothalamic-pituitary axis owing to illness. These changes are, in many respects, similar to those in adults who are severely ill. The physician must take all of these issues into account when evaluating the thyroid status of the preterm infant, particularly given the increased prevalence of congenital hypothyroidism in this age group.

Thyroid hormone production rates are higher per unit of body weight in neonatal infants and children than in adults. The daily -thyroxine requirement is about 10 µg/kg in the newborn, decreasing to about 1.6 µg/kg in the adult.
Aging and the Thyroid Gland

Reproducible thyroid function abnormalities are observed in aging patients. In the healthy patient, there is a normal free T₄ but a relatively lower serum TSH than in younger individuals. In addition, although some disagree, it appears that serum T₃ levels decline, especially in individuals older than age 100 years. The serum T₃/T₄ ratio also tends to be reduced in individuals in their eighth and ninth decades; in addition, the daily secretion rate of TSH is reduced.

Although these changes resemble those occurring in patients who are ill, serum rT₃ concentrations are not nearly as elevated as they are in hospitalized individuals, and whether the reductions in serum T₃ are pathologic or physiologic is still unclear. A decreased requirement of about 20% for thyroid hormone replacement in the hypothyroid elderly becomes apparent in the eighth decade.
Thyroid Function during Fasting or Illness

A number of changes may take place in thyroid function during nutritional deprivation or illness. The changes that are induced in these two conditions are similar and, therefore, are best discussed in concert. Many of the changes involve alterations in thyroid hormone metabolism and are alluded to in that discussion.

Effects of Nutritional Deprivation

Both short-term and long-term alterations in nutritional state affect various aspects of thyroid hormone economy, especially peripheral hormone metabolism, as previously discussed. When euthyroid lean or obese subjects are starved, the serum total and free T₃ levels decrease to subnormal levels. In general, the serum total and free T₃ concentration remains essentially unchanged, or total T₄ may decrease slightly because of a modest decrease in iodothyronine-binding proteins. As serum T₃ concentrations decrease, concentrations of rT₃ increase reciprocally, usually to values about twice normal, not because of a major increase in the production of rT₃, but because of a decrease in its clearance. The abnormal T₃ and rT₃ concentrations in serum are quickly restored to normal by administration of small quantities (200 kcal) of carbohydrate. Similar quantities of protein have no effect on the serum T₃ level but may lower the serum rT₃ level. Calories given as fat are ineffective.

Despite the decrease in free T₃ concentration with starvation, the basal serum TSH and the free T₄ concentration and its response to TRH infusion are essentially unchanged. This occurs despite a decrease in leptin, suggesting that this hormone is less crucial in maintaining TRH production in humans than in rats despite its positive stimulation of the human TRH promoter.

Basal oxygen consumption and heart rate decline, nitrogen balance returns toward normal, and peripheral steroid metabolism shifts toward the pattern seen in hypothyroidism. In some, but not all studies, these changes are partially reversed by administration of exogenous T₃ while fasting continues. The decrease in T₃ during fasting is viewed by many as a beneficial energy-sparing and nitrogen-sparing adaptation.

Chronic malnutrition, as in protein-calorie malnutrition and anorexia nervosa, is also associated with a decreased serum T₂ concentration. Serum T₆ levels also tend to be slightly decreased, but serum TSH concentrations and their response to exogenous TRH are usually normal. In contrast, overfeeding, particularly with carbohydrate, increases T₃ production rate, increases the serum T₃ level, lowers the serum rT₃ concentration, and increases basal thermogenesis.

Effects of Illness

The changes in circulating thyroid hormones in illness resemble those during fasting, except that they may be much more severe. In addition, in the severely ill patient, there is often a suppression of the pituitary hormone release, which is either endogenous, because of loss of hypothalamic input, or worsened by some agents, such as dopamine and glucocorticoids, often given to very ill patients. This condition has come to be called the euthyroid sick syndrome, nonthyroid illness, or the low T₃ syndrome. These terms refer to the global pattern of changes in thyroid physiology that occur during illness.

The changes in thyroid function are a continuum, with the abnormalities becoming progressively more severe in accordance with the patient’s clinical condition. The disruption in thyroid function in sick patients can be arbitrarily divided into three stages (Table 10-10):

<table>
<thead>

</tr>
</tbody>
</table>

In addition to the central changes in TSH regulation and the abnormalities in peripheral hormone metabolism, patients may also have abnormalities in thyroid function that may be attributed to changes in the circulating binding proteins and, especially in the case of sepsis, those caused by the marked reduction the TBG affinity due to the serpin cleavage of the carboxy-terminal fragment of TBG. In addition to these endogenous changes, the TSH-suppressive effects of therapeutic agents (e.g., dopamine, dobutamine, glucocorticoids) on the central thyroid axis may complicate and exacerbate the abnormality. Illness and surgery decrease the nocturnal pulsatile TSH surge, presumably by reducing TRH release.

After the initial recognition of this syndrome, a large number of studies were performed using the starved rat as a model. As we have come to recognize, thyroid physiology in the rat, especially during fasting, differs from that in humans. Therefore, many of the studies pointing to an effect of illness or starvation to impair D₁ activity, either through reductions in D₁ or a D₁ cofactor, may have limited applicability in humans. In addition, the role of leptin appears to be much more important in maintaining TRH synthesis in rodents than in humans. Patients with severe illness have high leptin levels despite suppression of the central hypothalamic-pituitary-thyroid axis. In humans, rT₃ production remains normal as long as TSH secretion is maintained. Therefore, the elevation in rT₃ indicates an impairment of its clearance and rT₃ uptake into D₁-expressing tissues is impaired during illness or fasting. This decreased transport is due either to ATP depletion or, perhaps, to substances that compete with rT₃ for cellular entry.

Because the serum T₃ can fall to undetectable levels during illness, it seems likely that all three pathways for T₃ production, TSH secretion and T₄ outer ring deiodination by D₁ and D₂, may be reduced. Again, it is not certain whether abnormalities, particularly in D₂, are a result of (1) decreased enzyme levels (e.g., as in skeletal muscle induced by TNF-α) (2) decreased uptake into the slowly equilibrating D₂-containing tissue pool, or (3) a reduction in D₂ due to accelerated proteolysis of this enzyme via the ubiquitin-proteasome pathway. T₃ uptake into rapidly equilibrating pools, such as those in the liver and kidney, is also reduced during fasting or...
in illness.

Although serum TSH concentrations in severely ill patients are reduced, an increase in TSH above the normal range may appear during recovery, with the elevation in TSH concentration persisting until circulating free T4 and T3 levels return to normal. This pattern can be confusing if the elevated TSH concentration is associated with the still-reduced concentrations of free T4. Such patients meet all laboratory criteria for primary hypothyroidism with the exception of the clinical context. Follow-up generally reveals a normalization of TSH and T4 within 1 to 2 months.

Despite the severity of the abnormalities, particularly in serum T3, it is still debatable whether therapeutic intervention should be initiated even in the most severely ill patients. This is because most controlled studies have not shown beneficial effects of T4 or T3 supplementation in such individuals. The one exception is the possible beneficial effect of T3 therapy in patients after coronary artery bypass grafting; one study showed a positive effect but a second showed no beneficial effect.

A promising alternative strategy has been initiated in a series of studies of patients with prolonged critical illness. In an attempt to correct the inappropriate catabolism and failure of fat mobilization of prolonged critical illness, infusions of GH-releasing peptide-2 (GHRP-2) and TRH have been given for 5-day periods in a randomized fashion. Increases in TSH, T3, and T4 (as well as in IGF-I) insulin and IGF-binding proteins 1, 3, and 5 and leptin occurred and were associated with positive effects on osteocalcin, and decreases in the urinary/urea creatinine ratio.

These results suggested that restoration of somatotroph and thyrotroph function simultaneously by replacement of deficient neuroendocrine peptides had significant beneficial effects on the disordered metabolism of severe chronic illness that cannot be achieved by isolated and supraphysiologic replacement of either thyroid hormone or growth hormone alone. Whether these encouraging results will be associated with an improved outcome remains to be demonstrated, but the results suggest that in prolonged critical illness the central hypothyroidism is not beneficial.

The Thyroid Axis and Neuropsychiatric Illness

Patients with neuropsychiatric disease can present with any of a number of abnormalities in thyroid function. Patients with bipolar disorders may show slight elevations in serum TSH and reductions in free T4, whereas patients with severe depression have slightly elevated serum T4 and reduced serum TSH levels. Other acutely psychotic patients may have either high or low serum TSH concentrations and tend to have elevated free T4 levels.

The etiologic mechanism of these minor abnormalities is not clear, but the thyroid function test results of such patients may resemble the results of those with primary thyroid disease and must be differentiated from these.
Hormonal Effects on Thyroid Function

Glucocorticoids

The acute administration of pharmacologic doses of glucocorticoid eliminates pulsatile release of serum TSH concentrations in normal patients, presumably by reducing TRH release. With continued administration, there is an escape from this suppression (Table 10-11). Pharmacologic doses of glucocorticoid decrease serum T₃ concentration in normal and hyperthyroid patients as well as in hypothyroid patients maintained on L-thyroxine. The latter finding and the accompanying increase in rT₃ production suggest that glucocorticoids increase D₃ activity. The decreases in TBG and TTR have only modest effects on total T₄ concentrations.

Primary adrenal insufficiency may be associated with reduced serum T₄ and elevated serum TSH concentrations, suggesting the coexistence of primary hypothyroidism. However, treatment of the adrenal insufficiency can lead to complete resolution of the abnormalities in thyroid function, suggesting that in some patients they are a consequence of glucocorticoid deficiency rather than primary thyroid disease. Nevertheless, the prevalence of primary hypothyroidism is increased in patients with autoimmune hypoadrenalism, so the two causes must be differentiated (see Chapter 37). Similarly, thyroid autoimmunity can develop in patients successfully treated for Cushing's disease.

Gonadal Steroids

Estrogen increases TBG sialylation and half-life in serum. Estrogen administration to postmenopausal women causes an increase of 15% to 20% in TSH. Presumably, this increases T₄ secretion, since total T₄ increases and free T₄ is unchanged. It is not certain whether this is a transient or persisting phenomenon. Estrogen also increases the L-thyroxine requirement in patients with primary hypothyroidism. Again, the cause of this change is unclear.

Growth Hormone

Growth hormone increases the serum free T₃ and decreases free T₄ in both L-thyroxine-treated and normal individuals, suggesting either suppression of D₃ activity or increased T₄ to T₃ conversion. This change would reduce requirements for L-thyroxine in patients receiving exogenous hormone.

LABORATORY ASSESSMENT OF THYROID STATUS

In considering the laboratory assessment of the patient with known or suspected thyroid disease, the physician should seek to arrive at both functional and anatomic diagnoses. Laboratory determinations will confirm whether there is an excess, normal, or an insufficient supply of thyroid hormone to verify the inferences from the clinical history and physical examination. The second is to ascertain the presence or absence of anatomic abnormalities in the thyroid gland itself.

Laboratory evaluation can be divided into five major categories:

1. Tests that assess the state of the hypothalamic-pituitary-thyroid axis.
2. Estimates of the free $T_3$ or $T_4$ concentrations in the serum.
3. Tests that reflect the impact of thyroid hormone on tissues.
4. Tests for evidence of the presence of autoimmune thyroid disease.
5. Tests that provide information about thyroidal iodine metabolism.

Techniques for evaluation of anatomic abnormalities of the thyroid gland (thyroid ultrasound) and thyroid isotopic scanning are covered in Chapter 13.

Tests of the Hypothalamic-Pituitary-Thyroid Axis

Thyrotropin

While they are an inherently indirect reflection of thyroid hormone supply, tests that assess the state of the hypothalamic-pituitary-thyroid axis play a critical role in the diagnosis of thyroid disease. This is because the rate of TSH secretion is exquisitely sensitive to plasma concentrations of free thyroid hormones, thus providing a precise and specific barometer of the patient's thyroid status (see Fig. 10-11). Exceptions to this rule do occur (see later) but are rare. For example, the feedback of TSH secretion in premature infants and children is less sensitive to free $T_4$ than is that of the adult, probably due to higher TRH secretion rates.

Immunometric assay technology now makes it possible to define the normal range for serum TSH and, hence, to ascertain (1) when thyroid function is inadequate and (2) when the hormone supply is excessive. This assay uses the TSH molecule as a link between a TSH antibody bound to an inert surface (e.g., particles, the side of a test tube) and a second antibody directed against a different TSH epitope that is labeled with a detectable marker (e.g., an enzyme, or a chemiluminescent reagent) (see Chapter 6). Thus, the signal generated is proportional to the concentration of TSH in the serum. This technique is more specific, sensitive, and rapid than radioimmunoassay.

The normal range of serum TSH concentration varies slightly in different laboratories but is most commonly 0.5 to 5 mU/L or 0.3 to 4.0 mU/L, depending on the TSH reference preparation and assay used. Not all immunometric TSH assays are equally sensitive and specific. A useful functional categorization is in terms of the minimal detectable TSH that can be quantified with a less than 20% coefficient of variation.

The term generation has been employed to categorize each assay with respect to its sensitivity. Each successive generation offers about a 10-fold improvement in sensitivity (Fig. 10-15). The first generation (TSH radioimmunoassay) has lower limits of detectability of approximately 1 mU/L, whereas the third generation assay has minimal detectable limits of about 0.004 mU/L. A minimally suitable TSH assay should be able to quantitate concentrations of TSH of 0.1 mU/L with a coefficient of variation of less than 20%, thus falling into the second-generation or third-generation category.

An artifically elevated result may be obtained using the immunometric technique with serum containing heterophilic antimouse immunoglobulin G antibodies (HAMA). Such antibodies may substitute for TSH and cause falsely high values.

In patients with hyperthyroidism (excess thyroid hormone secretion) and/or thyrotoxicosis (excess thyroid hormone from any cause), the TSH level is virtually always suppressed. The values fall into two general categories: (1) when the lower limit of normal and 0.1 mU/L and (2) less than 0.1 mU/L. Individuals in the former category are usually really asymptomatic (subclinical hyperthyroidism), whereas those in the latter category almost invariably have symptomatic thyrotoxicosis and a significant elevation in free $T_4$.

Patients with hypothyamic or pituitary hypothyroidism typically have normal, not suppressed, serum TSH level, and sometimes the TSH is even slightly elevated. In the latter case, the circulating TSH generally has reduced biologic activity because of abnormal glycosylation reflecting the disordered hypothalamic-pituitary relationship. Patients with primary hypothyroidism have serum TSH concentrations that range from minimally elevated to 1000 mU/L.

In general, the degree of TSH elevation correlates with the clinical severity. Patients with serum TSH values in the range of 6 to 15 mU/L have few, if any, symptoms and the serum free $T_3$ or free $T_4$ index (FT$_4$) or FT$_3$ index may be low-normal or even slightly reduced. Serum free $T_4$ concentrations are typically normal. Such findings indicate early thyroidal decompensation with a compensatory increase in TSH secretion. A detailed discussion of the various conditions associated with abnormal serum TSH concentrations follows a description of the quantitation of serum thyroid hormones.
Thyrotropin-Releasing Hormone Stimulation Test

The availability of sensitive TSH assays has virtually eliminated the need for the TRH test except in rare circumstances. If a reliable immunometric TSH assay is not available, a TRH infusion test may be performed. The extent of increased serum TSH concentration after TRH administration correlates well with the basal serum TSH concentration. Exogenous TRH thus acts as an amplifier to exaggerate any underlying abnormality in TSH secretion.

A dose of 200 to 400 µg is administered as a single intravenous (IV) infusion over 5 minutes. In normal individuals, the serum TSH concentration rises rapidly, reaches a peak in 20 to 30 minutes, and returns to basal values in 2 or 3 hours. In practice, specimens for TSH analysis need be drawn only just before and 30 minutes after TRH administration. Normal increments range between 5 and 30 mIU/L and average about 12 mIU/L. Responses to TRH are decreased by pharmacologic glucocorticoid treatment, levodopa, dopamine infusions, somatostatin or dopamine analogues, and responses are augmented by the dopaminergic antagonists metoclopramide and domperidone.

The negative feedback inhibition of basal TSH secretion or TRH-induced TSH release is so exquisitely sensitive that doses of exogenous hormone insufficient to increase the serum T₄ or T₃ concentrations above the normal range nonetheless decrease the TSH response to TRH. Conversely, small decreases in serum T₄ concentrations cause increased basal serum TSH concentrations and an increased response to TRH. Thus, an elevation in both serum TSH and free T₄ indicates (1) a TSH-producing pituitary tumor, (2) RTH (resistance to thyroid hormone), or (3) hyperthyroidism with an artifactual increase in TSH. TRH does not increase the artifactually elevated TSH but usually increases that in patients with RTH. The TRH response of thyrotroph tumors is variable.

A differentiation between hypothalamic and pituitary causes of central hypothyroidism by TRH testing is not possible. Other diagnostic modalities such as magnetic resonance imaging (MRI) are required for a definitive evaluation of such patients (see Chapter 8).
Quantification of Serum Thyroid Hormone Concentrations

Total Thyroxine and Triiodothyronine Levels

Quantitation of the circulating thyroid hormone concentration is essential to confirm that the thyroid status abnormality suggested by an abnormal TSH result is accurate and to document its severity. Sensitive and specific radioimmunoassays are available for measuring the total concentrations of \( T_4 \) and \( T_3 \) and some of their metabolic by-products. Because thyroid status correlates with free rather than total hormone concentration, the physician must also estimate the free hormone concentration.

by measuring it directly, or by measuring it indirectly (as in a free hormone index), or by measuring the concentration of TBG, the major carrier protein for \( T_4 \) and \( T_3 \) in human plasma.

The degree of abnormality in the free \( T_4 \) level generally correlates with the severity of the hormone excess or deficiency, whereas the serum TSH concentration indicates the impact of this abnormality in a specific patient. Total concentrations are measured in whole serum by immunoassays. Errors peculiar to tests for thyroid hormones result from competition for the labeled antigen between the specific antibody and the plasma-binding proteins unless binding of the hormone to these proteins is inhibited by one of various agents. Endogenous antibodies to \( T_4 \) or \( T_3 \) are present in rare patients and invalidate the assay (see Chapter 6).

The normal range for total \( T_4 \) in healthy, euthyroid adults with a normal circulating TBG concentration is 64 to 142 nmol/L (5 to 11 µg/dL). Normal serum \( T_3 \) concentrations are 1.1 to 2.9 nmol/L (70 to 190 ng/dL). At birth (cord serum), \( T_3 \) concentrations are about 50% of those in normal adults, but within a few hours this number rises abruptly, peaking at about 24 hours at concentrations in the low thyrotoxic range for adults. The \( T_3 \) concentration gradually decreases during the first few weeks of life but remains about 25% higher than values in adults through early adolescence. Serum \( T_3 \) values may decrease with age even in healthy individuals.

Radioimmunoassays for \( rT_4 \), \( T_3 \), triac, tetrac, and the di-o-dothyronines are of primary interest in the research setting because these iodothyronines are derived from the circulating \( T_4 \) or \( T_3 \), both of which can be easily quantitated. An exception may be compound W, an as-yet-unidentified product of \( T_3 \) metabolism in the fetal circulation that appears in maternal sera. If this is indeed the case, measurements of compound W may serve as a much needed index of the state of fetal thyroid function to monitor the effects of maternal antithyroid drug therapy on fetal thyroid function.

Free Thyroxine and Free Triiodothyronine

The most accurate and direct measurements of the concentrations of free \( T_4 \) and free \( T_3 \) in serum are obtained by assay of these hormones in a dialysate or ultrafiltrate of serum. Alternatively, serum can be enriched with tracer amounts of the labeled hormone, and the concentration of the isotope in the dialysate or ultrafiltrate is expressed as a fraction of that in undiluted serum. The absolute concentration of free hormone is the product of the total hormone concentration and the fraction that is dialyzable. As mentioned, about 0.02% of \( T_4 \) and 0.3% of \( T_3 \) are free (see Table 10-5). The normal ranges for free \( T_4 \) are 9 to 30 pmol/L (0.7 to 2.5 ng/dL); for free \( T_3 \), 5 to 8 pmol/L (0.2 to 0.5 ng/dL).

Because \( T_3 \) is the major secretory product of the thyroid gland and correlates most closely with the serum TSH, in most situations a free \( T_3 \) estimate is all that is required to ascertain the state of thyroid secretion or supply. A bewildering array of methods exist to quantify free \( T_4 \) or \( T_3 \) in whole serum that involve automation. Although many automated tests are said to be able to measure free \( T_4 \) directly, they do not; it appears that results in sera with abnormal binding proteins are not accurate (see Chapter 6).

There are two general categories of methods: (1) comparative free \( T_4 \) methods and (2) so-called free \( T_3 \) index methods.

Three general approaches are used:

- Two-step labeled hormone methods
- One-step labeled analogue methods
- Labeled antibody approaches

In general, two-step labeled hormone back-titration methods, compared with one-step analogue methods, are less subject to artifacts caused by abnormal binding proteins, changes in albumin and TBG, or increases in free fatty acids. Both methods are now being replaced by those designed to quantify the unoccupied TBG-binding sites. Although these methods are usually satisfactory in ambulatory patients with uncomplicated thyroid disorders, all general approaches may be subject to artifacts from endogenous antibodies to \( T_3 \), abnormal binding proteins, or illness. Thus, the clinician must be wary if the \( T_4 \) result by any method does not agree with the clinical state and the TSH. In such cases, another method should be used to estimate the free \( T_4 \) (e.g., quantitation of \( T_4 \) in a dialysate or ultrafiltrate), the free \( T_3 \) index should be measured, or the result should be ignored.

Free Thyroxine Index

Another means of partially circumventing the technical difficulties inherent in direct estimates of free \( T_4 \) concentrations is to determine the thyroid hormone-binding ratio (THBR) and to multiply this result by the total \( T_4 \) or \( T_3 \) concentration to estimate the free thyroid hormone concentration, termed the FT4 I or the FT3 I. Because the normal THBR is 1.0, the FT4 I has a normal range in units identical to that of THBR.

Because the THBR is proportional to the free fraction of the endogenous thyroid hormones in serum, it can be multiplied by the total \( T_4 \) or \( T_3 \) concentration to estimate the free thyroid hormone concentration, termed the FT4 I or the FT3 I. Because the normal THBR is 1.0, the FT4 I has a normal range in units identical to that
of the total T₄, or T₃ (e.g., 64 to 142 for SI units and 5 to 11 in gravimetric terms). A schematic demonstration of the relationships between total and free T₄, occupied and unoccupied TBG-binding sites, and the THBR is shown in Figure 10-16 for euthyroid individuals with variations in TBG concentrations and in Figure 10-17 for subjects with a constant TBG and alterations in serum thyroid hormone production rates.

Estrogen, pregnancy, and severe illness, compared with hyperthyroidism and hypothyroidism, are more common causes of changes in total T₄ concentrations (Table 10-12). In the euthyroid person, only about one third of the available binding sites on TBG are occupied by T₄, and the free T₄ fraction is 2 times 10⁻⁴ of the total. During pregnancy, the TBG-binding capacity, serum T₄, and the number of unoccupied TBG binding sites almost double, leading to almost a 50% reduction of the free T₄ fraction. This is reflected in a reduced THBR. If

![Figure 10-16 Pattern of changes in total serum thyroxine (T₄) concentrations and thyroid hormone-binding ratio (THBR) in euthyroid patients with alterations in circulating concentrations of thyroxine-binding globulin (TBG). To convert T₄ from nmol/L, to µg/dL (total) or pmol/L (free), divide by 12.87.](image)

...Continued...

The THBR is linearly related to the free fraction of thyroid hormones except at the extremes of its range. To derive the maximum information, therefore, it is important to consider both the calculated FT₄ and the pattern of the deviations of total hormone and THBR from normal. When concentrations of binding proteins are altered, the deviation of the total T₄ measurements from normal is in the opposite direction to that of the THBR (see Fig. 10-16, central panels). In this circumstance, one should be suspicious that an alteration in TBG, rather than an alteration in thyroid hormone production, is responsible for the abnormality in the total thyroid hormone level. However, when an elevated T₄ level is due to increased T₄ secretion or exogenous sources, the concentration of unoccupied TBG-binding sites is reduced and both the free fraction and the THBR are increased. Therefore, the free T₄ and the FT₄ are increased in parallel and to a greater extent than would be suggested from the change in the total hormone level.

The changes in hypothyroidism are in the opposite direction but of lower magnitude. The concentration of unoccupied TBG-binding sites does not increase greatly when the serum T₄ level decreases from a normal mean of 100 nmol/L to 30 nmol/L, and the decrease in the free T₄ fraction and the THBR are not large. Thus, the reduced FT₄ is hypothyroidism is due predominantly to the decrease in T₄ rather than to a decrease in its free fraction. The central panels in Figure 10-17 show the parallel deviations from normal hormone levels and THBR when the thyroid hormone supply is altered.

Simultaneous abnormalities in both TBG and thyroid hormone production may also occur. Hyperthyroidism should be suspected during pregnancy when the T₄ concentration is very high and the THBR is not subnormal. Similarly, a serum T₄ concentration in the lower portion of normal range for a nonpregnant woman, accompanied by a significant reduction in the THBR, indicates hypothyroidism.

![Figure 10-17 Pattern of changes in total serum thyroxine (T₄) concentration and thyroid hormone-binding ratio (THBR) in patients with hyperthyroidism or hypothyroidism with normal serum thyroxine-binding globulin (TBG) concentration.](image)

One should keep several caveats in mind when interpreting these results. The use of labeled T₄ in these tests in some assays can produce difficulties in three situations: (1) in patients with FDH (familial dysalbuminemic hyperthyroxinemia), (2) in the presence of endogenous antibodies directed against T₄, and (3) in sick patients. In patients with FDH, the abnormal albumin binds T₄, but not T₃, with increased avidity. Therefore, these patients have an elevated level of total T₄ and a reduced free fraction of T₄ but not T₃. An alternative approach to assessing the FT₄ is thyroid hormone binding in serum is to measure TBG either by saturation analysis or by radioimmunoassay. Normal concentrations of TBG by radioimmunoassay are about 270 nmol/L (1.0 to 1.5 mg/dL) and are only slightly higher in women than in men. However, the elastase released from leukocytes during infection (see earlier) reduces the binding affinity of TBG for T₄ (and T₃) but does not change its immunoreactivity or its binding capacity. With this proviso, the serum TBG concentration result can be employed in one of two ways:

1. Normalization of the T₄/TBG (or T₃/TBG) ratio yields values that correlate reasonably well with the FT₄ or FT₃.

2. Derivation of an FT₄ from concentrations of TBG and total T₄ and the association constant for the interaction between the two.

In most instances, values calculated in this manner correlate with the FT$_4$ determined by other techniques, although the T$_4$ /TBG ratio suggests a subnormal FT$_4$ in some euthyroid patients with an elevated TBG. [321]
Abnormal Thyrotropin or Thyroid Hormone Concentrations in Blood

There are many causes of abnormal TSH levels that should be considered by the clinician (Table 10-13). The clinical status and FT₄ levels allow assignment of the etiologic mechanism for these. Assay of the FT₃ level is rarely required but is included for completeness.

### Suppressed Thyrotropin Levels

The most common cause of a reduction in serum TSH is an excess supply of thyroid hormone due to either increased endogenous thyroid hormone production or excessive exogenous thyroid hormone. Because the concentration of TSH is inversely proportional to the degree of thyroid hormone excess, patients with clinical symptoms invariably have serum TSH concentrations below 0.1 mU/L. In such patients, the serum FT₄ is usually increased.

A low iodine intake may lead to clinical thyrotoxicosis, a suppressed TSH level, but only a high-normal FT₃. Therefore, in order to make a diagnosis of T₃ thyrotoxicosis, an FT₃ level is required. When the thyroid hormone supply is only slightly in excess of the requirement for that patient, serum

Arrows indicate the nature of the abnormality in the T₃ or T₄ index. Parentheses indicate that such a result is unusual but may occur.

TSH is suppressed but clinical manifestations are subtle or absent and the FT₄ and FT₃ are in the high-normal range. Such minimal changes can occur with euthyroid Graves' disease, autonomous thyroid hormone-producing adenomas, multinodular goiters, subacute or painless thyroiditis, and the ingestion of an amount of exogenous thyroid hormone slightly greater than that required for metabolic needs. In the absence of symptoms, this condition is termed subclinical hyperthyroidism.

The hypothalamic-pituitary-axial feedback loop is usually suppressed for up to 3 months after complete resolution of the thyrotoxic state. The best test for assessing the physiologic state in such patients is the FT₃ index. A common scenario with this pattern is during follow-up of patients receiving antithyroid drugs or for Graves' disease. With time, the TSH feedback regulatory loop normalizes and TSH secretion returns and becomes appropriate for the circulating free thyroid hormone concentration.

In stage 3 illness, with or without dopamine infusion or excess glucocorticoid, TSH is suppressed, causing assessment of thyroid functional status to be difficult. Because the FT₄ level may also be reduced in such patients, astute clinical judgment is required to assign thyroid status. Since HCG can stimulate the TSH receptor, conditions in which HCG is elevated (e.g., in the first trimester of pregnancy, during severe hyperemesis gravidarum, and in patients with hydatidiform mole or choriocarcinoma) are associated with mild to moderate hyperthyroidism and suppression of TSH. In euthyroid patients, TSH returns to normal in the second and third trimesters. A persistent and severely suppressed TSH level (<0.1 mU/L) in the pregnant patient during this time suggests that hyperthyroidism is due to other causes.

Patients with psychosis or depression may have abnormalities in the hypothalamic-pituitary-thyroid axis, although these findings are rarely associated with clinical symptoms. Typically, TSH is suppressed but in some patients it may be spontaneously elevated.
with glucocorticoids may transiently suppress TSH, chronic treatment does not. Rarely, patients with genetic deficiency of the PIT1 protein or with a mutation in the TSH-subunit have severe hypothyroidism and no detectable TSH (see Chapter 12).

Elevated Thyrotropin Levels

Elevations in TSH nearly always suggest a reduced supply of T₄ or T₃, which may be permanent or transient. Acutely ill patients may have elevated serum TSH levels, as in renal insufficiency, or may experience an asynchronous return of the hypothalamic-pituitary and thyroid axes to normal as they recover from acute illness; the latter case, patients have a transient form of primary hypothyroidism.

Iodine deficiency is the most common cause of elevated TSH worldwide, but this does not occur in North America.

Patients with resistance to thyroid hormone may be clinically hyperthyroid, euthyroid, or hypothyroid. The most common laboratory pattern is a serum TSH that is normal in absolute terms but inappropriately high for the elevated FT₄ I. Individuals with a more marked pituitary than general resistance to thyroid hormone (sometimes called pituitary RTH or PRTH) have symptoms suggesting hyperthyroidism, an elevated FT₄ I, and a normal or even elevated serum TSH. These patients must be differentiated from the equally rare patients with a thyrotroph tumor in whom the persistent secretion of TSH causes hyperthyroidism (see Chapter 8).

Patients with hypothalamic-pituitary dysfunction may have clinical and chemical hypothyroidism but low-normal or even elevated serum TSH concentrations. The explanation for this paradox is that the biologic effectiveness of the circulating TSH is impaired because of abnormal glycosylation secondary to reduced TRH stimulation of the thyrotrophs. Nonetheless, the abnormal TSH is a suitable antigen in the immunometric assay.

Some patients with psychiatric illness may have elevated TSH levels for reasons that are not understood. In adrenal insufficiency, TSH levels may be modestly elevated but return to normal with glucocorticoid replacement. In patients with antimouse IgG antibodies, TSH is usually artifactually elevated, often greatly so (see Chapter 6).

Despite the utility and general efficacy of the serum TSH measurement alone as a screening tool for identifying patients with thyroid dysfunction, a patient should not receive treatment for this dysfunction solely on the basis of an abnormal TSH level. The TSH assay is an indirect reflection of thyroid hormone supply and does not, by itself, permit a conclusive diagnosis of a specific disorder of thyroid hormone production.
Concordant and Divergent Abnormalities of Serum Thyroxine and Triiodothyronine Concentrations

One suspects that millions of dollars might be saved each year by the judicious selection of thyroid tests. In the authors' experience, far too many serum T₃ measurements are performed. Serum T₄ is rarely required for the accurate evaluation of the patient with an abnormal TSH level and is almost always an indirect reflection of the serum T₃ supply. Serum T₃ results are virtually useless in the hospitalized patient. Nonetheless, the endocrinologist is often asked to interpret abnormal or discordant serum T₃ and T₄ values (Table 10-14).

</table>

An increase in serum TBG concentration secondary to increased estrogen is the most common cause of simultaneous elevations of serum total T₄ and T₃. Other causes of TBG elevation are listed in Table 10-12. Thyrotoxicosis due to hyperthyroidism is usually associated with an increased T₃/T₄ ratio, whereas that due to thyroiditis or exogenous T₃-thyroxine is associated with a decreased T₃/T₄ ratio. In patients with RTH, serum total and free T₄ and T₃ concentrations are elevated, although typical clinical features of thyrotoxicosis are often lacking, and both basal serum TSH concentrations and the response to TRH are normal or increased.

In all these conditions, serum T₃ concentrations are normal. Certain pharmacotherapeutic agents may elevate the serum T₃ concentration by inhibiting the conversion of T₄ to T₃ by D₁ and D₂ or by interfering with the cellular uptake of T₄. Agents that inhibit peripheral T₃ production include amiodarone and oral cholecystographic agents, such as iopanoic acid, sodium iopodate, tyropanoate, and iobenzamic acid (see Fig. 10-7). Propranolol in high doses, but not other β-adrenergic agents, can inhibit D₁ and, at doses greater than 160 ng/day, can lower serum T₃. The T₃ increase is a compensatory response to the blockade of T₃ production attributed to these agents, and the T₃ and TSH eventually normalize with a T₄ level that is elevated as long as thyroid function is normal.

Decreased T₄, increased TSH

Patients receiving replacement therapy with either liothyronine (T₃) or with agents with a higher T₃/T₄ ratio than in human thyroid secretion (11/1 by weight), including liotrix and desiccated thyroid, usually have a low-normal FT₄ when doses are titered to return serum concentrations of TSH to normal. T₃ levels are transiently decreased. Patients with T₃ levels as low as 2.5 ng/dl have been reported, and in these cases FT₄ levels may be >2 ng/dl. These patients require frequent follow-up (see Table 10-12).
elevated if serum is drawn between 1 and 4 hours after the patient ingests the medication.

Increased Thyroxine, Normal Triiodothyronine

The reasons for the decreased T₄ and normal T₃ in early hypothyroidism or during iodine deficiency have been discussed earlier (see "Iodine Deficiency"). Many drugs lower the serum T₄ concentration by interfering with the binding of T₄ to plasma proteins or by accelerating T₄ metabolism or both. Therapeutic doses of phenytoin lower the serum FT₄ I concentration, sometimes into the hypothyroid range. Although high concentrations of the drug can inhibit the binding of T₄ and T₃ to TBG in vitro, a drug-induced acceleration of T₄ disposal and, perhaps, central TSH suppression appear to be responsible for the reduced T₄.

Enhancement of hepatic disposal of T₄ by induction of cytochrome CYP3A4 in patients receiving carbamazepine, rifampin, phenobarbital, and phenytoin causes increased glucuronide conjugation of T₄ and T₃. This does not pose a problem in euthyroid patients. In hypothyroid patients, however, the levothyroxine dose must be increased.

Serum T₃ concentrations usually remain at low-normal levels.

Decreased Thyroxine, Decreased Triiodothyronine

Hypothyroidism of any origin and TBG deficiency are the most common causes of parallel reductions in serum T₄ and T₃ (see Table 10-12). In addition, salicylates, especially salsalate, inhibit the binding of T₄ and T₃ by serum proteins in vitro and have comparable effects in vivo when given in high doses. Initially, serum free T₄ and T₃ concentrations increase, but the consequent increased MCRs of the hormones, combined with the suppression of the hypothalamic-pituitary axis, lead to a new equilibrium in which serum total T₄ and T₃ values are decreased and free T₄, free T₃, and TSH values return to normal.

Marked lowering of the serum T₄ concentration and moderate decreases in the serum T₃ level may also occur in patients receiving the nonsteroidal anti-inflammatory drug (NSAID) fenclofenac. Patients are clinically euthyroid, and serum TSH levels are normal. Administration of L-asparaginase has the same rapid effect owing to inhibition of TBG synthesis. Stage 3 (severe) illness reduces both serum T₄ and T₃ (see Table 10-10).
Tests That Assess the Metabolic Impact of Thyroid Hormones

Abnormalities in the supply of thyroid hormone to the peripheral tissues are associated with alterations in a number of metabolic processes that can be quantitated. Some of these may be useful in the rare patient in whom serum TSH is not an accurate barometer of thyroid status, such as the patient with RTH. Such tests may be the sole means of evaluating the metabolic response of the peripheral tissues to thyroid hormones in such patients.

**Basal Metabolic Rate**

Thyroid hormones increase energy expenditure and heat production, as manifested by weight loss, increased caloric requirement, and heat intolerance. Because it is impractical to measure heat production directly, the basal metabolic rate measures oxygen consumption under specified conditions of fasting, rest, and tranquil surroundings. Under these conditions, the energy equivalent of 1 L of oxygen is equivalent to 4.83 kcal.

Under basal conditions, approximately 25% of oxygen consumption is due to energy expenditure in visceral organs, including the liver, kidneys, and heart; 10% in the brain; 10% in respiratory activity; and the remainder in skeletal muscle. Because energy expenditure is related to functioning tissue mass, oxygen consumption is related to some index thereof, most often body surface area. Calculated in this way, basal oxygen consumption (resting energy expenditure) is higher in men than in women and declines rapidly from infancy to the third decade and more slowly thereafter.

Values in patients, calculated as a percentage of established normal means for gender and age, normally range from -15% to +5%. In severely hypothyroid patients, values may be as low as -40%. In thyrotoxic patients, these values may reach +25% to 50%. Abnormal, usually elevated values, are seen in patients with burns and with systemic disorders (e.g., febrile illnesses, pheochromocytoma, myeloproliferative disorders, anxiety, and disorders associated with involuntary muscular activity). Interestingly, the changes in resting energy expenditure correlate well with the FT₄ and TSH in hypothyroid patients who are taking varying doses of levothyroxine.

**Biochemical Markers of Thyroid Status**

Occasionally, a diagnosis of thyroid dysfunction is first suspected as a result of an abnormality in a laboratory test performed in the course of an evaluation for an unrelated medical problem. Classical examples are a markedly elevated creatine kinase MM isoenzyme or LDL cholesterol level leading to the recognition of hypothyroidism. Other similar markers are listed in Table 10-15. These tests are not useful in the diagnosis of thyroid disease, but some, such as sex hormone-binding globulin (SHBG), ferritin, or LDL cholesterol, have been used as end points in clinical studies of the responsivity of the liver to thyroid hormone in patients with RTH.
Serum Thyroglobulin

The sensitivity of modern Tg assays is 1 ng/mL or even less. The results can be artifactually altered by serum anti-Tg antibodies, and serum should be screened for Tg antibodies with a sensitive Tg-antibody immunoassay. In immunoradiometric assays, interferences lead to underestimations or false-negative values. Tg is normally present in serum, with the concentration ranging up to 90 pmol/L (50 ng/mL); mean normal values vary with the assay used but are on the order of 30 pmol/L (20 ng/mL).

Concentrations are somewhat higher in women than in men and are elevated several-fold in pregnant women and in newborns. Levels are elevated in three types of thyroid disorders:

- Goiter and thyroid gland hyperfunction
- Inflammatory or physical injury to the thyroid gland
- Differentiated follicular cell-derived thyroid tumors

Values are elevated in both endemic and sporadic nontoxic goiter, and the degree of elevation correlates with the thyroid size. Transient elevations occur in patients with subacute thyroiditis and as a result of trauma to the gland during thyroid surgery or after $^{131}$I therapy. Subnormal or undetectable concentrations are found in patients with thyrotoxicosis factitia and aid in differentiating this disorder from other causes of thyrotoxicosis with a low radioactive iodine uptake (RAIU).

Antithyroglobulin antibodies interfere with measurements of the Tg concentration, thus precluding its use in patients with Hashimoto’s disease. Serum Tg concentrations are increased in patients with both benign and differentiated malignant follicular cell-derived tumors of the thyroid and do not serve to distinguish between the two. After total thyroid ablation for papillary or follicular thyroid carcinoma, Tg should not be detectable and its subsequent appearance signifies the presence of persistent or recurrent disease. Secretion of Tg is TSH-dependent. Therefore, the serum Tg level may rise when suppressive therapy is withdrawn or after injections of rTSH, and this increases the sensitivity of the marker for the detection of persistent or recurrent thyroid carcinoma, even when $^{131}$I scans are negative.
Tests for Thyroid Autoantibodies

Graves’ disease and Hashimoto’s disease are well characterized and interrelated autoimmune thyroid disorders (AITDs). Thus, circulating antibodies and T cells against one or another thyroid antigen are often present.

Three varieties of thyroid autoantibodies are useful and widely available for clinical diagnostic use receptor [Table 10-16]. In this section, antibodies to Tg and thyroid peroxidase (TPO) are discussed. Antibodies directed against the TSH receptor,

TSH, thyrotropin.

the cause of hyperthyroidism in patients with Graves’ disease, are covered in greater detail in Chapter 11.

Antibodies to Thyroid Peroxidase and Thyroglobulin

Table 10-17 summarizes some advantages and disadvantages of available techniques for measuring thyroid autoantibodies. The original technique of hemagglutination has many disadvantages, including lack of IgG specificity, low sensitivity, and operator dependency. Modern assay techniques have good precision because they depend on the direct measurement of the interaction between autoantibody and autoantigen (i.e., the interaction between labeled thyroid antigen and the patient’s serum). In general, the more sensitive an assay, the more it tends to be specific and precise. However, because many normal individuals exhibit low levels of autoantibodies, the clinical specificity of the more sensitive tests is reduced and the absolute concentration becomes more important; the higher the concentration of autoantibody, the greater the clinical specificity.

The prevalence of detectable thyroid autoantibodies in various disorders is shown in Table 10-18; however, data on concentration tend to vary from assay to assay even with the use of standardization.

ELISA, enzyme-linked immunosorbent assay.

The actual standard serum preparation, however, cannot be included in every assay. Instead, a serum pool is usually compared and normalized to the original standard. Yet autoantibodies differ considerably in their affinity and epitope recognition of antigen. Hence, despite this attempt at standardization, assay results from different commercial assays may still vary considerably. When following antibody titers (e.g., after the treatment of thyroid cancer), it is important to use the same autoantibody assay.

IDDM, insulin-dependent diabetes mellitus; Tg, thyroglobulin; TPO, thyroid peroxidase.

among laboratories, assays for thyroid autoantibodies should be standardized (i.e., results should be expressed in relation to a widely available standard preparation, as with hormone immunoassays). Although there are no formal “international standards” for human thyroid autoantibodies, TgAb and TPOAb standard sera are available from the National Institute for Biological Standards in the United Kingdom and are an essential component of many thyroid autoantibody assays. Such results can then be expressed in units per milliliter.

The actual standard serum preparation, however, cannot be included in every assay. Instead, a serum pool is usually compared and normalized to the original standard. Yet autoantibodies differ considerably in their affinity and epitope recognition of antigen. Hence, despite this attempt at standardization, assay results from different commercial assays may still vary considerably. When following antibody titers (e.g., after the treatment of thyroid cancer), it is important to use the same autoantibody assay.

### Pathogenic Role of Thyroglobulin and Thyroid Peroxidase Antibodies

Tg and TPO autoantibodies are a secondary response to thyroid injury and do not cause disease themselves. Both types of antibodies are polyclonal, and although they are of the IgG class, are not restricted to one particular IgG subclass. Polyclonality mitigates against a primary role in disease, but these antibodies may be important in determining the end-organ effects and may also be determinants of chronicity.

Whereas both TPOAb and TgAb levels correlate with lymphocytic infiltration of the thyroid gland, they do not transfer disease from mother to fetus or between animals. Thus, thyroid antibodies to Tg and TPO do not initiate disease. Both antibodies, however, may have complement-fixing cytotoxic activity, and TPOAb
autoantibodies, in particular, correlate with thyroidal damage and lymphocytic infiltration. Patients with AITDs have autoantibody "fingerprints," a characteristic spectrum of Tg and TPO autoantibodies belonging to IgG1, IgG2, IgG3, and IgG4 subclasses. This pattern may be inherited as an autosomal dominant trait within families.\[351\] [352]

Because IgG1 antibodies fix complement, whereas IgG4 antibodies do not, for example, this pattern of distribution may affect the disease phenotype.

**Thyroid Autoantibodies in Hashimoto’s Disease**

The disease most associated with TgAb and TPOAb is autoimmune thyroiditis, a term that embraces both goitrous Hashimoto's disease and atrophic thyroid failure. The titers of these antibodies correlate with the degree of thyroidal lymphocytic infiltration. Immunoassays show that both TgAb and TPOAb are found in almost 100% of such patients, but TPO antibodies are of higher affinity and in higher concentrations. This may be because TgAb is bound by circulating Tg, causing its concentration to be underestimated. In an unclear clinical situation, positive TgAb and TPOAb levels are diagnostic of primary autoimmune thyroid disease.

Antibody measurements may also be useful prognostically in mildly (subclinically) hypothyroid patients (i.e., with elevated TSH and normal T₄ levels), since the rate of overt hypothyroidism is about 3% to 5% per year in patients with a mildly increased TSH level and positive thyroid autoantibodies. Falling titers of TgAb indicate a good prognosis in treated thyroid cancer patients who show this autoantibody (20% of patients) and TPOAb has been shown to be an important predictor of postpartum thyroiditis, a transient form of autoimmune thyroiditis found in 8% to 10% of all women and in 33% or more of TPOAb-positive mothers.

**Thyroid Autoantibodies in Graves’ Disease**

Antibodies to Tg and TPO are also detectable in 50% to 90% of patients with Graves' disease, indicative of the associated thyroiditis that is evident histologically. Hence, Graves' disease may occur on a background of autoimmune thyroiditis. Although the presence of such autoantibodies favors a diagnosis of an autoimmune cause for the hyperthyroidism over other causes, the tests are neither sensitive nor specific in this setting and are interpretable only as part of the clinical scenario.

**Thyroid Autoantibodies in Nonautoimmune Thyroid Disorders**

Antibodies to Tg and TPO are more common in patients with sporadic goiter, multinodular goiter, and isolated thyroid nodules and cancer than in the general population. This finding usually represents an associated thyroiditis on histologic examination. Low levels of thyroid autoantibodies may occur transiently in patients with subacute (de Quervain's) thyroiditis but correlate poorly with disease course and are probably a nonspecific response to thyroid injury. There is also a higher prevalence of thyroid autoantibodies in other autoimmune diseases, such as insulin-dependent diabetes mellitus (IDDM), indicative of a common genetic susceptibility and etiology.

**The "Normal" Population**

Although the prevalence of thyroid autoantibodies depends on the technique used for detection, autoantibodies to Tg and TPO are common in the general population (see Table 10-18) and, at all ages, are almost five times more common in women than in men. The tendency to secrete thyroid autoantibodies is inherited in a mendelian-dominant manner and has been linked to polymorphisms in the CTLA-4 gene. Selected groups at risk include younger women and relatives of patients with anAITD, in whom the incidence is higher. Low levels of autoantibodies to TPO and Tg are of uncertain significance in the presence of normal thyroid function; however, within a family with anAITD, they remain a significant risk factor.

**Clinical Utility: Establishment of Disease Etiology**

Thyroid failure has a variety of causes, and autoimmune thyroid disease can be inferred by the presence of a family history of Graves’ disease or Hashimoto’s disease. However, the only simple way of confirming the autoimmune diathesis, other than biopsy, is the presence of significant levels of thyroid autoantibodies. The measurement of thyroid autoantibodies also allows the generation of data regarding the prevalence of AITDs within the patient's family.

**Prediction of Disease Onset**

Patients with increased TSH and normal T₄ levels progress to overt thyroid failure at a rate of about 5% per year if thyroid autoantibody levels are elevated. Hence, patients with mild (subclinical) hypothyroidism (increased TSH levels but apparently normal free T₄ values) and thyroid autoantibodies are at twice the risk for development of thyroid failure as patients without thyroid antibodies.

**Thyroid Cancer**

Approximately 20% to 40% of patients with thyroid cancer have thyroid autoantibodies, and their presence (indicating underlying immunoreactivity against thyroid cell antigens) may suggest a better prognosis for these patients. After total thyroidectomy and radiodine ablation, a sensitive assay should show a serum Tg level below 1 ng/mL. The presence of TgAb significantly interferes with this assessment, and attempts to correct for the presence of TgAb using Tg recovery from the serum are not always helpful. A falling titer or total loss of TgAb in such patients, however, is an important and reliable prognostic sign indicating the absence of thyroid cell antigens.

**Risk Analysis for Postpartum Thyroid Disease**

The prevalence of PPTD is 8% to 10% in the first 4 to 12 months after delivery. More than 33% of women who are TPOAb-positive early in pregnancy, particularly patients with high thyroid autoantibody levels, develop some form of PPTD. Hence, the measurement of TPOAb is important in pregnancy screening.

**Risk Analysis for Early Pregnancy Loss**

Thyroid autoantibodies are markers of an at-risk pregnancy but do not imply that thyroid dysfunction causes the increased risk. Many studies have shown double the rate of pregnancy loss in women with these antibodies. However, the presence of thyroid autoantibodies appears to be a signal of immune uncertainty. The role of placental megalin receptors, which may be activated by TgAb, is also of interest.

**Thyroid Disease Screening in Associated Autoimmune Conditions**

AITDs occur commonly with other forms of autoimmune disease. For example, patients with IDDM are at particular risk, and the presence of thyroid autoantibodies is helpful in selecting patients for monitoring of thyroid function.
Radioiodine Uptake

The only direct test of thyroid function employs a radioactive isotope of iodine as a tag for the body’s stable form of iodine. $^{127}$I. Most often the test involves the measurement of the fractional uptake by the thyroid of a tracer (i.e., a chemically inconsequential) dose of radioiodine. However, several factors have caused this test to be less frequently used and less valuable for diagnosis of thyroid disorders than in the past; specifically, (1) the improvement in indirect methods for assessing thyroid status and (2) the decrease in normal values for thyroid RAIU consequent to the widespread increase in daily dietary iodine intake. $^{366}$

Both $^{131}$I (half-life, 8.1 days) and $^{123}$I (half-life, 0.55 days) emit gamma radiation, which permits their external detection and quantitation at sites of accumulation, such as the thyroid gland. These isotopes ($I^*$) are physiologically indistinguishable, not only from one another but also from the naturally occurring $^{127}$I, which permits their use as valid tracers. The shorter half-life of $^{123}$I is preferable because the radiation delivered to the thyroid per amount of administered $^{123}$I is only about 1% of that delivered by $^{131}$I.

Physiologic Basis

When tracer quantities of inorganic radioiodine are administered either orally or intravenously, the isotope quickly mixes with the endogenous stable iodide in the extracellular fluid and begins to be removed by the two major sites of clearance, the thyroid gland and the kidneys. As this process continues, the plasma level of $I^*$ decreases exponentially. Normally, low values are reached by 24 hours, and inorganic $I^*$ is virtually undetectable in the plasma 72 hours after its administration. The thyroid content of $I^*$ increases rapidly during the early hours, then at a decreasing rate until a plateau is approached. The proportion of administered $I^*$ that is ultimately accumulated by the thyroid gland is a function of the clearance of iodide by the thyroid and kidneys. The relation is simply expressed as follows:

$$\text{RAIU at } \frac{C_T}{C_T + C_K}$$

where $C_T$ is the thyroid iodide clearance rate and $C_K$ is the renal iodide clearance rate.

The normal thyroid iodide clearance rate is approximately 0.4 L/hour, and the renal iodide clearance rate is 2.0 L/hour. Thus, the uptake of $I^*$ normally approximates 0.17 of the administered dose.

Measurements of the RAIU are generally made at 24 hours, both as a matter of convenience and because the value at 24 hours is usually near the plateau. The RAIU usually indicates the rate of thyroid hormone synthesis and, by inference, the rate of thyroid hormone release into the blood.

Radioactive Iodine Uptake

Little difference is noted if the uptake is measured at any time during the day following that on which the isotope was administered. For calculating therapeutic radioiodine doses in treating thyrotoxic Graves’ disease, an uptake at 3 to 6 hours may produce results comparable to those found at 20 to 28 hours. $^{367}$ With the use of this modified early RAIU measurement, diagnosis and treatment of thyrotoxic Graves’ disease can be accomplished on the same day.

In general, the range of normal values for the 24 hr radioiodine uptake in North America is approximately 5% to 25%. Higher values may indicate iodine deficiency or thyroid hyperfunction. As with other procedures, however, values in patients with mild hyperthyroidism may be at or just above the upper limit of the normal range (Table 10-19).

Exogenous Thyroid Hormones

Increased availability of iodine
Cardiac or renal insufficiency
Increased hormone release

States Associated with Increased Radioactive Iodine Uptake

Hyperthyroidism

Hyperthyroidism causes an increased RAIU unless body iodide stores are increased. Such increases in uptake are always evident except in patients with severe thyrotoxicosis, in whom release of hormone can be so rapid that the thyroid content of I\(^{131}\) has decreased to the normal range by the time the measurement is made. This condition is rare and is usually associated with obvious thyrotoxicosis.

Aberrant Hormone Synthesis

The RAIU can be increased in the absence of hyperthyroidism in disorders in which iodine accumulation is normal but the secretion of hormone is impaired, such as in patients with abnormal thyroglobulin synthesis. The magnitude of the increase in uptake and the time at which the plateau is achieved vary with the nature and severity of the disorder. Differentiation of these states from hyperthyroidism is generally not difficult; in the former, clinical findings and laboratory evidence of hyperthyroidism are lacking, and indeed hypothyroidism may be present.

Iodine Deficiency

The RAIU is increased in acute or chronic iodine deficiency, as demonstrated by measurement of urinary iodine excretion, with urinary iodine values lower than 100 \(\mu g/day\) indicating deficiency. Chronic iodine deficiency is usually the result of an inadequate content of iodine in the food and water (endemic iodine deficiency). Patients with cardiac, renal, or hepatic disease may develop iodine deficiency if given diets severely restricted in salt, especially if diuretic agents are administered.

Response to Thyroid Hormone Depletion

Rebound increases in the RAIU are seen after withdrawal of antithyroid therapy, after subsidence of transient or subacute thyroiditis, and after recovery from prolonged suppression of thyroid function by exogenous administered. A striking increase in RAIU occurs in patients with iodide-induced myxedema after cessation of iodide administration. The duration of the rebound depends on the time required to replenish thyroid hormone stores.

Excessive Hormone Losses

In patients with nephrotic syndrome, excessive losses of hormone in the urine occurring in association with urinary loss of binding protein cause a compensatory increase in hormone synthesis and in the RAIU. A similar sequence may occur when losses of hormone via the gastrointestinal tract are abnormal, as in chronic diarrheal states or during ingestion of agents (e.g., soybean protein, cholestyramine) that bind T\(_4\) in the gut.

States Associated with Decreased Radioactive Iodine Uptake

A general increase in iodine intake has made RAIU values in hypothyroidism indistinguishable from those at the lower end of the normal range. Therefore, the major indication for measuring the RAIU is to establish the causes of thyrotoxicosis associated with decreased values of the RAIU.

Hypothyroidism

The problems involved in using the RAIU as an aid to the diagnosis of hypothyroidism have been discussed.

Exogenous Thyroid Hormone: Thyrotoxicosis Factitia

Except in disorders in which homeostatic control is disrupted or overridden (e.g., with Graves' disease or autonomously functioning thyroid nodules), administration of exogenous thyroid hormone suppresses TSH secretion and reduces the RAIU, usually to values below 5%.

Low values of the RAIU in a patient who is clinically thyrotoxic may indicate the presence of thyrotoxicosis factitia, the syndrome produced by the ingestion of excess thyroid hormone. The unmeasurably low level of T\(_g\) in serum differentiates thyrotoxicosis from other causes of thyrotoxicosis with a decreased RAIU.

Disorders of Hormone Storage

The RAIU is usually low in the early phase of subacute thyroiditis and in chronic thyroiditis with transient hyperthyroidism. In these instances, inflammatory follicular disruption leads to loss of the normal storage function of the gland and leakage of hormone into the blood. In the early stage of subacute thyroiditis, leakage of hormone is usually sufficient to suppress TSH secretion and the RAIU. Transient hyperthyroidism often occurs late in both diseases, when stores of preformed hormone are depleted; the RAIU may return to normal or increased values at that time.

Exposure to Excessive Iodine

Exposure to excessive iodine is the most common cause of a subnormal RAIU. Such decreases are spurious in the clinical sense because they do not indicate decreased absolute iodine uptake or decreased hormone production but can be produced by the introduction of excessive iodine in any form (organic, inorganic, or elemental). Special offenders are organic iodinated dyes used as x-ray contrast media and amiodarone (see Table 10-8). The duration of suppression of the uptake varies among individuals and with the compound administered. In general, dyes used for pyelography or computed tomography are cleared within weeks, whereas amiodarone may influence the uptake for up to 12 months because of its storage in fat.

A single large dose of inorganic iodide can decrease the uptake for several days, and chronic ingestion of iodide may depress the uptake for many weeks. Lugol's solution or saturated solution of potassium iodide (SSKI) in the usual dosage (2 to 5 drops three times/day) can deliver up to about 500 \(\mu g\) of iodine daily, as opposed to the customary intake of about 200 \(\mu g/day\) in the United States. Excessive quantities of iodine may also be present in vitamin and mineral preparations, vaginal or rectal suppositories, and iodinated antiseptics such as povidone (see Table 10-8). In patients with thyrotoxicosis, the RAIU may help to differentiate excessive hormone synthesis with an increased RAIU from destructive thyrotoxicosis with a subnormal RAIU. Inhibition of uptake by excess stable iodine is of shorter duration in hyperthyroid than in normal individuals.
The measurement of urinary iodine excretion is an invaluable means of establishing or excluding the existence of excessive body iodide stores; a random urine sample can be obtained, and the 24-hour iodine excretion can be extrapolated from the iodine/creatinine ratio. Values in excess of several milligrams per day can explain a low RAIU value, whereas values less than 1 mg/day suggest that a low RAIU value is due to one of the other disorders discussed in this section.

Figure 10-18 Examination of the thyroid gland. A. Sagittal section demonstrates relations of the isthmus of the normal thyroid gland. The superior border is inferior to the cricoid cartilage. The inferior thyroid border is essentially at the level of the superior surface of the manubrium. The inferior portions of the lateral lobes (not shown) extend more inferiorly than the isthmus. B. The cricoid cartilage is regarded as an important landmark. Especially when the thyroid gland is thought to be essentially normal or subnormal in size, the cricoid should be located. This is easily accomplished. The index fingers are then inserted so that their superior portion rests against the inferior portion of the cricoid while the inferior portion of these fingers is over the superior portion of the thyroid. The second and third fingers are rotated over other portions of the gland to evaluate its size, contour, consistency, possible adherence to surrounding structures, and other features. Because there is marked variation among different subjects in the length and thickness of the neck and in the length of the trachea superior to the level of the manubrium, the relative position of the thyroid may vary. In some cases, essentially all of the thyroid gland rests posterior to the sternum. In most instances, however, by having the patient moderately extend the neck (short of tightening the anterior neck muscles) and swallow repeatedly, it is possible to palpate most or all of the gland. Despite marked variations in neck-chest relations, thyroid tissue, when present, is found within 1 cm of the cricoid. By concentrating the palpation meticulously in the area where the thyroid is normally found, with rare exceptions the examiner can outline small as well as enlarged glands.
CLINICAL EVALUATION AND INITIAL LABORATORY TESTING

Manifestations of thyroid disease are usually due to (1) excessive or insufficient production of thyroid hormone, (2) local symptoms in the neck (principally goiter but occasionally pain or compression of adjacent structures), or, (3) in the case of Graves' disease, ophthalmopathy or dermopathy. Although attention is directed initially at the major features, it is crucial to define the metabolic state and to ascertain the nature of the underlying disorder. A functional diagnosis of thyroid disease is based on a carefully taken history, a thorough search for the physical signs of hypothyroidism or thyrotoxicosis, and an appraisal of the results of laboratory tests. Although conditioned by the functional diagnosis, the anatomic diagnosis depends largely on the examination of the thyroid gland itself.

Physical Examination

Local examination of the neck is best accomplished with the patient seated in a good light and with the neck moderately extended. The patient must be provided with a cup of water to facilitate swallowing.

The physician first inspects the neck from the front and on the sides, especially while the patient swallows, with the neck slightly extended. The presence of old surgical scars, distended veins, and redness or fixation of the overlying skin should be noted. If a mass is present, attention should be directed to its location and to whether it moves when the patient swallows.

The position of the trachea is noted. Movement on swallowing is a characteristic of the thyroid gland because it is enshrouded in the pretracheal fascia; this feature distinguishes a goiter from most other neck masses. If a goiter is large, however, that it occupies all the available space in the neck or if the thyroid gland is the seat of an invasive carcinoma or Riedel's thyroiditis that has caused fixation to adjacent structures, movement on swallowing may be lost. The physician should also inspect the dorsum of the tongue, which is the origin of the thyroglossal duct and rarely the seat of lingual thyroid tissue.

Standing behind the seated patient, the physician may examine the thyroid gland by palpating with the fingertips of both hands. The position of the cricoideal cartilage is determined first because the superior border of the isthmus lies just below it (see Fig. 10-18). The isthmus is a band of tissue crossing the front of the trachea joining the two lobes. The examiner then attempts to outline the thyroid gland and to determine the limits of the lower borders of the lateral lobes while the patient swallows sips of water at appropriate intervals. With practice, a normal thyroid gland can usually be palpated, particularly in women.

An alternative approach to the thyroid gland examination is for the physician to face the seated patient and use gentle pressure with the thumb to locate the thyroid isthmus. The right thumb is then moved laterally, without release of pressure, to compress the right lobe of the thyroid against the trachea as the patient again swallows sips of water. This strategy allows the palpat ing thumb to slide under and laterally displace the medial border of the sternocleidomastoid muscle. A similar strategy with the left thumb is employed for the left lobe. This technique is especially useful as an aid in detecting small nodules that may not be easily appreciated with the posterior approach.

The examiner notes the shape of the gland, its size in relation to normal, and its consistency, which is usually slightly more firm than adipose tissue. The normal thyroid lobe is approximately the same in size in frontal projection as the terminal phalanx of the patient's thumb. Whereas the diffuse colloid goiter and the hyperplastic gland in Graves' disease tend to be softer than normal, the gland in Hashimoto's disease is usually firm. In rare circumstances, the gland that is the seat of carcinoma or Riedel's thyroiditis may be "stony" hard. Irregularities of the surface, variations in consistency, and tender areas should be noted. If nodules are palpated, their shape, size, position, transluency, and consistency in relation to the surrounding tissue should be determined.

A search should be made for the pyramidal lobe, a thin band of tissue extending upward from the isthmus to the thyroid cartilage to the right or left of the midline. The pyramidal lobe may be mistaken for a pretracheal lymph node that sometimes accompanies thyroid carcinoma or thyroiditis. It is usually palpable in patients with generalized thyroid disease, such as Hashimoto's or Graves' disease. Thyroglossal cysts are midline masses that remain attached to the base of the tongue by the fibrotic thyroglossal duct and that move upward when the tongue is protruded.

During palpation, a vascular thrill may be felt that, in the absence of cardiac disease, is suggestive of hyperthyroidism. Finally, palpation should always include examination of the regional lymph nodes.

Auscultation of the neck can indicate the vascularity of an enlarged gland. A systolic or continuous bruit is sometimes heard over a hyperplastic gland. The physician should take care to distinguish a thyroid bruit from a murmur transmitted from the base of the heart or from a venous hum that can be obliterated by gentle compression of the external jugular vein or by turning the patient's head. A venous hum is generally found in younger patients with high cardiac output, such as in Graves' disease or severe anemia.

An arm-raising test is useful when a retrosternal goiter is suspected. The basis for this maneuver is that if the size of the thoracic inlet is already reduced by a retrosternal goiter, raising both arms until they touch the sides of the head further narrows the thoracic inlet and causes congestion and venous engorgement of the face and, sometimes, respiratory distress (Pemberton's sign) or even (rarely) syncope.

In addition to examination of the thyroid gland and the regional lymph nodes, the physician should seek evidence of compression or displacement of adjacent structures. Hoarseness may indicate compression of the recurrent laryngeal nerve, usually by a malignant thyroid neoplasm, and this possibility should be confirmed by laryngoscopy. Displacement of the trachea may be evident, and inspiratory stridor may indicate compression of the trachea.
Laboratory Evaluation

Initial laboratory tests for any patient with suspected thyroid disease should include an immunometric TSH assay. If the physician is reasonably confident that a functional disorder of the thyroid is present, an FT₄ or FT₃ should be included as an initial test to confirm the presence and assess the degree of the abnormality inferred from the TSH result. There is rarely reason to measure total T₃ in the initial evaluation unless the patient is receiving liothyronine or liotrix. More extensive guidelines for laboratory procedures relevant to specific thyroid conditions are discussed in Chapter 11, Chapter 12, and Chapter 13.

Chapter 11 - Thyrotoxicosis

Terry F. Davies
P. Reed Larsen

OVERVIEW

The term thyrotoxicosis refers to the biochemical and physiologic manifestations of excessive quantities of the thyroid hormones. We prefer the term thyrotoxicosis rather than hyperthyroidism to describe this disorder, because it need not originate in the thyroid gland. The term hyperthyroidism is reserved for disorders that result from overproduction of hormone by the thyroid gland itself, of which Graves’ disease is the most common (Table 11-1). The manifestations depend on the severity of the disease, the age of the patient, the presence or absence of extrathyroidal manifestations, and the specific disorder producing the thyrotoxicosis.

Peripheral Clinical Manifestations (Table 11-2)

Skin and Hair

The most characteristic change in thyrotoxicosis is the warm, moist feel of the skin that results from cutaneous vasodilatation and excessive sweating. Although the hands are usually warm and moist, the texture of the hands may be altered by occupational or environmental factors; hence, texture is best assessed on the inner aspect of the arm or over the chest. The elbows are smooth and pink, the complexion is rosy, and the patient blushes readily. Palmar erythema may resemble “liver palms,” and telangiectasia may be present. Increased diffuse pigmentation resembles that in adrenal insufficiency, but buccal pigmentation does not occur. The hair is fine and friable, and hair loss may be excessive. A history of early graying in the patient or in relatives is said to be common in Graves’ disease. The nails are often soft and friable. A characteristic finding is Plummer’s nails, a term applied to separation of the distal margin of the nail from the nail bed, with irregular recession of the junction (onycholysis).

Eyes

Retraction of the upper eyelid, evident as the presence of a rim of sclera between the lid and the limbus, is common in all forms of thyrotoxicosis, regardless of the underlying cause, and is responsible for the bright-eyed “stare” or “fish eyes” of the patient with thyrotoxicosis. Lid lag is the phenomenon in which the upper lid lags behind the globe when the patient is asked to gaze slowly downward, and globe lag occurs when the globe lags behind the upper lid when the patient gazes slowly upward. The movements of the lids may be jerky and spasmodic, and a fine tremor of the lightly closed lids can often be observed in severe cases. These ocular manifestations appear to be the result of increased adrenergic activity. It is important to differentiate these ocular manifestations, which occur in all forms of thyrotoxicosis, from those of infiltrative orbitopathy, which are characteristic of hyperthyroid Graves’ disease (see later).

Cardiovascular System

Alterations in cardiovascular function are due to increased circulatory demands that result from the hypermetabolism and the need to dissipate the excess heat produced. At rest, peripheral vascular resistance is decreased and cardiac output is increased as a result of an increase in stroke volume and heart rate. Thyroid hormones in excess have a direct inotropic effect mediated by alterations of contractile proteins. Tachycardia is almost always present, and tachycardia during sleep (pulse rate >90 beats/minute) serves to distinguish tachycardia of thyrotoxic origin from that of psychogenic causes. Widening of the pulse pressure is due to an increase in systolic pressure and a decrease in diastolic pressure.

RAIU, radioactive iodine uptake; TSH, thyrotropin.

*Except for iodine-induced hyperthyroidism, associated with increased values of RAIU. Associated with decreased values of RAIU.

The increased force of cardiac contraction is often felt by the patient as palpitations and may be evident on inspection or palpation of the precordium. Because of the diffuse and forceful nature of the apex beat, the heart may seem enlarged but echocardiographic findings are usually normal. Heart sounds are loud and ringing, and a systolic or even a late diastolic or presystolic murmur (Means-Lerman scratch) may be present at the apex. A scratchy systolic sound along the left sternal border, resembling a pleuropericardial friction rub, may also be heard. These manifestations usually abate when a normal metabolic state is restored. Mitral valve prolapse occurs more frequently than in the normal population and may persist indefinitely.
Cardiac arrhythmias are almost invariably supraventricular. Approximately 10% of patients with thyrotoxicosis have atrial fibrillation, and a similar percentage of patients with otherwise unexplained atrial fibrillation are thyrotoxic. In a study of more than 2000 individuals 60 years of age or older, atrial fibrillation developed in 28% of those with a suppressed thyrotropin (TSH, or thyroid-stimulating hormone) level. 3 Paroxysmal supraventricular tachycardia may be demonstrable or may be suggested by the history. Systolic time intervals are altered in thyrotoxicosis, the pulse-ejection period is shortened, and the ratio of pre-ejection period to left ventricular ejection time is decreased.

The adequacy of the circulation is an important issue. The increased cardiovascular cost of a standard workload or metabolic challenge is adequately met if the patient is not or has not previously been in heart failure. Thus, in most patients without underlying heart disease, cardiac competence is maintained. Mild edema may occur in the absence of heart failure. Thyrotoxicosis may lead to congestive heart failure, but even so, the circulation time may remain short. Heart failure usually occurs in patients with preexisting heart disease, but it may not be possible to determine whether underlying heart disease is present until after thyrotoxicosis is relieved.

Atrial fibrillation decreases the efficiency of the cardiac response to any increased circulatory demand and may play a role in causing cardiac failure. Attempts to convert atrial fibrillation to sinus rhythm are usually of no avail while thyrotoxicosis is present. Regardless of the type of rhythm, the response to digitalis is decreased, possibly because of accelerated metabolism of the drug, and large quantities may be required to produce a clinical effect. Resistance to digitalis and failure of cardiac decompensation to respond to a usually adequate regimen should suggest the possibility of thyrotoxicosis. It is obviously important to deal definitively with thyrotoxicosis in a patient with concomitant heart disease.

Sympathetic Nervous System

Many of the manifestations of thyrotoxicosis and sympathetic nervous system activation are similar. As judged from the plasma concentrations of epinephrine and norepinephrine, as well as their urinary excretion and that of their metabolites, the activity of the sympathetic nervous system is not increased in patients or animals with thyrotoxicosis, and thyroid hormones may exert effects separate from, but similar and additive to, those of the catecholamines. Consideration of the relationship between catecholamines and thyroid hormone excess and deficiency reveals the futility of attempting a generalization in this area. 4

The reduction in heart rate and in some clinical manifestations of hyperthyroidism induced by -blockade in patients with this condition has led to the concept of an increased sympathetic tone or increased cardiac sensitivity to the sympathetic nervous system. Careful studies have shown that this is clearly not the case in terms of the heart. 4 Adequate -adrenergic blockade reduces the basal level of cardiac output, but the slope of the epinephrine dose-response curve is not altered in hyperthyroidism. In other tissues, the situation may be even more complex and species differences may exist.

In hyperthyroid patients, there are no alterations in -adrenergic receptor number on lymphocytes and no changes in lymphocyte -adrenergic responsiveness, suggesting that clinical effects are direct on the target cell. However, the 1-adrenergic receptor is down-regulated by thyroid hormone. 5

In normal subjects given thyroid hormone for 10 days, the -adrenergic receptor number in fat and skeletal muscle increased 60% and 30%, respectively, but metabolic and hemodynamic sensitivity to infused epinephrine in vivo were not altered. 6 7 There was no evidence of increased glycoemic, lipolytic, glycojenolytic, or ketogenic sensitivity to catecholamines,
when caloric intake exceeds the metabolic demand. Anorexia, rather than hyperphagia, occurs in about one third of elderly thyrotoxic patients and contributes to the picture of apathetic thyrotoxicosis.

Stools are frequently soft and the frequency of bowel movements is increased, but diarrhea is rare. When constipation has preceded the development of thyrotoxicosis, bowel function may become normal. Anorexia, nausea, and vomiting are uncommon but may occur with severe disease. These symptoms, as well as abdominal pain, may be forerunners of accelerated thyrotoxicosis. The increased gastric emptying and intestinal motility in thyrotoxicosis appear to be responsible for slight malabsorption of fat, and these functions return to normal when a normal metabolic state has been restored. Celiac disease and Graves’ disease may coexist, and a high proportion of patients have gastric achlorhydria. In most cases, acid secretion returns after relief of the thyrotoxicosis. Autoantibodies against gastric parietal cells are detectable in some patients with Graves’ disease, and approximately 3% have pernicious anemia. In the oral glucose tolerance test, the glycemic peak is frequently delayed.

Hepatic dysfunction occurs, particularly when thyrotoxicosis is severe; hypoproteinemia and increases in serum alanine aminotransferase and alkaline phosphatase levels may be present. Hepatomegaly and jaundice occasionally develop. Splanchnic oxygen consumption is increased, whereas splanchnic blood flow is essentially unchanged. As a result, the arteriovenous oxygen difference across the splanchnic bed is increased; hence, hypoxia may contribute to hepatic dysfunction. Hypoxia and the relative caloric deprivation may partly account for the depletion of hepatic glycogen that is evident both in the response to glycogenolytic agents and on direct analysis. In the absence of severe thyrotoxicosis or congestive heart failure, the liver usually appears normal on light microscopic examination. Ultramicrorscopic examination of the liver reveals enlarged mitochondria and hypertrophic smooth endoplasmic reticulum. Graves’ disease and autoimmune hepatitis may also coexist.

Nervous System

Alterations in nervous system function in patients with thyrotoxicosis are manifested by nervousness, emotional lability, and hypokinesia. The nervousness is not typical of the patient who is chronically anxious but, rather, is characterized by restlessness, shortness of attention span, and a compulsion to be moving around, sometimes referred to as almost “fidgeting.” Unlike the patient with neurocirculatory asthenia, the thyrotoxic patient wishes to be active but is hampered by fatigue and is tired from the neck down rather than from the top of the head down. Fatigue may be due both to muscle weakness and to the insomnia that is commonly present. In some patients, severe wasting and fatigue impair overall activity. Emotional lability causes patients to lose their temper easily and to have episodes of crying with only slight provocation. In rare cases, mental disturbance may be severe; manic-depressive, schizoid, or paranoid reactions may emerge.

The hypokinesia of the thyrotoxic patient is characteristic. During the interview, the patient cannot sit still, may drum on the table, may tap a foot, or may shift positions frequently. Movements are quick, jerky, exaggerated, and often purposeless. In children, in whom such manifestations tend to be more severe, Sydenham’s chorea may be suggested. Examination also reveals a fine, rhythmic tremor of the hands, tongue, or lightly closed eyelids. With the aid of a magnifying glass, a tremor of the eyeballs may be seen. The tremor may sometimes mimic that of parkinsonism, and coexisting parkinsonism should be considered. The electroencephalogram reveals an increase in fast-wave activity, and in patients with convulsive disorders, the frequency of seizures is increased.

The physiologic basis of these nervous system findings is not well understood; they may reflect increased adrenergic activity because some improvement occurs during treatment with adrenergic antagonists. The widespread distribution of thyroid hormone receptors in the brain makes it likely that alterations in cerebral metabolism are induced by thyroid hormone excess. Nevertheless, oxygen consumption by the brain is not altered.

Muscle

Weakness and fatigability are usually not accompanied by objective evidence of muscle disease except for the generalized wasting associated with loss of weight. Often the weakness is most prominent in the proximal muscles of the limbs, causing difficulty in climbing stairs or in maintaining the leg in an extended position. The latter maneuver can be employed to assess the degree of muscle weakness.

Occasionally, in severe untreated cases, muscle wasting that again tends to be proximal develops out of proportion to the overall loss of weight (thyrotoxic myopathy). In the extreme form, the patient may be unable to rise from a sitting or lying position and may be virtually unable to walk. This disorder may resemble progressive muscular atrophy or polymyositis; however, fasciculation is absent, and little if any inflammatory change is evident on biopsy. Instead, the muscle is atrophic and infiltrated with fat cells and lymphocytes. Electron microscopy reveals abnormal mitochondria and dilatations of the myotubular system. Electromyograms reveal a decreased duration of action potentials and an increased number of polyphasic potentials. The biochemical basis of the muscle weakness is uncertain but may be related to the impaired ability to phosphorylate creatine.

Myopathy affects men with thyrotoxicosis more commonly than women and may overshadow the other manifestations of the syndrome. In the most severe forms, the myopathy may involve the more distal muscles of the extremities and the muscles of the trunk and face. Although myopathy of ocular muscles is unusual, the disorder may mimic myasthenia gravis or the ophthalmic form of myasthenia. Muscular strength returns to normal when a normal metabolic state is restored, but muscle mass takes longer to recover.

Graves’ disease occurs in about 3% to 5% of patients with myasthenia gravis, and myasthenia gravis develops in about 1% of patients with Graves’ disease. Antibodies and T cells specific for receptors of the TSH receptor (TSHR) and the acetylcholine receptor are involved in the pathogenesis of the two diseases. Unlike thyrotoxic myopathy, the association of myasthenia gravis with Graves’ disease has a distinct female preponderance. Although the effect of both thyrotoxicosis and its alleviation on the course of myasthenia gravis is variable, in most instances myasthenia is accentuated during the thyrotoxic state and improves when a normal metabolic state is restored.

Periodic paralysis of the hypokalemic type may occur together with thyrotoxicosis, and its severity is accentuated by the latter disorder. The coincidence of the two disorders is particularly common in Asian and Latino men.

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is generally associated with the following:

1. Increased excretion of calcium and phosphorus in urine and stool.
2. Demineralization of bone, as demonstrated by routine bone densitometry.
3. Occasionally, pathologic fractures, especially in older women.

In these instances, the pathologic changes are variable and may include ostestis fibrosa, osteomalacia, and osteoporosis.

Urinary excretion of collagen breakdown products is increased, indicating increased turnover of collagen. Kinetic studies indicate an increase in the exchangeable calcium pool and acceleration of both bone resorption and accretion, particularly the former. The changes lead to decreased bone density and a propensity to hip fractures in later years. As thyrotoxicosis is treated, bone density may improve. Postmenopausal women, however, may have a permanent reduction in bone density that may require treatment with agents that increase bone density (see Chapter 29). Much controversy has existed over the induction of decreased bone density by thyroid hormone replacement therapy in hypothyroidism and thyroid hormone suppression therapy in patients with thyroid cancer. Suffice it to say that postmenopausal women who receive excessive thyroid hormone are at certain risk of bone damage, but careful replacement therapy does not harm to anyone.

Hypercalcemia can occur in patients with thyrotoxicosis. The total serum calcium concentration is increased in as many as 27% of patients, and the ionized serum calcium level is elevated in 47%. The concentrations of heat-labile serum alkaline phosphatase and osteocalcin may also be elevated. These findings resemble those of primary hyperparathyroidism, but the concentration of immunoreactive parathyroid hormone in serum is decreased in most thyrotoxic patients with
hypercalcemia. True primary hyperparathyroidism and thyrotoxicosis may sometimes coexist. Hypercalcemia may be severe enough to induce anorexia, nausea, vomiting, polyuria, and occasionally impairment of renal function. The alterations in calcium metabolism in thyrotoxicosis may be due to a direct effect of thyroid hormones in stimulating bone resorption and are reversed when the eumetabolic state is restored. Plasma 25-hydroxyvitamin D, (25-hydroxycholecalciferol) levels are decreased in thyrotoxic patients, and this alteration may contribute to the decreased intestinal absorption of calcium and osteomalacia noted in some patients.

Renal Function: Water and Electrolyte Metabolism

Thyrotoxicosis produces no symptoms referable to the urinary tract other than mild polyuria. Nevertheless, renal blood flow, glomerular filtration, and tubular reabsorptive rates are increased. Total amounts of body water and exchangeable potassium are decreased, possibly because of a decrease in lean body mass, but the amount of exchangeable sodium tends to be increased. Serum sodium, potassium, and chloride concentrations are normal. In patients with thyrotoxicosis, the level of exchangeable magnesium is normal; the serum magnesium concentration is often decreased, and urinary magnesium excretion is increased.

Hematopoietic System

Red blood cells are usually normal, as judged by the usual indices, but red blood cell mass is increased. The increase in erythropoiesis appears to be due both to the direct effect of thyroid hormones on the erythroid marrow and to increased production of erythropoietin. A parallel increase in plasma volume also occurs, resulting in a normal hematocrit value. Other abnormalities in thyrotoxicosis include a reduced content of zinc and carbonic anhydrase and an increased content of sodium in red blood cells, probably because the activity of Na⁺-K⁺-ATPase is impaired (in contrast with the increased Na⁺-K⁺-ATPase activity sometimes seen in other tissues).

Approximately 3% of patients with Graves' disease have pernicious anemia, and an additional 3% have antibodies to intrinsic factor but normal absorption of vitamin B₁₂. Autoantibodies against gastric parietal cells may also be present in patients with Graves' disease, and the requirements for vitamin B₁₂ and folic acid appear to be increased. Rarely, thyrotoxicosis is associated with a mild hypocromic anemia characterized by adequate stores of iron in marrow and responsive to large doses of pyridoxine (vitamin B₆).

The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased, leading to a relative lymphocytosis. The numbers of monocytes and eosinophils may also be increased. Splenic enlargement occurs in about 10% of the patients, and thymic and lymph node enlargement is common. These abnormalities are thought to be a reflection of the autoimmune aspects of Graves' disease because they do not occur in thyrotoxicosis stemming from other causes.

Platelet levels and the intrinsic clotting mechanism are normal, but factor VIII concentrations are often elevated and return to normal when the thyrotoxicosis is treated. Despite this elevation, there is an enhanced sensitivity to anticoagulants of the coumarin series because of accelerated clearance of the vitamin K-dependent clotting factors. Somewhat paradoxically, the dosage of such anticoagulants may have to be reduced in thyrotoxic patients and is increased in hypothyroid patients. Coincidental autoimmune thrombocytopenia may also occur.

Pituitary and Adrenocortical Function

The thyrotoxic state imposes several challenges on pituitary and adrenocortical function. The inactivation of cortisol is accelerated, including reduction of the A ring, which is rapidly followed by conjugation, and oxidation of the 11-hydroxy group to a keto group as a result of an increase in 11β-hydroxysteroid dehydrogenase (HSD) activity. As a result of these changes the disposal of cortisol is accelerated, but its rate of secretion is also increased, so the plasma cortisol concentration remains normal. The concentration of corticosteroid-binding globulin in plasma is normal. Urinary excretion of free cortisol and 17-hydroxycorticosteroids is normal or slightly increased, whereas urinary excretion of 17-ketosteroids may be reduced.

Basal pituitary-adrenal function is adequate, as indicated by normal plasma cortisol concentrations, and the response to an acute challenge, such as that imposed by insulin-induced hypoglycemia, is adequate. The rate of turnover of aldosterone is increased, but the plasma level is normal. Plasma renin activity is increased, and sensitivity to angiotensin II is reduced.

The response of plasma growth hormone concentration to insulin-induced hypoglycemia is subnormal, particularly in those with severe disease. This observation may not indicate deficient growth hormone production but, rather, may reflect depletion of pituitary stores from caloric inadequacy or accelerated removal of growth hormone from plasma. Incomplete suppression of plasma growth hormone concentration by induced hyperglycemia may also reflect prolonged caloric deprivation.

Reproductive Function

Thyrotoxicosis in early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated. Thyrotoxicosis after puberty influences reproductive function, especially in women. An increase in Iβ-hormone sometimes occurs in both men and women. The intermenstrual interval may be prolonged or shortened, and menstrual flow is initially diminished and ultimately ceases. Fertility may be reduced, and if conception takes place, the risk of miscarriage is increased. The association of thyroid autoantibodies and increased pregnancy loss is not related to changes in thyroid function; the thyroid autoantibodies are thought to represent a marker of immune instability predisposing to pregnancy interruption, as seen in an animal model.

In some patients, menstrual cycles are predominantly anovulatory with oligomenorrhea; in most patients, however, ovulation occurs, as indicated by a secretory endometrium. In the former situation, a subnormal midcycle surge of luteinizing hormone (LH) may be responsible. In premenopausal women with thyrotoxicosis, basal plasma concentrations of LH and follicle-stimulating hormone (FSH) are reportedly normal but may display enhanced responsiveness to gonadotropin-releasing hormone (GnRH).

Thyrotoxicosis, whether spontaneous or induced by triiodothyronine (T₃), is accompanied by an increase in the concentration of sex hormone-binding globulin in plasma. As a result, the plasma concentrations of total testosterone, dihydrotestosterone (DHT), and estradiol are increased, but their unbound fractions are normal or transiently decreased. The increased binding in plasma is responsible for the decreased metabolic clearance rate of testosterone and DHT. In the case of estradiol, however, the metabolic clearance rate is normal, suggesting that tissue metabolism of the hormone is increased.

Conversion rates of androstenedione to testosterone, estrone, estradiol, and of testosterone to DHT are increased. The increased rate of conversion of androgens to estrogens may be the mechanism of gynecomastia and erectile dysfunction in about 10% of thyrotoxic men and may be one mechanism of menstrual irregularities in women. Another more likely mechanism of menstrual changes is the disruption in amplitude and frequency of LH/FSH pulses due to thyroid hormone influences on GnRH signaling.

Catecholamines and Serotonin

Many effects induced by thyroid hormones are reminiscent of those induced by epinephrine, including tachycardia, increased cardiac output, and enhanced glycolysis, lipolysis, and calorigenesis (see earlier). Moreover, the fact that some of the manifestations of thyrotoxicosis among them eyelid retraction, tremor, excessive sweating, and tachycardia are at least partly alleviated by adrenergic antagonists has been interpreted as indicating that a state of increased adrenergic activity exists in the thyrotoxic organism. As discussed earlier, however, this apparent adrenergic hyperactivity appears to be a consequence of a direct effect of thyroid hormones on these tissues or due to decreased vagal tone.

Plasma levels of epinephrine and norepinephrine are normal but 24-hour catecholamine secretion may be increased.

Some manifestations of thyrotoxicosis, such as flushing, sweating, tachycardia, and gastrointestinal hypermotility, are also reminiscent of those of carcinoid syndrome. However, plasma serotonin levels, urinary 5-hydroxyindoleacetic acid excretion, and platelet monoamine oxidase activity are normal.
The stimulation of energy metabolism and heat production is reflected in the increased basal metabolic rate, increased appetite, and heat intolerance and in a sometimes slightly elevated basal body temperature. Despite an increased food intake, a state of chronic caloric and nutritional inadequacy often ensues, depending on the degree of increased metabolism. Both synthesis and degradation of protein are increased (the latter to a greater extent than the former), with the result that there is a net decrease in tissue protein, as indicated by negative nitrogen balance, loss of weight, muscle wasting, weakness, and mild hypoalbuminemia. The oral glucose tolerance curve is often abnormal and varies from one in which the peak glycemia is increased and somewhat delayed to one that is frankly diabetic. Plasma insulin concentrations, however, are increased, suggesting insulin resistance. The pathogenesis of these alterations remains to be defined. Preexisting diabetes mellitus is exacerbated by thyrotoxicosis, one cause being increased degradation of insulin.

Both synthesis and degradation of triglycerides and of cholesterol are increased, but the net effect is one of lipid degradation, as reflected by an increase in the plasma concentration of free fatty acids and glycerol and a decrease in the serum cholesterol level; serum triglyceride levels are usually slightly decreased. Postheparin lipolytic activity is reported to be decreased in some studies and increased in others. The enhanced mobilization and oxidation of free fatty acids in response to fasting, catecholamines, and growth hormone are probably due to activation of adenylate cyclase and result in a tendency to ketosis and to fatty infiltration of the liver, depending on the degree of caloric deprivation.
Composite Clinical Picture and Laboratory Tests in Thyrotoxic States

The effects of thyrotoxicosis on the major organ systems are the same, regardless of the underlying cause. Their frequency and intensity and other findings with which they are associated are influenced by the nature of the underlying disorder. To a large extent, the same is true of laboratory test results. Consequently the clinical picture, laboratory features, and differential diagnosis are considered in relation to the specific etiologic mechanisms (see Table 11-1).
ROBERT GRAVES’ DISEASE

Background

Robert Graves’ disease, although first described by Parry in 1825, is best known as Graves’ disease in the English-speaking world and as von Basedow’s disease on the continent of Europe because of the prominence of the disease reports by these eminent physicians. It is the most enigmatic and, in areas of iodine abundance, one of the most common of thyroid diseases.

Presentation

Graves’ disease is characterized by diffuse goiter, thyrotoxicosis, infiltrative orbitopathy and ophthalmopathy, and occasionally infiltrative dermopathy. In the individual patient, thyroid disease and the infiltrative phenomena may occur singly or together but run courses that are largely independent. The thyroid component is closely related to autoimmune thyroiditis (Hashimoto’s disease) in its pathogenesis and clinical course. In Graves’ disease, hyperthyroidism occurs in the presence of some degree of chronic thyroiditis and may ultimately be replaced, in the long term, by thyroid hypofunction. Conversely, hyperthyroidism may occasionally supervene in patients with preexisting Hashimoto’s thyroiditis. Both of these diseases may occur within the same family.

Autoimmune Characteristics

Autoimmune thyroid disease is characterized by the occurrence in the serum of antibodies against thyroid peroxidase (TPO) (the “microsomal” antigen), thyroglobulin (Tg), and the TSHR. T-cell mediated autoimmunity can also be demonstrated against the three primary thyroid antigens, as judged by a variety of criteria, including the ability of the T cells to elaborate various lymphokines and to exhibit a mitogenic response when exposed to thyroid antigens or to peptide sequences from the antigens. Autoimmune thyroid disease is also characterized by lymphocytic infiltration of the thyroid gland or remnant thyroid bed. In patients and their relatives, there is an increased frequency of other disorders of autoimmune origin, such as insulin-dependent diabetes mellitus, pernicious anemia, myasthenia gravis, adrenal atrophy, Sjögren’s syndrome, lupus erythematosus, rheumatoid arthritis, and idiopathic thrombocytopenic purpura [(see Chapter 37)].

Circulating autoantibodies specific to hyperthyroid Graves’ disease are directed against the TSHR (TSHR Abs) and behave as thyroid-stimulating antibodies. These antibodies can compete for the binding of TSH to its specific receptor site in the cell membrane (Fig. 11-1) and can activate adenylate cyclase as TSH agonists (Fig. 11-2). Simlar but distinct autoantibodies in the sera of some patients with autoimmune thyroiditis do not stimulate the thyroid cell and may block the ligand-binding site and act as TSH antagonists [(Fig. 11-3)].

The thyroid gland itself is a site of thyroid autoantibody secretion in autoimmune thyroid disease via the B cells that form part of the intrathyroidal infiltrate. Transplantation of Graves’ thyroid tissue into T-cell-deficient and B-cell-deficient mice with severe combined immunodeficiency (scid) mice results in the appearance of human thyroid autoantibodies, including TSHR Abs, in the serum. Additional evidence for a role of the thyroid itself in antibody production comes from animal models of thyroiditis and from the decline in thyroid autoantibody levels after antithyroid drug treatment, thyroidectomy, or radioiodine ablation. After thyroidectomy and radiiodine treatment, however, some patients show no decline in autoantibody secretion, which suggests extrathyroidal sources of continued production.

Pathology

In patients with Graves’ disease, the thyroid gland is characterized by a nonhomogeneous lymphocytic infiltration with an absence of follicular destruction (Fig. 11-4). Antithyroid drug treatment may reduce the degree of infiltration. Although the intrathyroidal lymphocyte population is mixed, most are T lymphocytes; B-cell germinal centers are less common than in autoimmune thyroiditis. However, both intraepithelial T cells and plasma cells can be seen in peripolesis within the thyroid follicles. Follicular epithelial cell size correlates with the intensity of the local infiltrate, suggesting local thyroid cell stimulation by TSHR Abs. Memory T cells may predominate within the T-cell population, but this finding can vary from patient to patient. Activated B-cell and T-cell markers are more frequent in intrathyroidal lymphocyte cultures than in peripheral blood cultures.

Prevalence

In the United States, the prevalence of Graves’ disease is uncertain but is assumed to be similar to that of the one well-designed epidemiologic survey published. This survey came from Whickham, a small town in the northeast of England (2800 in population), an area thought to be representative of the United Kingdom. The results indicated a prevalence of 2.7%, past and present, in women and a prevalence about one tenth as frequent in men. Overall, the incidence was estimated, in women, to be 1 case per 1000 per year over a 20-year follow-up. Graves’ disease is the most common cause of spontaneous hyperthyroidism in patients younger than 40 years of age, and the hazard rate does not change with age. The overall prevalence of autoimmune thyroid disease, comprising Graves’ disease and autoimmune thyroiditis, approaches or exceeds that of diabetes mellitus (Table 11-3).
Pathogenesis

The Major Antigen of Graves' Disease—the Thyrotropin Receptor

The TSH receptor (TSHR) is G protein-linked with seven transmembrane domains and employs cyclic adenosine monophosphate (cAMP) and the phosphoinositol pathways for signal transduction. The human TSHR (hTSHR) is the primary autoantigen of Graves' disease, as shown by the development of hyperthyroidism in mice and hamsters after immunization.

![Figure 11-2: Stimulation of adenylyl cyclase activity in human thyroid membranes by serum immunoglobulin G in normal control subjects and patients with thyroid disease.](Figure Not Available)

with hTSHR antigen (Fig. 11-5) (Figure Not Available) (see also Color Plate). Putative extrathyroidal TSHR messenger RNA (mRNA) and receptor protein have been reported in many other tissues, including extraorbital adipocytes, muscle cells, lymphocytes, and fibroblasts, but the physiologic and pathologic role of TSH receptors in these sites is still under investigation.

Molecular Biology of the Human Thyrotropin Receptor

Cloning of TSHR complementary DNA (cDNA) of animals and humans made it possible to define the structure of the hTSHR gene and its chromosomal location (14q31). The hTSHR gene spans more than 60 kb and is split into 10 exons. Seven hydrophobic transmembrane spanning regions in the hTSHR indicate that it is a member of the G protein-coupled receptor gene superfamily, and those receptors with large extracellular domains have been designated subgroup B. The hTSHR-specific mRNA of human thyroid consists of a major 4.3-kb transcript and additional smaller species, indicating that mRNA undergoes alternate splicing.

Protein Structure of the Human Thyrotropin Receptor

The hTSHR holoreceptor consists of a 100-kd, glycosylated, 744-amino acid sequence and a 20-amino acid signal peptide. ProTSHR is cleaved into two subunits, (or A) and (or B), which are linked by disulfide bonds to form the physiologic receptor. The 50-kd subunit is water-soluble and may contain the TSH-binding site, previously referred to as long-acting thyroid stimulator (LATS)-absorbing activity (LAA). The 30-kd subunit is water-insoluble, contains the membrane spanning domain, with its three extracellular loops and three cytoplasmic loops, and is 70% to 75% homologous with the LH/human chorionic gonadotropin (hCG) receptor. Shedding of the subunit has been suggested in vitro. The TSHR forms dimers and multimeric complexes on the thyroid cell surface, and these are of unclear physiologic significance.

Autoantibodies to the Thyrotropin Receptor

In Graves' disease, TSHR Abs bind to the TSH receptor, activate adenylate cyclase, induce thyroid growth, increase vascularity, and cause an increased rate of thyroid hormone production and secretion. TSHR Abs in patients with Graves' disease are referred to as stimulating or agonist types of TSHR Abs, as first described by Adams and Purves. Other varieties of TSHR Abs may also be present, namely a receptor antibody that acts as a TSH antagonist and referred to as blocking TSHR Abs or a neutral form of antibody with no functional effect on the receptor. Blocking TSHR Abs may be coincident with the stimulating type and may also predominate in certain patients after treatment with radioactive iodine, antithyroid drugs, or surgery. Blocking TSHR Abs can also be found in 15% of patients with autoimmune thyroiditis, particularly in patients without a goiter (the atrophic variety). TSHR Abs are not detectable in the normal population with the use of currently available methods.

Immunoreactivity of Thyrotropin Receptor Autoantibody

The self-infusion of sera from patients with Graves' disease caused thyroid stimulation and was the first demonstration of the role of TSHR Abs in the induction of human hyperthyroidism. Another example of the in vivo effects of TSHR Abs came from studies in neonates demonstrating the transplacental stimulation of the fetal thyroid in mothers with high titers of TSHR Abs. TSHR Abs show light chain restriction in many patients with Graves' disease, and TSHR Abs that exhibit TSH agonist bioactivity are in the immunoglobulin G1 (IgG1) subclass; both observations suggest oligoclonality.

As discussed earlier, autoantibodies that bind to the TSH may or may not activate adenylate cyclase and may thus be either TSH-stimulating or TSH-blocking (see Fig. 11-3). Further complicating this issue is the fact that many patients have both TSH-stimulating and TSH-blocking antibodies, the degree of thyroid...
stimulation depends on the relative concentration and bioactivity of the different autoantibodies.

Prevalence of Thyrotropin Receptor Autoantibodies in Graves' Disease

The fact that TSHRABs are detectable only in patients with autoimmune thyroid disease indicates that the autoantibodies are disease-specific, in contrast with the high prevalence of Tg antibodies and TPO antibodies in the normal population. Furthermore, TSHRABs are unique human autoantibodies and do not occur in natural animal disease. A total of 80% to 100% of untreated hyperthyroid patients with Graves’ disease have detectable TSHRABs with thyroid-stimulating activity. The levels of TSHRABs are decreased by treatment of the disease and, when they persist, are predictive of failure of response to antithyroid drug treatment. With time, TSHRAB-blocking auto-antibodies may become the prevalent type after treatment of Graves’ disease.

*Per 1000 population per year over a 20-year period.

Antibodies interact with either linear (conformationally independent) or nonlinear (conformationally dependent) areas of a target molecule called the epitope. The strength of the binding of antibodies to target antigen (affinity of the antibody) depends largely on the number of binding sites the antibody has with the antigen. These sites contribute to the binding energy, which is therefore likely to be greater for large nonlinear epitopes than for small linear peptides. High-affinity antibodies are thus most likely to interact with nonlinear epitopes and to depend on the natural conformation of the target molecule.

The T-cell receptor is also a member of the Ig receptor superfamily but interacts only with a complex of antigen and HLA molecule. The CD8 T cells recognize target antigen complexed with HLA class I molecules (A, B, and C), and CD4 T cells recognize antigen complexed with HLA class II molecules (D, P, and Q). The antigen that interacts with T cells when complexed with autologous HLA molecules is a 15amino acid linear peptide derived from the whole antigen molecule.

Thyroid antigens are endocytosed by antigen-presenting cells (APCs), such as macrophages and dendritic cells, and secretory state.

Principles of Antigenic Recognition

Antibodies interact with either linear (conformationally independent) or nonlinear (conformationally dependent) areas of a target molecule called the epitope. The strength of the binding of antibodies to target antigen (affinity of the antibody) depends largely on the number of binding sites the antibody has with the antigen. These sites contribute to the binding energy, which is therefore likely to be greater for large nonlinear epitopes than for small linear peptides. High-affinity antibodies are thus most likely to interact with nonlinear epitopes and to depend on the natural conformation of the target molecule.

The T-cell receptor is also a member of the Ig receptor superfamily but interacts only with a complex of antigen and HLA molecule. The CD8 T cells recognize target antigen complexed with HLA class I molecules (A, B, and C), and CD4 T cells recognize antigen complexed with HLA class II molecules (D, P, and Q). The antigen that interacts with T cells when complexed with autologous HLA molecules is a 15amino acid linear peptide derived from the whole antigen molecule. Thyroid antigens are endocytosed by antigen-presenting cells (APCs), such as macrophages and dendritic cells; peptide breakdown products are then bound to HLA molecules, and the entire complex is transported to the cell surface where the peptide lies within a clearly defined binding groove within the HLA molecule.

In addition to the recognition of antigen (the first immune cell signal), immune cells (both T and B) also depend on secondary signals to enter an active proliferative and secretory state. Cytokines originating from T cells serve as secondary B-cell signals. Important second signals for the T cells include the CD80 (B7) family of molecules, and the entire complex is transported to the cell surface where the peptide lies within a clearly defined binding groove within the HLA molecule.

Figure 11-6 Human thyrotropin receptor (hTSH-R) exon structure. Outline structure of the TSH-R (A) in comparison with the porcine luteinizing hormone receptor (pLH-R) and rat follicle-stimulating hormone receptor (fFSH-R) genes and (B) the exon/intron organization of the TSH-R gene. A shows the similarity (%) between the hTSH-R and the pLH and rFSH receptors, respectively. (From Gross B, Mirahl M, Sar S, et al. Composite structure of the human TSH receptor gene. Biochem Biophys Res Comm 1991; 177:679687.)

Thyrotropin Receptor Autoantibody Epitopes

The extracellular domain of the TSHR is the major site of TSHRAB binding (see Fig. 11-7). The difference in functional activity of different TSHRABs also depends on receptor conformation and affinity. The use of recombinant chimeric TSH/LH receptors has suggested at least two major regions of TSHRAB binding that may convey thyroid-stimulating activity (the N-terminal end) and thyroid-blocking activity (the C-terminal end); however, the situation is probably more complex than this. Prokaryotic TSHR extracellular domain has also been used to identify immunogenic regions using antibodies from immunized mice and from patients with Graves’ disease. These data suggested that some TSHRABs may also recognize linear epitopes, but these may be neutral rather than pathologic antibodies.

Control of Thyrotropin Receptor Function in Graves’ Disease

Like TSH, TSHRABs cause cAMP-mediated generation of thyroid hormone and Tg, uptake and release of iodine, stimulation of protein synthesis, and cell growth.

Desensitization of the thyroidal cAMP response by prolonged exposure to TSHRABs can be observed in vitro but cannot be complete in vivo, or else patients would not remain hyperthyroid.

At lower levels of stimulation, the TSHR is positively regulated by TSH both in vivo and in vitro, and such resistance to desensitization by low levels of TSH may allow the hyperthyroid state to persist.

Principles of Antigenic Recognition

Antibodies interact with either linear (conformationally independent) or nonlinear (conformationally dependent) areas of a target molecule called the epitope. The strength of the binding of antibodies to target antigen (affinity of the antibody) depends largely on the number of binding sites the antibody has with the antigen. These sites contribute to the binding energy, which is therefore likely to be greater for large nonlinear epitopes than for small linear peptides. High-affinity antibodies are thus most likely to interact with nonlinear epitopes and to depend on the natural conformation of the target molecule.

The T-cell receptor is also a member of the Ig receptor superfamily but interacts only with a complex of antigen and HLA molecule. The CD8 T cells recognize target antigen complexed with HLA class I molecules (A, B, and C), and CD4 T cells recognize antigen complexed with HLA class II molecules (D, P, and Q). The antigen that interacts with T cells when complexed with autologous HLA molecules is a 15amino acid linear peptide derived from the whole antigen molecule. Thyroid antigens are endocytosed by antigen-presenting cells (APCs), such as macrophages and dendritic cells; peptide breakdown products are then bound to HLA molecules, and the entire complex is transported to the cell surface where the peptide lies within a clearly defined binding groove within the HLA molecule.

In addition to the recognition of antigen (the first immune cell signal), immune cells (both T and B) also depend on secondary signals to enter an active proliferative and secretory state. Cytokines originating from T cells serve as secondary B-cell signals. Important second signals for the T cells include the CD80 (B7) family of cell surface molecules found on APCs (e.g., macrophages and dendritic cells) that combine with CD28 on the T-cell surface and the CD40/CD40 ligand interaction, where CD40 is found more often on nonprofessional APCs (e.g., fibroblasts and thyroid cells). B cells and T cells that interact with specific antigen in the absence of a second signal may be deleted by apoptosis or may survive in a state of anergy (i.e., desensitized). Hence,

Data shown as 3H-thymidine uptake at 18 hours.
deletion and anergy combine to help define the repertoire of immune responses in an individual.

The Autoimmune Response

It is helpful to know whether autoimmune reactions are multireactive (representative of a secondary polyclonal immune response) or more focused, involving a restricted number of B cells and T cells. In autoimmune disease, a restricted immune response has been observed at the onset of the disease. The following discussion presents some of the evidence for this in Graves' disease.

Intrathyroidal T Cells

As described earlier, T cells in patients with autoimmune thyroid disease are reactive to thyroid antigens and to peptides derived from these antigens. About 10% of activated T cells infiltrating the thyroid gland in patients with autoimmune thyroid disease proliferate in response to thyroid cell antigens. Intrathyroidal T cells from patients with Graves' disease exhibit characteristics of helper T-cell subset 1 (Th1) (which secrete interleukin-2 [IL-2] and interferon) and Th2 (which secrete IL-4). Such T-cell populations enhance thyroid autoantibody secretion. Memory T cells enhance thyroid autoantibody secretion and may have both helper and cytotoxic (apoptosis-inducing) T-cell activity. The thyroid gland in patients with Graves' disease exhibits a small degree of apoptosis.

Bystander Activation

T-cell receptors (TCRs) consist of two noncovalently linked chains ( and ), each with variable (V), diversity (D, mainly), and junctional (J) regions. The V, D, and J genes code for the antigen recognition sites on the TCR that determine antigen specificity. In addition to the many V (>100) and J (>50) genes, random nucleotide (N) additions and deletions to the D region (the CDR3 region or DND region) provide additional complexity to the TCR repertoire. Studies of the V and V families expressed by intrathyroidal T cells from patients with Graves' disease have shown that human TCR V gene expression by T cells from within the thyroid gland differed from hTCR V gene expression found in peripheral blood from the same individuals. Additional evidence has been obtained in the thyroid gland for the presence of clonally expanded T cells based on the presence of multiple identical sequences within the generated fragments. Such information further documents that Graves' disease is an antigen-driven disorder that causes oligoclonal T-cell expansion. Similar data have been obtained in rheumatoid arthritis, multiple sclerosis, and other autoimmune diseases.

Regulatory T Cells

The presence of reduced levels of circulating CD8 (suppressor/cytotoxic) T cells in patients with Graves' disease suggested that a lack of suppressor/cytotoxic T cells might be responsible for the breakdown of tolerance in Graves' disease. However, thyroid hormone excess itself may give rise to changes in T-cell numbers. The immune system does exert some of its overall control via "regulatory" cells, including the secretion of T-cell cytokines and the suppressive influence of "anergized" T cells. In addition to these regulatory cells, other important mechanisms include both positive and negative selection of T cells and B cells in the thymus, and deletion of immature immune cells via antigen-initiated apoptosis, which takes place in the peripheral immune system. Deletion probably occurs when T cells and B cells see antigen in the absence of second signals (see earlier). When a mature immune cell sees antigen in the absence of second signal, it may become desensitized rather than deleted, a phenomenon known as anergy. Together, deletion, anergy, and apoptosis account for immunosuppression. However, certain HLA-DR haplotypes are associated with reduced suppressor T-cell function. For example, normal individuals with HLA-DR3 have reduced suppressor activity compared with non-DR3 individuals.

The Insult

Initiation is thought to occur with an insulin that leads to an immune response. This may take the form of a direct insult to the thyroid gland by a viral infection or another external influence, including trauma leading to activation of T cells or may be initiated elsewhere in the body. In the latter case, it would be the arrival of activated T cells in the thyroid gland that would start the process. Such an arrival may be nonspecific because the same T cells may arrive in many glands but the patient has a particular susceptibility to autoimmune thyroid disease (see "Risk Factors" later).

Bystander Activation

Evidence has mounted from a model of insulitis that bystander activation of local resident antigen-specific T cells may initiate autoimmunity. The presence of activated T cells within the thyroid gland following an insult may induce, via cytokine secretion, the activation of local thyroid-specific T cells. This series of events can occur only in a susceptible individual with the right immune repertoire. Bystander activation would arise from any activated T cells within the thyroid gland, which may be activated by many different infections and antigens unrelated to the thyroid gland itself. The attractiveness of this model is that many different types of infections would lead to the same clinical disease phenotype. There is much evidence for residual thyroid-resident T cells in the glands of patients with Graves' disease.

Molecular Memory (Specificity Crossover)

In addition to the effects of the direct release of cytokines from T cells activated elsewhere via the bystander effect, intrathyroidal T cells may become activated in another nonspecific way. Structural similarity between different antigens can lead to specificity crossover (or molecular mimicry). Antigenic similarity between bacteria...
and viruses and human proteins is common, and in one study 4% of monoclonal antibodies raised against a variety of viruses cross-reacted with antigens in tissues. Furthermore, mice infected with reovirus type 1 developed an autoimmune polyendocrinopathy with autoantibodies directed against normal pancreas, pituitary, thyroid, and gastric mucosa, suggesting molecular mimicry between a reoviral antigen and a common tissue antigen. Molecular mimicry has also been reported between Yersinia enterocolitica and the TSHR based on the observed cross-reaction between sera from patients with Yersinia infection and sera from patients with Graves’ disease and between retroviral sequences and the TSH receptor.

**Thyroid Cell Involvement by Aberrant Expression of Class II HLA Antigens**

Normal thyroid epithelial cells do not express HLA class II antigens, but they are expressed in thyroid glands from patients with autoimmune thyroid disease (Fig. 11.11) (see also Color Plate). As proposed by Hanafusa and colleagues, a local insult, such as a viral infection of the thyroid gland, can cause production of interferon or other cytokines in the thyroid gland, which in turn would induce HLA class II expression. This first-time expression would lead to enhanced presentation of thyroid autoantigens to the immune system and activation of local autoreactive thyroid-specific T cells in a susceptible individual. Support for this concept comes from the in vivo induction of MHC class II molecules on mouse thyrocytes by interferon that also induced autoimmune thyroiditis and the demonstration of the necessity for MHC class II antigen expression on TSH receptor expressing fibroblasts used in the induction of Graves’ disease in mice. A number of viruses may also induce MHC class II expression independent of immune cell cytokine secretion, including reovirus types 1 and 3 and cytomegalovirus.

**Cryptic Antigenic Epitopes**

T-cell tolerance depends on the visualization of self-antigens in sufficient amounts to initiate continuous T-cell deletion and anergy induction. However, many molecules are not seen in sufficient concentrations to cause the removal of T cells that may react to them. These antigens contain what are sometimes called cryptic epitopes. Hence, T cells specific for these cryptic epitopes may be present in normal immune repertoires. They may then induce autoaggressive T cells if such an epitope is uncovered or increased in concentration by a local insult. HLA class II antigen expression in a situation where it normally does not occur, such as the thyroid epithelial cell, would then allow the presentation of these normally cryptic thyroid antigens to local autoreactive T cells if they are present.
Risk Factors for Graves’ Disease

Genetic Susceptibility

The development and the subsequent course of Graves’ disease are greatly influenced by heredity. The role of heredity

factors is evidenced by the increased incidence in members of patients’ families of other autoimmune disorders, such as Hashimoto’s disease, insulin-dependent diabetes (type 1) or pernicious anemia, and of autoantibodies against endocrine tissues, gastric parietal cells, and intrinsic factor. Indeed, the propensity for development of thyroid autoantibodies appears to be an autosomal dominant trait linked to the CTLA4 gene that codes for a modulator of the second signal to T cells, as discussed earlier. In addition, monozygotic twins have a higher concordance rate of Graves’ disease than do dizygotic twins, and this is true despite the rearrangement of B-cell and T-cell V genes that cause the immune repertoires of identical twins to differ. (see also Chapter 37).

Hence, Graves’ disease appears to be an oligogenic disorder with a number of genetic loci that may contribute to disease susceptibility. However, no thyroid-specific genes have been found to be involved, and only chromosomal loci, not actual genes, have been linked to the disease. There is an increased frequency of the HLA DR3 and DQA10501 haplotypes in whites with Graves’ disease, although the HLA region provides less than 5% of the genetic susceptibility because it is associated but not linked. (133 134 135)

Infection

It is not known whether a specific infection initiates Graves’ disease. If infection were the cause of Graves’ disease, an identifiable agent should be present in most patients, and transfer of the agent to susceptible recipients should transfer the disease. It has been suggested that Graves’ disease is “associated” with infectious agents (e.g., Y. enterocolitica), but no studies meet the necessary criteria to prove this. Infections of the thyroid gland itself (e.g., subacute thyroiditis, congenital rubella) are associated with autoimmunity. (136) Nevertheless, a causative role of infectious agents has not been definitively demonstrated in Graves’ disease, although thyroid disease can be induced in experimental animals by certain viral infections. (137 138) Reports of retroviral sequences in the thyroid glands of patients with Graves’ disease have not been confirmed. (139 140 141)

Stress

Graves’ disease commonly appears to become evident either after severe emotional stress, such as the actual or threatened separation from a loved one, or after an acute fright, such as an automobile accident. There are, in fact, many clinical experiences and reports associating major stress with the onset of Graves’ disease, including data on the high incidence of thyrotoxicosis among refugees from Nazi prison camps. Some data suggest that stress induces an overall state of immune suppression by nonantigen-specific mechanisms, perhaps secondary to the effects of cortisol and corticotropin-releasing hormone action at the level of the immune cell. Furthermore, more patients with Graves’ disease are said to give a history of major stress in the 12 months before disease onset compared with control groups.

Following the acute immune suppression by stress, there is presumably an overcompensation by the immune system when the suppression is released. This would then precipitate autoimmune thyroid disease, as in the postpartum period during which Graves’ disease may occur 3 to 9 months after delivery. The rebound phenomenon would result in greater immune activity than normal and would precipitate disease if the individual were genetically susceptible.

Gender and Gonadal Steroids

Graves’ disease is more common in women than in men (7 to 10:1) and tends to become more prevalent after puberty. The female preponderance and the fact that the disorder is uncommon before puberty have suggested that gonadal steroids may be responsible for this difference. Indeed, androgens may suppress experimental autoimmune thyroiditis. Estrogen has been shown to influence the immune system, particularly the B-cell repertoire, and may be a reason for this susceptibility. However, Graves’ disease continues to occur after the menopause and is still seen in men. In fact, when the disease develops in men, it tends to occur at a later age, to be more severe, and to be accompanied more often by ophthalmopathy. Such observations have suggested that perhaps it is the X chromosome rather than sex steroids that is the responsible element in female susceptibility. Women have two X chromosomes and, therefore, would receive twice the gene dose. A locus on the X chromosome has indeed been linked to Graves’ disease, but the gene responsible has not yet been located. The phenomenon of X-gene inactivation has also been invoked in autoimmune disease. Female cells may inactivate different X chromosomes, leading to potentially differing gene expression between somatic cells and immune cells.

Pregnancy

Graves’ disease is uncommon during pregnancy because hyperthyroidism is associated with reduced fertility and increased pregnancy loss. In addition, pregnancy is a time of immunosuppression, so that the disease tends to improve as pregnancy progresses. Both T-cell and B-cell functions are diminished, and the rebound from this immunosuppression may contribute to the development of postpartum thyroid disease. As many as 30% of young women give a history of pregnancy in the 12 months before the onset of Graves’ disease, indicating that postpartum Graves’ disease is a surprisingly common presentation and that pregnancy is a major risk factor in susceptible women.

Iodine and Drugs

Iodine and iodine-containing drugs, such as amiodarone, may precipitate Graves’ disease or its recurrence in a susceptible individual. Iodine is most likely to precipitate thyrotoxicosis in an iodine-deficient population simply by allowing TSHRAs to be effective in stimulating more thyroid hormone to be formed. Whether there is any other precipitating event is unclear. Iodine may also damage thyroid cells directly and release thyroid antigens to the immune system.

Irradiation

There is no evidence that radiation exposure itself is a risk factor for Graves’ disease. However, there is evidence that thyroid autoantibodies are more prevalent in the radiation-exposed population and thus this fact should be considered. In addition, radioactive iodine (RAI) treatment may cause the onset or worsening of clinical ophthalmopathy, but often this is transient (see later).
Pathogenesis of Graves’ Orbitopathy and Dermopathy

The pathogenesis of the orbitopathy and dermopathy is now better understood than ever before. The extraocular muscle and adipose tissue are swollen by the accumulation in the extracellular matrix of glycosaminoglycans that are secreted by fibroblasts under the influence of cytokines such as interferon from local lymphocytes (Fig. 11-12 and Fig. 11-13) (see also Color Plate). This accumulation disrupts and impairs the function of muscle. As the disease runs its course and inflammation decreases, the damaged muscles become fibrosed. Hence, histologic examination shows a patchy muscle infiltrate predominantly of T cells, and some muscle cells exhibit HLA class II antigen as seen within the thyroid gland. Such T cells react in vitro with retro-orbital tissue. The antigen to which they react may be the TSH receptor itself.

The TSHR mRNA and protein are expressed in fibroblasts and adipocytes and in many other cells. However, retro-orbital tissues seem to express more TSHR than other sites, and/or the TSHR-specific T cells have a propensity for the retro-orbital tissues. Whatever the mechanism, the current working hypothesis is that the immune system recognizes an antigen common to the thyroid gland and retro-orbital tissues (and skin) and is likely to be the TSHR itself, the main antigen of Graves’ disease. Furthermore, patients with the most severe orbitopathy have the highest titers of TSHR Abs, and the level of TSHR Abs correlates with the severity of the eye disease. There is currently no convincing evidence that specific antibodies against orbital tissue contents play a primary pathogenic role. More likely, antigen-specific T cells have the major role in initiating the disorder. However, such antibodies may serve as markers of extraocular muscle inflammation.
Risk Factors in Ophthalmic Graves’ Disease

There is no evidence that a separate and distinct genetic risk can be ascribed to severe ophthalmic Graves’ disease, suggesting that it is mainly environmental factors that lead to the enhanced retro-orbital inflammation in some patients. All of the same risk factors (e.g., infection, stress, gender and gonadal steroids, pregnancy, and drugs) apply to the onset of both thyroid and eye involvement in Graves’ disease.

For example, it is well known that eye disease in men may be worse than expected. However, there are two distinct risk factors that deserve attention. The first is smoking, which may increase the risk for ophthalmic involvement in many studies, perhaps by causing anoxia or simply direct inflammation. The second is radioiodine, which in controlled clinical trials accentuates ophthalmic Graves’ disease. However, this worsening is typically mild and transient and can be ameliorated with corticosteroid treatment for the subsequent 3 to 4 months. For this reason, some physicians are reluctant to prescribe radioiodine to patients with severe eye disease unless the patients are receiving corticosteroids.
Natural History and Course of Graves' Disease

The course of the thyrotoxic component of Graves' disease is variable and often erratic. In some patients, thyrotoxicosis persists, although it may vary in severity. In others, the course may be cyclic, exhibiting remissions of varying frequency, intensity, and duration. This cyclic feature has an important bearing on treatment. With the passage of months or years, thyrotoxicosis tends to give way to euthyroidism. Approximately one third of patients become hypothyroid within 20 years of treatment with antithyroid agents.

The orbitopathy may or may not commence together with the thyrotoxic component. Thus, thyrotoxic patients may initially be free from eye disease but are affected by it months or years later or not at all. Conversely, Graves' disease may begin with orbitopathy and only later, if at all, be associated with thyrotoxicosis. In euthyroid patients with orbitopathy, so-called euthyroid Graves' disease, evidence of a thyroid abnormality, as judged from thyroid function tests and tests for TSHR Abs and other thyroid autoantibodies is common. Some such patients become hypothyroid within a few years, some become hyperthyroid, and a few remain euthyroid. Many euthyroid patients do have evidence of chronic thyroiditis. The course of thyroid function in many of these patients is therefore unpredictable.

Figure 11-14 Chronic pretibial myxedema in a patient with Graves' disease and orbitopathy. The lesions are firm and nonpitting, with a clear edge to feel. (Courtesy of Dr. Andrew Werner, New York, N.Y.)
Histopathology

Thyroid Gland

The older designation for Graves’ disease, diffuse toxic goiter, denoted that the gland was both enlarged and uniformly affected. The gland might vary in consistency from softer than normal to firm and rubbery. The outer surface is usually smooth but may be somewhat lobular; rarely, the gland is grossly nodular prior to treatment. The cut surface is red and glistening. Microscopically, the follicles are small and lined with hyperplastic columnar epithelium and contain scant colloid that displays much marginal scalloping and vacuolization (see Fig. 11-4). Nuclei are vesicular and basally located and exhibit occasional mitoses. Papillary projections of the hyperplastic epithelium extend into the lumina of the follicles. Vascularity is increased, and there is a varying infiltration by lymphocytes and plasma cells that collect in aggregates and may form germinal centers. In such regions, thyroid epithelial cells express HLA class II antigens not seen in normal thyroid glands and are large, perhaps due to local stimulation by TSHR Abs (see Fig. 11-11).

When the patient is given iodine or antithyroid drugs, the thyroid gland may undergo involution if TSHR Abs decrease. Then hyperplasia and vascularity regress, papillary projections recede, and follicles enlarge and become filled with colloid once again.

Eyes

In patients with infiltrative orbitopathy, the volume of orbital contents is increased because of an increase both in retrobulbar connective tissue and in extracellular muscle mass (see Fig. 11-11). Some of the increase in connective tissue is due to edema resulting from accumulation in the ground substance of hyaluronic acid and chondroitin sulfates, which are hydrophilic. The extraocular muscles are swollen, and some fibers exhibit loss of striation, fragmentation, and lymphocytic infiltration. The lacrimal glands may also be involved. Ultimately, the tissues fibrose.

Skin

Dermopathy (Fig. 11-14) (see also Color Plate) is usually a late manifestation, and 99% of patients with infiltrative dermopathy have Graves’ orbitopathy. The content of hyaluronic acid and chondroitin sulfates in the dermis is increased, presumably by lymphokine activation of fibroblasts, causing compression of the dermal lymphatics and nonpitting edema; the collagen fibers are separated and fragmented, and early lesions contain lymphocytic infiltrate. TSH receptor expression can be demonstrated in fibroblasts and adipocytes, and TSHR Abs are high. Nodule and plaque formation may occur in chronic lesions. The cause of the characteristic location of the dermopathy is unclear but, presumably, depends on trauma to the exposed areas.
Pathophysiology

In patients with Graves’ disease, all aspects of thyroid hormone economy are abnormal, including disruption of the regulatory control of thyroid function; alterations in thyroid function itself; changes in the concentration, binding, and metabolism of thyroid hormones; and manifestations of thyroid hormone excess in the peripheral tissues. Abnormalities in these parameters also occur in other forms of thyrotoxicosis but may differ in kind or amount.

An abnormality or override of normal regulatory control is inherent in all forms of thyrotoxicosis, as illustrated by the reemergence of TSH secretion when thyrotoxicosis is relieved. In Graves’ disease, regulatory mechanisms are overridden by the action of TSHR autoantibodies of the stimulating variety. The resulting hyperfunction of the thyroid gland leads to suppression of TSH secretion that is reflected in a suppressed or an undetectable serum TSH level. The basal TSH level may also be suppressed in patients with euthyroid Graves’ disease (indicating the presence of mild excess of thyroid hormone) and in patients in apparent remission, indicating that thyroid hormone excess is not necessarily associated with clinical thyrotoxicosis.

In this context, the term functional autonomy is often misused when the intent is to imply that thyroid function is independent of TSH stimulation. True functional autonomy occurs when the thyroid gland is capable of functioning at a normal or an increased pace in the absence of both TSH and any other circulating thyroid stimulator. Defined in this way, functional autonomy occurs with toxic multinodular goiter and toxic adenoma but not in Graves’ disease. In Graves’ disease, the thyroid gland is controlled by an abnormal stimulator, the TSHRAbs (as in molar pregnancy, in which hCG is responsible). When that stimulator is withdrawn (i.e., when the disease enters remission), hyperfunction subsides, and the nonautonomous nature of thyroid function becomes evident in the reemergence of normal TSH secretion and control of thyroid function.

The disturbance of thyroid function in Graves’ disease leads to hypersecretion of thyroid hormones. Thyroid avidity for iodine is enhanced, and thyroid iodide clearance is thus increased from its normal rate of 6 to 7 mL/min to 2 L/min in the most severe cases. The increase in iodide clearance rate reflects enhanced thyroid blood flow, even if extraction of iodine is assumed to be complete, and hypervascularity, most likely mediated by local angiogenic factors secreted by the thyroid cells. The enhanced thyroid iodide clearance rate is also due to an increase in the overall glandular mass and its unit functional activity, so that iodide transport and probably organic binding are enhanced. The increase in iodide transport is partly responsible for the enhanced susceptibility of the hyperthyroid gland to the inhibitory effects of iodide on organic binding reactions.

As judged from the normal ratio of iodotyrosines to iodothyronines, the rate of the coupling reaction must also be increased. The molar ratio of T3 to thyroxine (T4) in Tg is about twice normal, and this increase in T3 production cannot be ascribed to intrathyroidal iodine deficiency because the iodine content of Tg and the number of T3 residues per molecule are normal. It may simply reflect chronic hyperstimulation of the gland. The rates of turnover and release of the glandular iodine pool are increased, often greatly so. The major product of glandular secretion is T4 but the ratio of T3 to T4 in the thyroid secretion is increased in proportion to the overproduction of T3. In some instances, T3 appears to be the major secretory product, so that the serum T3 level is increased while serum T4 concentration is within the normal range (T3 toxicity).

The proportion of total plasma T4 and T3 in the free or unbound state is increased both because of a slight decrease in concentration of thyroxine-binding globulin (TBG) and because of the increase in the concentration of Tg. The fractional turnover rates of T3 and T4 are increased, leading to increased amounts of hormone in the peripheral pool and to an increase in total daily turnover of T3 and T4. In severe cases, this rate may increase from the normal of about 100 nmol of T3 and 50 nmol of T4 daily to more than 600 nmol daily for both hormones. The total daily disposal of T4 is disproportionately increased relative to that of T3, indicating that the production rate of T4 is disproportionately increased, probably owing to both a preferential increase in thyroid secretion of T3 and increased peripheral conversion of T4 to T3 by D1.
Clinical Picture

Graves' disease is most common in the third and fourth decades of life, is rare before age 10 years, and occurs in the elderly, sometimes in an apathetic form. The features include diffuse goiter, thyrotoxicosis, infiltrative orbitopathy, and occasionally infiltrative dermopathy. Because the orbitopathy and dermopathy may be independent of other manifestations, they are discussed separately. In other respects, the symptoms and signs of thyrotoxicosis are the same in patients with other causes of hyperthyroidism (see Table 11-3).

In most patients, the thyroid gland is enlarged; hyperthyroidism in Graves' disease occurs in a gland of normal size in only a small fraction of patients, though in the elderly goiter may be absent in 20%. The size of the thyroid gland is most often two or three times normal but may be massively enlarged. The consistency varies from soft to firm and rubbery. The enlargement is usually symmetrical. The surface is generally smooth but may feel lobular. In severe cases, a thrill may be felt, usually over the upper poles, and a thrill is always accompanied by an audible bruit. The thrills and bruits due to increased blood flow and are usually continuous but sometimes are present only in systole. The bruit is most easily detected at the upper or lower poles and should not be confused with a venous hum or murmur arising from the base of the heart. Mitral valve prolapse is more common than in the normal population and may account for a cardiac murmur. A thrill or bruit is suggestive of hyperthyroidism due to Graves' disease.

Manifestations of Infiltrative Orbitopathy and Dermopathy

Signs and Symptoms

Spasm and retraction of the eyelids lead to widening of the palpebral fissures so that the sclera are exposed above the superior margin of the limbus (Fig. 11-15). Lid retraction may be asymmetrical. When the patient looks downward, the upper lid lags behind the globe, exposing more sclera. When the patient gazes upward, the globe is displaced posteriorly by pressure from the thumb. The movements of the lids are jerky and spasmodic, and the tightly closed lids may show a tremor. Simple lid retraction and globe and lid lag are often a manifestation of the thyrotoxicosis per se. These manifestations will often abate when the thyrotoxicosis is relieved. On the other hand, significant swelling and inflammation of the eyelids and conjunctiva, and orbital contents, infiltrative orbitopathy, or ophthalmomonympathy may occur.

The disease symptoms and signs of infiltrative orbitopathy may appear in varying combinations. Early symptoms and signs include a sense of irritation in the eyes, resembling that caused by a foreign body, and excessive tearing that is often made worse by exposure to air or wind, especially if exophthalmos is present. The conjunctiva may be injected. Exophthalmos is frequently asymmetrical and may cause a feeling of pressure behind the globes. When exophthalmos is pronounced, the eyes may not close during sleep, a condition termed lagophthalmos. Exophthalmos may be masked by periorbital edema, which is a common accompaniment and source of complaint. Patients frequently describe blurred vision and easy tiring of the eyes. Double vision may occur in combination with the foregoing symptoms or alone. In severe cases, color vision, and then visual acuity, may be decreased or lost and the corneas may ulcerate or become infected (Fig. 11-16G).

Infiltrative orbitopathy may follow an independent course from the thyrotoxic manifestations and is often uninfluenced by their treatment (Fig. 11-15. Infiltrative orbitopathy is evident in about 50% of patients, but ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) of the orbits reveals changes, such as swelling of extracocular muscles and increased retro-orbital fat, in virtually all patients with Graves' disease, including those in whom the clinical changes are minimal or absent (see Fig. 11-16). Occasionally, infiltrative orbitopathy occurs in the absence of hyperthyroidism (so-called euthyroid Graves' disease).

Physical Examination

The ocular findings are variable (see Fig. 11-16). Exophthalmos is usually bilateral and is often asymmetrical in degree. True unilateral exophthalmos is uncommon but can occur in the absence of thyrotoxicosis; the other eye usually becomes affected eventually. When one is following the course of the disease, the degree of exophthalmos must be measured objectively with the Hertel or Luedde exophthalmometer. This instrument permits measurement of the distance between the lateral angle of the bony orbit and an imaginary perpendicular tangent to the most anterior part of the cornea.

Generally, the upper limit of normal is 20 mm, although in African Americans 22 mm is normal. In severe exophthalmos, readings may be as high as 30 mm. To estimate the degree of exophthalmos, the physician can also stand behind the seated patient and look downward from above to assert the extent to which the eyes protrude beyond the plane of the forehead.

The lids are often reddened, and enlarged lacrimal glands may cause a bulging of the surface of the eyelids. The extent to which the upper and lower lids can be completely apposed should be determined because failure of apposition promotes drying and ulceration of the cornea. Injection of the bulbar conjunctiva may be accompanied by edema or frank chemosis, in which the edematous conjunctival bulges from under the lids and around the corneal limbus. Weakness of the extracocular muscles is evident in the patient's inability to achieve or maintain convergence. Upward gaze, and especially superolateral gaze, may be limited. Occasionally, upward gaze is paralyzed. In such cases, the neck is extended and the head is tilted backward to make possible a field of vision above the horizontal. Rarely, downward or inward gaze is impaired. Ophthalmoplegia usually occurs in association with other signs of infiltrative orbitopathy but may occur alone. In some cases, only a single muscle is affected (see Fig. 11-17).

An indication of the severity of the orbitopathy may be provided by an assessment of intracranial pressure, which can be measured by a specially devised instrument (an orbitonometer) or by clinical evaluation. The patient closes the eyes lightly, and the examiner determines the ease with which the globe can be displaced posteriorly by pressure from the thumb. The manifestations of extreme orbitopathy may be catastrophic and include subluxation of the globe. Blindness may result from ulceration or infection of the cornea secondary to incomplete apposition of the lids or to optic nerve ischemia due to reduced blood flow caused by increased intracranial and intraorbital pressure. In the most severe cases, which should now be unusual, ophthalmoscopic examination may reveal venous congestion and papilledema, these may be accompanied by visual field defects.

Classification and Objective Assessment of Graves' Orbitopathy

The American Thyroid Association has classified the eye changes of Graves' disease by using a mnemonic system in which the first letters of each category constitute the term NOSPECS (Table 11-4). NO connotes the absence or a mild degree of involvement. SPECS represents the more serious degrees of involvement. NOSPECS and the numerical indices derived from it are useful as a memory tool for physical examination. The system is less satisfactory for objective assessment of orbital changes.
Objective measurements for each eye separately should include the following:

1. Documentation of maximum lid fissure width.
2. Assessment of exposure keratitis with rose bengal or fluorescein.
3. Quantitation of extraocular muscle function (with the use of the Hess chart or Maddox rod test).
5. Measurements of visual acuity, fields, and color vision.

An overall activity score is helpful in the follow-up of such patients and can be determined by assigning 1 point each for the presence of spontaneous retrobulbar pain, pain on eye movement, eyelid erythema, conjunctival injection, chemosis, swelling of the caruncle, or eyelid edema or fullness. The range is thus 0 to 7. More sophisticated orbitopathy indices require careful assessment for their reproducibility (Table 11-5).

Infiltrative Dermopathy

Dermopathy occurs in 5% to 10% of patients with Graves' disease and is almost always accompanied by infiltrative orbitopathy, usually of severe degree. These lesions cause hyperpigmented, nonpitting induration of the skin of the legs, commonly over the pretibial area (pretibial myxedema) and the dorsa of the feet, usually in the form of individual nodules and plaques but occasionally becoming confluent with a smooth characteristic edge or shoulder (see Fig. 11-14). Rarely, lesions develop on the face, elbows, or dorsa of the hands. Clubbing of the digits is occasionally associated with long-standing thyrotoxicosis (thyroid acropachy) (see also Color Plate).
Laboratory Tests

In moderate or severe Graves’ disease, laboratory findings are consonant with the pathophysiology. The serum TSH level, when measured by a sensitive immunoassay, is almost totally suppressed, and serum T₄ and T₃ levels are elevated (see Table 10-13). The free T₄ and free T₃ indices are increased more than are the T₄ and T₃ levels. The serum T₃ concentration is proportionally more elevated than the serum T₄ level. The increase in thyroid iodide uptake and clearance rate is reflected in the increased radioactive iodine uptake (RAIU). In patients with severe accompanying illness, conversion of T₄ to T₃ may be impaired, permitting the return to normal of the serum T₃ concentration but usually not the free T₄ (T₄ toxicosis); a similar effect on the relation between serum T₄ and T₃ levels can be seen in patients with Graves’ disease who have been exposed to iodine. Occasionally, the discrepancy between T₄ and T₃ levels is exaggerated, the serum T₄ concentration being normal and the serum T₃ concentration alone being elevated (T₃ toxicosis).

The physiologic basis of these tests and the manner in which they are affected by factors other than thyroid disease have been discussed earlier (Chapter 10, Laboratory Assessment of Thyroid Status). Some practical aspects of the use of the tests in the diagnosis of Graves’ disease deserve emphasis. It is neither desirable nor feasible that all the major laboratory tests be used to make the diagnosis. Documentation that the serum TSH concentration is suppressed by an appropriate assay establishes the diagnosis of hyperthyroidism in most cases and excludes the possibility of TSH-induced hyperthyroidism (see later). Because there are other causes of suppressed serum TSH, such as depression and hypothalamic-pituitary disease.

### Measuring Thyrotropin Receptor Autoantibodies

Two types of tests are usually employed for the detection of TSHRAbs. The first test assesses the capacity of patient serum or IgG to inhibit the binding of \(^1\)-labeled TSH to TSH receptors from thyroid membrane preparations (available commercially) or to Chinese hamster ovary (CHO) cells expressing recombinant human TSHR. This protein-binding inhibition assay is of low cost and good precision, and the frequency of positive results in patients with active and untreated disease is on the order of 80% to 90%. Enhanced assays of this type have recently been evaluated but not yet independently.  

The second test assesses the capacity of patient's serum or IgG to stimulate adenylate cyclase or to enhance thyroid hormone or Tg secretion or iodine uptake in isolated thyroid epithelial cells or CHO-TSHR cells. Tests of this type are more expensive, have relatively poor precision, and are positive in 80% to 90% of the patients with active untreated Graves' disease. Because of the proliferation of acronyms describing these antibodies, the authors encourage the designation of the specific assay used.

Both types of tests are now available commercially. New techniques are now available for measuring TSHRAbs using recombinant antigens and chemiluminescent tags, but whether they are more sensitive remains to be determined.

### Standardization

As with all autoantibody tests, it is important to use an internationally accepted standard to allow comparison of results from different laboratories. A TSHRAb standard from the Medical Research Council (MRC) in Britain is sometimes employed. Results may be reported in MRC units. Alternatively, results have often been reported in terms of equivalent TSH units. However, the hTSHRAbs from different patients may not give parallel results with the MRC standards or TSH standards when measured in different dilutions. This means that the conversion of hTSHRAb data into MRC units or TSH units can be erroneous.

### Indications for Measuring Thyrotropin Receptor Autoantibodies

Quantitations of TSHRAbs may be a useful indicator of the degree of disease activity in an individual patient and confirm the clinical diagnosis of Graves' disease. However, a bioassay is...
not needed in a hyperthyroid patient because the patient is already demonstrating antibody bioactivity. Demonstration of TSHRAs may also be of diagnostic value in the euthyroid patient with exophthalmos, especially when it is unilateral. High TSHRAs in a pregnant woman with Graves’ disease increase the likelihood that neonatal thyrotoxicosis will be present in her offspring, and in this situation a bioassay is preferred to a radioassay.

Another use of TSHRAb testing is in the prognosis of patients with Graves’ disease who are treated with antithyroid agents. A persisting high level of TSHRAs is a useful predictor of relapse on cessation of the drug. Unfortunately, in patients with low or negative titers, the test is much less helpful. Furthermore, the presence of iodine deficiency may also interrupt the development of hyperthyroidism despite the presence of TSHRAs, and this has raised unjustified criticism of the usefulness of this test.
Differential Diagnosis

The patient with major manifestations of Graves' disease (namely thyrotoxicosis, goiter, and infiltrative orbitopathy) does not pose a diagnostic problem. In some patients, however, one of the major manifestations either dominates the clinical picture or is present alone, and the disorder may mimic another disease. All of these issues can be resolved by appropriate laboratory testing (see Table 10-13).

The diffuse goiter of Graves' disease may rarely be confused with that of other thyroid diseases if thyrotoxicosis is present. In subacute thyroiditis, particularly the painless variant, asymmetry of the gland, tenderness, and systemic evidence of inflammation assist in the diagnosis. The very low RAIU distinguishes this disease from Graves' disease. When Graves' disease is in a latent or inactive phase and thyrotoxicosis is absent, the goiter may require differentiation from Hashimoto's thyroiditis or simple nontoxic goiter as possible diagnoses. The goiter of Hashimoto's disease is somewhat lobulated and firmer and rubbery compared with that of Graves' disease. Serum levels of thyroid antibodies are generally higher in Hashimoto's disease but may not be helpful in distinguishing individual patients. In the absence of thyrotoxicosis, the diffuse goiter of Graves' disease cannot be distinguished from nontoxic, or simple, goiter. An abnormal serum TSH concentration and the presence of TSHRAbs indicate underlying Graves' disease, but their absence does not exclude quiescent disease.

Eye Disease

The orbitopathy of Graves' disease, if bilateral and associated with thyrotoxicosis past or present, does not require differentiation from exophthalmos of any other origin. However, unilateral exophthalmos, even when associated with thyrotoxicosis, should alert the physician to the possibility of a local cause. Other diseases that may produce either unilateral or bilateral exophthalmos include orbital neoplasms, carotid-cavernous sinus fistulae, cavernous sinus thrombosis, infiltrative disorders affecting the orbit, and pseudotumor of the orbit. Mild bilateral exophthalmos, generally without infiltrative signs, is occasionally present on a familial basis and also sometimes occurs in patients with Cushing's syndrome, cirrhosis.
Treatment of Hyperthyroidism

It is not yet possible to treat the basic pathogenic factors in Graves’ disease. Existing therapies for both the thyrotoxic and the ophthalmic manifestations are only palliative.

The lack of general agreement as to which therapy is the best is due to the fact that none is ideal, as reflected in the treatment guidelines of the American Thyroid Association. Because the therapeutic problems posed by thyrotoxicosis and orbitopathy differ, and because they run independent courses, their treatments are discussed separately. Treatment of thyrotoxicosis is designed to impose restraint on hormone secretion either by means of chemical agents that inhibit hormone synthesis or release or by reducing the quantity of thyroid tissue.

Antithyroid Agents

The mechanisms of action of the various antithyroid drugs are discussed in the section on the formation and secretion of thyroid hormones in Chapter 10.

Iodide Transport Inhibitors

Both thiocyanate and perchlorate inhibit thyroid iodide transport. As discussed earlier, however, theoretical and practical disadvantages attend their use except in special circumstances.

Thionamides

The major agents for treating thyrotoxicosis are drugs of the thionamide class, most commonly propylthiouracil, methimazole, and carbimazole. These agents inhibit the oxidation and organic binding of thyroid iodide and, therefore, produce intrathyroidal iodine deficiency that further increases the ratio of T\(_4\) to T\(_3\) in the thyroid secretion, as reflected in the high T\(_4\)/T\(_3\) ratio in the serum. In addition large doses of propylthiouracil, but not methimazole, impair the conversion of T\(_4\) to T\(_3\) by deiodinase type 1 in the peripheral tissues. Because of this additional action, large doses of propylthiouracil may provide rapid alleviation of severe thyrotoxicosis.

The half-life of plasma of methimazole is about 6 hours, whereas that of propylthiouracil is about 1.5 hours, and both drugs are accumulated by the thyroid gland. A single dose of methimazole may exert an antithyroid effect for longer than 24 hours. This provides a rational basis for the single-daily-dose regimen of methimazole for mild or moderate thyrotoxicosis. The propylthiouracil concentration in serum correlates with the extent of blockade of organic binding of iodine within the thyroid gland. These drugs cross the placenta and can inhibit thyroid function in the fetus. Some evidence suggests that methimazole may cross the placenta more readily than propylthiouracil, but both drugs have been used highly effectively in pregnancy (see discussion hyperthyroidism and thyrotoxicosis in pregnancy later).

Immunosuppressive Action of Thionamides

Thionamide drugs may also directly influence the immune response in patients with autoimmune thyroid disease. This action occurs within the thyroid gland, where the drugs are concentrated. The action on the thyroid cells themselves decreases thyroid antigen expression and decreases prostaglandin and cytokine release from thyroid cells. Thionamides also inhibit the generation of oxygen radicals in T cells, B cells, and particularly the APCs and hence may cause a further decline in antigen presentation. More recently, it has been shown that methimazole induces the expression of Fas ligand on the thyroid epithelial cell, thus inducing apoptosis of infiltrating lymphocytes such as T cells that express Fas and decreasing the lymphocytic infiltration (see Fig. 12-7 in Chapter 12).

The clinical importance of immunosuppression and induction of apoptosis compared with inhibition of thyroid hormone formation is unclear. However, the decrease in the immune infiltration of patients on such drugs and the fall in autoantibody levels after their introduction to a patient is powerful evidence of their effect.

Use of Thionamides

An initial dose of methimazole commonly employed is 10 to 15 mg twice a day. An equivalent dose of propylthiouracil is 150 mg every 8 hours. Carbimazole, which is converted to methimazole in vivo and is equivalent in potency, is widely used in Europe but not in the United States. These doses are effective in most patients, but in some no therapeutic response is seen, and in some patients doses of up to 60 mg of methimazole or an equivalent amount of propylthiouracil daily may be required.

It is unlikely that a true state of complete resistance to these agents ever occurs. The higher doses are required in patients with severe thyrotoxicosis and large thyroid glands, or possibly because of more rapid degradation of the drug within the gland or extrathyroidally. When large amounts are required, doses of propylthiouracil should be administered at 4- to 6-hour intervals.

The therapeutic response to effective antithyroid therapy invariably occurs after a latent period because the agents inhibit the synthesis but not the release of hormone; hence reduction in the supply of hormone to the tissues does not occur until glandular hormone stores are depleted (see Fig. 11-4 and Fig. 11-19). Although propylthiouracil differs from methimazole in having the additional effect of inhibiting the peripheral conversion of T\(_4\) to T\(_3\), there appears to be little difference in the duration of the latent period when either of these agents is employed alone in the usual dosage because the extrathyroidal effect of propylthiouracil on conversion of T\(_4\) to T\(_3\) is more apparent at dosages greater than 600 mg/day. This effect may be an advantage in the acute treatment of severe hyperthyroidism.

Factors that influence the duration of the latent period include the quantity of hormone initially stored in the thyroid gland, its inherent rate of release, and the effectiveness of blockade of new hormone synthesis achieved. In an iodine-rich thyroid gland, as when the patient has received medications containing iodine, the clinical response to antithyroid agents may be delayed for months. As would be expected, the latent period is shortened by administration of large doses (more than 600 mg daily of propylthiouracil), and such doses should be given when a more rapid therapeutic response is required. Generally, improvement within the first 2 weeks includes decreased nervousness and palpitations, increased strength, and weight gain. Usually, the metabolic state becomes normal within about 6 weeks. At this time, the dosage can often be reduced substantially to maintain a normal metabolic state.

During treatment, the size of the thyroid gland decreases in one third to one half of the patients. In the remainder, it may remain unchanged or even enlarge. In the latter situation, the change signals either an intensification of the disease process, which often requires that the dosage of drug be increased, or the production of hypothryroidism and increased TSH secretion as a result of excessive dosage.

It is important to differentiate between these causes. Clinical criteria are the main guidelines by which the adequacy of treatment is judged, but confirmation may be sought in the serum T\(_3\) and T\(_4\) levels. Mild thyrotoxicosis may persist despite a serum T\(_4\) concentration in the normal range because the serum T\(_3\) concentration may still be elevated. The latter phenomenon may also account for maintenance of a normal metabolic state in the setting of a subnormal serum T\(_4\) level. The serum TSH concentration may remain subnormal for many months, presumably secondary to accelerated conversion of T\(_4\) to T\(_3\). An enlarging thyroid gland in a treated patient with Graves’ disease may indicate the presence of a neoplasm and should be investigated appropriately.
Antithyroid agents can cause hypothyroidism if given in excessive amounts over long periods. When this occurs, the patient often complains of gain in weight, sluggishness, and fatigue, and signs of mild hypothyroidism may be present, especially a delay in the relaxation phase of the deep tendon reflexes. One major sign of incipient hypothyroidism is enlargement of the thyroid gland secondary to increased TSH. The hypothyroidism can be reversed by reducing the dosage of the antithyroid drug or by administering supplemental thyroid hormone. To forestall this development, which may also have adverse effects on preexisting orbitopathy, some physicians employ supplemental thyroid hormone routinely, the "block-and-replace" approach.

**Block-and-Replace Regimen**

The logic behind prescribing a full dose of a thionamide drug and adding T₄ supplements to prevent the patient from becoming hypothyroid is twofold. First, a few patients are difficult to keep euthyroid with thionamide therapy alone, and a block-and-replace regimen can be helpful and requires fewer office visits. Second, the immunosuppressive action of the thionamides may be helpful in attenuating the natural history of the autoimmune thyroid diseases directly.

Although some investigators found the relapse rate after the block-and-replace approach to be much reduced, others have found no difference. One group has reported that continuing levothyroxine replacement after withdrawal of antithyroid drugs also increased the remission rate, possibly because suppression of pituitary TSH inhibited expression of thyroid antigens and reduced immune stimulation (an effect influenced by the level of TSHRAbs). Such studies have not been reproduced, and this approach is not recommended.

### Predicting the Response to Drug Withdrawal

A central question in the treatment of Graves' disease to which there is no simple answer is the appropriate duration of antithyroid drug treatment. As discussed earlier, antithyroid therapy may alter the course of the underlying autoimmune process, but remission after withdrawal of treatment will persist only if the disorder has entered a latent or inactive phase. This latter transition and the normal decline in the levels of TSHRAbs are more likely to occur the longer the course of treatment. This reasoning is the basis for the traditional practice of continuing antithyroid treatment for 6 to 12 months or longer. However, persistence of high levels of circulating TSHRAbs during treatment of Graves' disease portends recurrence after withdrawal of antithyroid drugs in iodine-replete areas.

Factors preventing a recurrence include (1) a change from stimulating antibody to blocking antibody, which occurs rarely, and (2) the progression of concomitant thyroiditis. Furthermore, iodine deficiency itself may prevent the recurrence of Graves' disease. These factors may explain why some authors have been unable to confirm the predictive value of TSHRAb measurements. The use of poorly validated assays for TSHRAbs may compound this problem. However, most patients do not have persisting high levels of TSHRAb, and predicting their outcome is more difficult; additional factors need to be taken into account.

Other features associated with the likelihood of long-term remission after withdrawal of therapy (Table 11-6) include (1) the initial presence of T₄ toxicity, (2) a small thyroid gland (less than twice normal), (3) a decrease in the size of the thyroid gland, and (4) in particular, return of the TSH concentration to normal during treatment. HLA typing is not helpful in such predictions.

Hence, treatment should generally be continued for about 6 to 12 months and then withdrawn if the TSHRAbs disappear. Alternatively, if the patient's condition can be easily controlled with low doses of antithyroid drugs and the serum TSH has returned to the normal range, antithyroid drugs may be withdrawn and the serum TSH concentration measured at monthly intervals. About 75% of relapses occur in the first 3 months after withdrawal of therapy, and most of the remainder occur during the subsequent 6 months. Suppression of the TSH

### TABLE 11-6 -- Factors Favoring Long-Term Remission after Antithyroid Therapy for Graves' Disease

Concentration is the first signal of relapse even in the presence of a normal serum T₄ level.

### Long-Term Remission

The frequency with which long-term remission occurs after withdrawal of antithyroid therapy has decreased over the past 30 years. In part because of the increase in dietary iodine intake, but this decrease has also occurred in geographic regions where iodine intake has remained constant and low. Nevertheless, about one-third of patients experience a lasting remission. This fact alone indicates that antithyroid agents have a significant role as a sole therapy in the initial treatment of thyrotoxicosis.

### Adverse Reactions

Adverse reactions occur in a small number of patients taking thionamide drugs (Table 11-7). Agranulocytosis occurs in fewer than 1% of the patients, generally within the first few weeks or months of treatment. It is accompanied by fever and sore throat. When therapy is begun, the patient should be instructed to discontinue the drug and to notify the physician immediately should these symptoms develop. This precaution is more important than the frequent measurement of leukocyte counts. The frequency of lymphopenia in hyperthyroidism, a complete blood count with differential is recommended before antithyroid drug therapy is started. If the absolute neutrophil count falls below 1500 cells/µL, the drug should be withdrawn. If agranulocytosis occurs, the drug should be discontinued immediately and the patient treated with antibiotics as appropriate. Granulocyte colony-stimulating factor has been used to accelerate recovery that invariably takes place. Lymphocytes of patients who have developed agranulocytosis while taking propylthiouracil undergo blast transformation when exposed to propylthiouracil or methimazole; consequently, they should not be given a thionamide drug again. Granulocytopenia occurs during antithyroid therapy and is sometimes a forerunner of agranulocytosis, but, as already mentioned, it can also be a manifestation of thyrotoxicosis itself. For this reason, and as noted previously, a total white blood cell count with differential should be obtained before initiation of treatment with thionamide drugs.

Granulocytopenia that develops during the first few weeks of therapy may be difficult to interpret. In this circumstance, serial measurements of the leukocyte count should be made. If they display a downward trend, the antithyroid drugs should be discontinued. When serial measurements of the white blood cell count remain constant or return to normal, treatment need not be interrupted.

A rash that can take many forms, including hives, occurs in as many as 10% of patients. Less frequent reactions include arthralgia, myalgia, neuritis, hepatitis (with propylthiouracil) or cholestasis (with methimazole) and rare liver necrosis necessitating transplantation, thrombocytopenia, loss of or abnormal pigmentation of the hair, loss of taste sensation, enlargement.
of lymph nodes or salivary glands, edema, a lupus-like syndrome, and toxic psychoses. The mechanisms underlying these reactions are not known, although some reactions disappear with discontinuance of treatment. It is obviously helpful to have a baseline complete blood count and liver function studies before initiation of antithyroid drugs to help interpret the presence of some of these side effects. We believe that the suspicion of any serious manifestation should be an indication for abandonment of antithyroid therapy and a recourse to surgery or 131 I.

Iodine and Iodine-Containing Agents

Iodine is now rarely used as a sole therapy. The mechanism of action of iodine in relieving thyrotoxicosis differs from that of the thionamides. Although quantities of iodine in excess of several milligrams can acutely inhibit organic binding (acute Wolff-Chaikoff effect), this transient phenomenon probably does not contribute to the therapeutic effect. Instead, the major action of iodine is to inhibit hormone release (see Chapter 10). Administration of iodine increases glandular stores of organic iodine, but the beneficial effect of iodine is evident more quickly than the effects of even large doses of agents that inhibit hormone synthesis (Fig. 11-19). In patients with Graves’ disease, iodine acutely retards the rate of secretion of T₄, an effect that is rapidly lost when iodine is withdrawn. These features of iodine action provide both disadvantages and advantages. The enrichment of glandular organic iodine stores that occurs when this agent is given alone may retard the clinical response to subsequently administered thionamide, and the decrease in RAU produced by iodine prevents the use of radioiodine as treatment for several weeks. Furthermore, if iodine is withdrawn, resumption of accelerated release of hormone from an enriched glandular hormone pool may exacerbate the disorder.

Another reason for not using iodine alone is that the therapeutic response on occasion is either incomplete or absent, and even if initially effective iodine may lose its effect with time. (This phenomenon, which has been termed iodine escape, should not be confused with the escape from the acute Wolff-Chaikoff effect [see Chapter 10].) Nevertheless, the rapid slowing of hormone release by iodine makes it more effective than the thionamide drugs when prompt relief of thyrotoxicosis is mandatory (see Fig. 11-19). Therefore, aside from its use in preparation for subtotal thyroidectomy, iodine is useful mainly in patients with acute or impending thyrotoxic crisis, severe thyrotoxic disease, or acute surgical emergencies.

If iodine is used in these circumstances, it should be administered with large doses of a thionamide, as the severity of the thyrotoxicosis itself indicates. The dose of iodine required for control of thyrotoxicosis is approximately 6 mg daily, a quantity much less than that usually given. Six milligrams of iodine is present in one eighth of a drop of saturated solution of potassium iodide (SSKI) or an 0.8 drop of Lugol’s solution; many physicians, however, prescribe 5 to 10 drops of one of these agents three times daily. Although it is advisable to administer amounts larger than the suggested minimal effective dose, huge quantities of iodine are more likely to produce adverse reactions, including iodide myxedema. We recommend the use of a maximum of 3 drops of SSKI three times daily.

In patients who are so ill that medications cannot be taken by mouth, antithyroid agents can be triturated and administered by stomach tube; iodine can be given by the same route or can be absorbed through the mucosa. When use of a stomach tube is contraindicated, thionamide drugs cannot be administered because no parental preparations are available. Here, the disadvantages attendant on administration of iodine may be accepted if the clinical situation is sufficiently serious. Iodine appears to be particularly effective after administration of a therapeutic dose of 131 I for the rapid alleviation of thyrotoxicosis.

Reactions to Iodine

Adverse reactions to iodine are unusual and are generally not serious but may include rash, which may be acneiform; drug fever; sialadenitis; conjunctivitis and rhinitis; vasculitis; and a leukemoid eosinophilic granulocytosis. Sialadenitis may respond to reduction of dosage; in the case of the other reactions, iodine should be stopped.

Ipodate

In doses of 1 g daily, the iodine-containing choleystographic contrast agent sodium ipodate (or iopanoate) causes a prompt decrease in serum T₄ and serum T₃ concentrations in patients with hyperthyroidism. These effects are the result of both the release of iodine and the ability of the agent to inhibit peripheral T₃ production from T₄, a combination that can be useful in the seriously ill patient. As with iodine itself, however, withdrawal of the drug carries the risk of an exacerbation. Hence, if the patient is sufficiently ill to warrant treatment with ipodate, large doses of antithyroid agents should be administered concomitantly.

Other Antithyroid Agents

Lithium

Lithium carbonate also inhibits thyroid hormone secretion, but, unlike iodine, it does not interfere with the accumulation of radioiodine. Lithium, 300 to 450 mg every 8 hours, is employed only to provide temporary control of thyrotoxicosis in patients who are allergic to both thionamide and iodide. This is because the blocking effect is often lost with time. The goal is to maintain a serum concentration of 1 mEq/L.

Dexamethasone

Dexamethasone, 2 mg every 6 hours, inhibits the glandular secretion of hormone, inhibits the peripheral conversion of T₄ to T₃, and has immunosuppressive effects. The inhibitory effect of dexamethasone on the conversion of T₄ to T₃ is additive to that of propylthiouracil, suggesting a different mechanism of action. Concurrent administration of propylthiouracil, SSKI, and dexamethasone to the patient with severe thyrotoxicosis effects a rapid reduction in serum T₃ concentration, often to within the normal range in 24 to 48 hours.

Beta-Blocking Agents

Agents that block the response to catecholamines at the receptor site (e.g., propranolol) ameliorate some of the manifestations of thyrotoxicosis and are often used as adjuncts in management. Tremulousness, palpitations, excessive sweating, eyelid retraction, and heart rate decrease; effects are rapidly manifested and appear to be mediated largely through the adrenergic nervous system, although propranolol may also impair the conversion of T₄ to T₃.

Adrenergic antagonists are most useful in the interval when a response to thionamide or radioiodine therapy is being awaited. They are of limited usefulness in patients with mild to moderate disease but are useful in patients with severe thyrotoxicosis, such as those with impending or actual thyrotoxic crisis (see special aspects of thyrotoxicosis later). Adrenergic antagonists are especially useful when tachycardia is contributing to cardiac insufficiency. However, the fact that -adrenergic blockers can reduce cardiac output without altering oxygen consumption can have adverse effects in some organs, such as the liver, where the arteriovenous oxygen difference is already elevated in the hyperthyroid state. Moreover, because thyroid hormone has a direct effect on the myocardium independent of the adrenergic nervous system, adrenergic antagonists reduce the heart rate by an independent mechanism (see earlier discussion of catecholamine-thyroid interrelationships).

Propranolol is the most widely used agent because it is relatively free from adverse effects and can be given orally in a dose of 20 to 80 mg every 6 or 8 hours. For intravenous use, a shorter-acting agent may be preferred (see treatment of “Thyrotoxic Crisis [Thyroid Storm]). Propranolol is contraindicated in patients with asthma or chronic obstructive pulmonary disease because it aggravates bronchospasm. Because of its myocardial depressant action, it is also contraindicated in patients with heart block and in patients with congestive failure, unless severe tachycardia is a contributory factor. Whether propranolol should be given chronically to preganant women with hyperthyroidism has been questioned, and we avoid it where possible. Some studies indicate that its use causes no significant complications, whereas others report an association with small size of the fetus, low Apgar scores, and postnatal bradycardia and hypoglycemia.

Another -blocking agent is metoprolol, a longer-acting drug that allows a once-a-day regimen when treatment is likely to be prolonged. Calcium channel-blocking
agents such as dillazem may also be used when -blocking agents are contraindicated.

Surgery

Both types of ablative therapy—surgery and radiodine—ameliorate thyrotoxicosis by permanent removal or destruction of thyroid tissue, impairing the capacity of the gland to synthesize hormone. Antithyroid therapy, aimed at preserving the thyroid gland, and ablative therapy are different, and their opposite properties may be advantageous or disadvantageous, depending on one's point of view. The impermanence of antithyroid therapy leads to a relatively frequent recurrence, whereas recurrence is uncommon with ablative therapy. However, antithyroid therapy probably does not cause permanent hypothyroidism, whereas the frequency of permanent hypothyroidism is very high with ablative therapy.

The surgical procedure of choice for the treatment of Graves’ disease is a bilateral subtotal thyroidectomy that avoids the dangers of hypoparathyroidism and laryngeal nerve injury. Surgery is effective in relieving hyperthyroidism, the frequency of recurrent hyperthyroidism after subtotal thyroidectomy in adults being less than 5% even when the procedure is performed by experienced surgeons. Nevertheless the high prevalence of postoperative hypothyroidism makes surgery an imperfect treatment.

Table 11-8 is taken from summaries of results of surgery that have not changed significantly in recent years except for the large decline in mortality to near zero in most reports. The incidence of permanent hypothyroidism ranged in frequency from 4% to approximately 30% and was highest in clinics in which internists did the follow-up examinations. In a study conducted by internists, a mean frequency of postoperative hypothyroidism of 28% was found in patients followed for 1 to 16 years, and the frequency in patients followed for 10 years was 43%.

Although it was previously assumed that hypothyroidism usually develops within 1 year after operation, long-term studies indicated a progressive increase in the cumulative incidence with time, similar to that produced by radioiodine but of lesser magnitude. It is likely that the frequency of partial impairment of thyroid function (as revealed by small increases in serum TSH) is even higher than that of hypothyroidism because the aim of subtotal thyroidectomy is to decrease thyroid reserve. The increasing frequency with time of hypothyroidism may result from progressive restriction of blood supply or from autoimmune destruction of the thyroid remnant.

If eventual thyroid failure is a frequent consequence of the Graves’ disease process itself, the increase in the cumulative frequency with time of hypothyroidism after either surgery or radiodine therapy is to be expected and is unavoidable. Treatment that destroys thyroid tissue would accelerate the emergence of hypothyroidism resulting from the disease process itself.

There is an inverse relationship between the frequency of recurrence and that of hypothyroidism, and both partly depend on the amount of thyroid tissue left in place. When one considers that thyroid glands vary in size and degree of hyperfunction and that the techniques of surgeons vary to a considerable extent, it is remarkable that a normal metabolic state is restored for long periods in most patients. The reason for this favorable outcome may be that the amount of tissue remaining after operation is insufficient to sustain a normal metabolic state and hence becomes stimulated by endogenous TSH. In this way, the patient's homeostatic mechanism provides the adjustment in thyroid function that surgery alone could not. This hypothesis is supported by the return of serum TSH levels to normal in patients restored to a normal metabolic state by surgery. However, this explanation would suffice only in the absence of TSHR Abs, which rapidly decrease and disappear in many patients after surgery. How the autoimmune disease is suppressed following surgery is unclear, but clearly the release of thyroid antigen during the procedure must induce apoptosis of many of the clones of TSHR-specific T cells and B cells.

Complications of Surgery

Because the hazards of subtotal thyroidectomy are inversely related to the experience and skill of the surgical team, it is impossible to generalize about the frequency of complications. Furthermore, data from the era in which surgery was common are probably no longer applicable (see Table 11-8). Unless circumstances are otherwise compelling, thyroidectomy should not be performed by surgeons who do the operation only occasionally. Bleeding into the operative site, the most serious postoperative complication, can rapidly produce death by asphyxia and requires immediate evacuation of the blood and ligation of the bleeding vessel. Even with subtotal surgery, the recurrent laryngeal nerve can be damaged. If such damage is unilateral, it causes dysphonia that usually improves in a few weeks but that may leave the patient slightly hoarse. If laryngeal nerve damage is bilateral, obstruction of the airway can cause stridor within hours; tracheostomy is then required, at which time the nature of the damage to the nerves should be explored.

Hypoparathyroidism can be either transient or permanent. Transient hypoparathyroidism results from inadvertent removal of some parathyroids and impairment of blood supply to those that remain. Depending on the severity of these insults, symptoms and signs of hypocalcemia appear, usually within 1 to 7 days after surgery. The earliest evidence of hypoparathyroidism may be anxiety and mental depression, followed by paresthesias and heightened neuromuscular excitability, such as Chvostek's and Trousseau's signs and carpopedal spasm. The serum calcium level is subnormal, and the serum inorganic phosphate level is increased.

Severe hypoparathyroidism should be treated with intravenous calcium gluconate. Milder cases can be treated with oral calcium carbonate in a dose of 1 g three times daily. It is impossible at the onset to predict whether hypoparathyroidism will be permanent or will regress within a few weeks, as usually occurs. Some surgeons insist on prophylactic calcium and vitamin D after every thyroidectomy. Of course, this approach may hide any developing deficiency. With the increasing use of ambulatory thyroid surgery, it is likely that this approach will grow.

However, the hypocalcemia that occurs immediately after surgery for thyrotoxicosis may not be due to transient hypoparathyroidism, because it occurs more frequently here than after surgery for other thyroid disorders. Instead, it may be due to retention of calcium by bone because of the demineralization of bone that occurs in hyperthyroidism, which begins to be reversed after cure of the hyperthyroid state and may contribute to the modest elevation in alkaline phosphatase during recovery. The frequency of permanent hypoparathyroidism correlates with the proportion of the thyroid gland removed and with the frequency of postoperative hypothyroidism. The incidence of mild hypoparathyroidism (or diminished parathyroid reserve) detectable years after surgery is probably greater than is generally supposed. The treatment of hypoparathyroidism is discussed in Chapter 26.

Preparation for Surgery

Preoperative use of antithyroid agents has greatly decreased the morbidity and mortality rates of surgery for Graves’ disease because these drugs deplete glandular hormone stores and restore the metabolic state to normal. However, these agents do not improve the hyperplasia and hypervascularity of the gland unless TSHRAbs levels fall. Iodine, however, is reported to cause a decrease in height of the follicular cells, enlargement of follicles with retention of colloid, and reduction of hypervascularity. Hence, the aim of preoperative management is to restore the metabolic state to normal with antithyroid agents and then to induce involution of the gland with iodine.

Patients who are to undergo subtotal thyroidectomy are first given antithyroid therapy in the manner described earlier. Often, relatively large doses are given in order to hasten the clinical response and because surgical candidates are often patients with severe disease or large goiters. After the metabolic state is restored to normal, SSRI is added (3 drops three times daily) for a further 7 to 10 days. During this period, a preexisting bruit or thrill may decrease in intensity or disappear entirely and

the gland usually becomes firm.

Several cautions should be observed:

1. No date for surgery should be set until a normal metabolic state has been restored. Much too often, the operation is planned well in advance and the patient is given a standardized regimen independent of the clinical progress.

2. Therapy with iodine should not be started until a normal metabolic state has been restored; iodine should not be relied on to complete an as yet incomplete response to antithyroid therapy because iodine will enrich glandular hormone stores if the antithyroid drug is not entirely effective.

3. Antithyroid agents should not be withdrawn when iodine therapy is begun.

**Thyroid Surgery in the Hyperthyroid Patient**

Propranolol may be a useful adjunct in controlling signs and symptoms (see earlier) while the patient is being prepared for surgery. Propranolol has been used alone in preoperative preparation of the patient in whom surgery is to be undertaken, and although this mode of therapy is probably safe and effective in many patients with mild disease, thyroid crises can occur in patients receiving propranolol alone. Therefore, we believe that unless there is some compelling indication for the use of propranolol alone, restoration of the patient to a eumetabolic state, as outlined earlier, is appropriate before subjecting the patient to the stress of surgery.

**Radioiodine**

Radioiodine produces thyroid ablation without the complications of surgery. The principal disadvantages of radioiodine are the influence of radiation on Graves' ophthalmopathy and the high frequency of late hypothyroidism. Previously, there was concern that this form of therapy might also produce thyroid carcinoma, leukemia, or an increase in mutation rates. However, during the half-century in which radioiodine has been in use, no increased prevalence of thyroid or other carcinoma in treated patients has been noted. This phenomenon is to be contrasted with the increased prevalence of thyroid carcinoma in patients treated with low amounts of radiation in childhood or adolescence as exemplified by the results of the Chernobyl radiation leak. The prevalence of leukemia is also no greater in adults treated with radioiodine, and the frequency of genetic damage in the offspring of patients treated earlier with radioiodine does not appear to be increased.

Indeed, the conventional dose of radioiodine employed in the treatment of thyrotoxicosis delivers to the gonads a radiation dose about equivalent to that delivered by a barium enema examination or intravenous urogram.

In view of the lack of evidence of serious toxicity from radioiodine in doses generally employed for treating hyperthyroidism, the age limit for the use of radioiodine has been lowered progressively from the initial limit of 40 years, and in some clinics it is now employed in children and adolescents. Experience from the Chernobyl nuclear accident, which caused a large increase in the number of childhood thyroid cancers, may alter this trend, particularly for adolescents, and many physicians think that the use of any radioactivity in children should be avoided if possible. Hence, there is regional and international variation in the use of radioiodine therapy.

Attempts have been made to standardize the radiation delivered to the thyroid gland by varying the dose of radioiodine according to the size of the gland, the uptake of \(^{131}I\), and its subsequent rate of release (dosimetry). However, such calculations do not provide uniform results, probably because of variations in individual sensitivity. Hence, many physicians have settled on an arbitrary dose calculated to result in the delivery of 300 MBq (8 mCi) of \(^{131}I\) to the thyroid gland 24 hours after administration. Others aim to deliver 50 to 100 GY (5000 to 10,000 rad) to the gland.

**Hypothyroidism after Radioiodine**

Many reports have documented that the incidence of hypothyroidism is significant during the first year or two after treatment with RAI and continues to increase at a rate of approximately 5% per year thereafter. The incidence of postradioiodine hypothyroidism at 5 years is approximately 30% and at 10 years is approximately 40%, although values as high as 70% have been reported. Such values, of course, also depend on the dose delivered in the different centers.

The beneficial effect of radioiodine and the early induction of hypothyroidism are both consequences of radiation-induced destruction of thyroid parenchyma. Radiation thyroiditis may develop within the first few weeks of treatment, as evidenced by epithelial swelling and necrosis, disruption of follicular architecture, edema, and infiltration with mononuclear cells. Resolution of the acute phase is followed by fibrosis, vascular narrowing, and further lymphocytic infiltration. These changes account for the early response to radioiodine, be it favorable or excessive, but do not appear sufficient to account for the continuing development of hypothyroidism with time.

In some studies, the likelihood of hypothyroidism is increased by the presence of high levels of thyroid antibodies and, presumably, of thyroid specific T cells, at the time of treatment and with increasing age of the patient. The two predisposing factors may be related to one another. If this is true, it is unlikely that the early ablative effects can be obtained free from subsequent late effects, and doses of radioiodine sufficient to exert an early therapeutic action will inevitably be associated with a high frequency of delayed hypothyroidism.

This therapeutic dilemma with respect to radioiodine therapy is handled differently in different practices. Some continue to administer the conventional dose because of its effectiveness and because hypothyroidism, when it eventually occurs, can be easily treated. A disadvantage of such an approach is that the onset and progression of hypothyroidism may still be insidious, that prolonged follow-up of patients may not be possible, and that patients may not associate symptoms arising long after therapy with a complication. The advantage of this approach is that it minimizes the dangers of persistent or recurrent thyrotoxicosis, which may be hazardous, especially in the elderly.

One way to minimize the frequency of hypothyroidism is to administer a dose per gram of estimated weight that is larger the greater the gland size. In this way, many patients with large thyroid glands are given large doses, and the converse is true for thyroid glands that are small. However, regimens of this type do not appear to improve the treatment of hyperthyroidism in the short run, and it is not known whether the rate of later hypothyroidism is changed.

In a controlled, prospective study, the effects of a single conventional dose of approximately 5.2 MBq/g (140 µCi/g) of estimated glandular weight were compared with the effects of half the dose. Although the therapeutic effect of radioiodine developed more slowly in patients receiving the half-dose, and although a greater proportion required antithyroid drug therapy until this effect became apparent, the frequency of remission after 2 years was the same as that in patients receiving the conventional dose, and recurrence of thyrotoxicosis was no more common. In the full-dose group, the incidence of hypothyroidism was 6% at 1 year and 29% at 5 years, whereas in the half-dose group the corresponding values were 4% and 7%. However, thereafter the cumulative frequency with time with the low dose was...
similar to that observed with conventional doses. For these reasons, some physicians advocate an ablative approach to treatment.

The use of antithyroid drugs before RAI treatment is widely used to theoretically decrease a post-RAI increase in thyroid hormone release. This is considered especially dangerous in older age groups with ischemic heart disease in which cardiac deaths have been reported. Antithyroid drugs may also prevent the post-RAI increase in thyroid autoantibodies that may affect ophthalmopathy. It is important to monitor free T4 and free T3 levels in at-risk patients and to consider -adrenergic blockade whether or not antithyroid drugs are used before RAI treatment.

Orbitopathy and Radioiodine

As discussed earlier, Graves' orbitopathy is probably the result of a specific cytokine between retro-orbital and thyroid antigens, perhaps the TSH receptor itself. Any worsening of the autoimmune thyroid response might therefore worsen the orbital immune response. Following radioiodine therapy, the levels of circulating TSH-RAs are elevated strikingly, perhaps secondary to impairment of immune restraint caused by the intrathyroidal irradiation where regulatory cells may be more sensitive. This change is in keeping with exacerbation of preexisting myxedema after radioiodine administration. Similarly, carefully conducted studies indicate that eye disease worsens in about 10% of patients with Graves' orbitopathy who are treated with radioiodine (Fig. 11-22), although others disagree. Such changes, if any, are usually mild and temporary but on occasion can involve dramatic deterioration.

Some physicians advocate the use of glucocorticoids at the time of radioiodine treatment to prevent such effects. One regimen involves prednisone, 0.4 to 0.5 mg/kg 1 month before 131I treatment, with a gradual tapering over 3 to 4 months. Others suggest that radioiodine may not be the treatment of choice in patients with significant orbitopathy. However, maneuvers such as careful control of thyroid function before and after therapy and cessation of smoking by the patient may minimize ocular changes.

Other Side Effects of Radioiodine

Additional hazards may attend the use of radioiodine, particularly large doses. The parathyroid glands are exposed to radiation in patients treated with radioiodine. Although parathyroid reserve may be diminished in some patients, development of overt hypoparathyroidism is rare. The effect of radioiodine on other tissues that concentrate iodide (e.g., the salivary glands, the gastric glands, and the breasts) has received little attention.

Radiation thyroiditis itself may lead to an exacerbation of thyrotoxicosis 10 to 14 days after radioiodine is administered, with occasionally serious consequences, including precipitation of thyrotoxic crisis and aggravation of patients with severe thyrotoxicosis or cardiac insufficiency. In thyrocardiac disease, therefore, antithyroid drugs should be given for several weeks before radioiodine is given to deplete glandular hormone stores. This prevents an outpouring of hormone if severe radiation thyroiditis occurs. The antithyroid agent is withdrawn about 3 to 5 days before administration of the radioiodine; if the clinical condition warrants, the agent can be begun again 7 days later.

Because 131I administration is contraindicated during pregnancy, a pregnancy test should be carried out in women of childbearing age before 131I therapy is initiated if there is any possibility of pregnancy.

General Measures

Several general measures may contribute to the well-being of the patient with severe thyrotoxicity. Help with family responsibilities and avoidance of physical exertion are also important. In addition, a diet rich in protein, calories, and vitamins may repair the nutritional deficiencies that are common in thyrotoxic patients.

Choice of Therapy

The choice of therapy for thyrotoxicosis is influenced by emotional attitudes, economic considerations, and family and personal issues. Our choice of therapy takes into account the natural history of the disease, the advantages and disadvantages of the available therapies, and the features of the population group in which the patient falls. Apart from patients directly requesting surgery, this procedure is recommended only when the shortcomings of other modes of therapy are of particular importance (e.g., patients with antithyroid drug allergy, a cold nodule, patients with very large goiters, and patients with the need for a rapid return to normal).

Occasionally, in young adults, it is necessary to remove a diffuse toxic goiter because of obstructive symptoms or cosmetic disfigurement. Nevertheless, only a small percentage of patients with Graves' disease are recommended for surgery. The choice, therefore, is among antithyroid drugs, RAI, or a mixture of both.

In one common approach to therapy in adults, the physician initiates treatment with antithyroid drugs in all patients to produce a euthyroid state before reaching a final decision regarding a definitive therapeutic strategy. This allows the patient to return to a euthyroid status as rapidly as possible and provides an estimate of the antithyroid drug dose requirement. The magnitude of the drug requirement and the size of the thyroid gland are two of a number of factors considered in the evaluation of the patient with regard to the likelihood of a remission. The options for treatment are explained to the patient during these first months of contact, and individual recommendations are then formulated. This approach allows the establishment of a workable physician-patient relationship, which is especially important in addressing anxieties about the use of radioiodine. Such concerns lead many patients, especially those younger than 50 years of age, to elect a trial of antithyroid drugs before definitive therapy with 131I.

Patients with a large thyroid gland, a maintenance thionamide dose requirement of more than 400 mg/day of propylthiouracil, and high titers of TSH-RAs require prolonged antithyroid treatment and are advised that the chance of spontaneous remission is less than 30%. A therapeutic trial is generally pursued for 6 to 12 months if long-term thionamide therapy is selected. One can, in theory, treat forever unless side effects become a problem. When a decision in favor of radioiodine is made, I may be prescribed at a dose designed to result in the retention of about 300 MBq (8 mCi) in the thyroid gland at 24 hours. This estimate is based on a 123I uptake test performed immediately before treatment and at least 5 days after stopping thionamides. Patients with a larger goiter (more than four times normal) or those who have received large doses of propylthiouracil may require more radioiodine. Because 131I is given when the patient is euthyroid and this is a relatively large dose, no additional therapy is required immediately after treatment except for patients in whom a recurrence of hyperthyroidism poses a medical risk (e.g., patients with coronary artery disease or congestive heart failure).

Patients are seen at 4-week intervals after 131I administration, and hypothyroidism is treated when it appears with an elevated TSH level, generally within 3 months. Women planning to become pregnant are advised to wait for an arbitrary period of 6 months after 131I therapy to allow for resolution of any transient effects of gonadal radiation. If, after a period of 6 months, hyperthyroidism is still present and the patient is symptomatic, the treatment is repeated, generally with about 1.5 times the initial dose of 131I.
Although the foregoing reflects our approach to therapy, the opinions of thyroïdologists differ widely. \[151\] In view of the several approaches to treatment available, each with its advantages and disadvantages, it is incumbent on the physician to explain these factors thoroughly to patients, to indicate a preference and the reasons for it, and to allow the final choice to rest with the patient when appropriate.

### Hypothyroidism in the Recently Hypothyroid Patient

The early onset of hypothyroidism may cause distinct symptoms in the previously thyrotoxic patient after \[151\] or surgical treatment or even with high doses of thionamide drugs. Such patients may develop severe muscle cramps, often in large muscle groups such as the trapezius or latissimus dorsi or the proximal muscles of the extremities. Such symptoms can develop even when the serum hormone levels are only low-normal or slightly decreased and before the TSH concentration has risen. It is possible to mistake a symptom such as back pain for an unrelated illness unless the patient is warned in advance. It is also not unusual for patients to complain of hypothyroid symptoms when thyroid function test results return to within the normal range. Such patients appear to have trouble adjusting to the normal thyroid hormone levels after being exposed to excessive amounts for long periods.

### Treatment of Infiltrative Orbitopathy or Infiltrative Dermopathy

Infiltrative orbitopathy varies in severity from the common mild form to a severe form that threatens vision. The latter type is rare but remains difficult to treat. Indeed, the most effective therapies are merely palliative. The natural course of the disorder, which is variable and characterized by exacerbations and remissions, makes conclusions about the efficacy of any treatment difficult. A further source of confusion is the variable terminology for describing the manifestations of orbitopathy and the lack of rigid criteria for defining their severity. Use of the American Thyroid Association classification and its expanded indices, described earlier, is strongly recommended (see Table 11-4 and Table 11-5).

### Effect of Treatment of the Thyroid Gland on Orbitopathy

The first question that arises is whether different treatments for thyrotoxicosis affect the course of the eye disease differently. Subtotal thyroidectomy and thionamide drug therapy do not influence ophthalmopathy unless they lead to the development of hypothyroidism. Hypothyroidism has an adverse effect on the disorder and should be treated fully when it occurs. However, exogenous thyroid hormone in the absence of hypothyroidism does not improve the ophthalmopathy.

As discussed earlier, controlled studies suggest that radioiodine treatment may lead to a slight but significant worsening of orbitopathy (see earlier discussion), \[160\] and it may be best to avoid radioiodine in patients with severe eye disease. Alternatively, as mentioned earlier, coincidental glucocorticoid therapy may prevent deterioration of orbitopathy after radioiodine but may itself cause significant side effects. \[165\] Controlled, prospective studies of the influence of antithyroid drug treatment prior to radioiodine on oculare changes are needed.

### Symptomatic Treatment

Treatment modalities can be those that are largely symptomatic (useful mainly in the mild form) and those that attempt to arrest or reverse the progression of the disorder. With milder forms, little treatment is required. The patient who experiences photophobia and sensitivity to wind or cold air can benefit by wearing dark glasses, which also afford protection from foreign bodies. Elevation of the head of the bed at night and instillation of lubricants, such as 1% methylcellulose, may help when the eyelids do not appose completely during sleep. Artificial tears can be used during the day. Because the opthalmic manifestations tend to be self-limited and the progression to a more severe form is uncommon, such measures usually suffice to tide the patient over until the disorder regresses spontaneously.

### Glucocorticoids

The appearance of increasing proptosis with inability to appose the eyelids or of severe infiltrative manifestations such as chemosis warrants the use of more vigorous therapeutic measures. Such changes, even when severe, may respond favorably and rapidly to glucocorticoids. Some physicians use massive doses of prednisone (120 to 140 mg/day). If improvement occurs, the dose is decreased to the lowest level at which improvement is maintained. The latter dose is still likely to be large, but it is hoped that a halt to the progression or actual regression of the disease will occur before untoward effects make withdrawal of the drug necessary. Other physicians find that much smaller doses of prednisone (20 to 30 mg/day) can be highly effective with rapid reduction to a longer-term maintenance dose (10 to 15 mg/day). Intravenous hydrocortisone pulse therapy is said to have the advantage of fewer side effects than high doses of prednisone. \[169\] \[170\]

To circumvent the inevitable side effects of large doses of glucocorticoids, periodic injection of depot preparations of glucocorticoids subconjunctivally or into the retro-orbital space has been tried but is not recommended. Such treatment may have a dramatic effect on irritative symptoms as well as on diplopia, but the efficacy varies, and systemic effects of the glucocorticoids are sometimes seen. Moreover, this treatment entails the risk of puncture of the globe or a retro-orbital hematoma. It is important to protect the patient's bones during corticosteroid treatment, especially with a postmenopausal woman, and preferably with a bisphosphonate drug such as alendronate, given at 70 mg once a week (see Chapter 27).

### External Radiation

The value of external radiation to the orbits has been established by some, but not all, controlled trials. \[165\] \[171\] In fact, this treatment is steroid-sparing rather than steroid-replacing therapy and is said by some to work best in combination. \[172\] Whether it is more effective than prednisone therapy is unclear; as a result, the combined therapy has long been advocated. \[172\] The safe administration of highly collimated supervoltage radiation to the retro-orbital space requires experienced personnel. Exophthalmos and ophthalmoparesis are usually affected minimally. \[173\] There is a clear need for a reliable disease marker to monitor the effects of such treatment. A recent trial in mild eye disease failed to show any advantage to this approach. \[174\]

### Orbital Decompression

If glucocorticoid therapy and external radiation do not halt progression of the disease and if loss of vision is threatened either by ulceration or infection of the cornea or by changes in the retina or optic nerve, orbital decompression can be performed by a variety of techniques. \[175\] In some patients, a desire for a nearly complete cosmetic correction may be such that decompression surgery is the only therapy. This procedure usually involves removal of either the lateral wall or the roof of the orbit or resection of the lateral wall of the ethmoid sinus and the roof of the maxillary sinus. \[176\] This operation may cause diplopia, and even in the best of hands corrective muscle surgery may be necessary later.

### An Approach to the Treatment of Orbitopathy

There are no controlled trials to support the suggestion that infiltrative orbitopathy is benefited or that its progression is retarded by total ablation of the thyroid gland, whether surgery, radioiodine, or a combination of the two is used. Hence, we recommend a trial of oral glucocorticoid therapy for patients with severe or progressive orbitopathy. If effective doses cannot be tolerated, a course of external radiation may be attempted if edema predominates.

Along with these major forms of treatment local measures should be employed. Ulceration and infection of the cornea should be treated with antibiotics, lubricants, and protective shields. An attempt to appose the eyelids by means of sutures (tarsorrhaphy) should be performed only by an experienced ophthalmologist because sutures may be torn out and cause scarring.

The management of severe orbitopathy should never be undertaken by the endocrinologist or by the ophthalmologist acting alone. Close, coordinated observation of the effects of medical therapy and the progress of the disease is necessary to determine whether and when surgery is appropriate. Surgery almost invariably halts the
progress of the disease and preserves vision if it is performed in time. This decision is influenced by the ability of the available surgical team because the degree of success of such procedures is proportional to experience.

Treatment of Infiltrative Dermopathy

Treatment of infiltrative dermopathy is necessary as soon as the condition is recognized. The application of a topical, high-potency glucocorticoid preparation with an occlusive dressing may cause regression or disappearance of the lesion. Long-standing untreated dermopathy is more resistant to treatment.
Hyperthyroidism and Thyrotoxicosis in Pregnancy

As discussed earlier, postpartum thyroiditis with transient thyrotoxicosis may occur with some frequency (5% to 10%) during the postpartum period. An overactive thyroid gland, however, is much less common in pregnancy itself. When thyrotoxicosis is present during pregnancy, it is usually more severe and is usually due to Graves’ disease. Difficulty in conception and fetal wastage are increased in women with Graves’ disease, but occasional patients become pregnant despite antecedent untreated hyperthyroidism. More commonly, a woman under treatment for hyperthyroidism becomes pregnant, or hyperthyroidism develops after pregnancy is under way. Whatever the sequence, pregnancy complicates the diagnosis and treatment of hyperthyroidism in Graves’ disease and influences its severity and course.

Diagnosis

Pregnancy and hyperthyroidism are both accompanied by thyroid enlargement, a hyperdynamic circulation, and hypometabolism. Amenorrhea may occur in thyrotoxicosis not associated with pregnancy. In pregnancy, serum T4 and T3 levels are increased by changes in glycoprotein, and thus in both conditions, the total serum T4 and T3 levels are elevated. The most useful laboratory tests in their differentiation are measurement of the serum TSH and free T4 levels. Serum TSH is suppressed in hyperthyroidism during pregnancy, just as it is in nonpregnant patients. However, there is sometimes a modest suppression of TSH (between 0.1 and 0.4 mU/L) during the 8th to 14th weeks of normal pregnancy because of stimulation of the thyroid gland by hCG during this interval. A serum TSH below 0.1 mU/L and an elevated free T4 or free T3 level strongly suggests coexistent hyperthyroidism.

Treatment During Pregnancy

The management of hyperthyroidism during pregnancy can be an even greater problem than the diagnosis; however, pregnancy has an attenuating influence on the hyperthyroid state because of the immunosuppression associated with pregnancy, manifested here by a decrease in the level of thyroid autoantibodies (including levels of TSHRAbs).

Iodine and Beta-Blockers

One of the few clinical situations in which the biologic activity of the TSHRAbs is helpful in predicting its effect on the newborn.

Surgery

Surgery during the last trimester, and probably during the first trimester as well, is not desirable because of the possible induction of premature labor. Although surgery may be successful during the middle trimester, it is best to avoid major surgery during pregnancy if possible.

Antithyroid Drugs

Because antithyroid drug treatment poses no greater risk to the mother or fetus than does surgery and possibly involves less risk, medical therapy is the method of choice. Yet because of the usual improvement in the disease, the dosage of antithyroid drug required to control the disease in the latter phases of pregnancy is generally much less than that required in the same patient when she is not pregnant.

Certain aspects of placental physiology are relevant to the use of antithyroid drugs. Propylthiouracil and methimazole readily cross the placenta. They are concentrated in the fetal thyroid, and in excess quantity can cause goitrous hypothyroidism in the fetus. The administration of as little as 100 to 300 mg/day of propylthiouracil to the mother causes a slight decrease in serum T4 concentration and an elevated TSH level in neonates. The long-term complication of this mild hypothyroidism is unknown but should be kept in mind in view of the observations of reduced childhood intelligence when mothers have increased TSH levels. Although maternal T4 crosses the placenta (as obviously evidenced by infants born normal with congenital hypothyroidism), placental transfer is not efficient and varies from patient to patient. For these reasons, the flux of antithyroid agent to the fetus should be limited by giving the mother the smallest dosage of antithyroid agent that induces a physiologic state consistent with normal pregnancy. The serum free T4 level should be maintained in the upper normal range. However, the concentration of hormone is not as critical as the clinical status of the patient. A modest tachycardia is a physiologic response to the increased metabolic demands of pregnancy; and pulse rates of 90 to 100 beats/minute are well tolerated without evidence of myocardial decompensation during delivery.

In most cases, the daily maintenance dose of propylthiouracil should be 200 mg or less, although maintenance doses up to 600 mg may occasionally be required. Propylthiouracil has been generally preferred to methimazole because of the greater transplacental passage of the latter drug, but both drugs have proven equally safe in millions of pregnancies throughout the world and accumulate equally in breast.
Changes in the Immune Response

Pregnancy induces a variety of immune changes that are responses to the paternal foreign antigens that must not be rejected. These include a T-cell shift from Th1 to Th2 autoimmune responses and an overall decrease in all autoimmune responses as evidenced by marked decreases in thyroid autoantibodies. Following delivery, these immune changes are slowly lost and a return to normal is observed but only after a period of exacerbated autoimmune reactivity in which large increases in T-cell and autoantibody activity occur. It is at this time3 to 9 months post partum that autoimmune thyroid disease recurrence or new onset is seen. The mechanisms behind these changes are not fully understood, but maternal microchimerism has been invoked, among other theories, and appears to be associated with Graves' disease-susceptible HLA haplotypes.

Presentation

A high percentage of women in the 20- to 35-year age group give a history of pregnancy in the 12 months before the onset of Graves' disease. Pregnancy and the postpartum state also apparently influence the course of hyperthyroidism in Graves' disease. Patients in clinical remission during pregnancy are prone to postpartum relapse. In 41 pregnancies in 35 patients in remission, 78% were followed by development of thyrotoxicosis during the postpartum period. The patients with Graves' disease and postpartum thyrotoxicosis were classified into three categories:

1. Some patients had persistent recurrent hyperthyroidism with an elevated RAIU (classic Graves' disease).
2. Some had a transient disorder associated with a normal or an elevated RAIU (transient Graves' disease).
3. Some patients, especially those with the highest titers of TPOAb, experienced a transient thyrotoxicosis with a decreased RAIU that is the thyrotoxic phase of postpartum thyroiditis. This phase, in turn, may be followed by a hypothyroid phase (see later).

The Desire for Pregnancy

A special problem related to hyperthyroidism and pregnancy is presented by the patient who is in early remission after a course of antithyroid drug treatment or is being treated with antithyroid agents and wants to become pregnant in the near future. Management with antithyroid agents can be continued through pregnancy or reinstituted should hyperthyroidism recur, but in such instances definitive therapy (radioiodine or surgery) should be considered to forestall the complexities of managing hyperthyroidism during pregnancy. As with the therapy of Graves' disease in general, such decisions must involve education of the patient so that the risks and benefits of the various alternatives are clearly appreciated.

Nursing and Antithyroid Drugs

Older studies suggested that relatively more methimazole than propylthiouracil appeared in breast milk of women receiving these drugs, but more recent evidence shows little difference between them (see earlier). However, it is generally recommended that women who take antithyroid drugs should be advised not to nurse their infants because of the difficulty in monitoring young babies. No serious drug side effects have been reported in neonates whose mothers were taking antithyroid drugs, although periodic thyroid function tests would seem appropriate if the mother continues to breast-feed.
Treatment of Graves' Disease in Children and Adolescents

Thyrotoxicosis in childhood and adolescence is almost always the result of Graves' disease. Thyrotoxicosis in this age group is worthy of special consideration because treatment is less satisfactory than in adults. Hence, there is more uncertainty concerning its management, probably because the disease tends to be more severe in children.

Radioiodine

For several reasons, we do not often use radioiodine in the treatment of childhood thyrotoxicosis. At least three factors weigh against such use:

1. The enhanced carcinogenic potential of radiation in the thyroid gland of the infant or child is evidenced by the correlation between childhood thyroid carcinoma and a history of radiation therapy to the head, neck, or chest in childhood and the increased incidence of thyroid cancer in children exposed to radiation from the Chernobyl nuclear accident.
2. Among patients with thyrotoxicosis, those treated in childhood or adolescence are thought to be at greatest risk for transmitting genetic damage, although available data suggest that this may not be likely.
3. Postradioiodine hypothyroidism is a particularly undesirable complication in young children because inadequate or interrupted therapy can impair growth, development, and scholastic performance.

Antithyroid Drugs

The choice between destructive and antithyroid drug therapy may be a difficult one. The data indicate that children have a lower incidence of long-term remission after antithyroid therapy than adults, although some believe that thyrotoxicosis often undergoes remission after adolescence. A course of 1 to 2 years of antithyroid therapy seems reasonable, and a second course of antithyroid therapy is regularly employed if recrudescence or relapse occurs after the first course. Measuring TSHRAs may be helpful in assessing the child's progress. If sustained remission does not follow a second course of therapy and particularly if the patient has passed through adolescence during this period, radioiodine therapy or surgery may be considered.

Surgery

Most surgical series reveal a relatively high frequency of postoperative hypothyroidism in children. Recurrences are also more frequent, presumably as a result of attempts to avoid hypothyroidism. Complications such as hypoparathyroidism and recurrent laryngeal nerve damage must be borne over a long life span. All this leads to surgery's being less appropriate than antithyroid drugs for most children.
OTHER CAUSES OF THYROTOXICOSIS

Toxic Multinodular Goiter

Toxic multinodular goiter is a disorder in which hyperthyroidism arises in a multinodular goiter, usually of long standing, and is the result of one of several pathogenetic factors. It is important to avoid the term toxic nodular goiter because this confuses toxic multinodular goiter, as here described, with a toxic adenoma of the thyroid gland (see later).

Pathogenesis

The pathogenesis of toxic multinodular goiter cannot be considered apart from that of its invariable forerunner, nontoxic multinodular goiter, from which it emerges slowly and surreptitiously. Two hallmarks of the disorderstructural and functional heterogeneity and functional autonomyrevolve over time; the increase in the extent of autonomous function causes the disease to move from the nontoxic to the toxic phase, but the mechanisms of this change in all cases are uncertain. The somatic mutations in the TSHR gene demonstrated in toxic adenomas have been demonstrated in some cases of toxic multinodular goiter and appeared to differ from nodules to nodules. However, only about 60% of toxic nodules have TSHR mutations, and only a few have G protein mutations. Hence, there are many nodules with undetermined causes of their autonomy.

Studies show that radioiodine becomes localized in one or more discrete nodules, whereas iodine accumulation in the remainder of the gland is usually suppressed. Radioiodine is of little help because this confuses toxic multinodular goiter, as here described, with a toxic adenoma of the thyroid gland (see later).

The overproduction of thyroid hormone in toxic multinodular goiter is usually less than that in Graves' disease. First, the clinical manifestations of thyrotoxicosis are rarely flagrant. Second, the serum 

\[ T_4 \] and 

\[ T_3 \] concentrations may be only marginally increased, and a suppressed serum TSH level may be the only abnormality.

Finally, the total RAU is only slightly increased or within the normal range.

The mildness of the hyperthyroidism is consistent with either of its presumed pathogenetic origins. The effectiveness of any stimulus to hyperfunction may be blunted in a thyroid gland that is the seat of a preexisting nontoxic multinodular goiter because of the associated impairment in the efficiency of hormone synthesis. Toxic multinodular goiter is a common complication of nontoxic multinodular goiter, but its precise incidence is unknown. It usually occurs after the age of 50 years in patients who have had nontoxic multinodular goiter for many years. Like its forerunner, toxic multinodular goiter is many times more common in women than in men. Sometimes hyperthyroidism develops abruptly, usually after exposure to increased quantities of iodine, which permits autonomous foci to increase hormone secretion to excessive levels and which may simply exacerbate already established mild hyperthyroidism (iodine-induced hyperthyroidism, von Basedow's disease). In addition, Graves' disease may either present or develop in a multinodular gland, as confirmed by the presence of TSHRAbS of the stimulating variety.

Toxic multinodular goiter is almost never accompanied by infiltrative ophthalmopathy, and when the two coexist, it represents the emergence of Graves' disease. The clinical manifestations of toxic multinodular goiter also differ from those in Graves' disease. Cardiovascular manifestations tend to predominate, possibly because of the age of the patients, and include atrial fibrillation or tachycardia, with or without heart failure. Surveys have indicated that TSH was suppressed in 26% of elderly patients with atrial fibrillation (see also Table 11-2).

A decreased response to digitalis may alert the physician to the presence of thyrotoxicosis. Weakness and wasting of muscles are common. The nervous manifestations are less prominent than in younger patients with thyrotoxicosis, but emotional lability may be pronounced. Because of the physical characteristics of the thyroid gland and its frequent retrosternal extension, obstructive symptoms are more common than in Graves' disease. On palpation, the characteristics of the goiter are the same as those of the more common nontoxic multinodular goiter (see later). In as many as 20% of elderly patients with thyrotoxicosis, the thyroid gland is firm and irregular but not distinctly enlarged. Ultrasonographic examination confirms the diagnosis as toxic multinodular goiter rather than a single toxic adenoma or Graves' disease.

### Laboratory Tests and Differential Diagnosis

The challenge to determine whether the patient with a multinodular goiter is thyrotoxic can be resolved only with laboratory tests. If the free 

\[ T_4 \] index or free 

\[ T_3 \] index is elevated and the TSH level is suppressed, the diagnosis of hyperthyroidism is established. TSH levels intermediate between 0.1 and the 0.5 mIU/L lower limit of normal are not usually associated with significant symptoms. Such patients have thyroid autonomy but are not thyrotoxic. The pituitary-hypothalamic axis provides the most sensitive indicator of the level of thyroid hormone that is specifically relevant to the individual patient. Monitoring the concentration of serum TSH takes advantage of this sensitivity and is one of the most useful ways of establishing the existence of autonomous thyroid function. The RAU is of little help because thyrotoxicosis may exist in association with values that are normal or only slightly increased.

### Treatment

Radioiodine

Radioiodine is the treatment of choice for patients with toxic multinodular goiter despite disagreement about the size and number of doses required to achieve a therapeutic response. Along the eastern seaboard of the United States, the responsiveness of toxic multinodular goiter to radioiodine may differ little from that of the diffuse toxic goiter of Graves' disease. However, in areas where goiter was formerly endemic, such as the Great Lakes area of the United States, toxic multinodular goiter is said to be more resistant to radioiodine. The more resistant variety of toxic multinodular goiter may be a reflection of low radioiodine uptake for a

| Table 11-9 – Atrial Fibrillation and Thyrotoxicosis |
|---------------------------------|-----------|
| Total no. of patients examined | 443       |
| Euthyroid patients             | 303       |
| Hypothyroid patients           | 23        |
| Hyperthyroid patients          | 117 (26.4%) |

variety of reasons ranging from increased iodine consumption to low sodium-iodide symporter (NIS) activity.

Because of the age of the patient and variations in sensitivity to radioiodine, increased doses of RAI are often administered. These doses are likely to be larger than those used in Graves’ disease because the uptake of $^{131}$I tends to be lower and the gland larger. Many patients with this disorder have underlying heart disease. Therefore, the administration of radioiodine should be preceded by a course of antithyroid therapy until a eumetabolic state is achieved. Medication is then discontinued for at least 3 days before radioiodine is administered. Seven days thereafter, the antithyroid drug is reinstituted so that the thyrotoxicosis is controlled until radioiodine takes effect. After 6 to 8 weeks, the antithyroid drug is gradually withdrawn; if thyrotoxicosis recurs, a second course of therapy is given. This entire treatment sequence should be accompanied by adequate $\beta$-blockade if the cardiac status permits.

**Surgery**

Surgical therapy is often recommended after adequate preoperative preparation in patients with obstructive manifestations or when it is feared that such manifestations may result from the temporary thyroid enlargement that radioiodine sometimes produces, particularly in patients with retrosternal extensions of the goiter. In these patients, MRI is recommended to define the extent of the goiter and the adequacy of the tracheal walls. Respiratory function studies may also be helpful in assessing the need for surgery. When surgery is contraindicated, even significant obstructive symptoms can be relieved by adequate radioiodine therapy.
Toxic Adenoma (Plummer's Disease)

A third, less common form of hyperthyroidism is caused by one or more autonomous adenomas of the thyroid gland. As herein employed, the term toxic adenoma refers to a tumor in a thyroid that is otherwise intrinsically normal. The disorder is usually caused by a single adenoma that is palpable as a solitary nodule and therefore is sometimes referred to as hyperfunctioning solitary nodule or toxic nodule. Occasionally, two or three adenomas of similar character are present.

Pathogenesis

Toxic adenomas are true follicular adenomas (for histopathologic characteristics, see Chapter 13). The basic pathogenesis

Figure 11-23 (Figure Not Available) This diagram shows the thyrotropin (TSH) receptor and its ectodomain, transmembrane loops, and intracellular segment and illustrates activating and inactivating mutations of the TSH receptor. The amino acids are indicated by the single-letter code and numbered consecutively, starting with the transcription initiation codon. The vertical lines indicate exon boundaries. (From Sunthornthepvarakul T, Gottschalk ME, Hayashi Y, et al. Resistance to thyrotropin caused by mutations in the thyrotropin-receptor gene. N Engl J Med 1995; 332:1551-1557.)

of a large fraction of them is one of several somatic point mutations in the TSHR gene, commonly in the third transmembrane loop. These single nucleotide substitutions cause amino acid changes that lead to constitutive activation of the TSH receptor in the absence of TSH (Fig. 11-23) (Figure Not Available). It appears therefore that the TSHR is “tripped” from an off state to an on state. Similarly, loss of function rather than gain of function mutations may also occur in the TSHR gene and may cause hypothyroidism (see later). A small number of autonomous adenomas have mutations in the G protein genes that lead to a similar state of constitutive activation.

The course is one of progressive growth and increasing function over many years. At first, the adenoma may be present as a small nodule or may be palpable; in either case, it can be detected in a radioidine thyroid scan as a localized area of increased radioidine accumulation (Fig. 11-24) and much of the remainder of the gland may be suppressed. With further growth, a progressively increasing share of glandular function is assumed by the adenoma, with the result that the remaining tissue is increasingly suppressed. Ultimately the remainder of the gland is completely suppressed and atrophic.

![Image 11-24](https://example.com)

**Figure 11-24** Scanning of a hyperfunctioning hot nodule corresponding to physical examination with a faint outline of the remaining suppressed gland. In this unusual case, Graves' disease developed a few months later after an oral contrast agent load. (From Soule J, Mayfield R. Graves' disease after 131I therapy for toxic nodule. Thyroid 2001; 11:919-2.)

and the thyroid scan reveals function only in the adenoma (hot nodule).

Although continued growth of the adenoma causes secretion of excessive quantities of hormone, some time may pass before thyrotoxicosis becomes overt. The extranodular tissue usually retains its capacity to function if TSH is provided, either by exogenous administration or by ablation of the nodule.

Clinical Picture

Toxic adenoma occurs in a younger age group than does toxic multinodular goiter, often in patients in their 30s or 40s. Frequently there is a history of a long-standing, slowly growing lump in the neck. It is unusual for adenomas to produce thyrotoxicosis until they have achieved a diameter of 2.5 to 3 cm. The adenoma can undergo central necrosis and hemorrhage; as a result, the thyrotoxicosis may be relieved, the remainder of the thyroid gland may resume its function, and the adenoma may appear on a scan as a cold area, suggesting a thyroid carcinoma. Calcification in the area of hemorrhage may take place and may be evident on sonogram examination. Such calcification is usually gross and irregular and does not resemble the finely stippled calcification of the psammoma bodies seen in papillary cancers. If the TSH level is suppressed and the single nodule is seen by sonography, a thyroid radioidine uptake and scan would be necessary only as a prelude to ablative treatment.

The peripheral manifestations of toxic adenoma are generally milder than those of Graves' disease and are notable for the absence of infiltrative orbitopathy and myopathy: cardiovascular manifestations may be prominent. The nodule is usually felt as a smooth, well-defined, round or ovoid mass that is firm and moves freely on swallowing. Often the remainder of the gland is not palpable. A bruit is never present.

Laboratory Tests

The results of laboratory tests depend on the stage of the disorder. At first, serum thyroid hormone concentrations may be normal except for borderline suppression of the serum TSH. This, together with ultrasonographic examination to exclude multiple nodules, confirms the diagnosis. Later a thyroid scan may show localization of radioisotope in the palpated nodule, but this does not occur until TSH secretion is suppressed. If the nodule continues to grow, frank hyperthyroidism is accompanied by elevation of serum thyroid hormone levels and metabolic indices. When the nodule is small, the RAIU is normal but cannot be suppressed completely by exogenous thyroid hormone. However, TSH and, therefore, function in the extranodular tissue are suppressed by exogenous hormone, allowing identification of the autonomous nature of the nodular lesion by scanning even before the lesion has become sufficiently large to suppress serum TSH.

Occasionally, values for serum T3 concentration are normal, and only the serum T4 level is increased (T3 toxicity). Relative to its overall rate of occurrence, toxic adenoma is the most frequent cause of T3 toxicity. If there is any question about the presence of the suppressed lobe, exogenous recombinant human TSH may be administered before scanning to demonstrate uptake in this tissue. Incidental thyroid carcinoma may rarely coexist within a gland exhibiting a hyperfunctioning adenoma, and malignant nodules that cause functional hyperthyroidism are rare.

Treatment

Although many hyperfunctioning adenomas eventually cause clinical hyperthyroidism, some do so slowly and others not at all. Therefore, treatment of asymptomatic patients with functional adenomas is decided on an individual basis. The degree of TSH suppression is an index of the progression of thyroid hormone production by the adenoma. Suppression below the lower limits of normal indicates that hyperthyroidism is present and that therapy should be given except in unusual situations.

Two therapies are available: radioidine and surgery.

Radioidine

In terms of the specificity of treatment, functioning thyroid nodules should be ideal candidates for radioidine therapy. The radiation should, in theory, be directed almost exclusively to the diseased tissue. This is because TSH levels are suppressed and the normal thyroid tissue surrounding the nodule does not take up
radioiodine. However, this suppression may be incomplete, resulting in uptake of radioiodine, and thyroid failure may develop in many patients. For patients older than 20 years of age with a nodule 3 cm in diameter or smaller, $^{131}$I is an appropriate treatment if the risk of eventual hypothyroidism is acceptable.

In general, higher doses of radioiodine are required than in Graves' disease, namely 185 to 370 MBq (5 to 10 mCi) deposited at 24 hours. Because of the potential for hypothyroidism with higher $^{131}$I doses, prolonged follow-up is mandatory. Suppression of TSH by exogenous $T_3$, 25 µg/day for 7 days, may be used in appropriate patients to reduce $^{131}$I uptake by the normal thyroid tissue during therapy.

Surgery

Patients with large nodules accompanied by physical symptoms are most readily treated with surgical excision. Surgical excision is also often used in young patients. The toxic adenoma is not diffusely hypervascular, and consequently preoperative preparation with iodine is not required. In patients with overt thyrotoxicosis, however, a normal metabolic state should be restored with an antithyroid drug or -blockers before surgery.
Inherited Nonautoimmune Autosomal Dominant Hyperthyroidism

Toxic diffuse thyroid hyperplasia without the pathologic characteristics of autoimmune disease has been reported in a few families and appears to be inherited as an autosomal dominant condition. Polymorphic genomic mutations in the TSHR gene have been reported to cause constitutively activated TSHRs differing from family to family. Recessive mutations on both chromosomes have also been described as causing hyperthyroidism while the parents remained euthyroid. These gain of function mutations, mostly in the transmembrane regions of the TSHR, are similar to those somatic mutations seen in toxic adenomas but are in the germline (see Fig. 11-23) (Figure Not Available). Treatment is by radioiodine ablation or thyroidectomy, depending on the age of the patient.
Transient Hyperthyroidism

Subacute Thyroiditis

Subacute thyroiditis has been termed granulomatous giant cell or de Quervain’s thyroiditis. It is thought to be caused by a viral infection of the thyroid gland and often follows an upper respiratory illness. A tendency to a seasonal and geographic aggregation of cases has been noted. The mumps virus has been implicated in some cases, and coxsackievirus, influenza virus, echoviruses, and adenoviruses may also be etiologic agents. Evidence of thyroid autoimmunity is often present during the active phase of the disease. This autoimmunity is usually transitory, although some patients may retain evidence of thyroid autoimmunity for many years.

A small number of patients eventually develop autoimmune thyroid disease. It is likely that subacute thyroiditis is the clinical phenotype for a wide variety of virus infections that affect the thyroid gland. Subacute thyroiditis is uncommon, but mild cases may be mistakenly diagnosed as pharyngitis. Women are more frequently affected than men, and the peak incidence is in the fourth and fifth decades.

Histopathology

The histopathologic changes (Fig. 11-25) differ from those in Hashimoto’s disease. The lesions are patchy in distribution and vary in their stage of development from area to area. Affected follicles are infiltrated predominantly with mononuclear cells and show disruption of epithelium, partial or complete loss of colloid, and fragmentation and duplication of the basement membrane. To this extent, the histopathologic appearance may resemble that in Hashimoto’s disease.

A characteristic feature is the well-developed follicular lesion that consists of a central core of colloid surrounded by the multinucleate giant cells, from which stems the designation giant cell thyroiditis. Colloid may be found in the interstitium or within the giant cells (colloidophagy). The follicular changes progress to form granulomas. Interfollicular fibrosis and an interstitial inflammatory reaction are present to varying degrees. When the disease subsides, an essentially normal histologic appearance is restored.

Pathophysiology

Apoptosis of follicular epithelium and loss of follicular integrity are the primary events in the pathophysiology. Tg, preformed hormone, and abnormal iodinated materials are released into the circulation, often in quantities sufficient to elevate not just the serum Tg level but also the serum T4 and T3 concentrations, produce clinical thyrotoxicosis, and suppress TSH secretion. As a result of the last effect, all thyroid function is suppressed, the RAIU decreases to low levels, and hormone synthesis ceases. Destruction of the follicular epithelium is the primary contributor to lowering of the RAIU and disruption of hormone synthesis, because external TSH may fail to increase the RAIU normally. Later in the disease, when stores of preformed hormone are depleted, serum T4 and T3 concentrations decline, sometimes into the hypothyroid range, and the serum TSH level rises, often to elevated values. As the disease becomes inactive, the RAIU may be greater than normal for a time as hormone stores are repleted. Ultimately, when hormone secretion resumes, serum T4 and T3 concentrations rise, and serum TSH concentration decreases to normal values.

Clinical Picture

The characteristic feature is the gradual or sudden appearance of pain in the region of the thyroid gland with or without fever. The pain, which is aggravated by turning the head or swallowing, characteristically radiates to the ear, jaw, or occiput and may mimic disorders arising in these areas. The absence of pain does not exclude the diagnosis, because biopsy-proven painless, subacute thyroiditis occurs, but it must be distinguished from autoimmune thyroiditis. Hoarseness and dysphagia may be present, and patients may complain of palpitation, nervousness, and lassitude. Lassitude can be extreme, considering the local nature of the disease, and indicates a systemic component. Although acute manifestations are present in severe cases, in milder disease, which is often wrongly diagnosed, symptoms may be present for months.

On palpation, at least part of the thyroid gland is slightly to moderately enlarged, firm, even nodular, and usually exquisitely tender, one lobe frequently being more severely affected than the other. Indeed, the symptoms may be truly unilateral. The overlying skin may be warm and red. Occasionally the locus of maximal involvement migrates over the course of a few weeks to other parts of the gland.

The disease usually subsides within a few months, leaving no residual deficiency of thyroid function, but often passes through a transient phase of hypothyroidism, resembling the syndrome of transient silent autoimmune thyroiditis preceded by transient thyrotoxicosis. In rare cases, the disease may smolder, with repeated exacerbations over many months and with hypothyroidism sometimes being the final result.

Laboratory Tests

The laboratory findings vary with the phase of the disease. During the active phase, the erythrocyte sedimentation rate (ESR) can be increased to a remarkable extent. Indeed, a diagnosis...
of active subacute thyroiditis is hardly tenable when the ESR is normal. The leucocyte count is normal or, at most, moderately increased. The serum Tg level is characteristically high, in keeping with the degree of thyroid destruction.

Subacute thyroiditis is one of several causes of low-uptake thyrotoxicosis; the others are so-called silent thyroiditis (the early phase of Hashimoto’s disease [described earlier], thyrotoxicosis factitia, and iodine-induced hyperthyroidism. For reasons described earlier, the RAU is subnormal, despite the presence of normal, or often elevated, values of serum T₄ and T₃ concentrations. At this point in the course, basal serum TSH levels are suppressed. In the typical patient, TPO and Tg autoantibodies either are not detectable or are present in low levels. In milder cases, some uptake of radioiodine may persist in unaffected portions of the gland, as revealed by a radioiodine scan; however, this is unusual, and a diagnosis of active, subacute thyroiditis should be viewed with suspicion if the RAU is normal.

In the hypothyroid phase, serum T₄ and T₃ concentrations are low and the serum TSH concentration is appropriately elevated (see Fig. 11-26). With recovery, the RAU returns to normal or high levels, and values for serum T₄ and T₃ concentrations are restored to normal.

Differential Diagnosis

Subacute thyroiditis must be differentiated from (1) acute hemorrhagic degeneration in a preexisting thyroid nodule, (2) Hashimoto’s disease of acute onset, and (3) acute pyogenic thyroiditis.

Differentiation from hemorrhage into a nodule presents no difficulty when this occurs in a multinodular goiter, because other nontender nodules can be felt. Detection is more difficult when there is hemorrhage into a solitary nodule, but this should be easily seen on ultrasonography. In both varieties of hemorrhage, function in the remainder of the gland persists, and the ESR is rarely elevated.

Hashimoto’s disease of acute onset may be accompanied by pain and tenderness in the thyroid gland, but the gland usually is diffusely affected and may present as a truly painless thyroiditis with thyrotoxicosis and a decreased RAU but with a histologic picture of autoimmune thyroiditis and no giant cells, often termed hashitoxicosis. This may be difficult to distinguish from painless, subacute thyroiditis. Lack of elevation of the ESR and high titers of thyroid autoantibodies strongly suggest the former.

Acute pyogenic thyroiditis is distinguished by the presence of a septic focus elsewhere, by a greater inflammatory reaction in the tissues adjacent to the thyroid gland, and by much greater leukocytic and febrile responses. The RAU is usually preserved in acute pyogenic thyroiditis. Rarely, widespread infiltrating thyroid cancer can present with a clinical and laboratory picture almost indistinguishable from that of subacute thyroiditis. 

Treatment

In mild cases, aspirin, nonsteroidal anti-inflammatory drugs, or cyclooxygenase-2 inhibitors generally control the symptoms. In more severe cases, glucocorticoids (e.g., prednisone up to 40 mg/day) alleviate the manifestations but do not influence the underlying disease process. Hence, the symptoms may be exacerbated if treatment is withdrawn too early but do again respond if treatment is reinstituted. The chance of relapse may be minimized if glucocorticoid therapy is continued at a dose that maintains the patient in an asymptomatic state until the RAU has returned to normal. Thyroid hormone replacement therapy may decrease the size of the gland by suppressing TSH and by relieving the pressure on the thyroid capsule. Because TSH is needed for thyroid cell regeneration, however, such therapy should be decreased as the symptoms subside.

Thyrotoxicosis in Silent Thyroiditis

Thyrotoxicosis is associated with the early phase of subacute thyroiditis in both painful and painless variants. In addition, thyrotoxicosis can also occur without pain in early autoimmune thyroiditis (Hashimoto’s disease), in which biopsy of the thyroid gland reveals the histopathologic changes of Hashimoto’s disease rather than those of subacute thyroiditis (see Fig. 11-27). This syndrome has variously been alluded to as silent thyroiditis with thyrotoxicosis, hyperthyroiditis, or hashitoxicosis, and cannot be distinguished from the early phase of postpartum thyroiditis (see later).

The cardinal features are thyrotoxicosis associated with depressed values of the RAU in the absence of excess body iodide stores, lack of pain or tenderness in the thyroid area, and spontaneous resolution of the thyrotoxic phase of the disease. There is a tendency to pass through a transient euthyroid phase and then a hypothyroid phase before a long-term return to euthyroidism and a tendency for the syndrome to recur. The thyroid gland is enlarged in only about 50% of cases, and enlargement is usually mild and unaccompanied by nodularity. Thyrotoxicosis is usually mild, and this is reflected in the extent of elevation of serum T₄ and T₃ levels. High levels of TPO autoantibodies can be detected in most patients by sensitive assays. Systemic manifestations of inflammation are lacking, and the ESR is normal or nearly normal.

Several aspects of the pathophysiology of this disorder are instructive. As in subacute thyroiditis, because of widespread apoptosis and TSH suppression the rate of ongoing synthesis of thyroid hormones is negligible, justifying the classification of this disorder among those that lead to “thyrotoxicosis without hyperthyroidism.” Decreased values of the RAU are due partly to suppression of TSH secretion by the excess of circulating hormones because the serum TSH level is suppressed; function of the thyroid follicular cell is also impaired, however, because the RAU does not increase after administration of TSH, presumably secondary to T cellmediated and antibody-mediated thyroid cell death.

The tendency of the disorder to pass through a hypothyroid phase is not surprising, in view of the extensive depletion of glandular hormone stores that occur while hormone is leaking from the gland and new hormone synthesis is impaired.

The duration of the thyrotoxic phase averages about 1 to 2 months. About 50% of patients return to a euthyroid phase and remain well, at least for some time. In the remaining 50%, a hypothyroid phase may follow and last from 2 to 9 months. In most instances, euthyroidism is eventually restored, but permanent hypothyroidism may develop in some patients years later. About one-third of patients retain a goiter, usually with persistence of thyroid autoantibodies in the serum. The opposite sequelae of thyrotoxicosis may also occur months or years after restoration of a euthyroid state, and some patients experience multiple recurrences.

Treatment of the thyrotoxic phase consists of alleviation of the peripheral manifestations through the use of β-blockers or sedatives. Reportedly, prednisone (30 to 50 mg/day) decreases the duration of the thyrotoxic phase without the risk of relapse on its withdrawal but is not needed. If the hypothyroid phase is mild and brief, patients may not require treatment. When treatment with levothyroxine is needed, it should be undertaken with the understanding that it will be withdrawn approximately 6 months later, because the hypothyroidism is unlikely to be permanent.

The underlying nature of the disorder is an autoimmune
dysregulation. Extensive lymphocytic infiltration and the presence of plasma cells within the thyroid are similar to those seen in more classic Hashimoto's thyroiditis, as are the circulating thyroid autoantibodies. The latter, however, may merely reflect a response to the inflammatory release of antigens. The occurrence of the syndrome in patients known to also have Graves' disease, which we and others have observed, and the later emergence of hypothyroidism (Hashimoto's disease) are also consonant with an autoimmune etiology. On the other hand, the absence of high levels of circulating antithyroid antibodies in many patients and the permanent resolution indicate that the immune system regains its equilibrium in these patients. This provides a great opportunity to further our understanding of these control mechanisms.

Thyrotoxicosis in Postpartum Thyroiditis

The postpartum thyroiditis syndrome is similar in presentation, course, and pathophysiology to silent thyroiditis. Transient thyrotoxicosis with low RAIU may develop within 3 to 6 months after delivery and is often followed by a period of hypothyroidism of several months' duration and an eventual return to a euthyroid state. In some patients, only a hypothyroid phase is evident. The incidence of postpartum thyroiditis varies geographically but may occur in as many as 10% of women and in more than 30% of those with positive TPO autoantibodies. This argues for prenatal assessment for the presence of TPO antibodies. In women found to be positive for TPO antibodies, postpartum assessment of thyroid function is recommended at 2, 4, 6, and 12 months.

As in the similar syndrome of silent thyroiditis, not temporally related to pregnancy, recurrences are common after subsequent pregnancies. Most patients have a small goiter and positive tests for TPO antibodies, although levels may be low. The syndrome has also been observed post partum in patients known to have prepartum Graves' disease. There is a strong association with the HLADR3 and HLADR5 haplotypes, which are also associated with autoimmune thyroid disease. The occurrence of the disorder after delivery is probably due to a rebound of immune activity after its suppression during pregnancy. However, the role of fetal microchimerism has also been implicated in the initiation of disease.
Hyperthyroidism Caused by Thyrotropin or Thyrotropin Receptor Agonists

Rarely hyperthyroidism results from hypersecretion of TSH or TSH-like activity because of three causative factors:

1. A TSH-secreting pituitary adenoma.
2. Inappropriate hypersecretion of TSH secondary to localized pituitary resistance to thyroid hormones or increased secretion of TRH.
3. Excessive secretion of hCG from trophoblastic tumors.

All varieties are associated with a diffuse, hyperfunctioning goiter. Features of autoimmune thyroid disease are absent in these patients and in the families of patients.

When TSH is the cause, the serum TSH concentrations are not suppressed at a time when serum free \( T_4 \) or \( T_3 \) concentrations are elevated. \(^{234,235}\)

Thyrotropin-Secreting Pituitary Tumors

In the adenomatous variety, a mass lesion is present in the pituitary gland. (see Chapter 8). The concentration of free subunits of TSH in serum is elevated, and serum TSH concentrations may fall to increase after TRH administration. In patients with nonadenomatous TSH hypersecretion, in contrast, subunits are not present in the blood in high concentrations and the response to TRH is usually normal. \(^{236,237}\) In addition, patients with thyroid hormone resistance may respond to oral \( T_3 \) rather than \( T_4 \).

Patients with excess TSH in the absence of resistance present a difficult therapeutic problem. In some cases, TSH secretion can be suppressed if somewhat large doses of thyroid hormone are administered, but this results in worsening of the thyrotoxicosis. Hyperthyroidism can be controlled, of course, by thyroid ablation, but serum TSH levels then increase still further, raising the question as to whether a TSH-producing adenoma may ultimately develop. Bromocriptine, a dopamine agonist, may suppress TSH secretion and alleviate the hyperthyroidism in this disorder. \(^{238}\) Somatostatin analogues have also been used. However, TSH-producing tumors usually require surgical resection. \(^{239}\) \(^{240}\) \(^{241}\) Treatment with 3,5,3'-triiodothyroacetic acid has also been successful. \(^{242}\)

The occurrence of TSH-induced hyperthyroidism further supports the argument that a serum TSH concentration should be measured as part of the initial work-up of every patient who is hyperthyroid and has a diffuse goiter. The remote possibility that a patient with Graves’ disease might have an artifactual elevation of TSH concentration because of a heterophilic antibody cross-reacting with mouse immunoglobulin (see Chapter 6) must be kept in mind. \(^{243}\) For some sera, the use of a different assay kit may confirm the elevated level. Alternatively, mouse serum may be added to the assay tube to absorb the heterophile antibody.

A Note on Pituitary Resistance to Thyroid Hormone

In some patients with inherited thyroid hormone resistance due to mutations in the thyroid hormone receptor, the hypothalamic pituitary feedback mechanism may be more resistant to the effects of thyroid hormone compared with peripheral tissues, such as the heart. \(^{244}\) \(^{245}\) \(^{246}\) These patients may have a hyperthyroid appearance with tachycardia, nervousness, and goiter associated with an elevated free \( T_4 \) index. Because the thyroid hormone hyperproduction is TSH-driven, however, serum TSH concentrations are detectable (>0.1 mU/L) or even elevated inappropriately for the circulating thyroid hormone levels (see Chapter 12).

In general, the manifestations are due not to excessive but to inadequate thyroid hormone action, and these individuals may require treatment with thyroid hormone or thyroid hormone analogues and \(-\)adrenergic receptor-blocking agents rather than antithyroid drugs. \(^{247}\) \(^{248}\) This argues again for the appropriateness of at least one serum TSH measurement in every hyperthyroid patient because this is the only way that an accurate diagnosis can be achieved (see discussion of thyroid hormone resistance in topic of hypothyroidism). Rarely, families with just pituitary resistance to thyroid hormone (PRTH) may respond to treatment with liothyronine. \(^{249}\)

Hyperthyroidism in Trophoblastic Disease

Thyroid hyperfunction often accompanies hydatidiform mole, choriocarcinoma, or metastatic embryonal carcinoma of the testis. Such neoplasms, particularly hydatidiform mole, elaborate differentially glycosylated hCG molecules that exhibit crossover specificity for binding to the TSH receptor and can induce thyroid overactivity. \(^{250}\) \(^{251}\) \(^{252}\) \(^{253}\) Some patients have clinically overt thyrotoxicosis; however, clinical manifestations are usually not prominent, and goiter is absent or minimal despite laboratory evidence of a hyperthyroid state. Free \( T_4 \) or free \( T_3 \) levels are increased, and TSH values are suppressed. The reason for this discordance between the clinical and the laboratory indices is not known but the discordance may be due to the relatively short duration of thyroid hormone excess. The possibility of a molar pregnancy should always be considered in a young woman with thyrotoxicosis, because appropriate therapy is evacuation of the uterus.
Iodine-Induced Hyperthyroidism

Administration of supplemental iodine to subjects with endemic iodine deficiency goiter can result in iodine-induced hyperthyroidism and even Graves’ disease. This response, termed iodine-induced hyperthyroidism or the Jod-Basedow effect, occurs in only a small fraction of individuals at risk. The best-studied experience has been in Tasmania, where a temporary increase in thyrotoxicosis occurred shortly after the addition of small quantities of iodine to bread as a means of correcting iodine deficiency.

Studies revealed two major patterns of underlying thyroid disorder. In the first, especially common in older individuals, nodular goiter with areas of autonomous function were present and TSHRAs of the type found in Graves’ disease were not detectable in the blood. In the second pattern, which occurred in younger individuals with diffuse goiter, stimulating TSHRAs were often present. These findings suggest that the Jod-Basedow effect occurs only in thyroid glands in which function is independent of TSH stimulation. The occurrence of the Jod-Basedow effect should not be construed as a reason for failing to treat endemic iodine deficiency. Apart from the many other benefits that accrue from iodine treatment and prophylaxis, over the long run the frequency of spontaneous hyperthyroidism associated with the development of autonomous nodules is diminished.

Iodine-induced hyperthyroidism is an important disorder in areas of the world where dietary iodine intake is high. In regions where iodine intake is marginal but overt iodine deficiency is absent, moderate increments in iodine intake may induce hyperthyroidism in patients with autonomous thyroid nodules, and large pharmacologic doses of iodine, can do so in geographic areas where the iodine intake is more than adequate. Consequently, the physician must be alert to the possibility of inducing hyperthyroidism when administering large quantities of iodine in expectorants, radiographic contrast media, medications containing iodine (e.g., amiodarone), or any other form to patients with nodular goiter. Because nodular goiter is generally a disease of older people, induction of the Jod-Basedow phenomenon can have serious consequences, because enrichment of the thyroid gland with iodine forestalls administration of $^{131}$I and delays the response to antithyroid agents. In these patients, serum $T_3$ concentration is sometimes normal, although total and free $T_4$ concentrations are increased and TSH is suppressed. Confirmation that the patient has been exposed to large quantities of iodine can be obtained by demonstrating that the RAIU is low and urinary iodine excretion increased (more than several milligrams per day).

The treatment of these individuals may be difficult. Even after discontinuation of exogenous iodide, uptake of $^{131}$I by the thyroid gland may remain low, not adequate for conventional doses of radiiodine. The elevated thyroid hormone content also makes thionamide drugs less effective. In some cases, it may be necessary to treat such individuals for prolonged periods (6 to 9 months) before administering radiiodine therapy; if uptake is detectable, however, larger doses of radiiodine may be given to destroy thyroid tissue.

**Amiodarone**

Amiodarone is an iodine-rich drug that has become increasingly popular because of its effectiveness in combating severe cardiac arrhythmias. The drug has complex effects on the thyroid gland, although most patients (80%) remain euthyroid. Structurally, the drug resembles $T_3$ (Fig. 11-30) and contains 37% iodine. It has been estimated that a huge amount (200 mg/day) of iodide is made available in a daily dose of 600 mg. It has a half-life of 50 to 60 days and therefore remains available for a long period even after drug withdrawal.

Amiodarone inhibits types 1 and 2 5’-deiodinases and increases $T_3$ levels at the same time as it increases TSH. The drug may also compete for the $T_3$ receptor. Amiodarone also has a direct cytotoxic effect on thyroid cells via induction of apoptosis. In addition, an iodine load may precipitate thyroid autoimmune disease, as discussed earlier, in susceptible individuals and induces most commonly autoimmune hyperthyroidism, but Graves’ disease may also be precipitated. Most commonly, however, it is the influence of the iodine load that causes the clinical effects, particularly in areas of iodine deficiency where thyrotoxicosis is most commonly seen and in areas of iodine deficiency where hypothyroidism is most commonly seen.

Amiodarone-induced hyperthyroidism may develop either rapidly in a patient or even after a few years of treatment. The different presentations have been divided as follows:

- **Type I** occurs in abnormal thyroid glands secondary to iodine excess.
- **Type II** is secondary to drug-induced destructive thyroiditis, sometimes resulting in high serum IL-6 levels that can be checked in the serum.

Both types may occur together, and treatment is often a major challenge. Antithyroid drugs and radiiodine may be ineffective because of the large intrathyroidal iodine load. Thyroidectomy is therefore the treatment of choice if the patient’s clinical condition permits. This allows the continuation of the drug. The use of combined potassium perchlorate (1 g daily) and methimazole (40 mg daily) may be tried if surgery is not possible. A complete blood count must be checked regularly with such treatment, which is fraught with side effects. If Type II predominates, steroids may control the destructive thyroiditis (2 to 6 mg of dexamethasone daily). In contrast, when hyperthyroidism is the presentation, due to thyroid destruction at the onset of Hashimoto’s disease or the failure to escape from iodine blockade, levothyroxine replacement is effective. TSH should be monitored appropriately. If the drug is discontinued, there may be spontaneous remission. Potassium perchlorate may provide increased speed of recovery by discharging intrathyroidal iodide.

**Hamburger Thyrotoxicosis**

An unusual form of exogenous thyrotoxicosis occurred in the midwestern portion of the United States in 1984 and 1985. The source was the inclusion of large quantities of bovine thyroid in ground beef preparations. When the slaughtering practices were changed, this condition, called hamburger thyrotoxicosis, disappeared. Such a possibility, however remote, should be considered, especially if one is confronted with epidemic exogenous thyrotoxicosis. Here the cause was probably the direct ingestion of large amounts of thyroid hormone, but the additional iodine load and its consequences should also be considered.
Thyrotoxicosis Caused by Nonthyroid Sources of Thyroid Hormone

Thyrotoxicosis Factitia

Thyrotoxicosis that arises from the (usually chronic) ingestion of excessive quantities of thyroid hormone usually occurs in individuals with a background of underlying psychiatric disease, especially in paramedical personnel who have access to thyroid hormone or in patients for whom thyroid hormone medication has been prescribed in the past. Generally, the patient is aware of taking thyroid hormone but may adamantly deny it. In other instances, large doses of thyroid hormone or other thyroactive material, such as iodocasein, may be taken without the knowledge of the patient, usually as part of a regimen for weight reduction. Symptoms are typical of thyrotoxicosis and may be severe.

In the absence of preexisting thyroid disease, the diagnosis is made from the combination of typical thyrotoxic manifestations, together with thyroid atrophy and hypofunction. Infiltrative ophthalmopathy never occurs, but lid lag, stare, and other "thyrotoxic" eye signs may be present. Hypofunction of the thyroid gland is evidenced by suppressed serum Tg levels and subnormal values of RAIU, which can be increased by administration of TSH. Serum \( T_4 \) concentrations are increased unless the patient is taking \( T_3 \), in which case they will be subnormal. Serum \( T_3 \) concentrations are increased in either case. TSH levels are suppressed. The presence of low, rather than elevated, values of serum Tg concentration is a clear indication that the thyrotoxicosis results from exogenous hormone rather than thyroid hyperfunction.

This disorder may be confused with other varieties of thyrotoxicosis associated with a subnormal RAIU and absence of goiter, including the syndrome of Hashimoto's disease preceded by transient thyrotoxicosis (silent thyroiditis), ectopic thyroid tissue, and hyperfunctioning meta-static follicular carcinoma. Evidence for the latter two disorders can be obtained by demonstration of the ectopic focus or foci by external radioiodine scanning and the fact that serum thyroglobulin is increased in both conditions.

Differentiation from silent and painless thyroiditis may be difficult. The presence of circulating TPO and Tg antibodies points to painless chronic autoimmune thyroiditis, whereas a firm thyroid gland and a brief history suggest the painless variant of subacute thyroiditis.

Treatment consists of withdrawing the offending medication. Psychiatric help may be necessary.

Ectopic Thyroid Tissue

Thyroid tissue may be present in teratomas, especially in the ovary (struma ovarii), and such foci may produce thyrotoxicosis. Rarely, hyperfunctioning metastases of follicular carcinoma can produce thyrotoxicosis. The distinguishing features of such lesions have been discussed earlier.
Special Aspects of Thyrotoxicosis

T₃ Toxicosis

Concurrent measurements of T₃ and T₄ production rates have revealed a disproportionate increase in T₃ production in most patients with hyperthyroidism. Whether this phenomenon results solely from the preferential increase in thyroid synthesis of T₃, preferential intrathyroid T₃ to T₄ conversion or from a disproportionate increase in peripheral conversion of T₃ to T₄ is uncertain, but the preferential synthesis is probably responsible in most instances. In the extreme case, the production rate of T₃ alone is increased, resulting in the thyrotoxic state designated T₃ toxicity. In some patients, T₃ toxicity may be the forerunner of the usual form of thyrotoxicosis in which production of both T₃ and T₄ is increased, and in other patients it persists as such. T₃ toxicity may occur with Graves’ disease, toxic multinodular goiter, or toxic adenoma. (See Table 10-14.)

The prevalence is not known, but T₃ toxicity appears to be more common than the conventional types of hyperthyroidism in areas of iodine deficiency. In our experience, it tends to be more frequent in older people.

The diagnosis should be suspected in a patient with clinical manifestations of thyrotoxicosis in whom the serum T₄ level and free T₄ concentration or index are normal or decreased while the serum TSH concentration is suppressed. Documentation of an elevated free T₃ level confirms the diagnosis. The presence of a palpable goiter and a normal or increased RAIU excludes the diagnosis of thyrotoxicosis factitia induced by ingestion of T₃. Experience suggests that patients with T₃ toxicity are more likely to have a long-term remission after withdrawal of antithyroid drug therapy than patients with the usual form of thyrotoxicosis.

T₄ Toxicosis

T₄ toxicity refers to thyrotoxicosis with an increased serum T₄ concentration and free T₄ concentration or index but a normal or decreased serum T₃ concentration. This phenomenon occurs in two circumstances. One is iodine-induced thyrotoxicosis, in which about one third of the patients have a normal serum T₄ concentration and the remainder display proportionate elevations of serum T₃ and T₄ concentrations. The second is thyrotoxicosis accompanied by severe intercurrent illness. Here, that component of the serum T₄ usually contributed by peripheral T₃ monodeiodination. With is decreased or lacking, so the serum T₃ concentration, sustained mainly or entirely by direct thyroid secretion, is normal or low, although the serum T₄ concentration is high.

Concomitantly, the serum rT₃ concentration is increased, often markedly, owing to inhibition of its 5’monodeiodination. With recovery from the intercurrent illness, serum rT₃ concentration declines and serum T₄ concentration increases into the thyrotoxic range. T₄ toxicity of this type is so be differentiated from the low serum T₄ level and elevated serum T₄ concentration that are occasionally found in the euthyroid sick syndrome. A reduced serum TSH level may not distinguish patients who are hyperthyroid from those who are not. Some of these changes are thought to be cytokine-mediated.

Thyrotoxic Crisis (Thyroid Storm)

Thyrotoxic crisis, also called accelerated hyperthyroidism or thyroid storm, is an extreme accentuation of thyrotoxicosis. The crisis, however, may be exaggerated by an inexperienced physician. It is an uncommon but serious complication, usually occurring in association with Graves’ disease but sometimes with toxic multinodular goiter. Before the availability of adequate means for achieving full preoperative control, crisis frequently followed subtotal thyroidectomy (surgical crisis).

Thyrotoxic crisis is usually of abrupt onset and occurs in patients in whom preexisting thyrotoxicosis has been treated incompletely or has not been treated at all. Crisis is usually precipitated by infection, trauma, surgical emergencies, or operations and, less commonly, by radiation thyroiditis, diabetic ketoacidosis, toxemia of pregnancy, or parturition. The mechanism by which such factors worsen thyrotoxicosis may be related to cytokine release and acute immunologic disturbance caused by the precipitating condition. The serum thyroid hormone levels in crisis are not appreciably greater than those in uncomplicated thyrotoxicosis.

The clinical picture is one of severe hypermetabolism. Fever is almost invariable and may be severe; sweating is profuse. Marked tachycardia of sinus or ectopic origin and arrhythmias may be accompanied by pulmonary edema or congestive heart failure. Tremulousness and restlessness are present; delirium or frank psychosis may supervene. Nausea, vomiting, and abdominal pain may occur early in the course. As the disorder progresses, apathy, stupor, and coma may supervene, and hypotension can develop. If unrecognized, the condition may be fatal. This clinical picture in a patient with a history of preexisting thyrotoxicosis or with goiter or exophthalmos or both is sufficient to establish the diagnosis, and emergency treatment should not wait laboratory confirmation.

There are no foolproof criteria by which severe thyrotoxicosis complicated by some other serious disease can be distinguished from thyrotoxic crisis induced by that disease. In any event, the differentiation between these alternatives is of no great significance because treatment of the two is the same.

Treatment aims to correct both the severe thyrotoxicosis and the precipitating illness and to provide general support. The patient thought to have thyroid crisis should be monitored in a medical intensive care unit during the initial phases of therapy. The therapy itself is designed to inhibit hormone synthesis and release and to antagonize the adrenergically mediated aspects of peripheral thyroid hormone action.

Large doses of an antithyroid agent (300 to 400 mg of propylthiouracil every 4 hours) are given by mouth, by stomach tube, or, if necessary, per rectum. Propylthiouracil may be preferable to methimazole because it has the additional action of inhibiting the peripheral generation of T₃ from T₄ by Type I iodothyronine deiodinase. Administration of propylthiouracil initiates therapy for the postcrisis period and prevents enrichment of glandular hormone stores by the iodine, which administration is of more immediate importance. The latter agent, administered either as SSKI (5 drops every 6 hours), ipodate (0.5 g twice daily) or, if available, sodium iodide intravenously (0.250 g every 6 hours), acutely retards the release of hormone from the thyroid gland.

Propylthiouracil should be administered before iodine to inhibit the synthesis of additional thyroid hormones from the administered iodine. Nonetheless, because iodine blocks release of preformed thyroid hormones from the thyroid gland, its administration

Thyrotoxic Crisis (Thyroid Storm)

Thyrotoxic crisis, also called accelerated hyperthyroidism or thyroid storm, is an extreme accentuation of thyrotoxicosis. The crisis, however, may be exaggerated by an inexperienced physician. It is an uncommon but serious complication, usually occurring in association with Graves’ disease but sometimes with toxic multinodular goiter. Before the availability of adequate means for achieving full preoperative control, crisis frequently followed subtotal thyroidectomy (surgical crisis).

Thyrotoxic crisis is usually of abrupt onset and occurs in patients in whom preexisting thyrotoxicosis has been treated incompletely or has not been treated at all. Crisis is usually precipitated by infection, trauma, surgical emergencies, or operations and, less commonly, by radiation thyroiditis, diabetic ketoacidosis, toxemia of pregnancy, or parturition. The mechanism by which such factors worsen thyrotoxicosis may be related to cytokine release and acute immunologic disturbance caused by the precipitating condition. The serum thyroid hormone levels in crisis are not appreciably greater than those in uncomplicated thyrotoxicosis.

The clinical picture is one of severe hypermetabolism. Fever is almost invariable and may be severe; sweating is profuse. Marked tachycardia of sinus or ectopic origin and arrhythmias may be accompanied by pulmonary edema or congestive heart failure. Tremulousness and restlessness are present; delirium or frank psychosis may supervene. Nausea, vomiting, and abdominal pain may occur early in the course. As the disorder progresses, apathy, stupor, and coma may supervene, and hypotension can develop. If unrecognized, the condition may be fatal. This clinical picture in a patient with a history of preexisting thyrotoxicosis or with goiter or exophthalmos or both is sufficient to establish the diagnosis, and emergency treatment should not wait laboratory confirmation.

There are no foolproof criteria by which severe thyrotoxicosis complicated by some other serious disease can be distinguished from thyrotoxic crisis induced by that disease. In any event, the differentiation between these alternatives is of no great significance because treatment of the two is the same.

Treatment aims to correct both the severe thyrotoxicosis and the precipitating illness and to provide general support. The patient thought to have thyroid crisis should be monitored in a medical intensive care unit during the initial phases of therapy. The therapy itself is designed to inhibit hormone synthesis and release and to antagonize the adrenergically mediated aspects of peripheral thyroid hormone action.

Large doses of an antithyroid agent (300 to 400 mg of propylthiouracil every 4 hours) are given by mouth, by stomach tube, or, if necessary, per rectum. Propylthiouracil may be preferable to methimazole because it has the additional action of inhibiting the peripheral generation of T₃ from T₄ by Type I iodothyronine deiodinase. Administration of propylthiouracil initiates therapy for the postcrisis period and prevents enrichment of glandular hormone stores by the iodine, which administration is of more immediate importance. The latter agent, administered either as SSKI (5 drops every 6 hours), ipodate (0.5 g twice daily) or, if available, sodium iodide intravenously (0.250 g every 6 hours), acutely retards the release of hormone from the thyroid gland.

Propylthiouracil should be administered before iodine to inhibit the synthesis of additional thyroid hormones from the administered iodine. Nonetheless, because iodine blocks release of preformed thyroid hormones from the thyroid gland, its administration
blockade of atrio-ven-tricular node conduction.

When treatment is successful, improvement is usually manifested within 1 or 2 days and recovery occurs within a week. At this time, iodide and dexamethasone are gradually withdrawn and plans for long-term management are made.
Subclinical Hyperthyroidism

With the advent of thyroid function screening and the presence of highly sensitive TSH assays, many patients with mild thyroid disease now consult physicians for advice. The presence of a chronically suppressed serum level TSH with peripheral free thyroid hormone levels within the normal range has been defined as mild or "subclinical" hyperthyroidism. In a study of more than 25,000 people attending a health fair, 0.9% were found to have this condition.

Subclinical hyperthyroidism may occur with clinical symptoms and signs that include weight loss, anxiety, atrial fibrillation, and osteoporosis or with no symptoms at all. All of the causes of thyrotoxicosis may be associated with such a mild presentation, most often Graves’ disease and toxic multinodular goiter. Indeed, it is these patients who are the ones with precipitated severe thyrotoxicosis after an increase in their iodine intake.

Making the correct diagnosis is helpful in deciding treatment and excluding transient thyroiditis. When there are symptoms or obvious risks, treatment is required. If there are no signs or symptoms and the diagnosis has been made biochemically, watchful observation may be appropriate. In patients with mild Graves’ disease, a short course of low-dose antithyroid drugs may cure the condition. In the presence of toxic nodules, radioiodine may be more appropriate, particularly in elderly populations, whose risk of cardiac arrhythmias is increased.

Chapter 12 - Hypothyroidism and Thyroiditis

P. Reed Larsen
Terry F. Davies

HYPOTHYROIDISM

Many structural or functional abnormalities can impair the production of thyroid hormones and cause the clinical state termed hypothyroidism. The causes can be divided into six main categories:

1. Hypothyroidism with compensatory thyroid enlargement due to transient or progressive impairment of hormone biosynthesis (goitrous hypothyroidism).
2. Permanent loss or atrophy of thyroid tissue (iatrogenic hypothyroidism).
3. Transient hypothyroidism.
4. Consumptive hypothyroidism.
5. Central hypothyroidism, that is, hypothyroidism due to insufficient stimulation of a normal gland as a result of hypothalamic or pituitary disease or defects in the thyroid-stimulating hormone (TSH) molecule itself.
6. Resistance to thyroid hormone (RTH).

Primary hypothyroidism accounts for approximately 99% of cases, with fewer than 1% being due to TSH deficiency. Central hypothyroidism is discussed in Chapter 7 and Chapter 8.

Clinically apparent acquired impairment of thyroid function affects about 2% of adult women and about 0.1 to 0.2% of adult men. Subclinical hypothyroidism, an elevated TSH level in an asymptomatic patient, was recently found in 8.9% of a self-selected U.S. population of approximately 20,000. Neonatal screening programs for congenital hypothyroidism discover hypothyroidism in almost 1 in 3500 newborns.

Clinical Presentation

Hypothyroidism can affect all organ systems, and these manifestations are largely independent of the underlying disorder but are a function of the degree of hormone deficiency. The following sections discuss the pathophysiology of each organ system at various levels of thyroid hormone deficiency, from mild to severe. The term myxedema, formerly used as a synonym for hypothyroidism, refers to the appearance of the skin and subcutaneous tissues in the patient in a severely hypothyroid state (Fig. 12-1). Hypothyroidism of this severity is rarely seen today, and the term should be reserved to describe the physical signs.

Skin and Appendages

Hypothyroidism causes an accumulation of hyaluronic acid that alters the composition of the ground substance in the dermis and other tissues. This material is hygroscopic, producing the mucinous edema that is responsible for the thickened features and puffy appearance (myxedema) with full-blown hypothyroidism. Myxedematous tissue is characteristically boggy and nonpitting and is apparent around the eyes, on the dorsa of the hands and feet, and in the supracavicular fossae (Fig. 12-1). It causes enlargement of the tongue and thickening of the pharyngeal and laryngeal mucous membranes.

A histologically similar deposit may occur in patients with Graves’ disease, usually over the pretibial area (infiltrative dermopathy or pretibial myxedema). In addition to having a puffy appearance, the skin is pale and cool as a result of cutaneous vasoconstriction. Anemia may contribute to the pallor; hypercarotenemia gives the skin a yellow tint but does not cause scleral icterus. It causes enlargement of the tongue and thickening of the pharyngeal and laryngeal mucous membranes.

Wounds of the skin tend to heal slowly. Easy bruising is due to an increase in capillary fragility. Head and body hair is dry and brittle, lacks luster, and tends to fall out. Hair may be lost from the temporal aspects of the eyebrows, which is not specific for hypothyroidism. The secretion of the sweat glands and sebaceous glands are reduced, leading to dryness and coarseness of the skin, which in extreme cases may resemble ichthyosis.

In secondary hypothyroidism, the degree of hypothyroidism is less severe and the changes in the skin and its appendages may be less striking than in primary hypothyroidism. The skin is pale and cool and tends to be thinner and finely wrinkled, and infiltration of the tissues is less prominent. Depigmentation of areas that are normally pigmented, such as the areolae, occurs in a central but not primary hypothyroidism.

Histopathologic examination of the skin reveals hyperkeratosis with plugging of hair follicles and sweat glands. The dermis is edematous, and the connective tissue fibers are separated by an increased amount of metachromatically staining, periodic acid-Schiff positive mucinous material. This material consists of protein complexed with two mucopolysaccharides: hyaluronic acid and chondroitin sulfate B. The glycosaminoglycans are mobilized early during treatment with thyroid hormone, leading to an increase in urinary excretion of nitrogen and hexosamine.

Cardiovascular System

The cardiac output at rest is decreased because of reduction in both stroke volume and heart rate, reflecting loss of the inotropic and chronotropic effects of thyroid hormones. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These hemodynamic alterations cause narrowing of pulse pressure, prolongation of circulation time, and decrease in blood flow to the tissues. The decrease in cutaneous...
circulation is responsible for the coolness and pallor of the skin and the sensitivity to cold. In most tissues, the decrease in blood flow is proportional to the decrease in oxygen consumption, so the arteriovenous oxygen difference remains normal. The hemodynamic alterations at rest resemble those of congestive heart failure. However, in hypothyroidism, cardiac output increases and peripheral vascular resistance decreases normally in response to exercise unless the hypothyroid state is severe and of long standing.

In severe primary hypothyroidism the cardiac silhouette is enlarged (Fig. 12-2), and the heart sounds are diminished in intensity. These findings are the result largely of effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans, but the "flabby" myocardium may also be dilated. Pericardial effusion is rarely of sufficient magnitude to cause tamponade. In central hypothyroidism, the heart is typically small.

Angina pectoris is uncommon, but it may appear or worsen during treatment of the hypothyroid state with thyroid hormone. There is considerable controversy over whether hypothyroidism is a risk factor for atherosclerosis. The Whickham Study showed no increase in cardiovascular mortality in patients with subclinical hypothyroidism over 20 years, whereas the Rotterdam Study suggested that there was a twofold increase in risk. Systemic vascular resistance is increased, and hypertension is more common.

Electrocardiographic changes include sinus bradycardia, prolongation of the PR interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Pericardial effusion is probably responsible for the low amplitude in severe hypothyroidism. Rarely, complete heart block may be present, but this disappears when hypothyroidism is treated. Systolic time intervals are altered; the pre-ejection period is prolonged, and the ratio of pre-ejection period to left ventricular ejection time is increased. Echocardiographic studies have revealed a high frequency of asymmetrical septal hypertrophy and apparent obstruction of the left ventricular outflow tract, suggesting idiopathic hypertrophic subaortic stenosis. These findings disappear when the hypothyroidism is treated, and their hemodynamic significance is uncertain.

Serum levels of homocysteine, creatine kinase, aspartate aminotransferase, and lactate dehydrogenase may be increased. Typically, the isoenzyme patterns suggest that the source of the increased creatine kinase and lactate dehydrogenase is skeletal, not cardiac, muscle. All levels return to normal with therapy.

The combination of large heart, hemodynamic and electrocardiographic alterations, and the serum enzyme changes has been termed myxedema heart. Myxedema heart rarely causes heart failure by itself because the usual hemodynamic response to exercise in hypothyroidism is typically normal, although exceptions have been reported. In the patient with hypothyroidism, as in the normal individual, theValsalva maneuver leads to a decrease in pulse pressure, whereas in the patient with heart failure the pulse pressure does not decrease but displays the so-called square-wave response. In the absence of coexisting organic heart disease, treatment with thyroid hormone corrects the hemodynamic, electrocardiographic, and serum enzyme alterations of myxedema heart and restores heart size to normal.

Figure 12-2

A

B

Alimentary System

Although most patients experience a modest gain in weight, appetite is usually reduced. The weight gain that occurs is caused partly by retention of fluid by the hydrophilic glycoprotein deposits in the tissues. Peristaltic activity is decreased and, together with the decreased food intake, is responsible for the frequent complaint of constipation. The latter may lead to fecal impaction (myxedema megacolon). Gaseous distention of the abdomen (myxedema ileus), if accompanied by colicky pain and vomiting, may mimic mechanical ileus.

Elevations in the serum levels of carcinoembryonic antigen, which may occur on the basis of hypothyroidism alone, add to the impression that an organic obstruction is present. Acutees in the absence of another cause is unusual in hypothyroidism, but it can occur, usually in association with pleural and pericardial effusions. Like pericardial and pleural effusions, the ascitic fluid is rich in protein and glycosaminoglycans.

Achlorhydria after maximal histamine stimulation may be present in patients with primary hypothyroidism. Circulating antibodies against gastric parietal cells have been found in about one third of patients with primary hypothyroidism and may be secondary to atrophy of the gastric mucosa. Overt pernicious anemia is reported in about 12% of patients with primary hypothyroidism. The coexistence of pernicious anemia and other autoimmune diseases, such as gluten enteropathy, with primary hypothyroidism reflects the fact that autoimmunity plays the central role in the pathogenesis of these diseases (see Chapter 37).

Hypothyroidism has complex effects on intestinal absorption. Although the rates of absorption for many substances are decreased, the total amount absorbed may be normal or even increased because the decreased bowel motility may allow more time for absorption. Malabsorption is occasionally overt.

Liver function test results are usually normal, but levels of aminotransferases may be elevated, probably because of impaired clearance. The gallbladder contracts sluggishly and may be distended, but whether these changes predispose to the development of gallstones is unknown.

Atrophy of the gastric and intestinal mucosa and myxedematous infiltration of the bowel wall may be demonstrated on histologic examination. The colon may be greatly distended, and the volume of fluid in the rectal cavity is unusually increased. The liver and pancreas are normal.

Central and Peripheral Nervous System

Thyroid hormone is essential for the development of the central nervous system. Deficiency in fetal life or at birth causes retention of the infantile characteristics of the brain, hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vasculature. If the deficiency is not corrected in early postnatal life, the damage is irreversible. Deficiency of thyroid hormone beginning in adult life causes less severe manifestations that usually respond to treatment with the hormone. Cerebral blood flow is reduced, but cerebral oxygen consumption is usually normal; this finding is in accord with the conclusion that the oxygen consumption of isolated brain tissue in vitro, unlike that of most other tissues, is not stimulated by administration of thyroid hormones. In severe cases, decreased cerebral blood flow may lead to cerebral hypoxia.

All intellectual functions, including speech, are slowed. Loss of initiative is present, slow-wittedness and memory defects are common, lethargy and somnolence are prominent, and dementia in elderly patients may be mistaken for senile dementia. Psychiatric disorders are common and are usually of the paranoid or depressive type and may induce agitation (myxedema madness). Headaches are frequent. Cerebral hypoxia due to circulatory alterations may predispose to confusional attacks and syncope, which may be prolonged and lead to stupor or coma. Other factors predisposing to coma in hypothyroidism include exposure to severe cold, infection, trauma, hyperventilation with carbon dioxide retention, and depressant drugs.
of the pigment required for dark adaptation. Hearing loss of the perceptive type is frequent due to myxedema of the eighth cranial nerve and serous otitis media. Perceptive deafness may also occur in association with a defect in the organic binding of thyroidal iodide (Pendred's syndrome) (see discussion of iodine metabolism), but in these instances it is not due to hypothyroidism per se.

Thick, slurred speech and hoarseness are due to myxedematosus infiltration of the tongue and larynx, respectively. Body movements are slow and clumsy, and cerebellar ataxia may occur. Numbness and tingling of the extremities are frequent; in the fingers these symptoms may be due to compression by glycosaminoglycan deposits in and around the median nerve in the carpal tunnel (carpal tunnel syndrome). The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic "hang-up reflexes"; this phenomenon is due to a decrease in the rate of muscle contraction and relaxation rather than a delay in nerve conduction.

The presence of extensor planter responses or diminished vibration sense should alert the physician to the possibility of coexisting pernicious anemia with combined system disease. Electroneurographic changes include slow alpha wave activity and general loss of amplitude. The concentration of protein in the cerebrospinal fluid is often increased, but cerebrospinal pressure is normal.

Histopathologic examination of the brain in patients with untreated hypothyroidism reveals that the nervous system is edematous with mucinous deposits in and around nerve fibers. In patients with cerebellar ataxia, neural myxedematous infiltrates of glycosgen and mucinuous material are present in the cerebellum. There may be foci of degeneration and an increase in glial tissue. The cerebral vessels show atherosclerosis, but this is much more common if the patient has had coexistent hypertension.

Muscular System

Stiffness and aching of muscles are common and are worsened by cold temperatures. Delayed muscle contraction and relaxation cause the slowness of movement and delayed tendon jerks. Muscle mass may be reduced or enlarged due to interstitial myxedema. Muscle mass may be slightly increased, and the muscles tend to be firm. Rarely, a profound increase in muscle mass with slowness of muscular activity may be the predominant manifestation (the Kocher-Debri-Semelaigne, or Hoffmann) syndrome. Myoclonus may be present. The electromyogram may be normal or may exhibit disordered discharge, hyperirritability, and polyphasic action potentials.

On histopathologic examination, the muscles appear pale and swollen. The muscle fibers may show swelling, loss of normal striations, and separation by mucinous deposits. Type I muscle fibers tend to predominate.

Skeletal System: Calcium and Phosphorus Metabolism

Thyroid hormone is essential for normal growth and maturation of the skeleton, and growth failure is due both to impaired general protein synthesis and to a reduction in growth hormone, but especially of insulin-like growth factor I. Before puberty, thyroid hormone plays a major role in the maturation of bone. Deficiency of thyroid hormone in early life leads to both a delay in the development of growth plates and of an abnormal, stippled appearance of the epiphyseal centers of ossification (epiphyseal dysgenesis). Impairment of linear growth leads to dwarfism in which the limbs are disproportionately short in relation to the trunk but cartilage growth is unaffected. Urinary excretion of calcium is decreased, as is the glomerular filtration rate, whereas fecal excretion of phosphorus is variable. Calcium balance is also variable, and any changes are slight. The exchangeable pool of calcium and its rate of turnover are reduced, changes that reflect decreased bone formation and resorption. Because levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present; levels of 1,25(OH)2D are also increased.

Levels of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. The alkaline phosphatase level is usually below normal in infantile and juvenile hypothyroidism. Bone density may be increased. The radiologic appearance of the skeleton in cretinism and juvenile hypothyroidism are discussed subsequently.

Renal Function: Water and Electrolyte Metabolism

Renal blood flow, glomerular filtration rate, and tubular reabsorptive and secretory maxima are reduced. Blood urea nitrogen and serum creatinine levels are normal, but uric acid levels may be increased. Urine flow is reduced, and delay in the excretion of a water load may result in reversal of the normal diurnal pattern of urine excretion. The delay in water excretion appears to be due to decreased volume delivery to the distal diluting segment of the nephron as a result of the diminished renal perfusion; evidence supporting inappropriate secretion of vasopressin (syndrome of inappropriate antidiuretic hormone) is less compelling. These changes are reversed by treatment with thyroid hormone. The ability to concentrate urine may be slightly impaired. Mild proteinuria may occur.

The impaired renal excretion of water in the retention of water by the hydrophilic deposits in the tissues result in an increase in total body water, even though plasma volume is reduced. This increase accounts for the hyponatremia occasionally noted because the level of exchangeable sodium is increased. The amount of exchangeable potassium is usually normal in relation to lean body mass. Serum magnesium concentration may be increased, but exchangeable magnesium levels and urinary magnesium excretion are decreased.
In response to the diminished oxygen requirements and decreased production of erythropoietin, the red blood cell mass is decreased; this is evident in the mild normocytic, normochromic anemia that often occurs. Less commonly, the anemia is macrocytic, sometimes from deficiency of vitamin B₁₂. Reference has already been made to the high incidence of pernicious anemia (and of achlorhydria and vitamin B₁₂ deficiency without overt anemia) in primary hypothyroidism. (see Chapter 37). Conversely, overt and subclinical hypothyroidism is present in 12% and 15% of patients, respectively, with pernicious anemia. Folate deficiency by malabsorption or dietary inadequacy may also cause macrocytic anemia. The frequent menorrhagia and the defective absorption of iron resulting from achlorhydria may contribute to a microcytic, hypochromic anemia.

The total and differential white blood cell counts are usually normal, and platelets are adequate, although platelet adhesiveness may be impaired. If pernicious anemia or significant folate deficiency is present, the characteristic changes in peripheral blood and bone marrow will be found. The intrinsic clotting mechanism may be defective because of decreased concentrations in plasma of factors VIII and IX, and this, together with an increase in capillary fragility and the decrease in platelet adhesiveness, may account for the bleeding tendency that sometimes occurs.

### Pituitary and Adrenocortical Function

In long-standing hypothyroidism of thyroid origin, hyperplasia of the thyrotropes may cause the pituitary gland to be enlarged. This feature can be detected radiologically as an increase in the volume of the pituitary fossa. Rarely, the pituitary enlargement compromises the function of other pituitary cells and causes pituitary insufficiency or visual field defects. Patients with severe hypothyroidism may have increased serum prolactin levels that correlate with the level of serum TSH, and galactorrhea may develop in some patients. Treatment with thyroid hormone corrects serum prolactin and TSH levels and causes disappearance of galactorrhea, if present. The cause of hyperprolactinemia in hypothyroidism is uncertain but may result from enhanced sensitivity of the lactotropes to thyrotropin-releasing hormone (TRH). In severe primary hypothyroidism, the response of growth hormone to provocative stimuli, such as insulin-induced hypoglycemia or growth hormone-releasing hormone may be subnormal.

As a result of the decreased rate of turnover of cortisol due to decreased hepatic 11-hydroxysteroid dehydrogenase, type 1 (11-HSD-1), the 24-hour urinary excretion of cortisol and 17-hydroxycorticosteroids is decreased but the plasma cortisol level is usually normal (see Chapter 14). The responses of urinary 17-OH-corticosteroid to exogenous adrenocorticotropic hormone and metyrapone are usually normal but may be decreased. The response of plasma cortisol to insulin-induced hypoglycemia may be impaired.

In severe, long-standing primary hypothyroidism, pituitary and adrenal function may be secondarily decreased and adrenal insufficiency may be precipitated by stress or by rapid replacement therapy with thyroid hormone. The rate of turnover of aldosterone is decreased, but the plasma level is normal. Plasma renin activity is decreased, and sensitivity to angiotensin II is increased (see Chapter 15).

### Reproductive Function

In both sexes, thyroid hormones influence sexual development and reproductive function. Infantile hypothyroidism, if untreated, leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles. Paradoxically, primary hypothyroidism may also cause precocious sexual development and galactorrhea.

In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. These changes may be due to deficient secretion of luteinizing hormone. Rarely, in primary hypothyroidism, secondary depression of pituitary function may lead to ovarian atrophy and amenorrhea. Fertility is reduced, and spontaneous abortion may result, although many pregnancies are successful. Hypothyroidism in men may cause diminished libido, impotence, and oligospermia.

Values for plasma gonadotropins are usually in the normal range in primary hypothyroidism; in postmenopausal women, levels are usually somewhat lower than in euthyroid women of the same age but are nevertheless within the menopausal range. This provides a valuable means of differentiating primary from secondary hypothyroidism.

The metabolism of both androgens and estrogens is altered in hypothyroidism. Secretion of androgens is decreased, and the metabolism of testosterone is shifted toward estradiol and estrone rather than androsterone. With respect to estradiol and estrone, hypothyroidism favors metabolism of these steroids via 16-hydroxylation over that via 2-oxoxygenation, with the result that formation of estriol is increased and that of 2-hydroxyestrone and its derivative, 2-methoxyestrone, is decreased. The sex hormone-binding globulin in plasma is decreased, with the result that the plasma concentrations of both testosterone and estradiol are decreased, but the unbound fractions are increased. The alterations in steroid metabolism are corrected by restoration of the euthyroid state.

### Catecholamines

The plasma cyclic adenosine monophosphate (cAMP) response to epinephrine is decreased, suggesting a state of decreased adrenergic activity. The fact that the responses of plasma cAMP to glucose and parathyroid hormone are also decreased suggests that thyroid hormones have a general modulating influence on cAMP generation. The mechanism underlying the decreased adrenergic responsiveness is uncertain but probably results from impaired cAMP responses to norepinephrine.

### Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

The decrease in energy metabolism and heat production is reflected in the low basal metabolic rate, decreased appetite, cold intolerance, and slightly low basal body temperature. Both the synthesis and the degradation of protein are decreased, the latter especially so, the net effect being one of lipid accumulation, especially of low-density lipoprotein (LDL) and triglycerides. The decrease in the lipid degradation rate may reflect the decrease in post-heparin lipolytic activity, as well as reduced LDL receptors. High-density lipoprotein (HDL) concentrations are reduced. The increase in serum cholesterol in primary (but not central) hypothyroidism is accompanied by increased levels of serum phospholipids, serum triglycerides, and LDL. Plasma free fatty acid levels are decreased, and the mobilization of free fatty acids in response to fasting, catecholamines, and growth hormone is impaired. All of these abnormalities are relieved by treatment.
In a random group of 1149 Dutch women, 11% were found to have subclinical hypothyroidism (TSH > 4.0 µU/L with normal free thyroxine. There was an increased prevalence of aortic atherosclerosis (odds ratio, 1.7; confidence interval, 1.1 to 2.6) and myocardial infarction (odds ratio, 2.3; confidence interval, 1.3 to 4.0). Also, hyperhomocysteinemia, a risk factor for vascular disease, is present in patients with primary hypothyroidism and responds rapidly to levothyroxine replacement.
Current Clinical Picture

In the adult, the onset of hypothyroidism is usually so insidious that the typical manifestations may take months or years to appear and go unnoticed by family and friends. The gradual development of the hypothyroid state is due to slow progression both of thyroid hypofunction and of the clinical manifestations after thyroid failure is complete. This course is in contrast with the more rapid development of the hypothyroid state when replacement therapy is discontinued in a patient with treated primary hypothyroidism or when the thyroid gland of a normal subject is surgically removed. In such patients, manifestations of frank hypothyroidism are present by 6 weeks; by 3 months myxedema appears.

The clinical picture of hypothyroidism in the third millennium is, in general, much milder than that described 50 years ago in the first edition of this textbook. New scales for assessment of clinical symptoms suggesting hypothyroidism have been developed (Fig. 12-5). In general, many of the symptoms are similar but much less prevalent than they were and do not significantly discriminate the hypothyroid from the euthyroid patient (e.g., cold intolerance or pulse rate). The reason for this is largely the ready availability of sensitive and specific laboratory tests for hypothyroidism that allow recognition of the primary form of the disease long before severe symptoms have developed. Nonetheless, early symptoms are variable and nonspecific. There should be a low threshold for screening patients for primary hypothyroidism with a TSH determination because in every series there are a number of patients with significant biochemical abnormalities who do not score high on symptom and sign testing.

With respect to physical signs of hypothyroidism, the presence of coarse skin, peri-orbital puffiness that obscures the curve of the malar bone (see Fig. 12-1), cold skin, and delayed ankle reflex relaxation phase all are signs that should lead to appropriate diagnostic tests.

The unusual syndrome of acute hypothyroidism in the previously hyperthyroid patient that is characterized by painful cramping of large muscle groups is discussed under the topic ‘Treatment of Graves’ Disease’ (see Chapter 11).

Severe hypothyroidism is seldom apparent at birth, hence the requirement for systematic screening. The age at which symptoms appear depends on the degree of impairment of thyroid function (see Fig. 12-3 and Fig. 12-4). Severe hypothyroidism in infancy is termed cretinism. As the age at onset increases, the clinical picture of cretinism merges imperceptibly with that of juvenile hypothyroidism. Retardation of mental development and growth, the hallmark of cretinism, becomes manifest only in later infancy and is largely irreversible. Consequently, early recognition is crucial and can be achieved by population screening by measuring serum T4 or TSH concentrations routinely in neonates. During the first few months of life, symptoms of hypothyroidism include feeding problems, failure to thrive, constipation, a hoarse cry, and somnolence. In succeeding months, especially in severe cases, protuberance of the abdomen, dry skin, poor growth of hair and nails, and delayed eruption of the deciduous teeth become evident. Retardation of mental and physical development is manifested by delay in reaching the normal milestones of development, such as holding up the head, sitting, walking, and talking.

Impairment of linear growth results in dwarfism, with the limbs disproportionately short in relation to the trunk (see Fig. 12-3). Delayed closure of the fontanelles causes the head to be large in relation to the body. The naso-orbital configuration remains infantile. Maldevelopment of the femoral epiphyses results in a waddling gait. The teeth are malformed and susceptible to caries. The characteristic appearance includes a broad, flat nose, widely set eyes; peri-orbital puffiness; large protruding tongue; sparse hair; rough skin; short neck; and protuberant abdomen with an umbilical hemia. Mental deficiency is usually severe.

Radiologic examination of the skeleton is diagnostic. The skull shows a poorly developed base; delayed closure of the fontanelles; widely set orbits; and a short, flat nasal bone. The pituitary fossa may be enlarged. Shedding of deciduous teeth and eruption of permanent teeth are delayed (see Fig. 12-4).

The radiologic picture of epiphyseal dysgenesis is virtually pathognomonic of hypothyroidism in infancy and childhood and may involve any center of endochondral ossification, depending on the age at onset of the hypothyroid state; it is usually best seen in the femoral and humeral heads and the navicular bone of the foot. The centers of ossification appear late, so bone age is retarded in relation to chronologic age, and when they eventually appear, instead of a single center, multiple small centers are scattered throughout the length and shape of the bone (see Fig. 12-4). These small centers of ossification eventually coalesce and form a single center with an irregular outline and a stippled appearance (stippled epiphysis). Epiphyseal dysgenesis is evident only in centers that normally ossify at a time after the onset of the hypothyroidism. After a normal metabolic state is restored by treatment, centers destined to ossify at a later age develop normally.

Hypothyroidism that begins in childhood is termed juvenile hypothyroidism. The clinical manifestations are intermediate, between those of infantile and those of adult hypothyroidism, in that the developmental retardation is not as severe as that of cretinism and the manifestations of full-blown adult myxedema are rarely seen. Growth and sexual development are affected predominantly. Linear growth is severely retarded, and the rate of linear growth is usually less than that of weight gain. Sexual maturation and the onset of puberty are delayed. The result is a child who appears much younger than the chronologic age. Rarely, precocious puberty and galactorrhea occur. Intellectual performance is poor, but the mental deficiency is not as severe as that in cretinism.

The manifestations of adult hypothyroidism are present to a varying, but usually milder, degree. On radiologic examination, epiphyseal dysgenesis may be present and epiphyseal union is always delayed, resulting in a bone age that is retarded in relation to chronologic age.
Laboratory Evaluation

Primary and Central Hypothyroidism

A decrease in secretion of the thyroid hormones is common to all varieties of hypothyroidism, except for consumptive hypothyroidism and resistance to thyroid hormone (see later). In patients with primary thyroid disease, the cause of hypothyroidism in more than 99% of the patients, there is a significant increase in basal serum TSH concentration. A strategy for evaluating the patient suspected of hypothyroidism involves an initial TSH determination. If the suspicion of hypothyroidism is strong, a goiter is present or central hypothyroidism is part of the differential diagnosis, a free T3 or free T4 index (FT4I) should be included (see Chapter 10). If hypothyroidism is thought to be unlikely but must be excluded, only a TSH determination is required because primary hypothyroidism is almost always the cause. If TSH is elevated, an FT3 can be added to the same determination (see Chapter 10). As hypothyroidism becomes more severe, the serum TSH increases and serum FT4 and later serum triiodothyronine (T3) concentrations become subnormal, the former more rapidly than the latter (see Table 12-1). The persistence of a normal serum T3 is, in part, due to preferential synthesis and secretion of T3 by residual functioning thyroid tissue under the influence of the increased plasma TSH. In addition, the efficiency of conversion of T4 to T3 by D2 is increased as the serum T4 level falls. Consequently, the serum T3 concentration may remain within the normal range and is not a useful index of thyroid function in the hypothyroid patient.

Initial tests: Serum TSH, serum free T4 index, antibodies to TPO. A parenthesis indicates that the result is less common but may occur.

Results are grouped with respect to the serum TSH concentration. The different diagnoses possible for low, normal, or elevated free T4 index and TPO antibody results are indicated.

from hypothyroidic or pituitary disease (central or secondary hypothyroidism) is the most critical decision point in this pathway (see Fig. 12-6). A low thyroid hormone level with a normal or low TSH level should lead to an evaluation for the possibility of failure of other endocrine systems that require trophic pituitary hormones for normal function (Table 12-2) (see Chapter 7 and Chapter 8). The only exception to this is posthypothyroidal hypothyroidism, in which TSH levels may remain suppressed for several months even though hypothyroidism has been induced by 131I surgery, or antithyroid drugs (see Table 12-1). In some patients with central hypothyroidism, the basal serum TSH concentration (and the response to TRH) may even be somewhat elevated, but the TSH has reduced biologic potency even though it is immunologically reactive. In patients with an elevated TSH level and a reduced FT4I, the presence or absence of thyroid peroxidase (TPO) antibodies should be ascertained (see Fig. 12-6). The presence of TPO antibodies generally points to autoimmune thyroid disease (Hashimoto’s disease) as the cause of the hypothyroidism. On the other hand, the absence of TPO antibodies requires a search for less common causes of hypothyroidism such as transient hypothyroidism, infiltrative thyroid disorders, and external irradiation, as discussed later (see Table 12-1).

Tests that employ radiiodine to assess the function of the thyroid gland display a variable pattern, depending on the underlying thyroid disorder. When the amount of
thyroid tissue is reduced, the radioactive iodine uptake (RAIU) is subnormal. However, the diagnostic value of this finding in North America is minimized by the low normal range resulting from the high dietary iodine intake. Yet when hypothyroidism results primarily from a biochemical defect in thyroid hormone synthesis rather than thyroid cell destruction (thus leading to compensatory goitrogenesis), RAIU may be normal or increased. Specific functional patterns in relation to the causes of hypothyroidism are discussed later. Nonetheless, measurement of RAIU is almost never required in the diagnostic evaluation of the hypothyroid patient.

Differential Diagnosis

The clinical picture of fully developed hypothyroidism is characteristic enough to leave the diagnosis in little doubt. Despite the availability of inexpensive and specific tests, it is still surprising how often what is retrospectively obvious, severe, primary hypothyroidism is overlooked by experienced clinicians. If the diagnosis is not considered during the first meeting with the patient, it may take another 6 months before it is recognized that multiple, seemingly disparate complaints are due to hypothyroidism. A high index of suspicion is required to avoid this oversight.

For the milder forms of hypothyroidism, it may be necessary to differentiate them from several other states. The fact that these disorders often occur in older patients is partly responsible for the diagnostic uncertainty. In some cases, slowing of mental and physical activity, dry skin, and loss of hair may mimic similar findings in hypothyroidism. Furthermore, older people often become hypothermic with cold exposure. In patients with chronic renal insufficiency, anorexia, torpor, periorbital puffiness, sallow complexion, and anemia (e.g., see Fig. 12-1) may suggest hypothyroidism and may call for specific testing. Distinguishing nephrotic states from hypothyroidism by clinical examination alone may be even more difficult. In this disorder, waxy pallor, edema, hypercholesterolemia, and

Figure 12-6 -- Strategy for the laboratory evaluation of patients with suspected hypothyroidism. The principal differential diagnosis is between primary and central hypothyroidism. The serum thyrotropin (TSH) concentration is the critical laboratory determination that, in general, allows recognition of the cause of the disease. An exception is the individual with a recent history of thyrotoxicosis (and suppressed TSH) in whom a low free thyroxine (T₄) level may be associated with a reduced TSH level for several months after relief of the thyrotoxicosis. In patients with primary hypothyroidism, the absence of thyroid peroxidase (TPO) antibodies raises a possible diagnosis of transient hypothyroidism following an undiagnosed episode of subacute or postviral thyroiditis. In such patients, a trial of a reduced levothyroxine dosage after 4 months may reveal recovery of thyroid function thus avoiding permanent levothyroxine replacement. MRI, magnetic resonance imaging.
TSH receptor defect

**Resistance to Thyroid Hormone**

Generalized

*"Pituitary" dominant*

TPO, thyroid peroxidase; TSH, thyroid-stimulating hormone.

Hypometabolism may suggest hypothyroidism. In addition, the total serum T₄ concentration may be decreased if significant thyroglobulin is lost in the urine but the FT₄ and TSH would be normal.

In patients with pernicious anemia, psychiatric abnormalities, pallor, and numbness and tingling of the extremities may mimic similar findings in hypothyroidism. Although there is a clinical and immunologic overlap between primary hypothyroidism and pernicious anemia, this association is not invariable (see Chapter 37). The presence of hypothyroidism is often suspected in patients who are severely ill, especially in the elderly. In such patients, the total T₄ concentration may be decreased, often markedly so, but the FT₄ is generally normal unless the patient is severely ill (see Chapter 10). These features, together with the absence of an elevation of serum TSH, usually serve to differentiate the ill euthyroid patient from one with primary hypothyroidism.

Hypothyroidism may develop either because of some extrinsic factor or acquired condition or because of a congenital defect impairing thyroid hormone biosynthesis (see Table 12-2). Inadequate synthesis of hormone leads to hypersecretion of TSH, which in turn produces both goiter and stimulation of all steps in hormone biosynthesis capable of response. If the compensatory response is inadequate, goitrous hypothyroidism results. In some instances, however, the compensatory response overcomes the impairment in hormone biosynthesis, and the patient is euthyroid with a compensatory goiter. The latter condition is discussed in Chapter 13 under the topic "Simple or Nontoxic Goiter." Less commonly, hypothyroidism is associated with an atrophic gland or, in the case of a congenital abnormality, one that never developed properly. From a clinical standpoint, it is useful to classify patients with hypothyroidism into those with and those without goiter (see Table 12-2).
Hashimoto's disease, or autoimmune thyroiditis type 2A, is the most common cause of goitrous hypothyroidism in areas of the world in which dietary iodine is sufficient. Before discussing this entity, it is important to redefine the term autoimmune thyroid disease (Table 12-3). Many use the term autoimmune thyroiditis to cover both primary myxedema (nongoitrous) and classic Hashimoto's disease (goitrous). These are differing clinical manifestations of the same disorder that is also closely related to autoimmune hyperthyroidism/Graves' disease.

Autoantibodies to the TSH receptor that act as TSH antagonists may be the cause of some cases of the thyroid atrophy seen in primary myxedema and are seen less often in goitrous Hashimoto's disease. However, both Graves' and Hashimoto's diseases may occur within the same families and may share human leukocyte antigen (HLA) and other genetic susceptibility haplotypes. Furthermore, thyroid failure occurs in some patients with Graves' disease and hyperthyroidism and even orbitopathy develop in some patients with Hashimoto's disease. Both types of patients may have autoantibodies to thyroglobulin, TPO, and the TSH receptor. Hence, the diseases must be closely related, and autoimmune thyroid disease can be viewed as a spectrum from hyperthyroidism to hypothyroidism.

To bring some clarity to this situation, we should also redefine the term chronic thyroiditis. In pathologic terms, thyroiditis implies the presence of both a mononuclear cell infiltrate and destruction of thyroid follicles. However, these are arbitrary criteria. The term chronic thyroiditis is more appropriately defined simply as evidence of “intrathyroidal lymphocytic infiltration” without the necessity of follicular damage. Because by this definition patients with both Graves' disease and Hashimoto's disease have thyroiditis, replacement of the term autoimmune thyroid disease with the more correct term autoimmune thyroiditis allows a simple classification for autoimmune thyroid disease (Table 12-3).

Until the demonstration of circulating thyroid antigenspecific T cells and thyroid autoantibodies, the diagnosis of Hashimoto's disease could be confirmed only by biopsy of the thyroid. The ease with which we can now demonstrate high levels of circulating antibodies and thyroid antigenspecific T cells in most patients with Hashimoto's disease led to the use of the term autoimmune thyroiditis, which, as explained earlier, we prefer to use for any mononuclear infiltrate.
Hashimoto’s disease is common and may be increasing in frequency. The mean incidence in women is in the order of 3.5 cases per 1000 people per year and in men is 0.8 cases per 1000 people per year. No age group is exempt, although the prevalence increases with age. Hashimoto’s disease is the most common cause of goitrous hypothyroidism in areas of iodine insufficiency.

Pathophysiology.

Impairment of hormone synthesis is due to apoptotic destruction of the thyroid cells. The sick cells exhibit a defect in organic binding of thyroid iodide, as evidenced by a positive perchlorate discharge test (see Chapter 11 for a discussion of pendrin). In addition, release of iodopeptides, mostly thyroglobulin, is enhanced by cell lysis. Approximately 90% of the thyroid gland must be destroyed before hypothyroidism develops. The presence of lymphocytic infiltration of the thyroid (hence the older term lymphocytic thyroiditis), circulating thyroid autoantibodies, and clinical or immunologic overlap with other diseases with autoimmune components indicate that Hashimoto’s disease is an autoimmune thyroid disorder.

The current understanding of autoimmune mechanisms has been discussed earlier in Chapter 11. However, autoimmune thyroiditis is characterized by thyroid cell apoptosis leading to follicular destruction rather than thyroid stimulation and thyroid cell hyperplasia. Although both autoantibodies to thyroid peroxidase (TPOAb) and thyroglobulin (TgAb) may be complement-fixing and cytotoxic, the thyroid gland is infiltrated by both B cells and by T cells; the latter are armed with Fas ligand and capable of destroying thyroid cells expressing Fas via apoptosis (Fig. 12-7) (see also Color Plate). In addition, other cell death pathways may be involved. Fas expression on thyroid cells may be secondary to elaboration of a variety of cytokines from T cells that undergo blast transformation when exposed to thyroid antigens (thyrotropin receptor,

TPO, and thyroglobulin), suggesting that cell-mediated autoimmune mechanisms are pathogenetically involved. Indeed, a T-cell clone specifically cytotoxic for autologous thyroid cells in a patient with Hashimoto’s disease (Fig. 12-8) is reminiscent of animal models of cytotoxic T cells associated with experimental autoimmune thyroiditis. These manifestations of autoimmunity in Hashimoto’s disease and other autoimmune thyroid disorders reflect a hereditary susceptibility to thyroid disease that allows the survival and persistence of B cells and T cells directed against thyroid antigens. The fact that infusion of interleukin-2 and lymphokine-activated killer cells causes progression or development of hypothyroidism in patients with detectable TPOAb is additional evidence of the autoimmune nature of this disease.

Histopathology.

The thyroid gland is pale and firm. Histopathologic changes vary in type and extent but usually consist of diffuse lymphocytic infiltration with germinal center formation, obliteration of thyroid follicles by widespread apoptosis, and fibrosis (Fig. 12-9). In most cases, there is destruction of epithelial cells and degeneration and fragmentation of the follicular basement membrane. The remaining epithelial cells may be larger and show oxyphilic changes in the cytoplasm; these so-called Askanazy cells are virtually pathognomonic.

In some cases, epithelial hyperplasia may be prominent. Colloid is sparse. The interstitial tissue is infiltrated with lymphocytes that may form typical lymphoid follicles with germinal centers. Plasma cells may be prominent. Fibrosis is generally present in the older lesions but not to the extent seen in Riedel’s thyroiditis.

Histologically, two variants can be distinguished:

1. The oxyphilic variant displays more oxyphilic change, less fibrosis, and striking infiltration with lymphocytes forming germinal centers.
2. The fibrous variant is infiltrated mainly with plasma cells and displays more fibrosis.

Clinical differences between the two types are described later, but there is no evidence that the etiologic mechanisms are different. In the past, the diagnosis of Hashimoto’s disease required the presence of Askanazy cells or lymphoid follicles, but now the primary observation should be follicular destruction, often with macroscopic feature of the follicular spaces. The degree of lymphocytic infiltration usually correlates with the levels of circulating thyroid autoantibodies. Unlike the situation of diabetes mellitus, formal linkage of specific histocompatibility antigens with autoimmune thyroid disease has been difficult to demonstrate.

Hashimoto’s disease occurs with increased frequency in Down’s syndrome and (probably) gonadal dysgenesis. The fact that thyroid cells can express HLA-DR antigens, at least as a secondary phenomenon, indicates the potential role of these cells in perpetuating the immune response and may be related to the propensity of autoimmune disease for certain HLA-DR subgroups. Hashimoto’s disease almost certainly is associated with a polygenic susceptibility, HLA being one gene involved. Efforts are under way to identify non-HLA susceptibility genes in families with autoimmune thyroid disease. In this regard, polymorphisms in the CTLA4 gene have been linked to the propensity to secrete thyroid autoantibodies and may, in turn, be an important risk factor for disease itself.

Nongenetic Risk Factors.

Many of the factors that have been identified as increasing the risk for Graves’ disease (pregnancy, drugs, age and sex, infection, and irradiation) apply equally to autoimmune thyroiditis. These are detailed in Chapter 11 and are briefly considered here.

Pregnancy.

The recognition of transient postpartum thyroiditis as an important clinical entity has also provided an example of the immune manipulation of thyroid disease with a predictable onset and recovery (see Chapter 11). Maternal microchimerism may be an important component of this risk analysis. The disease is essentially postpartum Hashimoto’s disease except for its transient nature. Data suggest that 8% to 10% of women experience thyroiditis in the postpartum period with a variety of consequences (see later). Pregnancy is, therefore, an important risk factor, with transient postpartum thyroiditis developing in some patients and thyroid failure
differentiated permanently or in the early years after pregnancy in a significant proportion.

**Iodine and Drugs.**

Iodine and iodine-containing drugs (such as amiodarone) precipitate autoimmune thyroiditis in susceptible populations. This form should be distinguished from direct blockade and destruction of the thyroid gland by iodine. The mechanism of this precipitation is unknown. However, much evidence accumulated in animal models suggests that increased iodination of thyroglobulin enhances its immunoreactivity and that T-cell-reactive peptides may also be more antigenic when iodinated.

---

**Differential Diagnosis.**

Differential diagnosis of Hashimoto's disease from other uncomplicated disorders of the thyroid is facilitated by the demonstration that high levels of thyroid autoantibodies are common and in higher concentrations than thyroglobulin autoantibodies. Sometimes part of a gland with autoimmune thyroiditis may look and feel like a firm thyroid nodule, and ultrasonography should be performed to resolve the issue.

**Laboratory Tests.**

The results of the common tests of thyroid function depend on stage of disease. Rarely, the tests may suggest thyroid hyperfunction with a suppressed TSH but without overproduction of hormone. The RAU may be increased, but serum T₃ and T₄ levels may remain normal. At this stage, the patient may be euthyroid. As the TSH level rises, the glandular response at first compensates for the impairment of hormone biosynthesis. With time, the ability of the thyroid to respond to TSH diminishes, and the RAU and serum T₃ level decline to subnormal values. The serum T₃ concentration, however, may be slightly increased, probably reflecting maximal stimulation of the failing thyroid by the increased serum TSH level. The foregoing sequence, with still normal T₃ and T₄ and increased TSH levels, reflects the development of mild (subclinical) hypothyroidism.

The diagnosis of Hashimoto's disease is confirmed by the presence of thyroid autoantibodies in the serum, usually in high levels. TPO autoantibodies are more common and in higher concentrations than thyroglobulin autoantibodies. Sometimes part of a gland with autoimmune thyroiditis may look and feel like a firm thyroid nodule, and ultrasonography should be performed to resolve the issue.

**Cytokines.**

Treatment of patients with interferon-2 or interferon may precipitate the appearance of autoimmune thyroid disease. Destructive thyrotoxicosis may appear suddenly, but persistent Graves' disease may also develop in such patients. Autoimmune thyroid disease is more common in patients with preexisting TPOAbs.

**Infection.**

There is no direct evidence that infection causes autoimmune thyroiditis in humans. A number of viral infections in animals, however, do precipitate thyroid autoimmunity. In addition, there is evidence from long-term follow-up of patients with subacute thyroiditis (see later), thought to be a reaction to a viral infection, that persistent signs of thyroid autoimmune disease can be found. Infection remains a likely cause of a local or distant insult that is considered to be needed to precipitate autoimmune disease in susceptible individuals (see "Mechanisms in Graves' Disease," Chapter 11).

**Clinical Picture.**

Goiter, the hallmark of classic Hashimoto's disease, usually develops gradually and may be found during routine examination or by ultrasonography. On occasion, the thyroid gland enlarges rapidly and, when accompanied by pain and tenderness, may mimic de Quervain's or subacute thyroiditis. Some patients, particularly those with the fibrous variant, are hypothyroid when first seen. The goiter is generally moderate in size and firm in consistency and moves freely on swallowing. The surface is either smooth or scalloped, but well-defined nodules are unusual. Both lobes are enlarged, but the gland may be asymmetrical. The pyramidal lobe may be enlarged, and adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves, may be compressed. Enlargement of regional lymph nodes is unusual.

Although nongloutous Hashimoto's disease (atrophy hypothyroidism) is thought to be the end result of autoimmune destruction of the thyroid, the progression of goitrous Hashimoto's disease to the atrophied state is not commonly seen in the individual patient. Indeed, the histopathologic picture tends to remain rather static except for an increase in fibrous tissue.

Clinically, the untreated goiter remains unchanged or enlarges gradually over many years. The manifestations of hypothyroidism may develop over several years in patients who are initially euthyroid. Some, but not all, studies suggest an increased prevalence of thyroid carcinoma in Hashimoto's disease.

Occasionally, hyperthyroidism develops in patients with Hashimoto's disease. In other patients with early autoimmune thyroiditis, transient thyrotoxicosis (painless or silent thyroiditis with thyrotoxicosis) occurs as the result of thyroid cell destruction. In such cases, evidence of ongoing thyroid hyperfunction is lacking because the thyroid RAU is depressed. As described earlier, a phase of transient hypothyroidism begins 3 to 6 months post partum in 30% of women with autoimmune thyroiditis, as evidenced by the presence of TPOAbs. The history may suggest earlier mild thyrotoxicosis (see syndromes associated with transient hyperthyroidism in Chapter 11).

**Iodine and Drugs.**

Iodine and iodine-containing drugs (such as amiodarone) precipitate autoimmune thyroiditis in susceptible populations. This form should be distinguished from direct blockade and destruction of the thyroid gland by iodine. The mechanism of this precipitation is unknown. However, much evidence accumulated in animal models suggests that increased iodination of thyroglobulin enhances its immunoreactivity and that T-cell-reactive peptides may also be more antigenic when iodinated.
occurs more commonly in Hashimoto's disease than in other thyroid disorders. The frequent coexistence of hypothyroidism and Hashimoto's disease serves to distinguish this disease from nontoxic goiter and thyroid neoplasms.

Differentiation of euthyroid Hashimoto's disease from a diffuse nontoxic goiter is often difficult, although diffuse nontoxic goiter tends to be softer than that of Hashimoto's disease and ultrasonic examination may reveal the heterogeneity of Hashimoto's disease. In adolescents, differentiation of Hashimoto's disease from diffuse nontoxic goiter is even more difficult because in this age group Hashimoto's disease may not be accompanied by such high levels of thyroid autoantibodies. The presence of well-defined nodules usually distinguishes nontoxic multinodular goiter from Hashimoto's disease.

Differentiation between Hashimoto's disease and thyroid carcinoma can sometimes be made on clinical grounds. Thyroid carcinoma is usually nodular and firm or hard and may be fixed to adjacent structures. Compression of the recurrent laryngeal nerve with hoarseness is virtually pathognomonic of thyroid carcinoma but occurs late in the disease progression. A history of a recent enlargement of the goiter is more common in thyroid carcinoma than in Hashimoto's disease. Enlargement of regional lymph nodes also suggests thyroid carcinoma. In thyroid carcinoma, ultrasound examination or radioiodine scanning of the thyroid may reveal only the isolated lesion. In Hashimoto's disease, activity is usually heterogeneous.

Treatment.

In many patients, no treatment is required because the goiter is small and the disease is asymptomatic, with the TSH level remaining in the normal range (autoimmune thyroiditis type 1). In other patients, treatment with thyroid hormone is directed at alleviating goiter, hypothyroidism, or both (autoimmune thyroiditis type 2A).

Levothyroxine treatment is indicated in patients when the goiter presses on adjacent structures or is unsightly, and it is most effective in goiters of recent onset. In long-standing goiter, treatment with thyroid hormone is usually ineffective, possibly because of fibrosis.

Glucocorticoids may cause regression of the goiter and decrease autoantibody levels, but these agents are not recommended in the usual case because of untoward side effects and the return of activity after treatment is withdrawn.

Full-replacement doses of thyroid hormone should be given when hypothyroidism or subclinical hypothyroidism supervenes. Surgery is justified if pressure symptoms or unsightly enlargement persists after a trial of suppressive therapy. Administration of levothyroxine should be continued after surgery because hypothyroidism is inevitable. The importance of maintaining the serum TSH level within the normal range is covered later, under Treatment.

Iodine Deficiency (Endemic Goiter)

The term endemic goiter denotes any goiter occurring in a region where goiter is prevalent. As mentioned, endemic goiter almost always occurs in areas of environmental iodine deficiency. Although this condition is estimated to affect more than 200 million people throughout the world and is of major public health significance, it is most common in mountainous areas, such as the Alps, Himalayas, and Andes, or in the Great Lakes and Mississippi Valley regions of the United States, owing to the depletion of iodine consequent to the persistent glacial run-off in these regions.

The causative role of iodine deficiency in the genesis of endemic goiter is supported by the inverse correlation between the iodine content of soil and water and the incidence of goiter, the kinetics of iodine metabolism in patients with the disorder, and a decrease in incidence after iodine prophylaxis. The latter accounts for its absence in the population residing in the Great Plains region of the United States.

The occurrence of endemic goiter can be spotty, even within an area of known iodine deficiency; the role of dietary minerals or naturally occurring goitrogens and of pollution of water supplies has been suggested in instances of this type. For example, in the Cauca Valley of Colombia, waterborne goitrogens have been implicated, and in many areas of endemic iodine deficiency, consumption of cassava meal, which gives rise to thiocyanate, aggravates the iodine-deficient state by inhibiting thyroid iodide transport.

Most abnormalities in iodine metabolism in patients with endemic goiter are consistent with the expected effects of iodine deficiency (see Chapter 10, “Iodine Metabolism”). Thyroid iodide clearance rates and RAU are increased in proportion to the decrease in the urinary excretion of stable iodine. The absolute iodine uptake is normal or low. In areas of moderate iodine deficiency, the serum T4 concentration is usually in the lower range of normal; in areas of severe deficiency, however, values are decreased. Nevertheless, most patients in these areas do not appear to be in a hypothyroid state because of an increase in the synthesis of the catabolically more efficient T3 at the expense of T4, and because of an increase in the activity of thyroidal D1 and D2 (see Fig. 10-12).

The incidence and severity of endemic goiter and the metabolic state of the goitrous patient depend mainly on the degree of iodine deficiency. In the absence of hypothyroidism, the effects of the goiter are mainly cosmetic. When the goiter becomes nodular, however, hemorrhage into a nodule may cause acute pain and swelling, mimicking subacute thyroiditis or neoplasia. The goiter may also compress adjacent structures, such as the trachea, esophagus, and recurrent laryngeal nerves. The borderline nature of the iodine supply in many countries of western Europe is exemplified by the development in Belgium of compensatory goiter during pregnancy due to the increased requirement for thyroid hormone during gestation. It is possible that some pregnant patients may have inadequate iodine supplies. An annual injection of iodized oil is another effective means of administering iodine, and endemic goiter can be treated by the addition of iodine to communal drinking water.

Administration of iodine has little, if any, effect on a long-standing endemic goiter, but it causes the early endemic hyperplastic goiter of iodine deficiency to regress. Similarly, thyroid hormone usually has no effect on long-standing goiter or on established mental or skeletal changes, but it should be given in full-replacement doses if there is evidence of hypothyroidism. This is of paramount importance in pregnant women. Surgical treatment is indicated if the adjacent structures are compressed or if the goiter is either very large or is enlarging rapidly.

Endemic Cretinism

Endemic cretinism is a developmental disorder that occurs in regions of severe endemic goiter. Both parents of an endemic cretin are usually goitrous, and in addition to the features of sporadic cretinism described earlier, endemic cretins often have deaf-mutism, spasticity, motor dysfunction, and abnormalities in the basal ganglia demonstrable by magnetic resonance imaging.

Three types of cretins can be discerned: (1) hypothyroid cretins, (2) neurologic cretins, and (3) cretins with combined features of the two. The pathogenesis of neurologic cretinism is obscure but may be due to severe thyroid hormone deficiency during a critical early phase of central nervous system development in utero. Some cretins are goitrous, but the thyroid may also be atrophic, possibly as a consequence of exhaustion atrophy from continuous overstimulation or the lack of iodine.

Iodide Excess

Goiter and hypothyroidism, either alone or in combination, are sometimes induced by chronic administration of large doses of iodine in either organic or inorganic form (see Table 10-8). Iodide-induced goiter was formerly seen in patients with chronic respiratory disease, who were given potassium iodide as an
Patients with cystic fibrosis.
Patients with Graves' disease, especially after its treatment with radioiodine.

Among these groups, many, but not all, individuals display a positive iodide-thioracil discharge test, indicating a defect in the thyroid organic binding mechanism (see Chapter 10, "Iodine Metabolism"). However, intrinsic thyroid disease need not be present because a propensity to develop iodide goiter and hypothyroidism has also been demonstrated in patients who have undergone hemithyroidectomy for a solitary thyroid nodule in whom the remaining lobe was histologically normal. In these patients, as in those with Hashimoto's disease or Graves' disease studied prospectively, individuals with the highest basal serum TSH concentrations, even within the normal range, were those who developed iodide goiter. Iodinated contrast material, amiodarone and povidone iodine are common sources.

Goiter and hypothyroidism commonly occur in newborn infants born to women given large quantities of iodine during pregnancy, and death from neonatal asphyxia has been reported (see Fig. 10-13). In such cases, the mother is usually free from goiter. Pregnant women should not receive large doses of iodine (>1 mg/ day) over prolonged periods (>10 days), especially near term. Maternal amiodarone therapy causes thyroidal dysfunction in up to 20% of newborns. It is not known whether iodide goiter in newborns results from an inherent hypersensitivity of the fetal thyroid or from the fact that the placenta concentrates iodide several-fold or both.

As discussed earlier (see Chapter 10, "Regulation of Thyroid Function"), large doses of iodine cause an acute inhibition of organic binding that abates in the normal individual, despite continued iodine administration (acute Wolff-Chaikoff effect and escape). Iodide goiter appears to result from a more pronounced inhibition of organic binding and the failure of the escape phenomenon. As a consequence of decreased hormone synthesis and the consequent increase in TSH, iodide transport is enhanced. Because inhibition of organic binding is a function of the intrathyroidal concentration of iodide, a vicious circle, augmented by this increase in serum TSH, is set in motion.

The disorder usually appears as a goiter with or without hypothyroidism, although in rare instances iodine may produce hypothyroidism unaccompanied by goiter. Usually the thyroid gland is firm and diffusely enlarged, often greatly so. Histopathologic examination reveals intense hyperplasia. The FT4 concentration is low, TSH concentration is increased, and the 24-hour urinary iodine excretion and the serum inorganic iodide concentration are increased. The disorder regress after iodine is withdrawn. Thyroid hormone may also be given to relieve severe symptoms.

### Drugs Blocking Thyroid Hormone Synthesis or Release

Ingestion of compounds that block thyroid hormone synthesis or release may cause goiter with or without hypothyroidism. Apart from the agents used in the treatment of hyperthyroidism, antithyroid agents may be encountered either as drugs for the treatment of disorders unrelated to the thyroid gland or as natural agents in foods. Goiter with or without hypothyroidism can occur in patients given lithium, usually for bipolar manic-depressive psychosis. Like iodide, lithium inhibits thyroid hormone release, and in high concentrations can inhibit organic binding reactions. At least acutely, iodide and lithium act synergistically in the latter respect. The mechanisms underlying the several effects of lithium are uncertain; what differentiates patients who develop goiter during lithium therapy from those who do not is also unclear. Underlying autoimmune thyroiditis may be at least one factor because many patients with this combination have autoimmune thyroid disease.

Other drugs that occasionally produce goitrous hypothyroidism include para-aminosalicylic acid, phenylbutazone, aminoglutethimide, and ethionamide. Like the thionamides, these drugs interfere with both the organic binding of iodine and the later steps in hormone biosynthesis. Although soybean flour is not an antithyroid agent, soybean products in feeding formulas formerly resulted in goiter in infants by enhancing fecal loss of hormone, which, together with the low iodine content of soybean products, produced a state of iodine deficiency. Feeding formulas containing soybean products are now enriched with iodine.

Cigarette smoking increases the risk of hypothyroidism in patients with underlying autoimmune thyroid disease. Although the mechanism is unclear, certain components of cigarette smoke, including thiocyanate, hydroxyperidine, and benzopyrene derivatives, may be responsible.

Both the goiter and the hypothyroidism usually subside after the antithyroid agent is withdrawn. If continued administration of pharmacologic goitrogens is required, however, replacement therapy with thyroid hormone causes the goiter to regress.

### Goitrogens in Foods or as Endemic Substances or Pollutants

Antithyroid agents also occur naturally in foods. These are widely distributed in the family Cruciferae or Brassicaceae, particularly in the genus Brassica, including cabbages, turnips, kale, kohlrabi, rutabaga, mustard, and various plants that are not eaten by humans but that serve as animal fodder. It is likely that some thiocyanate is present in such plants (particularly cabbage). Cassava meal, a dietary staple in many regions of the world, contains linamarin, a cyanogenic glycoside, the metabolism of which leads to the formation of thiocyanate. Ingestion of cassava can accentuate goiter formation in areas of endemic iodine deficiency. Except for thiocyanate, dietary goitrogens influence thyroid iodine metabolism in the same manner as do the thiocyanides, which they resemble chemically; their role in the induction of disease in humans is uncertain. Waterborne, sulfur-containing goitrogens of mineral origin are believed to contribute to the development of endemic goiter in certain areas of Colombia.

A number of synthetic chemical pollutants have been implicated in causing goitrous hypothyroidism, including polychlorinated biphenyls and resorcinol derivatives. Perchlorate has also been noted in high concentrations in geographic regions in which explosives were made. It is not clear whether the concentrations are significant enough to produce hypothyroidism.

### Cytokines

Patients with chronic hepatitis C or various malignancies may be given interferon or interleukin-2. Such patients may experience hypothyroidism, which is usually transient but may persist. These agents activate the immune system and can induce a clinical picture suggesting an exacerbation of underlying autoimmune disease such as occurs during postpartum thyroiditis (see Chapter 11) and Chapter 37. Graves’ disease with hypothyroidism may also develop, and ablative therapy may be required to treat this condition. Patients with preexisting evidence of autoimmune thyroid disease who have positive TPO antibodies are probably at higher risk for this complication and should be monitored carefully during and after a course of treatment with either of these cytokines. Autoimmune hypothyroidism may also develop after successful treatment of Cushing's disease, presumably as a result of the release of the glucocorticoid-induced immunosuppression.

### Congenital Causes

Inherited defects in hormone biosynthesis are rare causes of goitrous hypothyroidism and account for only about 10% to 15% of the 1 in 3500 newborns with congenital hypothyroidism. In most instances, the defect appears to be transmitted as an autosomal recessive trait. Individuals with goitrous hypothyroidism are believed to be homozygous for the abnormal gene, whereas euthyroid relatives with slightly enlarged thyroids are presumably heterozygous. In the latter group, appropriate functional testing may disclose a mild abnormality of the same biosynthetic step that is defective in the homozygous individual. In contrast with nontoxic
goiter, which is more common in females than in males, these defects, as a group, affect females only slightly more commonly than males. Although goiter may be present at birth, it usually does not appear until several years later. Therefore, the absence of goiter in a child with functioning thyroid tissue does not exclude the presence of hypothyroidism. The goiter is initially diffusely hyperplastic, often intensely so, suggesting papillary carcinoma, but eventually becomes nodular. In general, the more severe the biosynthetic defect, the earlier the goiter appears, the larger it is, and the greater the likelihood of early development of hypothyroidism or even cretinism. Five specific defects in the pathways of hormone synthesis have been identified.

**Iodide Transport Defect**

Iodide transport defect is rare, a result of impaired iodide transport by the sodium-iodide symporter (NIS) protein mechanism and is reflected by defective iodide transport in the thyroid, salivary gland, and gastric mucosa. Administration of iodide, by raising the plasma concentration, increases the intrathyroidal concentration of iodide sufficiently to permit the synthesis of normal quantities of hormone, demonstrating that this is the cause of the deficiency.

**Defects in Expression or Function of Thyroid Peroxidase**

TPO is a protein that is required for normal synthesis of iodothyronines. Quantitative or qualitative abnormalities of TPO have been identified in 1 in 66,000 infants in the Netherlands. The most common of the 16 mutations identified in 35 families was a GGCC insertion in exon 8, leading to premature termination of TPO synthesis.

**Pendred’s Syndrome**

The most common presentation in patients with Pendred’s syndrome is a defect in iodine organification accompanied by sensory nerve deafness. The abnormality is in the PDS gene encoding pendrin, which is involved in the apical secretion of iodide into the follicular lumen (see Fig. 10-2 and Chapter 10, "Iodine Metabolism"). Thyroid function is only mildly impaired in this disorder.

**Defects in Thyroglobulin Synthesis**

Defects in the synthesis of thyroglobulin due to genetic causes are rare, having been identified only in a small number of families with congenital hypothyroidism. Some defects lead to premature termination of translation, whereas another defect causes deficiency in endoplasmic reticulum processing of the thyroglobulin molecule. The complex regulation and huge size of this gene makes screening for mutations a difficult task, and considerable work is still required to unravel the extent of the defects in this gene.

**Iodotyrosine Dehalogenase Defect**

The pathogenesis of goiter and hypothyroidism in the iodotyrosine dehalogenase defect is complex. The major abnormality is an impairment of both intrathyroidal and peripheral deiodination of iodotyrosines, presumably because of a lack (or dysfunction) of the iodotyrosine dehalogenase. The gene encoding this enzyme has yet to be identified.

As a consequence of intense thyroid stimulation and lack of intrathyroidal recycling of iodide derived from dehalogenation, iodide is rapidly accumulated by the thyroid gland and is rapidly released; moniodotyrosine (MIT) and diiodotyrosine (DIT) are elevated in plasma and, together with their deaminated derivatives, in the urine. Hypothyroidism is presumed to result from the loss of large quantities of MIT and DIT in the urine and to secondary iodine deficiency. The goiter and hypothyroidism are relieved by administration of large doses of iodide.

**Thyroid Infiltration**

A number of infiltrative or fibrosing conditions may cause hypothyroidism. Some are often associated with goiter, such as Riedel’s struma (see later). Others, such as amyloidosis, [hemochromatosis](https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6101377/), or [scleroderma](https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6101377/) may not be. Although the other manifestations of these conditions are usually obvious and hypothyroidism is only a complication, the presence of significant hypothyroidism without evidence of autoimmune thyroiditis should lead to a consideration of these rare causes of this condition.

**Atrrophic Hypothyroidism**

In some patients, manifestations of hypothyroidism are apparent but there is no obvious thyroid enlargement (atrophic hypothyroidism). This may be due to either acquired or congenital abnormalities, prominent among the former being Autoimmune Thyroiditis Type 2B (Table 12-3). The pathophysiology and thyroid function tests are similar to those found when goiter is present.

**Acquired Causes**

**Nongoitrous Hypothyroidism**

Hypothyroidism in the absence of a classic Hashimoto’s goiter has often been termed primary hypothyroidism (or myxedema); this condition is more common in women than in men and occurs most often between the ages of 40 and 60 years. Many years ago, the presence of circulating thyroid autoantibodies in almost all patients and the clinical and immunologic overlap with autoimmune diseases indicated that this represented the end stage of an autoimmune thyroiditis in which goiter either did not develop or went unnoticed (Autoimmune Thyroiditis 2B). Although most cases are due to autoimmune-induced apoptosis of the thyroid epithelial cells, some cases of nongoitrous hypothyroidism are also associated with TSH receptor antibodies that block the response of thyroid cells to endogenous TSH (see Chapter 11). In primary thyroid failure, the thyroid gland is not usually palpable but may be normal in size or even somewhat enlarged on sonography and of firm consistency. Circulating TPOAbs or TgAbs are detectable in most patients but may be absent in long-standing disease.

**Postablative Hypothyroidism**

Postablative hypothyroidism is a common cause of thyroid failure in adults. One type follows total thyroidectomy usually performed for thyroid carcinoma. Although functioning remnants may be present, as indicated by foci of radiiodine accumulation, hypothyroidism invariably develops. Another etiologic mechanism is subtotal resection of the diffuse goiter of Graves’ disease or multinodular goiter. Its frequency depends on the amount of tissue remaining, but continued autoimmune destruction of the thyroid remnant in patients with Graves’ disease may be a factor because some studies suggest a correlation between the presence of circulating thyroid autoantibodies in thyroiditis and the development of hypothyroidism after surgery. Hypothyroidism can be manifested during the first year after surgery, but, as with postradioiodine hypothyroidism, the incidence increases with time to approach 100%. In some patients, mild hypothyroidism appears during the early postoperative period and then may occasionally remit, as also occurs after radioiodine treatment.

Hypothyroidism after destruction of thyroid tissue with radiiodine is common and is the one established disadvantage of this form of treatment for hyperthyroidism in adults. Its frequency is determined, in large part, by the dose of radiiodine but is also influenced by variations in individual susceptibility, including autoimmune factors. The incidence of post-radioiodine hypothyroidism increases with time, approaching 100%. Although the FT₃ is low in patients with postablative hypothyroidism, serum TSH levels may be anomalously low for several months after either surgical or ¹³¹I-induced hypothyroidism if TSH synthesis has been suppressed for a long period prior to treatment.

Primary atrrophic thyroid failure may also develop in patients with Hodgkin’s disease after treatment with mantle irradiation or after high-dose neck irradiation for other forms of lymphoma or carcinoma. Surgical, radiiodine, or external beam therapy may also lead to a state of subclinical hypothyroidism, which usually...
(5 to 15 mU/L), low-to-normal FT₄, and a normal serum T₃ concentration (see Table 12-1).

### Congenital Causes

#### Thyroid Agenesis or Dysgenesis

Developmental defects of the thyroid are often responsible for the hypothyroidism that occurs in 1 in 3500 newborns. These defects may take the form of complete absence of thyroid tissue or failure of the thyroid to descend properly during embryologic development. Thyroid tissue may then be found anywhere along its normal route of descent from the foramen caecum at the junction of the anterior two thirds and posterior third of the tongue (lingual thyroid) to the normal site or below. Absence of thyroid tissue or its ectopic location can be ascertained by scintiscanning.

As indicated, a number of proteins are known to be required for normal thyroid gland development. These include the thyroid-specific transcription factor PAX8 as well as thyroid transcription factors 1 and 2 (TTF1 and 2). It might be anticipated that defects in one or more of these proteins may explain abnormalities in thyroidal development. These have been identified in several patients with PAX8 mutations, and a mutation in the human TTF2 gene was associated with thyroid agenesis, cleft palate, and choanal atresia. Despite a specific search, no mutations have been found in the TTF1 gene in infants with congenital hypothyroidism.

#### Thyroid Aplasia Due to Thyrotropin Receptor Unresponsiveness

Several families exist in which thyroid hypoplasia, high TSH concentrations, and a low free T₄ level are associated with loss-of-function mutations in the TSH receptor. The thyroid glands were in the normal location but did not trap perchentenate (TCO₄⁻). Somewhat surprisingly, thyroglobulin levels were still detectable. The molecular details of these patients are still under study.

A second type of abnormality that may cause TSH unresponsiveness is a mutation in the Gs protein that occurs in pseudohypoparathyroidism type 1A. These patients have inactivating mutations in the -subunit of the Gs protein and, consequently, mild hypothyroidism. Other as yet unexplained patients with elevated TSH levels and hypothyroidism in which the molecular nature of the defect has not been defined have been reported.

### Transient Hypothyroidism

Transient hypothyroidism is defined as a period of reduced FT₄, I with suppressed, normal, or elevated TSH levels that are eventually followed by a euthyroid state. This unusual form of hypothyroidism usually occurs in the clinical context of a patient with subacute (postviral), lymphocytic (painless), autoimmune, or postpartum thyroiditis. These conditions are reviewed in detail in Chapter 11.

The patient reports mild to moderate symptoms of hypothyroidism of short duration, and serum TSH concentrations are typically elevated, although not greatly so. The patient often has a preceding episode of symptoms consistent with mild or moderate thyrotoxicosis. If these symptoms cannot be elucidated from the history, it may be difficult to distinguish such patients from those with a permanent form of hypothyroidism. In the early phases of post-thyroiditis hypothyroidism, TSH concentrations may still be suppressed even though the FT₄ is low because of the delayed recovery of pituitary TSH synthesis, such as in patients with Graves’ disease or with toxic nodules who have undergone surgery and who have experienced rapid relief of hypothyroidism. In that situation, the TSH response to hypothyroidism may be suppressed for many months, in post-thyroiditis hypothyroidism, this period is rarely longer than a few weeks.

A significant fraction (33%) of women with autoimmune thyroiditis but normal thyroid function have episodes of hypothyroidism during the postpartum period. In some, the preceding hyperthyroidism is relatively asymptomatic, which can make an accurate clinical diagnosis difficult. Patients who have had an episode of typical subacute postviral thyroiditis with pain, tenderness, and hyperthyroidism are not difficult to recognize.

Diagnostic evaluation should include a determination of TSH, FT₄, I, and TPOAbs. Negative or low antibodies argue strongly for a nonautoimmune cause. This is significant, in that it may be possible for the patient not to be treated only temporarily for hypothyroidism. In such patients, a trial of a lower levothyroxine dosage after 3 to 6 months may reveal that thyroid function has recovered. This may also occur in patients with hypothyroidism that follows acute autoimmune thyroiditis (e.g., in the postpartum period), but it is somewhat less likely to occur because of the underlying progressive nature of the autoimmune thyroiditis.

In patients with hypothyroidism due to postviral thyroiditis, the thyroid gland is usually relatively small and atrophic. In patients with hypothyroidism that follows an episode of acute lymphocytic thyroiditis, the gland is usually slightly enlarged and somewhat firm, reflecting the underlying scarring and infiltration associated with that condition.

### Consumptive Hypothyroidism

Consumptive hypothyroidism is the term given to an unusual cause of hypothyroidism that has been identified in infants with visceral hemangiomas or related tumors. The first patient reported with this syndrome presented with abdominal distention caused by a large hepatic hemangioma with respiratory compromise secondary to upward displacement of the diaphragm. However, clinical signs suggested hypothyroidism, which was confirmed by finding a markedly elevated TSH level and undetectable T₄ and T₃ levels. The infant’s response to an initial IV infusion of levothyroxine was transient, leading to the decision to use parenteral thyroid hormone replacement to relieve the clinical hypothyroidism. The accelerated degradation of thyroid hormone was apparent from the fact that it required 96 µg of thyroid hormone replacement to relieve the clinical hypothyroidism. During this phase, the patient is euthyroid but has a modest increase in the serum TSH level.
The presence of an elevated glycoprotein -subunit in patients with pituitary tumor but not in those with thyroid hormone resistance.

3. Development of analogues of thyroid hormone with TR, as opposed to mixed or TR preferential effects, may eventually prove useful in treatment.

Cardiovascular manifestations of the condition.

Individuals this is not the case, suggesting that there may be mutations in coactivator proteins or one of the RXR receptors, which can also present in a similar fashion.

Laboratory results may be the first clear evidence that a patient otherwise thought to have hyperthyroidism has RTH. These tests show the unusual combination of an

Thyroid hormone action.

10% of such individuals. Other neuropsychological abnormalities have also been described.

Abnormalities in neuropsychological development exist, with an increased prevalence of attention deficit hyperactivity disorder, which is found in approximately 10% of such individuals. Other neuropsychological abnormalities have also been described.

Deafness in patients with RTH reflects the important role of

HESX1

in Chapter 7 and Chapter 8, and those causes with relatively specific thyroid-related deficiencies are mentioned here for completeness. In addition to pituitary tumors, hypothalamic disorders, and the like, an unusual cause of secondary hypothyroidism occurs in individuals given bexarotene (a retinoid X [RXR] receptor agonist) for T-cell lymphoma. This drug suppresses the activity of the human TSH -subunit promoter in vitro. Serum T4 concentrations are reduced about 50%, and patients experience clinical benefit from thyroid hormone replacement. Dopamine, dobutamine, high-dose glucocorticoids, or severe illness may suppress TSH release transiently, leading to a pattern of thyroid hormone abnormalities suggesting central hypothyroidism. As discussed earlier, this severe state of hypothalamic-pituitary-thyroid suppression is a manifestation of stage 3 illness.

Although these agents might be expected to have similar effects when given chronically, they do not; nor does somatostatin have a similar effect when given for acromegaly, although it does block the response of TSH to TRH and it has been administered to patients with thyrotropin-secreting pituitary adenomas.

Congenital defects in either the stimulation or the synthesis of TSH or in its structure have been identified as rare causes of congenital hypothyroidism. These include the consequences of defects in several of the homeobox genes, including POU1F1 (formerly termed Pit-1), PROP1, and HESX1. The latter factor is necessary for the development of the hypothalamus, pituitary, and olfactory portions of the brain, and its targeted deficiency in the mouse produces a condition resembling sepi-toptic dysplasia in humans.

Defects in POU1F1 and PROP1 cause hereditary hypothyroidism, usually accompanied by deficiencies in growth hormone and prolactin. One patient has been identified with a familial defect in the TRH receptor gene. All of these conditions are associated with the typical pattern of reduced FT4, T3, and TSH.

Structural defects in TSH have also been described. These include those with a mutation in the CAGYC peptide sequence of the -subunit, thought to be necessary for its association with the -subunit or defects that produce premature termination of the TSH -subunit gene. As mentioned, some of these abnormalities may be associated with elevations in TSH, suggesting the diagnosis of primary hypothyroidism, but the TSH molecule is immunologically, but not biologically, intact.

Resistance to Thyroid Hormone

Patients with resistance to thyroid hormone (RTH) may have features of hypothyroidism if the resistance is severe and affects all tissues. Alternatively, patients with RTH may have hyperthyroidism if the resistance is more severe in the hypothalamic-pituitary axis than in the remainder of the tissues. In clinical terms, patients in the former group are said to have generalized resistance to thyroid hormone, whereas patients in the latter group are said to have pituitary resistance to thyroid hormone. Patients with both forms almost always have mutations in one allele of the TR-beta (TR) gene that interfere with the capacity of that receptor to respond normally to T3, usually by reducing its binding affinity.

The mutations in the TR gene causing RTH cluster in three areas of the thyroid hormone receptor, which have been recognized to have important contacts with the hydrophobic ligand-binding domain cavity of TR as recognized from its crystal structure. The mutations do not interfere with the function of the DNA-binding domain, its co-repressor binding domain, or its region of heterodimerization with RXR. Some mutations affect the activation domain in the carboxy-terminus of the TR receptor.

RTH is probably produced by the heterodimerization of the mutant TR with RXR or homodimerization with a normal TR or TR. These mutant TR-containing dimers compete with wild-type TR-containing dimers for binding to the thyroid hormone response elements (TREs) of thyroid hormone-dependent genes.

Because these complexes bind co-repressor molecules that cannot be released in the absence of T3 binding, genes containing these TREs are more repressed than they would be normally at the prevailing concentrations of circulating thyroid hormones. Receptors that contain mutations in the activation domain may have a combination of both decreased affinity for T3 as well as impaired activating potential.

Thus, the mutant TR complex can interfere with the function of the three normal TR-expressing genes, producing a pattern termed dominant negative inhibition with an autosomal dominant pattern of inheritance. At least 400 families have been identified with this condition, and there are probably many more unreported cases. The gene frequency estimate is about 1 : 50,000, and the study of the function of the mutant receptors in this disorder has provided valuable insights into the mechanism of thyroid hormone action.

Patients with RTH usually are recognized because of thyroid enlargement, which is present in about two thirds of these individuals. Despite one's expectations, patients usually report a peculiar mixture of symptoms of hyperthyroidism and hypothyroidism. With respect to the heart, palpitations and tachycardia are more common than a reduced heart rate; however, patients may also demonstrate growth retardation and retarded skeletal maturation. This has been attributed to the fact that thyroid hormone effects in the heart appear to be primarily dependent on TR rather than TR, whereas the hypothalamic-pituitary axis is primarily regulated through TR, particularly TR2.

Abnormalities in neuropsychological development exist, with an increased prevalence of attention deficit hyperactivity disorder, which is found in approximately 10% of such individuals. Other neuropsychological abnormalities have also been described.

Because patients may present with symptoms suggesting hyperthyroidism, it is important to keep this diagnosis in mind in a patient with tachycardia, gaiter, and elevated thyroid hormones. RTH is discussed here because a reduced response to thyroid hormone is the biochemical basis for the condition. However, the laboratory results may be the first clear evidence that a patient otherwise thought to have hyperthyroidism has RTH. These tests show the unusual combination of an increased FT4, accompanied by normal or slightly increased TSH levels. Thus, the principal differential diagnosis is between a TSH-secreting pituitary tumor and RTH.

Factors that may assist in the differential diagnosis are as follows:

2. Normal thyroid hormone levels in family members of individuals with TSH-induced hyperthyroidism due to pituitary tumor.
3. Presence of an elevated glycoprotein -subunit in patients with pituitary tumor but not in those with thyroid hormone resistance.

A definitive diagnosis requires sequencing of the TR gene demonstrating the abnormality. Although virtually all patients with RTH have such abnormalities, in a few individuals this is not the case, suggesting that there may be mutations in coactivator proteins or one of the RXR receptors, which can also present in a similar fashion.

Treatment is difficult because thyroid hormone analogues designed to suppress TSH, thereby relieving the hyperthyroxinemia, may lead to worsening of the cardiovascular manifestations of the condition. Therapy with 3,5,3'-triiodothyroacetic acid (TRIAC) has been used in several patients. The development of analogues of thyroid hormone with TR, as opposed to mixed or TR preferential effects, may eventually prove useful in treatment.
Treatment

Hypothyroidism, either primary or central, is gratifying to treat because of the ease and completeness with which it responds to thyroid hormone. Treatment is nearly always with levothyroxine, and the proper use of this medication has been reviewed extensively. A primary advantage of levothyroxine therapy is that the peripheral deiodination mechanisms can continue to produce the amount of T <sub>3</sub> required under physiologic control. If one accepts the principle that replicating the natural state is the goal of hormone replacement, it is logical to provide the "prohormone" and allow the peripheral tissues to activate it by physiologically regulated mechanisms.

Pharmacologic and Physiologic Considerations

Levothyroxine has a 7-day half-life; about 80% of the hormone is absorbed relatively slowly and equilibrates rapidly in its distribution volume, therefore avoiding large postabsorptive perturbations in FT <sub>3</sub> levels. With its long half-life, omission of a single day's tablet has no significant effect and the patient may safely take an omitted tablet the following day. In fact, the levothyroxine dosage can be calculated almost as satisfactorily on a weekly, as on a daily, basis.

According to the U.S. Pharmacopeia, the levothyroxine content of replacement tablets must be between 90% and 110% of the stated amount, although narrower restrictions are being introduced in the United States. The availability in many countries of a multiplicity of tablet strengths with content ranging from 25 to 300 µg allows precise titration of the daily levothyroxine dosage for most patients with a single tablet, improving compliance significantly.

The typical dose of levothyroxine, approximately 1.6 to 1.8 µg/kg ideal body weight per day (0.7 to 0.8 µg/pound), generally results in the prescription of between 75 and 112 µg/day for women and 125 to 200 µg/day for men. Replacement doses need not be adjusted upward in obese patients. This dosage is about 20% greater than the T <sub>4</sub> production rate owing to incomplete absorption of the levothyroxine. In patients with primary hypothyroidism, these amounts usually result in serum TSH concentrations that are within the normal range. Because of the 7-day half-life, approximately 6 weeks is required before there is complete equilibration of the FT <sub>3</sub> and FT <sub>4</sub> levels.

Accordingly, assessments of the adequacy of a given dose or the effects of a change in dosage should not be made until this interval has passed.

By and large, levothyroxine products are clinically equivalent, although problems do occur. However, the variation permitted by the U.S. Food and Drug Administration in tablet content can result in slight variations in serum TSH in patients with primary hypothyroidism even when the same brand is used. Although the serum TSH level is an indirect reflection of the levothyroxine effect in patients with primary hypothyroidism, it is superior to any other readily available method of assessing the adequacy of therapy. Return of the serum TSH level to normal is therefore the goal of levothyroxine therapy in the patient with primary hypothyroidism. Some patients may require slightly higher or lower doses than generally used, owing to individual variations in absorption, and a number of conditions or associated medications may change levothyroxine requirements in patients with established hypothyroidism (see later).

In decades past, desiccated thyroid was successfully employed for the treatment of hypothyroidism and still accounts for a small fraction of the prescriptions written for thyroid replacement in the United States. Although this approach was successful, desiccated thyroid preparations contain thyroid hormone derived from animal thyroid glands that have significantly higher ratios of T <sub>3</sub> to T <sub>4</sub> than the 1:11 value in normal human thyroid gland. Accordingly, such preparations may lead to supraphysiologic levels of T <sub>3</sub> in the immediate postabsorptive period (2 to 4 hours) owing to the rapid release of T <sub>3</sub> from thyroglobulin, its immediate and nearly complete absorption, and the 1-day period required for T <sub>4</sub> to equilibrate with its 40-L volume of distribution (see Table 10-5).

Mixtures of liothyronine and levothyroxine (liothrix) contain in a 1-grain (64-mg) equivalent tablet (Thyrolar in the United States), the amounts of T <sub>3</sub> (12.5 µg) and T <sub>4</sub> (50 µg) present in the most popular desiccated thyroid tablet. The levothyroxine equivalency of a 1-grain desiccated thyroid tablet or its liothrix equivalent can be estimated as follows. The 12.5 µg of liothyronine (T <sub>3</sub>) is completely absorbed from desiccated thyroid or from liothrix tablets. Liothyronine is approximately 80% absorbed, and about 36% of the 40 µg of levothyroxine absorbed is converted to T <sub>3</sub>, with the molecular weight of T <sub>3</sub> (651) being 84% that of T <sub>4</sub> (777). Accordingly, a 1-grain tablet should provide about 25 µg of T <sub>3</sub> (12.5 ± 12.1), which would be approximately equivalent to that obtained from 100 µg of levothyroxine. This equivalency ratio can be used as an initial guide in switching patients from desiccated thyroid or liothrix to levothyroxine.

As indicated earlier, the use of levothyroxine as thyroid hormone replacement is a compromise with the normal pathway of T <sub>3</sub> production, in which about 80% of T <sub>3</sub> is derived from T <sub>4</sub> 5-monodeiodination and approximately 20% (6 µg) is secreted directly from the thyroid gland. Studies in thyroidecstomized rats, for example, show that it is not possible to normalize T <sub>3</sub> simultaneously in all tissues by an IV infusion of T <sub>4</sub>. However, it should be recalled from the earlier discussion of T <sub>4</sub> deiodination that the ratio of T <sub>3</sub>/T <sub>4</sub> in the human thyroid gland is about 0.09 but is 0.17 in the rat thyroid gland. Thus, about 40% of the rat's daily T <sub>3</sub> production is derived from the thyroid versus about 20% in humans. Accordingly, the demonstration that T <sub>3</sub> alone cannot provide normal levels of T <sub>3</sub> in all tissues in the rat is of interest but is not strictly applicable to thyroid hormone replacement in humans. Nonetheless, the ratio of T <sub>3</sub>/T <sub>4</sub> in the serum of a patient receiving levothyroxine as the only source of T <sub>3</sub> must be about 20% lower than that in a normal individual.

Similarly, the quantity of levothyroxine required to normalize TSH in an athyreotic patient results in a slightly higher serum T <sub>3</sub> concentration than is present in normal individuals. Although this may, to some extent, compensate for the lack of T <sub>3</sub> secretion, the fact that T <sub>3</sub> has an independent mechanism for TSH suppression owing to the intracellular generation of T <sub>3</sub> in the hypothalamic-pituitary-thyroid axis results in a portion of the feedback regulation being independent of the plasma T <sub>3</sub> concentration.

Does this slightly lower T <sub>3</sub> concentration in patients receiving levothyroxine make any difference physiologically? Probably not, although the question is difficult to answer definitively because the most readily measurable end point, TSH, cannot be used. In one study, patients who received 12.5 µg of T <sub>4</sub> as a substitution for 50 µg of their levothyroxine preparation scored, on average, somewhat higher on tests of mood than when they were taking levothyroxine alone. The dosage of thyroid hormone used in these studies was excessive, as judged by the fact that 20% of the group had serum TSH values below normal on either regimen and the test period was only a few months, making it difficult to extrapolate to the chronic replacement setting.

On the other hand, another study showed that the FT <sub>3</sub> I correlated as closely with the resting energy expenditure, as did TSH levels in a group of patients in whom small supplements or decrements in their ideal replacement levothyroxine dosage were made. The correlation with serum T <sub>3</sub> was not statistically significant, suggesting that in humans, perhaps as a result of differences in the peripheral metabolism of T <sub>4</sub>, from that in rodents, the FT <sub>3</sub> I may be as accurate as the TSH value as an index of satisfactory thyroid hormone replacement. The practical difficulty with the design of tablets providing combinations of T <sub>3</sub> and T <sub>4</sub> is that the approximate dose of 6 µg of T <sub>3</sub> provided would need to be released in a sustained fashion over 24 hours, which is quite different from the rapid absorption of T <sub>3</sub> with a peak at 2 to 4 hours when given in its conventional form. Thus, for the present, it appears that the current approach to thyroid replacement using levothyroxine, although not a perfect replication of the normal physiology, is satisfactory for most patients.

Institution of Replacement Therapy

The initial dose of levothyroxine prescribed depends on the degree of hypothyroidism and the age and general health of the patient. Patients who are young or middle-aged and otherwise healthy with no associated cardiovascular or other abnormalities and mild to moderate hypothyroidism (TSH concentrations 5 to 50 mIU/L)
can be given a complete replacement dose of about 1.7 µg/kg of ideal body weight. The resulting increase in serum \( T_4 \) concentration to normal requires 5 to 6 weeks, and the biologic effects of \( T_4 \) are sufficiently delayed that these patients do not experience adverse effects. At the other extreme, the older patient with heart disease, particularly angina pectoris, without reversible coronary lesions, should be given small initial doses of levothyroxine (25 or even 12.5 µg/day), and the dosage should be increased in 12.5 µg increments at 2- to 3-month intervals with careful clinical and laboratory evaluation.

The goal in the patient with primary hypothyroidism is to return serum TSH concentrations to normal, reflecting normalization of that patient's thyroid hormone supply. This usually results in a mid to high-normal serum FT\(_4\) level. The serum FT\(_4\) should be evaluated 6 weeks after a theoretically complete replacement dose has been instituted to allow minor adjustments to optimize the individual dose. In patients with central hypothyroidism, serum TSH is not a reliable index of adequate replacement and the serum FT\(_4\) should be restored to a concentration in the upper half of the normal range. Such patients should also be evaluated and treated for glucocorticoid deficiency before institution of thyroid replacement (see Chapter 8).

Although the adverse effects of the rapid institution of therapy are unusual, pseudotumor cerebri has been reported in profoundly hypothyroid juveniles between ages 8 and 12 years who were given even modest initial levothyroxine replacement. This complication appears 1 to 10 months after initiation of treatment and responds to acetazolamide and dexamethasone.

The interval between the initiation of treatment and the first evidence of improvement depends on the strength of dose given and the degree of the deficit. An early clinical response in moderate to severe hypothyroidism is a diuresis of 2 to 4 kg. The serum sodium (Na\(^+\)) level increases even sooner if hyponatremia was present initially. Thereafter, pulse rate and pulse pressure increase, appetite improves, and constipation may disappear. Later, psychomotor activity increases and the delay in the deep tendon reflex disappears. Hoarseness abates slowly, and changes in skin and hair do not disappear for several months. In individuals started on a complete replacement dose, the serum FT\(_4\) level should return to normal after 6 weeks; a somewhat longer period may be necessary for serum TSH levels to return to normal, perhaps up to 3 months.

In addition to myxedema coma (see later), it is sometimes clinically appropriate to alleviate hypothyroidism rapidly. For example, patients with severe hypothyroidism withstand acute infections or other serious illnesses poorly and myxedema coma may develop as a complication. In such circumstances, rapid repletion of the peripheral hormone pool in the average adult can be accomplished by a single IV dose of 500 µg of levothyroxine. Alternatively, by virtue of its rapid onset of action, levothyroxine (25 µg orally every 12 hours) can be administered if the patient can take medication by mouth. With both approaches, an initial effect is achieved within 24 hours. Parenteral therapy with levothyroxine is then continued with a dose that is 80% of the appropriate oral dose but not in excess of 1.4 µg/kg of ideal body weight. Because of the possibility that rapid increases in metabolic rate will overtax the existing pituitary-adrenocortical reserve, supplemental glucocorticoid (IV hydrocortisone 5 mg/hour) should also be given to patients with severe hypothyroidism receiving high initial doses of thyroid hormones. Finally, in view of the tendency of hypothyroid patients to retain free water, IV fluids containing only dextrose should not be given.

When replacement therapy is withdrawn for short periods (4 to 6 weeks) for purposes of evaluating therapy for thyroid cancer, rapid reinitiation of levothyroxine using a loading dose of three times the daily replacement dose for 3 days can usually be given unless there are other complicating medical illnesses. When hypothyroidism results from administration of iodine-containing or antithyroid drugs, withdrawal of the offending agent usually relieves both the hypothyroidism and the accompanying goiter, although it is appropriate to provide interim replacement until the gland recovers its function. This is especially true for amiodarone, which may remain in tissues for up to a year.

**Infants and Children**

In infants with congenital hypothyroidism, the determining factor for eventual intellectual attainment is the age at which adequate treatment with thyroid hormone is begun. The therapy for infants with congenital hypothyroidism should consist initially of raising the serum T\(_4\) level to more than 130 nmol/L (10 µg/dL) as rapidly as possible and maintaining it at that level for the first 3 to 4 years of life. This is usually accomplished by administering an initial levothyroxine dose of 50 µg/day, which is higher than the adult dose on a weight basis and in keeping with the higher metabolic clearance of the hormone in the infant. The serum TSH concentration may not return to normal even with this high dose because of residual reset of the pituitary feedback mechanism. After 2 years of age, however, a TSH level in the normal range is an index of optimal therapy as it is in adults.

**Monitoring Replacement Therapy**

Monitoring the adequacy of, and compliance with, thyroid hormone therapy in patients with primary hypothyroidism is easily done by measurement of serum TSH. This value should be within the normal range for an assay sufficiently sensitive to measure, with confidence, the lower limit of the normal range. The normal serum TSH concentration varies between 0.5 and 4.0 mU/L in most second-generation and third-generation assays, and results within this range are associated with the elimination of all clinical and biochemical manifestations of primary hypothyroidism, except in patients with RTH.

After the first 6 months of therapy, the dose should be reassessed because restoration of euthyroidism increases the metabolic clearance of T\(_4\). A dose that was adequate during the early phases of therapy may not be adequate when the same patient is euthyroid owing to an acceleration in the clearance of thyroid hormone. Under normal circumstances, the finding of a normal serum TSH level on an annual basis is adequate to ensure that the proper dose is prescribed and is being taken by the patient. If the serum TSH level is above the normal range and noncompliance is not the explanation, small adjustments, usually in 12-µg increments, can be made with reassessment of TSH concentrations after full equilibration (6 weeks) with the new dose to confirm that such adjustments are appropriate. In North America, this strategy is simplified by the availability of multiple tablet strengths, many of which differ by only 12 µg. Most patients can receive the same dose until they reach the 7th or 8th decade, at which point a downward adjustment of 20% to 30% is indicated because thyroid hormone clearance decreases in the elderly.

Thyroid hormone requirements may be altered in several situations. (Table 12-4). A reduction in replacement dosage may be required in women who are receiving androgen therapy for adjuvant treatment of breast carcinoma. Most other conditions or medications increase the levothyroxine requirement in patients receiving maintenance therapy. During pregnancy, the levothyroxine requirement is increased by 25% to 50%. Hypothyroid patients who are planning a pregnancy should be advised to increase the dose by up to 50% as soon as the diagnosis is confirmed because the change in requirement appears soon after implantation. The increased requirement is probably due to a combination of factors, including increases in thyroid hormone-binding globulin and the volume of distribution of T\(_4\), an increase in body mass, and an increase in D3 in placenta and perhaps the uterus. The increased requirement

T4, thyroxine; T3, triiodothyronine.

persists throughout pregnancy but returns to normal within a few weeks after delivery. Therefore, the dose should be reduced to the original pre-pregnancy level at
the time of delivery. Maternal T4 is critically important to the athyreotic fetus, and pregnant patients should be monitored carefully. Other conditions in which levothyroxine requirements are increased (Table 12-4) include malabsorption due to either bowel disease or adsorption of levothyroxine to coadministered medications such as sucralfate, aluminum hydroxide and perhaps calcium carbonate, ferrous sulfate, lovastatin, or various resins. Certain medications, notably rifampin, carbamazepine, phenytoin, and sertraline increase the clearance of levothyroxine by inducing CYP3A4 in the liver. Estrogen given to postmenopausal women may act in the same way, although the changes in thyroglobulin and distribution volume make the exact resolution of the cause of the increased levothyroxine requirement uncertain. Amiodarone increases levothyroxine requirements by blocking conversion of T4 to T3, and perhaps by interfering with T3-thyroid hormone receptor binding. Selenium deficiency is rare, but because it is rate-limiting in the synthesis of D1, a deficiency, such as may occur in patients receiving diets restricted in protein, may increase levothyroxine requirements.

Occasionally, in patients who have been treated with radioactive iodine for Graves’ disease or toxic nodular goiter, some degree of thyroid hormone secretion persists and, although inadequate, is autonomous. Such patients have a suppressed TSH on what otherwise would be considered a replacement dose of levothyroxine. The levothyroxine dose in these individuals should be reduced until TSH levels rise to normal, keeping in mind that several months may be required before TSH secretion recovers after its prolonged suppression. Because of

either the delayed effects of radiiodine or the natural history of Graves’ disease, per se, this autonomous T4 secretion may decrease with time, leading to an increase in levothyroxine requirements in subsequent years. Rarely, the opposite occurs: that is, a patient treated with radiiodine develops an increased TSH level, but, after several months of therapy, the requirement for such replacement is either reduced or eliminated. This may reflect transient impairment of thyroid function by a combination of preirradiation antithyroid drug therapy and immediate effects of radiation on the thyroid. In such patients, frequent monitoring of levothyroxine replacement is required to avoid over-replacement.

In North America, clinical experience with the most commonly used levothyroxine preparations suggests that these products are equally effective, and this is supported by small clinical trials. Nonetheless, the possibility of a problem with tablet levothyroxine content should be considered if a new preparation changes the biologic effects of the same dosage.

Adverse Effects of Levothyroxine Therapy

Although the administration of excessive doses of levothyroxine causes osteoporosis in postmenopausal patients, most authorities believe that returning thyroid status to normal does not have adverse effects on bone density. Administration of excessive doses also increases cardiac wall thickness and contractility and, in elderly patients, increases the risk of atrial fibrillation.

In some patients, TSH levels remain elevated despite the prescription of adequate replacement doses. This is most often a consequence of poor compliance. The combination of normal or even elevated serum FT4 values and elevated TSH levels can occur if the patient does not take levothyroxine regularly but ingests several pills the day before testing. The integrated dose of levothyroxine over prior weeks is best reflected in the serum TSH level, and noncompliant patients require careful education as to the rationale for the treatment. Subtle changes in dietary habits, such as increasing the ingestion of bran-containing products, may decrease levothyroxine absorption, and their recognition requires a careful history.

Patients with Hypothyroid Symptoms Despite Restitution of Normal Thyroid Function

In rare circumstances, symptoms consistent with hypothyroidism persist despite appropriate treatment of the hypothyroid state. Such patients should be educated as
to the relationship between symptoms of hypothyroidism and the role of thyroid hormone in relieving these, and other causes should be sought for the
symptomatology. In rare cases, hypothyroid symptoms are associated with hypometabolism despite normal levels of serum thyroid hormones and TSH. Such
patients may have RTH in peripheral but not central tissues, a situation that has been documented only rarely.
Special Aspects of Hypothyroidism

Subclinical Hypothyroidism

The term subclinical hypothyroidism designates a situation in which an asymptomatic patient has a low-normal FT₄ but a slightly elevated serum TSH level. Other terms for this condition are mild hypothyroidism, predichondal hypothyroidism, biochemical hypothyroidism, and decreased thyroid reserve (see Table 12-1). The TSH elevation in such patients is modest, with values typically between 5 and 15 mIU/L. This syndrome is most often seen in patients with early Hashimoto’s disease and is a common phenomenon, occurring in 7% to 10% of older women.

A number of studies on the effects of thyroid hormone treatment in such patients have used physiologic end points (e.g., measurements of various serum enzymes, systolic time intervals, serum lipids, psychometric testing), and results have been variable. In the most carefully controlled studies, one or another of the parameters has returned to normal in about 25% to 50% of patients. In general, FT₄ and TSH levels normalize, but FT₃, usually normal at the outset, does not change. In one study that employed a double-blind, crossover approach, the 4 of 17 women who improved could be differentiated from the remainder only by a somewhat lower serum free T₃ at the start of the study. Modest improvements in cardiac indices have been noted in some but not all reports, and the same is true for lipids. Thus, when one is confronted with this clinical situation, there is no clearly correct approach.

One factor favoring a decision to recommend levothyroxine therapy is the presence of antibodies to TPO or thyroglobulin or the presence of a goiter. There is a risk of progression of thyroid dysfunction in patients with Hashimoto’s disease, and this premonitory sign of thyroid failure is, to many, a justification for initiating therapy. To be weighed against this are the expense and bother of daily medication, not acceptable to some patients, and the possibility that overdosage with levothyroxine may exacerbate osteoporosis or cause cardiac arrhythmias. If a therapeutic trial is performed, the TSH concentration should be monitored carefully and should not be reduced below normal. If no therapy is given, such patients should be monitored at intervals of 6 to 12 months both clinically and by measurements of serum TSH.

Metabolic Insufficiency

Non-specific symptoms of true hypothyroidism include mild lassitude, fatigue, slight anemia, constipation, apathy, cold intolerance, menstrual irregularities, loss of hair, and weight gain (see Fig. 12-5). For this reason, some patients with such complaints but with normal laboratory results have been considered candidates for levothyroxine therapy. The response to thyroid hormone therapy is sometimes gratifying, at least initially, but symptomatic improvement usually disappears after a time unless the dose is increased. Eventually, even larger doses fail to alleviate the symptoms, confirming that they do not arise from a deficiency of thyroid hormone. Thus, thyroid hormone therapy should be avoided in patients with no biochemical documentation of impaired thyroid function. Furthermore, even in patients with subclinical hypothyroidism, symptoms may be out of proportion to FT₄ abnormalities. It is unwise to raise the patient’s expectations that such symptoms will be relieved by correction of mild biochemical abnormalities.

Thyroid Function Testing in Patients Receiving Replacement Therapy

Physicians are frequently confronted with patients receiving levothyroxine in whom the historical diagnosis of hypothyroidism has been made on what appear to be questionable grounds. In this circumstance, it may be impossible to determine, from retrospective clinical or laboratory findings, whether thyroid hormone replacement is indicated. If serum TSH is in the normal range and primary hypothyroidism is suspected, a simple way of assessing the need for levothyroxine therapy is to switch levothyroxine to every-other-day dosage or to reduce the daily dose by 50% and to reevaluate TSH and FT₄ after 4 weeks. If there has been no significant increase in TSH concentration and FT₄ remains constant during that period, levothyroxine is withdrawn and blood tests are repeated 4 and 8 weeks later.

If the initial TSH level is suppressed, indicating overreplacement, the dose should be reduced until TSH becomes detectable before this trial is instituted. If central hypothyroidism is suspected, the FT₄ must be monitored during these procedures.

Emergency Surgery in the Hypothyroid Patient

The perioperative course of patients with untreated hypothyroidism has been evaluated in several studies. In general, such patients were not recognized to be hypothyroid or did not require surgery despite the presence of significant hypothyroidism. Complications were uncommon. Perioperative hypotension, ileus, and central nervous system disturbances were more common in hypothyroid patients, and patients with major infections had fewer episodes of fever than did euthyroid control subjects. Other complications were delayed recovery from anesthesia and abnormal hemostasis, possibly owing to an acquired form of von Willebrand’s disease.

From these studies, one may conclude that emergency surgery should not be postponed in hypothyroid patients but that such patients should be rigorously monitored for evidence of carbon dioxide retention, bleeding, infection, and hyponatremia. These findings are also relevant to the treatment of hypothyroid individuals with symptomatic coronary artery disease. Considering the lack of significant increase in perioperative complications in the hypothyroid patient, the option of surgery for remendable coronary artery lesions is open to hypothyroid individuals without the risk of a myocardial infarction in association with restitution of the euthyroid state (see later).
Coexisting Coronary Artery Disease and Hypothyroidism

In many patients with coronary artery disease and primary hypothyroidism, cardiac function is corrected during institution of levothyroxine therapy because of a decrease in peripheral vascular resistance and improvement in myocardial function. However, patients with preexisting angina pectoris should be evaluated for correctable lesions of the coronary arteries and treated appropriately before levothyroxine is administered. Retrospective studies indicate that this approach is safer than the institution of replacement therapy prior to angiography and angioplasty or even coronary artery bypass grafting.

In a few patients, lesions may not be remediable or small-vessel disease is severe even after bypass grafting, so that complete replacement cannot be instituted. Such patients must receive optimal antianginal therapy combined with β-adrenergic receptor blockers in judicious quantities, and complete restitution of the euthyroid state may not be possible.

Thyroid Hormone for Compromised Cardiovascular Function

In addition to the issues raised in patients with combined hypothyroidism and coronary artery disease, there is interest in the potential therapeutic use of thyroid hormone in the treatment of patients with either cardiomyopathy or status postcoronary artery bypass grafting (CABG) or other cardiac procedures. As expected, T₃ levels are reduced in patients with advanced congestive heart failure, as with any illness. In one report, 23 patients with advanced heart failure (mean ejection fraction, 22%) were given up to 2.7 µg/kg of liothyronine over 6 hours with an increase in cardiac output and decrease in systemic vascular resistance but without increase in heart or metabolic rate. Similar effects were seen with a dose of liothyronine, 110 µg, over 6 hours after CABG. In addition, decreases in the frequency of atrial fibrillation following surgery were found in liothyronine-treated patients, although this was not confirmed in a second study. However, there were no adverse effects associated with the infusion of T₃ in either study.

Liothyronine has also been given postoperatively for congenital heart disease and, again, an improvement in cardiac output and decrease in vascular resistance occurred without adverse side effects. These results suggest that, in certain selected circumstances, liothyronine may be useful as adjunctive therapy in patients with congestive heart failure because of its effect of relaxing vascular smooth muscle. It is conceivable that more selective thyroid hormone analogues may be on the horizon that might produce this effect but not increase myocardial oxygen demands.
Screening for Primary Hypothyroidism

The high incidence of primary hypothyroidism in women, particularly if the 7% to 10% prevalence of subclinical hypothyroidism is included, raises the issue of whether the cost of systematic periodic screening of an asymptomatic population is justified. A number of studies have addressed this complex issue. The conclusions depend, to a great extent, on assumptions regarding the effectiveness and economic value of therapy in asymptomatic patients with TSH elevation alone. One study concluded that the cost of an every-5-year TSH determination for women and men would be approximately $9000 per quality-adjusted life-year in women. Other studies have indicated somewhat lower financial benefits. An assessment of TSH levels at 5-year intervals in women older than age 50 years seems justified, but further analyses of more extensive screening programs are in order.

A second complex issue involves whether women planning pregnancy should be screened for the presence of hypothyroidism as a routine part of a prenatal visit. This question is raised because of the results of a study indicating that mild to modest hypothyroidism is associated with an impairment of mental development in infants of mothers with elevated TSH during the first trimester. The prevalence of hypothyroidism during pregnancy has been found to be approximately 2%, and screening of all patients has been advocated by several professional organizations.

Maternal FT₄I concentrations in the lowest 10% of the normal range, even with normal TSH levels, have also been suggested as a risk factor for impaired neuropsychological development of the fetus. It is not clear why this is a risk factor for impaired fetal neuropsychological development, because such patients are not hypothyroid. For the moment, it appears that any patient with a family history of autoimmune thyroid disease, with symptoms suggesting hypothyroidism, or with thyroid enlargement should be screened for thyroid dysfunction prior to pregnancy or as soon after conception as is feasible.
Myxedema Coma

Myxedema coma is the ultimate stage of severe long-standing hypothyroidism. This state, which almost invariably affects older patients, occurs most commonly during the winter months and is associated with a high mortality rate. It is usually, but not always, accompanied by a subnormal temperature. Values as low as 23°C having been recorded. The external manifestations of severe myxedema, bradycardia, and severe hypotension are invariably present. The characteristic delay in deep tendon reflexes may be lacking if the patient is areflexic. Seizures may accompany the comatose state. Although the pathogenesis of myxedema coma is not clear, factors that predispose to its development include exposure to cold, infection, trauma, and central nervous system depressants or anesthetics. Alveolar hypoventilation, leading to carbon dioxide retention and narcosis, and dilutional hyponatremia resembling that seen with inappropriate secretion of arginine vasopressin (AVP) may also contribute to the clinical state.

From the foregoing, it appears that myxedema coma should be readily recognized from its clinical signs, but this is not the case. After a brain stem infarction, elderly patients with features suggestive of hypothyroidism may be both comatose and hypothermic. In addition, hypothermia of any cause, due for example to exposure to cold, may cause changes suggestive of myxedema, including delayed relaxation of deep tendon reflexes. The importance of the difficulty in diagnosing myxedema coma is that a delay in therapy worsens the prognosis. Consequently, the diagnosis should be made on clinical grounds, and, after sending blood for thyroid function tests, therapy should be initiated without awaiting the results of confirmatory tests because mortality may be 20% or higher.

Treatment consists of administration of thyroid hormone and correction of the associated physiologic disturbances. Because of the sluggish circulation and severe hypometabolism, absorption of therapeutic agents from the gut or from subcutaneous or intramuscular sites is unpredictable, and medications should be administered intravenously if possible. Administration of levothyroxine as a single IV dose of 500 to 800 µg serves to replete the peripheral hormone pool and may cause improvement within hours. Daily doses of IV levothyroxine, 100 µg, are given thereafter. Hydrocortisone (5 to 10 mg/hour) should also be given because of the possibility of relative adrenocortical insufficiency as the metabolic rate increases.

Alternatively, IV liothyronine may be given at a dose of 25 µg every 12 hours. Others have used a combination of 200 to 300 µg T₄ and 25 µg T₃ intravenously as a single dose, followed by 25 µg T₃ and 100 µg T₄ 24 hours later, and then 50 µg T₄ daily until the patient regains consciousness. Hypotonic fluids should not be given because of the danger of water intoxication owing to the reduced free water clearance of the hypothyroid patient. Hypertonic saline and glucose may be required to alleviate severe dilutional hyponatremia and the occasional hypoglycemia.

A critical element in therapy is support of respiratory function by means of assisted ventilation and controlled oxygen administration. Internal warming by gastric perfusion may be useful, but external warming should be avoided because it may lead to vascular collapse due to peripheral vasodilatation. Further heat loss can be prevented with blankets. An increase in temperature may be seen within 24 hours in response to levothyroxine. General measures applicable to the comatose patient should be undertaken, such as frequent turning, prevention of aspiration, and attention to fecal impaction and urinary retention.

Finally, the physician should assess the patient for the presence of coexisting disease, such as infection and cardiac or cerebrovascular disease. In particular, the myxedematous patient may be afebrile despite a significant infection. As soon as the patient is able to take medication by mouth, treatment with oral levothyroxine should be instituted.
THYROIDITIS

Overview

Thyroiditis is a term indicating the presence of thyroid inflammation, and thus comprises a large group of diverse inflammatory conditions. These include the following:

1. Autoimmune or quasi-autoimmune causes.
2. Viral or postviral conditions.
3. Infections, including those of bacterial and fungal origins.
4. A chronic sclerosing form of thyroiditis, termed Riedel's thyroiditis (or struma).
5. Miscellaneous causes of various types, including radiation-induced and granulomatous causes, such as sarcoidosis.

Not only are the causes of thyroiditis extremely varied; their clinical presentations may also be diverse and are difficult to categorize in a simple fashion (Table 12-5). Thus, as already discussed, autoimmune thyroiditis may present with hypothyroidism but often patients remain euthyroid for long periods after the disease is initiated. On the other hand, in a euthyroid patient with Hashimoto's disease who becomes pregnant, the postpartum period is often complicated by an acute form of hyperthyroidism due to the transient exacerbation of thyroiditis, often followed by a period of hypothyroidism.

A similar syndrome has been observed in nonpregnant patients, called silent or painless thyroiditis. It is manifested primarily as thyrotoxicosis of sudden onset without localized pain and often without evidence of autoimmune disease. This condition may be viral in origin in some patients; however, the most classic presentation of viral thyroiditis is as subacute, nonsuppurative thyroiditis, also known as de Quervain's thyroiditis, pseudotuberculous thyroiditis, or migratory or creeping thyroiditis. Unlike typical autoimmune thyroiditis, this condition is characterized by extreme thyroid tenderness, with pain radiating to the oropharynx and ears, and must be differentiated from acute suppurative thyroiditis caused by bacterial or fungal infection. [306]

Thus, inflammatory conditions of the thyroid present a dilemma because one must decide whether to discuss these entities as a group with the common denominator of inflammation or to categorize them according to their principal clinical effects, namely thyrotoxicosis or thyroid hormone deficiency. We have chosen the latter approach and have already discussed autoimmune thyroiditis, the major cause of thyroid gland failure (see Table 12-2). However, patients with acute autoimmune thyroiditis may also develop thyrotoxicosis, such as in postpartum silent or painless thyroiditis (see Chapter 11 on autoimmune thyroiditis). These patients must be differentiated from those with Graves' disease. In addition, some patients with viral thyroiditis have thyrotoxicosis as a major manifestation with varying degrees of neck discomfort ranging from none to full-blown subacute, nonsuppurative (granulomatous) thyroiditis. For that reason, this thyroiditis syndrome is also discussed in Chapter 11, even though the pain associated with the typical form of this condition makes the principal differential diagnosis lie between that and pyogenic thyroiditis. In that context, subacute thyroiditis is also mentioned later.

Acute Infectious Thyroiditis

Although the thyroid gland is remarkably resistant to infection, congenital abnormalities of the piriform sinus, underlying autoimmune disease, or immunocompromise of the host may lead to the development of an infectious disease of the thyroid gland. The etiology may be any bacterium, including Staphylococcus, Pneumococcus, Salmonella, or Mycobacterium tuberculosis. In addition, infections with certain fungi, including Coccidioides immitis, Candida, or Aspergillus and Histoplasma have been reported.

The most common cause of repeated childhood pyogenic thyroiditis, particularly in the left lobe, is a consequence of an internal fistula extending from the piriform sinus to the thyroid. This sinus is the residual connection following the path of migration of the ultimobranchial body from the fifth pharyngeal pouch to the thyroid gland. The predominance of thyroiditis of the left lobe is explained by the fact that the right ultimobranchial body is often atrophic, whereas this is not the case for the left side. Nonetheless, a patient with a completely normal thyroid gland may develop bacterial thyroiditis. This is an extremely rare disease even as a complication of direct puncture of the thyroid gland, such as in fine-needle aspiration. In individuals with midline infections, persistence of the thyroglossal duct should be considered.

Incidence

Infectious thyroiditis is extremely rare, with no more than a few cases being seen in large tertiary care centers.

Clinical Manifestations

The clinical manifestations of infectious thyroiditis are dominated by local pain and tenderness in the affected lobe or entire gland. This is accompanied by painful swelling and difficulty on swallowing. Because of the tendency for referral of pain to the pharynx or ear, the patient may not recognize the tenderness in the anterior neck. Depending on the virulence of the organism and the presence of septicemia, symptoms such as fever and chills may also accompany the condition.

The major differential diagnosis lies between an infectious form of thyroiditis and subacute, nonsuppurative thyroiditis. It is instructive to compare the principal features of these two diseases to arrive at an accurate diagnosis (Table 12-6). By and large, patients with acute thyroiditis caused by a bacterium are much sicker than patients with subacute thyroiditis; they have more severe and localized tenderness and are less likely to have laboratory evidence of hyperthyroidism, which is present in approximately 60% of patients with subacute thyroiditis. Ultrasonographic examination often reveals the abscess in the thyroid gland or evidence of swelling, and needle aspiration may help pinpoint the responsible organism. A gallium scan will be positive as a result of the diffuseness of the inflammation and, particularly in children with thyroiditis of the left lobe, a barium swallow showing a fistula connecting the piriform sinus and left lobe of the thyroid is diagnostic.

Occasionally, pertechnetate scanning is useful in showing normal function of one lobe of the thyroid gland, which is much less common in subacute thyroiditis (which more often affects the entire gland). Needle aspiration should be used to drain the affected lobe, although occasionally surgical drainage may be required. If a piriform sinus fistula can be demonstrated, it must be removed to prevent recurrence of the problem.
gland have been reported.

The prognosis is excellent with preservation of thyroid function in general, although post-thyroiditis thyroid function tests should be monitored to ascertain that thyroid failure has not occurred.
Riedel's Thyroiditis

Riedel's chronic sclerosing thyroiditis is rare and dramatic and occurs chiefly in middle-aged women. The etiologic mechanism is uncertain, although some cases are considered to be an advanced state of Hashimoto's disease. This condition is characterized by fibrosis of the thyroid gland and adjacent structures and may be associated with fibrosis elsewhere, especially in the retroperitoneal area. The presence of eosinophils has been demonstrated histologically, suggesting a unique autoimmune response to fibrous tissue.

Symptoms develop insidiously and are related chiefly to compression of adjacent structures, including the trachea, esophagus, and recurrent laryngeal nerves. Constitutional evidence of inflammation is uncommon. The thyroid gland is moderately enlarged, stony hard, and usually asymmetrical. The consistency of the gland and the invasion of adjacent structures suggest carcinoma, but there is no enlargement of regional lymph nodes. Temperature, pulse, and leukocyte count are normal. Severe hypothyroidism is unusual but does occur, as does loss of parathyroid function. The RAIU may be normal or low. Circulating thyroid autoantibodies are less common and are found in lower titers than in Hashimoto's disease.

Surgery may be required to preserve tracheal and esophageal function. If extensive involvement of perithyroid tissues is present, resection of the isthmus may relieve some symptoms. Treatment with thyroid hormone relieves the hypothyroidism but has no effect on the primary process, which may progress inexorably. Immunosuppressive treatment and even chemotherapy has been tried in individual cases.
Miscellaneous Causes

Only a few causes of generalized inflammation of the thyroid gland have been reported. These include inflammation arising after $^{131}$I treatment of individuals for Graves’ disease, a residual thyroid lobe in a patient with thyroid cancer of the contralateral lobe, and thyroiditis arising from external-beam therapy for conditions such as Hodgkin’s or non-Hodgkin’s lymphoma, breast carcinoma, or other lesions of the oropharynx. In general, only radiiodine-induced thyroiditis is associated with pain and glucocorticoid treatment may be useful in symptomatic therapy.

Chapter 13 - Nontoxic Goiter and Thyroid Neoplasia

Martin-Jean Schlumberger
Sebastiano Filetti
Ian D. Hay

After thyroid dysfunction and neck pain, the discovery of an apparent structural abnormality of the thyroid gland is the most common reason for a patient to seek the expertise of a clinical thyroidologist. In this chapter, we review the imaging techniques available for evaluating thyroid structural abnormalities; the units of measurement used in evaluation of the radiation dose and radioactivity are defined in Table 13-1.

Goiter resulting in thyrotoxicosis and other thyroid conditions arising from autoimmune thyroid disease are considered in Chapter 11 and Chapter 12.

This chapter describes simple or nontoxic goiter in addition to the increasingly recognized problem of nodular thyroid disease. Moreover, thyroid neoplasia, both benign and malignant, is discussed authoritatively. We consider an appropriate histologic classification and staging of thyroid cancer and present a management program for the most common thyroid cancer types.
EVALUATION OF STRUCTURAL ABNORMALITIES BY IMAGING TECHNIQUES

External Scintiscanning

Localization of functioning or nonfunctioning thyroid tissue in the area of the thyroid gland or elsewhere is made possible by techniques of external scintiscanning. The underlying principle is that isopes that are selectively accumulated by thyroid tissue can be detected and quantified in situ and the data transformed into a visual display. Two types of apparatus are available.

The rectilinear scanner is a device that moves a highly collimated (focused) scintillation detector back and forth across the area of study in a series of parallel tracks. A printing device records a mark whenever a predetermined number of counts has been received to provide a visual representation of the localization of radioactivity.

The stationary scintillation camera has now replaced the rectilinear scanner in most centers. It is equipped with a pinhole collimator that views the entire field of interest and translates the counting rates from specific areas of the field into images. Radioactivity in specific areas can be quantified. These cameras provide better resolution than rectilinear scanners, but anatomic localization may be more difficult.11

Several radioisotopes are employed in thyroid imaging. Technetium 99m (99mTc) pertechnetate is a monovalent anion that is actively concentrated by the thyroid gland but undergoes negligible organic binding and diffuses out of the thyroid gland as its concentration in the blood decreases. The short physical half-life of 99mTc (6 hours), its low fractional uptake, and its transient stay within the thyroid make the radiation delivered to the thyroid gland by a standard dose very low. Consequently, the intravenous administration of large doses (>37 MBq [1 mCi]) permits, about 30 minutes later, adequate imaging of the thyroid.

Two radioactive isotopes of iodine have been used in thyroid imaging. Iodine 131 (131I) was commonly used in the past and is still useful when functioning metastases of thyroid carcinoma are being sought; however, 131I is a beta emitter, its physical half-life is 8.1 days, and the energy of its main gamma ray is high and thus poorly adapted for its detection.12 131I is, in many respects, ideal but is expensive. The energy of its main gamma ray is adapted for its detection by gamma cameras. Its short half-life (0.55 day) and the absence of beta radiation result in a radiation dose to the thyroid that is about 1% of that delivered by a comparable activity of 123I. It is the isotope of choice for thyroid scintigraphy in pediatric practice.

The most important use of scintigraphic imaging of thyroid tissue is to define areas of increased or decreased function ("hot" or "cold" areas, respectively) relative to function of the remainder of the gland, provided that they are 1 cm in diameter or larger. Almost all malignant nodules are hypofunctioning, but more than 80% of benign nodules are also nonfunctioning. Conversely, functioning nodules (hot nodules), particularly if they are either more active than surrounding tissue or the sole functioning tissue, are rarely malignant.

In the past, several nuclear medical tests were used to evaluate thyroid disorders. In patients with a single area of thyroid uptake, scintiscans after administration of exogenous thyrotropin (TSH) may demonstrate the presence of hemiagenesis of the thyroid or document the functional capability of suppressed thyroid tissue. Conversely, scans performed after a period of exogenous thyroid hormone administration (suppression scans) can reveal areas of autonomous function that may not be detectable in baseline studies. These tests should no longer be used because the use of sensitive TSH assays and of scanning with a gamma camera permits the diagnosis of most of these hot nodules. Scintiscanning with radioactive iodine can also be used to demonstrate that intrathoracic masses represent thyroid tissue, to detect ectopic thyroid tissue in the neck, and to detect functioning metastases of thyroid carcinoma.

The choice of the scanning agent depends on many factors. 99mTc pertechnetate delivers a small dose of radiation to the thyroid gland, is readily available, and is inexpensive. Because imaging is performed soon after administration of the scanning agent, the entire procedure requires only a single visit to the laboratory. However, 5% to 10% of thyroid tumors appear to be functioning when examined with 99mTc pertechnetate but not with radiiodine. Because 99mTc pertechnetate imaging is done early, the intravascular activity and the activity in salivary tissue may obscure or confuse the findings. For the same reason, 123I Tc pertechnetate is inappropriate for scanning subternal or intrathoracic goiter or for detecting ectopic tissue in the neck. In these cases, radioactive iodine should be used.

Total-body scanning is performed with 131I in the follow-up of patients with papillary and follicular thyroid carcinoma. As detailed subsequently, radiiodine uptake by neoplastic tissue may be found only after TSH stimulation and is always lower than in normal thyroid tissue. For this reason, sufficiently high doses of 131I should be given, and scanning should be performed 2 to 3 days after the dose (or even later), when background blood activity is low and when the contrast is optimal. Scanning conditions should be optimized, preferably by use of a gamma camera with two opposed heads equipped with thick crystals and high-energy collimators.

Scanning at low speed with spot images on regions of interest is performed. There are two aims: (1) to verify the completeness of ablation and to detect and localize foci of uptake, and (2) to quantify any uptake. This quantification permits a dosimetric evaluation that indicates the usefulness of 131I treatment.

The most important use of scintigraphic imaging of thyroid tissue is to define areas of increased or decreased function ("hot" or "cold" areas, respectively) relative to function of the remainder of the gland, provided that they are 1 cm in diameter or larger. Almost all malignant nodules are hypofunctioning, but more than 80% of benign nodules are also nonfunctioning. Conversely, functioning nodules (hot nodules), particularly if they are either more active than surrounding tissue or the sole functioning tissue, are rarely malignant.
Fluorescent Scan

Fluorescent scanning provides information concerning the content of stable iodine within the gland. In this technique, discrete zones of the thyroid gland are subjected to radiation from radioactive americium ($^{241}$Am) or from an x-ray tube. When incident radiation encounters $^{127}$I, a fluorescent x-ray, registered by a suitable detector, is emitted. Nonfunctioning nodules generally have a low iodine content and are therefore cold on fluorescent scan; thyroid iodine is depleted during subacute thyroiditis and increased during chronic iodine overload, such as with amiodarone treatment. The technique has limited clinical utility.
Ultrasonography

Sonography is noninvasive, is less expensive than computed tomography (CT) or magnetic resonance imaging (MRI), and produces no known tissue damage. No special preparation of the patient is necessary, and the technique requires only portable equipment, allowing it to be performed in the physician's examining room. A major limitation of ultrasonography is a high degree of observer dependence.

High-frequency sound waves are emitted by a transducer and reflected as they pass through the body, whereupon the returning echoes are received by the transducer, which also acts as a receiver. The amplitude of the reflections of the sound waves is influenced by differences in the acoustic impedance of the tissues encountered by the sound; for example, fluid-filled structures reflect few echoes and therefore have no or few internal echoes and well-defined margins; solid structures reflect varying amounts of sound and thus have varying degrees of internal echoes and less well-defined margins; and calcified structures reflect virtually all incoming sound and yield pronounced echoes with an acoustic "shadow" posteriorly.

High-frequency sound waves, such as those used in current thyroid sonography, are attenuated rapidly in the body tissues. Therefore, they cannot be used to image structures deeper than about 5 cm from the skin. Fortunately, the thyroid gland is usually well within this limit and can be completely imaged. 1

High-frequency (7 to 13 MHz), small-parts instruments have become widely available since the middle 1980s and provide good spatial resolution and image quality. 2 The theoretical axial resolution of these systems is about 1 mm; no other thyroid imaging method can achieve this degree of resolution. 3 Intrathyroidal nodules as small as 3 mm in diameter and cystic nodules as small as 2 mm can be readily detected. 4 Color flow Doppler ultrasonography allows visualization of very small vessels, so that vascularity of thyroid nodules can be assessed, but its diagnostic performance for malignancy is lower, as compared with fine-needle aspiration biopsy (FNAB).

Thyroid sonography is typically performed with the patient supine. The patient's neck is hyperextended by a pad centered under the scapulae to provide optimal exposure. The examiner usually sits at the head of the examining table and can steady the transducer by resting an elbow or a forearm on the table next to the patient's head. The thyroid gland must be examined thoroughly in transverse and longitudinal planes. Imaging of the lower poles can be enhanced by swallowing, which momentarily raises the thyroid gland in the neck. The examination should cover the entire gland, including the isthmus. Imaging should also include the region of the carotid artery and jugular vein to identify enlarged cervical lymph nodes. 5

The normal thyroid parenchyma has a characteristic homogeneous medium-level echogenicity, with little identifiable internal architecture (Fig. 13-1). The surrounding muscles have the appearance of hypoechoic structures. The air-filled trachea in the midline gives a characteristic curvilinear reflecting surface with an associated reverberation artifact. The esophagus is usually hidden from sonographic visualization by the tracheal air shadow. A portion of the esophagus, however, may swing laterally, usually toward the left, where it may lie adjacent to the posteromedial surface of the thyroid.

Neck ultrasonography may confirm the presence of a thyroid nodule when the findings on physical examination are equivocal. A diagrammatic representation of the neck showing the location or locations of any abnormal finding is a useful supplement to the routine film images recorded during an ultrasound examination. 6 Such a cervical map (Fig. 13-2) can help communicate the anatomic relationships of the pathology more clearly to the referring clinician and serves as a reference for the sonographer on follow-up examinations.

In patients with known thyroid cancer, sonography can be useful in evaluating the extent of disease, both preoperatively and postoperatively. In most instances, sonography is not performed routinely before thyroidectomy but can be useful in patients with large cervical masses for evaluation of nearby structures (e.g., the carotid artery and internal jugular vein) to exclude the possibility of direct invasion or encasement by the tumor.

Alternatively, in patients who present with cervical lymphadenopathy caused by papillary thyroid carcinoma (PTC) but in whom the gland is palpably normal, sonography may be used preoperatively to detect an occult, primary intrathyroidal focus. Some surgeons do regularly obtain a preoperative sonogram in patients with PTC or medulary thyroid carcinoma (MTC) in order to identify prior to surgery the anatomic locations of any sonographically suspicious regional lymph nodes and thereby to permit planning of the extent of nodal dissection. Occasionally, a hand-held ultrasound probe can be used intraoperatively to identify imparable residual cancer that has been identified by preoperative ultrasonography and proved to be cytologically positive by ultrasound-guided FNAB.

After surgery for thyroid cancer, sonography is the preferred method for detecting residual, recurrent, or metastatic disease in the neck. 7 In patients who have undergone less than a near-total thyroidectomy, the sonographic appearance of the remaining thyroid tissue may be an important factor in the decision whether to recommend completion thyroidectomy. Also, it is more sensitive than neck palpation in detecting recurrent disease within the thyroid bed and metastatic disease in cervical lymph nodes. 8,9,10 The location at the lower part of the neck and the sonographic appearance (hypoechoic, without a central echogenic line), the size (>1 cm in diameter), the shape (round), the presence of fine microcalcifications or a cystic component, and the use of color Doppler ultrasonography (hypervascularization) may aid in recognition of lymph node metastases. Sonography may also be useful to guide fine-needle biopsy of thyroid bed masses and lymph nodes, especially when these abnormalities are not palpable. 11,12,13
Computed Tomography

The CT appearance of the anatomic structures depends on the attenuation of the tissue examined. The thyroid gland, because of its high concentration of iodine, has higher attenuation than do the surrounding soft tissues.\[13\]

The diagnostic utility of CT in the evaluation of nodular thyroid disease is limited because thyroid masses, whether benign or malignant, may be hypodense, hyperdense, or isodense compared with adjacent normal thyroid tissue.\[14\] In aggressive pathologic processes, such as anaplastic thyroid carcinoma, CT can define the extension of the tumor to the mediastinum and its relationships to surrounding structures, such as the carotid artery, jugular vein, and trachea, before attempted surgical excision. In patients with known thyroid cancer, CT is less useful in evaluating recurrence in the neck because of the difficulty in detecting small masses in the indistinct tissue planes in the postoperative neck.\[15\] CT imaging can, however, improve the detection of lymph node metastases in the neck, although there is considerable overlap in the appearance of malignant and inflammatory nodes and CT lacks the ability to guide fine-needle biopsy of minimally enlarged nodes.\[7\] In patients with thyroid cancer, CT is used most frequently to search for lymph node metastases in the mediastinum and for distant metastases in the chest and abdomen.

CT scanning can provide useful information regarding the presence and extent of intrathoracic (subternal) goiters. The CT findings of an intrathoracic mass in continuity with the thyroid gland, with high attenuation on noncontrast-enhanced images and marked enhancement after intravenous contrast material injection, all suggest intrathoracic goiter.\[16\] Radionuclide scanning can also be performed in this clinical setting, but false-negative results can occur when little or no functional tissue is present in the intrathoracic goiter. Because of the necessity of infusing iodine-containing contrast agents, CT should be performed at least 4 weeks before any radiiodine therapy.\[16\]
Magnetic Resonance Imaging

Because the hydrogen atoms of different tissues have different relaxation times (termed T1 and T2), a computer-assisted analysis of T1-weighted and T2-weighted signals is used to differentiate the thyroid gland from skeletal muscles, blood vessels, or regional lymph nodes. Normal thyroid tissue tends to be slightly more intense than muscle on a T1-weighted image, and tumors often appear more intense than normal thyroid tissue.

MRI is rapidly evolving, with improvements in spatial resolution, reduction of artifacts, and development of new contrast agents. Currently obtained MR images have superior tissue contrast resolution but poorer spatial resolution than comparable CT images. Like CT, MRI does not distinguish benign from malignant nodules and does not assess functional status; however, it can define the anatomic extent of large goiters with great clarity. Coronal and sagittal images provide a simultaneous view of the cervical and thoracic components of substernal goiters. The relation of the goiter to surrounding vessels in the mediastinum is also well visualized.

Recurrent neoplasms in the thyroid bed or regional lymph nodes can be detected with MRI. MRI is more accurate than palpation and comparable in accuracy to CT. Recurrence is characterized by a mass with low to medium intensity on T1-weighted images and medium to high signal intensity on T2-weighted images. Conversely, scar tissue or fibrous tissue has low signal intensity on both T1-weighted and T2-weighted images. Tumor invasion of adjacent skeletal muscle has high signal intensity on T2-weighted images. Edema or inflammation in the muscle can cause a similar appearance and can be difficult to differentiate from recurrent tumor.
Positron Emission Tomography

Positron emission tomography (PET) is a special nuclear medical imaging technique that is both quantitative and tomographic. The radionuclide used emits a positron that is converted into a pair of photons after a short path of a few millimeters in the tissue. The coincidence detection of the two photons, which travel on a line in opposite directions, permits the localization of the site of the radionuclide decay.

The agent most widely used with PET is $^{18}$F-fluorodeoxyglucose ($^{18}$FDG). This agent is transported and phosphorylated as a glucose substitute but remains metabolically trapped inside tumor cells because of its inability to undergo glycolysis.

PET scanners with a large field of view permit in vivo images related to regional glucose metabolism, with high sensitivity and a spatial resolution less than 5 mm. Superimposition of CT and PET images greatly improves both the sensitivity and specificity of the technique and the anatomic localization of any focus of abnormal uptake. Elevated glucose metabolism is present in most malignant tumor tissues, and PET scanning has been shown to be particularly useful for the detection of lymph node metastases in the neck or mediastinum in patients with papillary and follicular thyroid carcinoma who have no tumoral radioiodine uptake. High uptake has also been observed in several thyroid diseases, such as thyroiditis, but PET cannot be used to differentiate benign from malignant thyroid nodules.
The clustering of goiters within families.

The persistence of goiters in areas where a widespread iodine prophylaxis program has been properly implemented.

Pathogenesis and Pathophysiology

Goiter has been traditionally regarded as the adaptive response of the thyroid follicular cell to any factor that impairs thyroid hormone synthesis. This classic concept no longer appears to encompass the many aspects of goiter. Indeed, goiter is characterized by a variety of clinical, functional, and morphologic presentations, and whether this heterogeneity represents different entities remains to be clarified. Also, iodine deficiency as the sole factor responsible for goiter appears to be an oversimplification. Thus, not all inhabitants in an iodine-deficient region develop goiter; moreover, endemic goiter has been observed in countries with no iodine deficiency, and even with iodine excess, and has not been observed in some regions with severe iodine deficiency.

The role of genetic factors is suggested by several lines of evidence, such as

1. The clustering of goiters within families.
2. The higher concordance rate for goiters in monozygotic than in dizygotic twins.
3. The female/male ratio (1.1 in endemic versus 7.1 to 9.1 in sporadic goiters).
4. The persistence of goiters in areas where a widespread iodine prophylaxis program has been properly implemented.

By studying families affected by goiter, researchers have been able to detect several gene abnormalities involving proteins related to thyroid hormone synthesis, such as mutations in thyroid globulin (Tg), sodium/iodide symporter (NIS), thyroid peroxidase (TPO), pendrin syndrome (PDS), and TSH receptor (TSHR) genes. In addition, two loci for this disorder have been identified. The first locus, identified on chromosome 14q, was designated MNG1 (Online Mendelian Inheritance in Man [OMIM] 138800) for multinodular goiter; the other, MNG2 (OMIM 300273), maps to chromosome Xp22. Although an autosomal dominant inheritance has been demonstrated in several families, multiple genes may be involved in other families. This may explain why predisposing gene alterations remain unidentified in most patients with simple goiter. Such genetic predispositions are believed to cause abnormalities in thyroid hormone synthesis. Thus, in some cases, defects can be detected by abnormalities of perchlorate discharge (see Chapter 10); more often, however, no abnormality can be demonstrated.

Goiter should thus be regarded as a complex trait in which both genetic susceptibility and environmental factors probably contribute to the development of disease. Whereas iodine deficiency represents the main environmental factor in the genesis of endemic goiter, other factors, such as cigarette smoking, infections, drugs, and goitrogenic factors, may play a role in the genesis of goitrous disease together with a genetic background of susceptibility. Interestingly, in a population-based twin study, a critical role of the genetic background in the etiology of goiter was demonstrated in females.

TSH has long been considered the major agent determining thyroid growth in response to any factor that impairs thyroid hormone synthesis. When such factors are operative, hypersecretion of TSH stimulates thyroid growth and increases the aspects of hormone biosynthesis that are capable of response. As a consequence of the increase in thyroid mass and functional activity, a normal rate of hormone secretion is restored and the patient is goitrous but eumetabolic. Indeed, in the rare clinical setting of functioning pituitary tumor, the increased blood TSH levels typically cause an enlargement of the thyroid gland.

It is interesting that goiter is also a typical part of the clinical picture of Graves’ disease, in which a stimulatory growth effect on thyroid tissue is induced by thyroid-stimulating antibody through TSHR activation. Moreover, thyroid enlargement may appear during the course of Graves’ disease when increased TSH levels result from overtreatment with antithyroid drugs. In addition, toxic thyroid hyperplasia is usually present in non-autoimmune autosomal dominant hyperthyroidism, a disorder related to germ lineactivating mutations of the TSHR gene. This clinical condition further emphasizes the role of TSH-TSHR system activation in the genesis of thyroid hyperplasia in diffuse nontoxic or toxic goiter.

This concept of the pathogenesis of nontoxic goiter is inconsistent with the fact that the serum TSH concentration is normal in most patients with nontoxic goiter. Nonetheless, a participatory role of TSH in the maintenance of goiter is indicated by the regression of goiter that sometimes follows administration of suppressive doses of thyroid hormone.

Several possible mechanisms may accommodate these apparently divergent findings. The mechanism with experimental support in rats is that iodine depletion enhances the promotion of thyroid growth by TSH. Hence, any factor that impairs intrathyroidal iodine levels may lead to gradual development of goiter in response to normal concentrations of TSH.

A second possibility is that the increase in serum TSH concentration is significant but too small to be detected by immunoassay methods.

Finally, a goitrogenic stimulus may have been present in the past but may no longer be detectable at the time of study. Thus, the residual normal TSH concentration can maintain but not initiate goiter. However, this primary, if not exclusive, role for TSH in determining thyroid growth and hyperplasia has been challenged.

Indeed, a complex network of both TSH-dependent and -independent pathways directs thyroid follicular cell growth and function and plays a role in the goitrogenic process. In particular, a variety of growth factors, derived either from the blood stream or through autocrine or paracrine secretion, may serve to regulate thyroid cell proliferation and differentiation processes. Among these factors, epidermal growth factor (EGF) and insulin-like growth factor (IGF) have been recognized as thyroid growthpromoting substances in different species.

IGF-I stimulates cell proliferation and differentiation (i.e., thyroglobulin expression) in thyroid tissue both in vitro and in vivo. Indeed, enhanced IGF-I expression may play a role in the goitrogenic process. In this regard, it is worth emphasizing that acromegalic patients with elevated levels of serum growth hormone and IGF-I and normal TSH levels have an increased prevalence of goiter. Similarly, fibroblast growth factor (FGF) stimulates thyroid function, and its expression has been associated with thyroid hyperplasia. Interestingly, the proliferation effect of these growth factors also occurs through stimulation of their respective receptors in normal TSH levels have an increased prevalence of goiter.

In the propylthiouracil-induced goiter in the rat, Wollman and colleagues recognized the importance of the development of new blood vessels in goiter formation and demonstrated that growth of perfusible blood vessels was induced by angiogenic factors produced by follicular cells. Indeed, many molecules involved in promoting or inhibiting thyroid angiogenesis, including vascular endothelial growth factor, angiopoietins 1 and 2, hepatocyte growth factor, endothelin, angiogenin or thrombospondin, angiostatin, and endostatin, have now been identified.

Goitrogenesis, therefore, appears to be a complex process in which TSH, growth factors, and angiogenic substances either play a distinct and separate role or act
synergistically through complex interaction mechanisms.

Another pathogenetic concept is based on autoradiographic and clinical studies of normal thyroid tissue and nontoxic and toxic multinodular goiters. Early in the course of goiter formation, areas of microheterogeneity of structure and function are intermixed and include areas of functional autonomy and small areas of focal hemorrhage. Indeed, as judged from the presence of scattered foci of persistent radioactive uptake in the thyroid glands of patients given suppressive doses of thyroid hormone before surgery, some cells with functional autonomy are present in the normal thyroid gland; this is in accordance with the heterogeneous staining for NIS observed in normal thyroid and goitrous tissues. Thus, in addition to the variability in thyroid microcirculation, heterogeneity may result from clonal differences among cells that give rise to thyroid follicles, some being more and some less responsive to external stimulation factors, including TSH, and others being autonomous from the outset. This concept implies that the anatomic and functional heterogeneity observed within the thyroid at the outset of the disease is exaggerated by prolonged stimulation.

Further insights into the pathogenesis of sporadic multinodular goiter have been gained by assessment of the clonality of individual thyroid nodules. Polyclonality implies a multicellular origin related to the proliferation of a group of cells, whereas a monoclonal tumor is thought to be formed by expansion of a single cell. Studies involving X-chromosome inactivation analysis have produced variable results in multinodular goiters. Some dominant nodules are monoclonal, especially if they showed evidence of recent rapid growth. Other researchers have found a monoclonal pattern in only a minority of large nodules.

Two groups reported that in multinodular glands more than one nodule can be monoclonal, and both monoclonal and polyclonal nodules can coexist within the same gland. Analysis of hyperplastic nodules by rigid criteria also indicated that morphologically indistinguishable hyperplastic thyroid nodules may be either monoclonal or polyclonal. Monoclonal adenomas within hyperplastic thyroid glands may reflect a stage in progression along the hyperplasia-neoplasia spectrum; accumulation of multiple somatic mutations may subsequently confer a selective growth advantage to this single-cell clone.

Cytogenetic and in situ hybridization studies also support the idea of a biologic continuum and karyotypic evolution between hyperplastic nodules and true follicular adenomas.

Eventually, the amount of functionally autonomous tissue in a multinodular goiter may be sufficient to suppress TSH secretion. Ultimately, autonomous hyperfunction may be sufficient to produce subclinical or overt thyrotoxicosis, or thyrotoxicosis may supervene when the patient is exposed to an iodine load. For this reason, patients with nontoxic multinodular goiter should not be given medications that contain iodine and should be observed after radiologic procedures that involve administration of iodinated contrast media. Some investigators administer antithyroid agents to patients with nodular goiter who are to receive agents containing iodine. This is a reasonable suggestion, especially in areas of iodine deficiency where iodbasedow is likely to occur.

Nontoxic goiter has a female preponderance (7:1 to 9:1) and seems to be common during adolescence or pregnancy. There appears to be no physiologic increase in thyroid volume during normal adolescence, and development of a goiter during adolescence is a pathologic rather than a physiologic process. However, as evidenced by sonographic measurement of thyroid volume in women living in an area of moderate iodine intake, normal pregnancy is goitrogenic, especially in women with preexisting thyroid disorders. The increased thyroid volume during pregnancy is associated with biochemical features of thyroid stimulation (i.e., an increased triiodothyronine/thyroxine [T3/T4] ratio) owing to slightly elevated serum TSH levels at delivery or a high human chorionic gonadotropin (hCG) concentration during the first trimester. Repeated pregnancies may play a role in the development of later thyroid disorders, a relation that might explain the high prevalence of thyroid disorders in women.
Pathology

Simple goiter is a noninflammatory, non-neoplastic, diffuse or nodular enlargement of the thyroid gland without hyperthyroidism. The gland is usually large and may have a distorted shape (Fig. 13-3). The cut surface shows areas of nodularity, fibrosis, hemorrhage, and calcification. The nodules vary in size, number, and appearance, the last according to their colloid or cellular content. Single or multiple cystic areas may contain colloid or brown fluid, representing previous hemorrhage.

Histologically, nodules contain irregularly enlarged, involuted follicles distended with colloid or clusters of smaller follicles lined by taller epithelium and containing small colloid droplets. These microfollicles may be surrounded by an edematous or a fibrous stroma. Large nodules tend to compress the surrounding parenchyma and may have a partially developed fibrous capsule. Markedly distended follicles may coalesce to form colloid cysts several millimeters in diameter.

The nodules tend to be incompletely encapsulated and are poorly demarcated from and merge with the internodular tissue, which also has an altered architecture. However, the nodules in some glands appear to be localized, with areas of apparently normal architecture elsewhere. Here, the distinction from a follicular adenoma may be difficult, and some pathologists apply terms such as colloid or adenomatous nodules to such lesions. Studies of clonality may be helpful in distinguishing between focal or nodular hyperplasia and true adenomas. Whereas nodular goiters are polyclonal in origin, solitary thyroid nodules are monoclonal and therefore true benign neoplasms.
Clinical Picture

Diffuse or nodular goiters are usually not associated with abnormal thyroid hormone secretion. Therefore, affected patients do not exhibit clinical symptoms or signs of thyroid dysfunction. The only clinical features of nontoxic goiter are those of thyroid enlargement. Nearly 70% of patients with sporadic nontoxic goiter complain of neck discomfort; the remainder have cosmetic concerns or a fear of possible malignancy.

Large goiter, which may displace or compress the trachea, esophagus, and neck vessels, can be associated with symptoms and signs including inspiratory stridor, dysphagia, and a choking sensation. These obstructive symptoms may be accentuated by the so-called Pemberton maneuver. This maneuver, which consists of "elevating both arms until they touch the sides of the head," is considered positive if, after a minute or so, congestion of the face, some cyanosis, and lastly distress become apparent. Compression of the recurrent laryngeal nerve, with hoarseness, suggests carcinoma rather than nontoxic goiter, but vocal cord paralysis can occasionally result from benign nodular goiters. Hemorrhage into a nodule or cyst produces acute, painful enlargement locally and may enhance or induce obstructive symptoms.

Endogenous subclinical thyrotoxicosis caused by autonomously functioning nodules should be carefully investigated. It is particularly relevant in elderly patients, whose cardiac morphology and function may be affected, thereby increasing their risk of developing cardiac arrhythmias.
Laboratory Tests

Serum TSH, measured in a highly sensitive immunometric assay, combined with a single measurement of free thyroid hormone concentrations may be used as a first-line screening test. Serum free thyroid hormones and TSH are, by definition, within the normal range. However, the T₃/T₄ ratio may be increased, perhaps reflecting defective iodination of Tg. Patients with sporadic nontoxic goiter tend to have high-normal free T₄ and T₃ concentrations and low TSH levels. The prevalence of so-called subclinical hyperthyroidism is higher when patients with nodular goiter have clear-cut autonomous areas on scintigraphy.

An undetectable serum TSH, even associated with normal free thyroid hormone levels, should suggest the possibility of toxic, autonomously functioning nodular areas in the goiter. Such a finding should prompt further cardiac investigation, especially in elderly patients, whose risk of atrial fibrillation may be increased as much as threefold when serum TSH levels are less than 0.1 mU/L. Moreover, it has been demonstrated that this condition, by affecting cardiac morphology and function, has a relevant clinical impact even in young patients and that many patients are, in fact, symptomatic. Therefore, this disorder should be considered a mild form of tissue thyrotoxicosis that may necessitate treatment.

In a cross-sectional study of 102 patients with sporadic nontoxic goiter, the serum TSH level correlated negatively with the thyroid volume, which in turn correlated positively with both the age of the patient and the duration of the goiter. In a prospective study of 242 patients with nodular goiter, no correlation was found between thyroid volume and any thyroid biochemical parameters, but there were significant negative correlations between the number of nodules identified by ultrasonography and the levels of basal TSH and the TSH response to thyrotropin-releasing hormone (TRH) stimulation.
Imaging in Goiter Evaluation

A diagnosis of goiter usually does not warrant the use of imaging procedures. When a nodular goiter is present, however, both scintigraphy and sonography provide useful information for disease management and treatment. Indeed, the former should be used to detect hot or warm nodules in the thyroid tissue. This finding affects the therapeutic approach. Sonography should be used to assess both morphology and size of the goiter. Thus, sonography in patients with a nodular goiter may allow a determination of the number and the individual features of the nodules and serve as guidance for FNAB. Sonography also permits an accurate, objective measure of goiter growth over time or after treatment.

Conventional radiography of the neck and the upper mediastinum should be used to determine the presence of tracheal compression. CT and MRI are indicated in the presence of intrathoracic goiter to define the relationships with surrounding structures.
Differential Diagnosis

The differential diagnosis of nontoxic goiter can be considered in functional and anatomic terms. As indicated, the same factors that lead to goitrous hypothyroidism can, if they are less severe, cause nontoxic goiter. Consequently, some patients with putative nontoxic goiter are slightly hypothyroid. On the other hand, foci of autonomous function may develop in multinodular goiters in which the spectrum of function can range from clinical euthyroidism with intact regulatory control to euthyroidism with some degree of functional autonomy to thyrotoxicosis. [76]

Anatomically, the diffuse stage of nontoxic goiter can resemble the thyroid of either Graves’ or Hashimoto’s disease. If Graves’ disease is not in an actively thyrotoxic phase, and if the ocular manifestations are lacking, there is no way to distinguish between the two except to demonstrate the presence of TSHR antibody in the serum. In one study of 108 patients with diffuse nontoxic goiter observed for more than 5 years, 33% had a family history of autoimmune thyroid disease and five patients developed Graves’ disease during follow-up. [77] Diffuse nontoxic goiter is sometimes also difficult to differentiate from Hashimoto’s disease, although the thyroid of Hashimoto’s disease is usually firmer and more irregular. Demonstration of high titers of antithyroid antibodies should indicate autoimmune disease.

In its multinodular stage, nontoxic goiter may suggest thyroid carcinoma. The approach to distinguishing between the two is discussed in the following section on thyroid neoplasms.
Treatment

Patients with small, asymptomatic goiters can be monitored by clinical examination and evaluated periodically with ultrasound measurements. In fact, goiter growth can be variable, and some patients have stable goiters for many years.

For more than a century, thyroid "feeding" has been employed to reduce the size of nontoxic goiters. The 1953 report of Greer and Astwood, in which two thirds of patients' goiters regressed with thyroid therapy, led to widespread acceptance of suppressive therapy despite some doubts about the value of such therapy. An overview of studies performed from 1960 to 1992 suggested that 60% or more of sporadic nontoxic goiters respond to suppressive therapy. In a prospective placebo-controlled, double-blind randomized clinical trial, 58% of the thyroxine-treated group had a significant response at 9 months, as measured by ultrasonography, in contrast with 5% after placebo. However, ultrasonographic measurement of goiter size demonstrated a return to pretherapy values within 3 months of treatment discontinuation.

Therefore, maintenance of the size reduction may require continuous long-term treatment. Nodular goiters appear to be less responsive than diffuse goiters, and the therapeutic efficacy of thyroxine treatment is increased in younger patients and in those with small or recently diagnosed goiters.

It has been proposed that a basal serum TSH greater than 1 mU/L in a patient with sporadic nontoxic goiter is an indication to administer levothyroxine to lower the serum TSH level to the low-normal range (0.5 to 1.0 mU/L). Others have suggested that TSH levels on treatment should be subnormal but not profoundly suppressed (0.1 to 0.3 mU/L). The validity of this approach remains to be ascertained. If the goiter size decreases or remains stable, treatment should be continued indefinitely, with periodic monitoring of serum TSH levels to detect possible development of functional autonomy.

A major concern in relation to long-term thyroxine suppression therapy is the possibility of detrimental effects on the skeleton and heart. It has been reported that TSH suppression therapy is associated with variable degrees of bone loss, particularly in postmenopausal women. However, other studies did not demonstrate significant change in bone mass after long-term thyroxine therapy. Furthermore, although marginal cardiac changes may occur with levothyroxine therapy, there is no evidence that levothyroxine per se is detrimental to the heart. It is now generally accepted that TSH should be suppressed with the lowest effective dose of levothyroxine, usually between 1.5 and 2.0 μg/kg body weight per day; the risk of deleterious effects may be minimized by monitoring serum TSH and free T<sub>4</sub> concentrations.

Surgery for simple nontoxic goiter is physiologically unsound because it further restricts the ability of the thyroid to meet hormone requirements. Nevertheless, surgery may become necessary because of persistence of obstructive manifestations despite a trial of levothyroxine. Surgery, which should consist of a near-total or total thyroidectomy, rapidly and effectively removes the goiter, but recurrence is seen in about 10% to 20% within 10 years. Surgical complications have been reported in 7% to 10% of cases and are more common with large goiters and with reoperation. Prophylactic treatment with levothyroxine after goiter resection probably does not prevent recurrence of goiter.

Traditionally, the role of <sup>131</sup>I therapy for nontoxic goiter was to reduce the size of a massive goiter in elderly patients who were poor candidates for surgery or to treat goiter that recurs after resection. However, several studies have demonstrated that primary treatment of multinodular goiter with <sup>131</sup>I is followed by a reduction in thyroid volume.

![Figure 13-4 Median changes in thyroid volume alterations after iodine 131 treatment in 39 patients with nontoxic multinodular goiter who remained euthyroid after a single dose. Bars represent quartiles. (From Nygaard B, Hegedus L, Gervil M, et al. Radioiodine treatment of multinodular nontoxic goiter. BMJ 1993; 307:828832.)](image)

A randomized trial comparing levothyroxine therapy with radioactive iodine treatment (120 μCi/g corrected for 24-hour thyroid uptake) showed impressive differences in outcome. After <sup>131</sup>I therapy, 97% of patients responded, with a mean decrease in goiter size of 39% at 1 year and 48% at 2 years; the initial side effects were neck tenderness and slight thyrotoxic symptoms in 12% of patients, and at 2 years 35% of patients were hyperthyroid and 10% had subclinical thyrotoxicosis. In contrast, with levothyroxine therapy 43% of patients responded with a mean decrease of 23% at 1 year and 22% at 2 years; the initial side effect was a mild thyrotoxicosis in 30% of patients and at 2 years a significant decrement in spine bone density.

It was formerly argued that treatment of large goiters or goiters with substernal extension with <sup>131</sup>I should be avoided because of the risks of acute swelling of the gland and consequent tracheal compression. Ultrasonographic studies of thyroid volume after <sup>131</sup>I have failed to demonstrate significant early volume increase. Moreover, decreased tracheal deviation and increased tracheal lumen size were demonstrable by MRI in patients who had compression by nontoxic goiters with substernal extension.

Therefore, it appears that <sup>131</sup>I treatment of nontoxic multinodular goiter is effective and safe, but hypothyroidism may occur in 22% to 40% within 5 years after <sup>131</sup>I therapy. Regular follow-up, preferably by a systematic annual recall scheme, is necessary. Although reassuring data are available on the long-term thyroid and nonthyroidal cancer risk after <sup>131</sup>I treatment in hyperthyroidism, the follow-up of patients with <sup>131</sup>I-treated nontoxic goiters is short-term and involves small numbers of patients. Children and adolescents should not be treated with <sup>131</sup>I. Stimulation with low doses of recombinant human TSH (rTSH) (0.01 to 0.03 mg) increases the thyroid <sup>131</sup>I uptake and therefore may allow the administration of a lower dosage of <sup>131</sup>I. Long-term randomized studies comparing the effects, side effects, and costs and benefits of surgery and <sup>131</sup>I treatment need to be performed.
THYROID NEOPLASIA

In an era when patients are advised on self-examination to detect cancer at an early stage, the finding of a palpable mass in such a superficial location as the thyroid gland can be disconcerting. The affected patient is likely to seek medical evaluation. At the end of an appropriate investigation, the clinician can usually reassure the patient that the nodule is benign. Alternatively, if the evaluation does suggest malignancy, the patient can be advised that the management of typical thyroid cancer is effective and usually consists of surgical resection, followed by medical therapy and regular surveillance. The major challenge in this circumstance is to determine whether the discovered thyroid nodule is malignant.

Some degree of consensus has been achieved with regard to both the initial evaluation of nodular thyroid disease and the management of differentiated thyroid cancer. But important clinical and biologic questions remain unanswered. In the following discussion, we describe a clinical approach to nodular thyroid disease and present a widely used scheme for classifying and staging tumors of the thyroid gland. We also review the features of the principal types of benign and malignant thyroid neoplasms and the controversies in the management of differentiated thyroid carcinoma.

Initial Investigation

Thyroid tumors are the most common endocrine neoplasms. They usually arise as anterior neck nodules that usually can be localized to the thyroid gland by palpation. Most of these nodules are benign hyperplastic (or colloid) nodules or benign follicular adenomas, but about 5% to 10% of nodules coming to medical attention are carcinomas. Differentiating true neoplasms from hyperplastic nodules and distinguishing between benign and malignant tumors are major challenges.

Moreover, with the widespread practice of medical checkups in healthy individuals and the increasing use of imaging technology, this problem is likely to become more common. High-resolution ultrasound studies suggest that the prevalence of nodular thyroid disease in healthy adults is above 60%. However, during 2001 in the United States, only about 19,500 new cases of thyroid cancer were likely to be diagnosed. Therefore, most of these so-called thyroid incidentalomas are obviously benign and do not progress to clinical tumors.

In identifying the nodules that are likely to be malignant, a thorough history and a careful physical examination should be supplemented with laboratory testing, imaging procedures, and, most important, FNAB of the nodule in question. With the use of this approach, it is possible to assess the likelihood of malignancy and to advise appropriate treatment in the majority of patients.

History and Physical Examination

Historical features that favor benign disease include the following:

1. A family history of Hashimoto's thyroiditis, benign thyroid nodule, or goiter.
2. Symptoms of hypothyroidism or hyperthyroidism.
3. A sudden increase in size of the nodule with pain or tenderness, suggesting a cyst or localized subacutethyroiditis.

Historical features that suggest malignancy include the following:

1. Young (<20 years old) or old (>70 years old) age;
2. Male sex;
3. A history of external neck radiation during childhood or adolescence;
4. Recent changes in speaking, breathing, or swallowing;
5. A family history of thyroid cancer or multiple endocrine neoplasia (MEN) type 2.

On physical examination, manifestations of thyroid malignancy should be sought, including firm consistency of the nodule, irregular shape, fixation to underlying or overlying tissues, and suspicious regional lymphadenopathy.

In both prospective and retrospective studies, the sensitivity and specificity rates for detecting thyroid malignancy by history and physical examination were about 60% and 80%, respectively. In these historical series, only about 20% of patients with later confirmed malignancy had, when initially seen, neither suspicious historical features nor evidence of potential malignancy on neck examination. Further testing may include assessment of thyroid function, measurement of tumor markers, genetic screening, thyroid imaging, and the only decisive parameter, FNAB.

Laboratory Evaluation

The serum TSH level is measured to exclude thyroid dysfunction. Patients with thyroid cancer rarely have abnormalities in serum TSH levels. A low (suppressed) serum TSH level may indicate a toxic nodule and should lead to thyroid scintigraphy. Measurement of serum anti-TPO antibody and anti-Tg antibody levels may be helpful in diagnosis of chronic autoimmune thyroiditis, especially if the serum TSH level is elevated. In chronic autoimmune thyroiditis, the thyroid gland's size and consistency may simulate either a solitary nodule or bilateral nodules. Evidence of autoimmune thyroiditis, however, does not preclude the presence of cancer in the gland.

Follicular cell-derived thyroid cancers (FCTCs) may release increased amounts of Tg into the blood stream. Unfortunately, there is overlap of serum Tg levels in FCTCs and in a number of benign conditions, and measurement of serum Tg levels is not useful in the initial work-up of nodular thyroid disease. Similarly, some investigators routinely measure calcitonin (CI) levels in all patients with nodular thyroid disease to identify cases of MTC. In fact, the calcitonin level is increased in virtually all patients with clinical MTC. However, because of the rarity of unsuspected MTC, the high frequency of false-positive results that may prompt a thyroidectomy despite a reassuring cytologic result, and the unknown clinical relevance of medullary microcarcinomas, it is neither cost-effective nor necessary to determine calcitonin levels in patients with nodular thyroid disease in the absence of clinical suspicion of MTC or abnormal cytologic findings.

The molecular abnormality in more than 95% of familial MTC cases is a germline mutation of the RET proto-oncogene that is located on the long arm of chromosome 10. Many investigators advocate RET mutation testing in all patients with MTC, including apparently sporadic cases, because 4% to 6% of such patients have germline mutations of the gene. Such tests are highly accurate, reproducible, and reliable. If a mutation is found, family members at risk are then tested to identify affected individuals. A negative result obviates the need for any further testing, and individuals who harbor such mutations should undergo prophylactic total thyroidectomy to prevent later development of the multicentric MTC that occurs in this disorder.

Thyroid Imaging

The traditional imaging procedure is thyroid scintigraphy using radiiodine, technetium-99m Tc. Most thyroid carcinomas are inefficient in trapping and organifying iodine and appear on scans as areas of diminished isotope uptake, so-called cool or cold nodules. Unfortunately, most benign nodules also do not concentrate iodine and therefore are cold nodules. Furthermore, not all nodules with normal or slightly increased uptake are benign and may appear cold on a thyroid scan with radioactive iodine.

The only situation in which an iodine scan can exclude malignancy with reasonable certainty is in the case of a toxic adenoma, which is characterized by significantly
increased uptake within the nodule and markedly suppressed or absent uptake in the remainder of the gland. These lesions account for fewer than 10% of thyroid nodules and are almost invariably benign.\(^{138}\) When isotopic thyroid scanning is compared with history and physical examination, most authors have found scanning to be of negligible or no value for the diagnosis of malignancy.\(^{139,140}\)

In an attempt to improve the performance of isotopic scanning, a number of radioisotopes other than iodine-related compounds have been tried, such as thallium 201 (\(^{201}\)Tl)\(^{12,13}\) and \(^{99m}\)Tc-labeled methoxysobutyl isonitrile (MIBI). In the hands of dedicated experts, these techniques may be valuable, but they are expensive and their widespread use must await more extensive evaluation.

Ultrasonography is capable of detecting even minute thyroid nodules and increases the sensitivity of carcinoma detection but does little to enhance specificity. In fact, of 1000 normal control subjects, 65% had detectable nodularity on high-resolution scanning.\(^{141}\) Attempts have been made to develop criteria for distinguishing benign and malignant nodules. Echo-free (cystic) and homogeneously hyperechoic lesions are reputed to carry a low risk of malignancy.\(^{12,142}\) Positive predictive criteria of malignancy include solid hypoechoic nodules, presence of calcifications, irregular shape, absence of halo, and absence of cystic elements; however, in one study only 64% of malignant nodules displayed patterns typical of malignancy.\(^{143}\) In addition, nodules that can be clearly identified as benign by sonography are uncommon, limiting the usefulness of ultrasound scanning.

Ultrasonography is useful in identifying hypoechoic nodules that should be submitted to FNAB and also in examining the rest of the thyroid gland and lymph node areas.\(^{144}\) It may also be used in case of nonpalpable nodules to guide FNAB, especially when the diameter of the nodule is 1 cm or more.\(^{12,145}\) Cystic lesions may be recognized by aspiration of the fluid and ethanol injection to avoid recurrence; this is optimally performed under ultrasonographic guidance.\(^{146}\)

CT scanning and MRI in the initial diagnosis of thyroid malignancy do not provide higher-quality images of the thyroid and cervical nodes than those of ultrasonography. CT examination of the lower central neck is preferable when tracheal or mediastinal invasion is suspected.

*The suspicious category includes follicular neoplasms (hyperplastic nodules, follicular adenomas, and follicular carcinomas) and some Hurthle cell tumors.

FNAB of thyroid nodules has eclipsed all other techniques for diagnosing thyroid cancer, with reported overall rates of sensitivity and specificity exceeding 90% in iodine-sufficient areas.\(^{12,146}\) The technique is easy to perform and safe, with only a handful of complications having been reported in the literature.\(^{12,147}\) and causes little discomfort. However, care must be taken to obtain an adequate specimen; most authors recommend between three and six aspirations.\(^{12,148}\) A satisfactory specimen contains at least five or six of the 10 to 15 well-preserved cells. The cells are categorized by their cytologic appearances into benign, indeterminate or suspicious, and malignant (Table 13-2).

The diagnosis of PTC by FNAB on the basis of characteristic nuclear changes is particularly reliable and accurate, with sensitivity and specificity both approaching 100%. For follicular neoplasms, however, the performance of FNAB is inferior. If strict criteria for malignancy are used, sensitivity may be as low as 8%.\(^{12,149}\) If any follicular neoplasm that is not clearly benign on cytologic examination is classified as cancerous, sensitivity rises to about 90% or more. Unfortunately, this increase is associated with a considerable drop in specificity to less than 50% (i.e., a large number of false-positive results). This seriously limits the usefulness of FNAB in iodine-deficient regions, where the incidence of thyroid follicular carcinoma (FTC) approaches that of PTC and where both follicular adenomas and hyperplastic adenomatous nodules are prevalent.

TPO immunochemistry with a monoclonal antibody (MoAb 47) shows promise in improving the accuracy of FNAB for follicular lesions.\(^{12,149}\) For 100% sensitivity, a specificity of almost 70% has been achieved with this technique. Pending independent confirmation of these results, TPO immunocytochemistry may be a valuable adjunct to the standard cytologic techniques. The use of large-needle biopsy in addition to standard FNAB has improved diagnostic accuracy in difficult FNA cases.\(^{12,150}\) but the technique is more exacting than FNAB alone and is associated with increased morbidity and, possibly, increased complication rates.

Particularly for cystic thyroid nodules, sampling from the margin of the nodule, rather than from the cystic fluid and debris in the center, increases accuracy.\(^{12,151}\) Ultrasonographically guided FNA can be used for this purpose (Fig. 13-5). Although such guided biopsies are sometimes helpful, routine use of ultrasound-guided biopsy for clinically palpable nodules is not any better than “freehand” aspiration.\(^{12,152}\) However, some centers are evaluating this approach to allow recognition of FNA of nonpalpable nodules 1 cm or smaller in size and to reduce the number of passes to three.\(^{12,153}\)

In some European centers, both preoperative FNAB and intraoperative frozen section are combined in endemic goitrous regions with high rates of follicular tumors.\(^{12,154}\) In the hands of experienced surgeon-pathologist teams, this approach results in less than 5% misdiagnoses, as evidenced by subsequent review of paraffin-embedded specimens. The approach avoids unnecessarily extensive surgery in patients with benign tumors, achieves resection of nearly all malignant tumors, and rarely necessitates a second operation for completion thyroidectomy.\(^{12,155}\) Such an approach is employed at the Mayo Clinic and at the Institut Gustave Roussay, where intraoperative frozen section is routine.

Apart from its limited utility in the evaluation of follicular neoplasms, the only other limitation of FNAB is nondiagnostic specimens, which may be obtained in up to 20% of cases.\(^{12,156}\) Although repeated aspiration increases both the accuracy and the rate of diagnostic aspirations, even repeated attempts may sometimes fail. Many persistently nondiagnostic FNAB specimens may be neoplastic, possibly 50%.\(^{12,154}\) Hence, either close observation or surgical removal of the nodule is probably the best option. Some authorities recommend a trial of TSH suppression, which can sometimes shrink benign nodules.\(^{12,153}\) However, a significant proportion of benign nodules do not shrink, and some carcinomas do shrink; consequently, the diagnostic value of TSH suppression is doubtful. Whether ultrasound-guided FNAB can help overcome this problem is unclear, but confirmation is required.\(^{12,157}\) Figure 13-6 is an algorithm for the management of nodular thyroid disease in which FNAB is the first diagnostic test and subsequent management is based on cytologic results.
The most expeditious way to diagnose thyroid malignancy is to obtain a thorough history and physical examination, followed by FNAB and evaluation of the sample by an experienced cytologist. In some cases, FNAB should be performed under ultrasound guidance. Imaging procedures, in addition to ultrasonography, and other tests may occasionally be helpful, but diagnostic thyroid scintiscanning, as traditionally practiced, is of little or no value and should be abandoned.

In iodine-sufficient areas with a high relative prevalence of PTC, the combination of history and physical examination and FNAB is usually sufficient to confirm malignancy. Conversely, if history and physical examination, FNAB, and ultrasonography do not suggest malignancy, the chances of missing PTC are probably less than 1%. In areas where the prevalence of follicular tumors is higher, more patients may require neck exploration because FNAB may not be conclusive; in experienced hands, however, intraoperative frozen sections can limit the number of unnecessarily extensive, bilateral procedures. Surgery should also be considered for large tumors (>4 cm), especially in young subjects, in order to avoid repeated evaluations; in addition, because these tumors may be composed of various cell populations, results of FNAB may be less reliable. Finally, micronodules less than 1 cm in diameter, found incidentally during imaging, do not need to be tested any further, unless there are sonographic features suggestive of PTC or MTC. The usual advice is to repeat ultrasonography of such lesions after an interval of 6 to 12 months.
Classification of Thyroid Tumors

Histologic Classification

Two monographs have had a major impact on the histologic classification of thyroid tumors. One is from the World Health Organization (WHO),[147] the other, from the Armed Forces Institute of Pathology (AFIP).[148] The classification described in Table 13-3 is modified from the guidelines described by these organizations.[147][148]

Lesions of follicular cell origin constitute more than 95% of the cases, and the remainder are largely made up of tumors exhibiting C cell differentiation.[149] Mixed medullary and follicular carcinomas, made up of cells with both C-cell and follicular differentiation, are rare and of uncertain histogenesis.[147] Nonepithelial thyroid tumors mainly include malignant lymphomas, which may involve the thyroid gland as the only manifestation of the disease or as part of a systemic disease. True sarcomas and malignant hemangioendotheliomas are exceptional. Blood-borne metastases to the thyroid are not uncommon at autopsy in patients with widespread malignancy but rarely cause clinically detectable thyroid enlargement.

Staging of Thyroid Carcinoma

In addition to the histologic classification of thyroid tumors developed by WHO and AFIP groups, the International Union Against Cancer (UICC) and the American Joint Committee on Cancer have agreed on a staging system in thyroid cancer.[150]

As stated by the AJCC, “the principal purpose served by international agreement on the classification of cancer cases by extent of disease was to provide a method of conveying clinical experience to others without ambiguity.”[150]

The AJCC based its system of classification on the TNM system, which relies on assessing three components: (1) extent of the primary tumor (T), (2) absence or presence of regional lymph node metastases (N), and (3) absence or presence of distant metastases (M).

The TNM system allows a reasonably precise description and recording of the anatomic extent of disease. The classification may be either clinical (cTNM), based on evidence (including biopsy) acquired before treatment, or pathologic (pTNM), by which intraoperative and surgical pathology data are available. Obviously, pTNM classification is preferable because a precise size can be assigned to the primary tumor, the histo-type is identified, and extrathyroid invasion is demonstrated unequivocally.

Typically, the primary thyroid tumor (T) status is defined according to the size of the primary lesion:

T1, greatest diameter 1 cm or smaller

* T, size of primary thyroid tumor (T1, 1 cm; T2, >1 cm; T3, >4 cm; T4, extrathyroid invasion); N, regional nodal metastases (0, absent; 1, present); M, distant metastases (0, absent; 1, present).
A thyroid tumor with four degrees of T, two degrees of N, and two degrees of M can have 16 different TNM categories.

For purposes of tabulation and analysis, these categories have been condensed into a convenient number of TNM stage-groupings (Table 13-4). Whereas head and neck cancer is usually staged entirely on the basis of anatomic extent, in thyroid cancer staging both the histologic diagnosis and the age of the patient for PTC and FTC are included because of their importance in predicting the behavior and prognosis of thyroid cancer.

According to this staging scheme, all patients younger than age 45 years with PTC or FTC are in stage I, unless they have distant metastases (DM), in which case they would be in stage II. In young patients and especially in children, the risk of recurrence is high and may be underestimated by the TNM staging system. Older patients (aged 45 years or more) with node-negative papillary or follicular microcarcinoma (T1 N0 M0) are in stage I. Tumors between 1.1 and 4.0 cm are classified as stage II, and those with either nodal spread (N1) or extrathyroidal invasion (T4), stage III.

For MTC, the scheme is similar, in that microcarcinoma is stage I and a node-positive tumor is stage III. There is no age distinction for MTC, although age is a significant independent prognostic indicator in most multivariate analyses, and local (extrathyroidal) invasion is grouped within stage II. For patients with MTC and older patients with PTC or FTC, stage IV denotes the presence of DMs. Independent of age or tumor extent, all patients with undifferentiated (anaplastic) cancer are considered to be in stage IV.
Follicular Adenoma

Follicular adenoma is a benign, encapsulated tumor with evidence of follicular cell differentiation. It is the most common thyroid neoplasm and may be found in 4% to 20% of glands examined at autopsy. The tumor has a well-defined fibrous capsule that is grossly and microscopically complete. There is a sharp demarcation and distinct structural difference from the surrounding parenchyma. These adenomas vary in size, but most have a diameter of 1 to 3 cm at the time of excision. Degenerative changes, including necrosis, hemorrhage, edema, fibrosis, or calcification, are common features, particularly in larger tumors.

Follicular adenomas can be classified into subtypes (Table 13-5) according to the size or presence of follicles and degree of cellularity. Each adenoma tends to have a consistent architectural pattern. Microfollicular, normofollicular, and macrofollicular adenomas owe their names to the size of their follicles compared with follicles in the neighboring, non-neoplastic areas of the gland. Trabecular adenomas are cellular and consist of columns of cells arranged in compact cords. They show little follicle formation and rarely contain colloid. A variant, the hyalinizing trabecular adenoma, has unusually elongated cells and prominent hyaline changes in the extracellular space.

The histologic differences between these subtypes are striking but of no clinical importance. The only practical value of the classification is that the more cellular a follicular nodule is, the more one should search for evidence of malignancy in the form of invasion of blood vessels and capsule, either singly or in combination. Atypical adenomas are hypercellular or heterogeneous, or both, with gross and histologic appearances.

Figure 13-7 Genetic events in thyroid tumorigenesis. Activating point mutations of the RAS genes are found with a similar frequency in follicular adenomas and follicular carcinomas and are considered an early event in follicular tumorigenesis. The PPAR-PAX8 rearrangement was found only in follicular carcinomas. Rearrangements of transmembrane receptors with tyrosine kinase activity (RET, TRK genes) are found only in papillary thyroid carcinomas. Inactivating point mutations of the P53 gene are found only in poorly differentiated and anaplastic thyroid carcinomas. Activation of the cyclic adenosine monophosphate pathway, by point mutation of the thyrotropin receptor (TSH-R) or the subunit of the G protein genes, leads to the appearance of hyperfunctioning thyroid nodules. Gs stimulatory guanylyl nucleotide protein.

that suggest the possibility of malignancy but not invasion. They account for fewer than 3% of all follicular adenomas. Follow-up indicates that this lesion behaves in a benign fashion. The fact that the tumor does not recur or produce metastases after removal does not prove that it is actually benign; removal may have interrupted a natural history that would have culminated in invasion and metastases.

The most important cytologic variant is the oxyphilic or oncocytic (Hürthle cell) adenoma, which is composed predominantly (at least 75%) or entirely of large cells with granular, eosinophilic cytoplasm. Ultrastructurally, the cells are rich in mitochondria and may exhibit nuclear pleomorphism with distinct nucleoli. Although all such neoplasms are thought by some to be potentially malignant, the biologic behavior and clinical course of oncocytic tumors correlate closely with the histology and the size of the initial lesion. The absence of invasion predicts a benign outcome, but larger tumors may rarely be associated with later recurrence or metastases, even in the absence of obvious microscopic evidence of invasion; fortunately, such an occurrence is extremely rare, and generally a diagnosis of benign Hürthle cell adenoma can be reliable. Some normofollicular adenomas may contain pseudopapillary structures that can be confused with the papillae of papillary carcinoma. These structures are probably an expression of localized hyperactivity and are most common in adenomas that show autonomous function.

In the majority of hyperfunctioning follicular adenomas, activating point mutations have been identified in the TSHR or in the subunit of the stimulatory guanyl nucleotide protein (Gαs). Such mutations may impair guanosine triphosphatase (GTP) activity, trapping the G protein in a state of constitutive activation, resulting in enhanced cyclic adenosine monophosphate (cAMP) production and constitutive hyperstimulation of the cells.
Papillary Thyroid Carcinoma

PTC has been defined as "a malignant epithelial tumor showing evidence of follicular cell differentiation, and characterized by the formation of papillae and/or a set of distinctive nuclear changes." The most common thyroid malignancy, PTC constitutes 50% to 90% of differentiated FCTCs worldwide.

Papillary thyroid microcarcinoma (PTM) is defined by the WHO as a PTC 1 cm in diameter or smaller. The incidence rates for clinically diagnosed PTC in the United States are approximately 5 per 100,000 for tumors larger than 1 cm in diameter and 1 per 100,000 for PTM. By contrast, the incidence of PTM in autopsy material from various continents ranges from 4% to 36.

Typically, PTC shows a predominance of papillary structures, consisting of a fibrovascular core lined by a single layer of epithelial cells, but the papillae are usually admixed with neoplastic follicles having characteristic nuclear features.

The nuclei of PTC cells have a distinctive appearance that has a diagnostic significance comparable to that of the papillae. Indeed, the preoperative diagnosis of PTC can often be made on the basis of the characteristic nuclear changes seen in FNA material. Nuclei are larger than in normal follicular cells and overlap, they may be fissured like coffee beans, chromatin is hypodense (ground glass nuclei), limits are irregular, and they frequently contain an inclusion corresponding to a cytoplasmic invagination.

Several subtypes exist:

1. The tumor is designated a follicular variant of PTC when the lining cells of the neoplastic follicles have the same nuclear features as seen in typical PTC and the follicular predominance over the papillae is complete.
2. The diffuse sclerosing variant is characterized by diffuse involvement of one or both thyroid lobes, widespread lymphatic permeation, prominent fibrosis, and lymphoid infiltration.
3. The tall cell variant is characterized by well-formed papillae that are covered by cells twice as tall as they are wide.
4. The columnar cell variant differs from other forms of PTC because of the presence of prominent nuclear stratification.

Molecular Pathogenesis

The thyroid follicular cell may give rise to both benign and malignant tumors, and the malignancy can be of either papillary or follicular histotype. There is no evidence that benign tumors ever undergo malignant transformation into classic PTC. Structural abnormalities of the chromosomes may occur in about 50% of PTCs, frequently involving the long arm of chromosome 10. The RET proto-oncogene is located on chromosome 10q11-2. It encodes a transmembrane receptor with a tyrosine kinase domain. Its ligands are the glial cell linederived neutrophilic factor (GDNF) and the neurturin, both of which induce protein dimerization. RET activation was first demonstrated in transfusion experiments and has been found only in PTC tumors. It was therefore called RET/PTC.

All activated forms of the RET proto-oncogene are the consequence of oncogenic rearrangements fusing the tyrosine kinase domain of the RET gene with the 5' domain of different genes. The foreign gene is constitutively expressed, and its 5' domain acts as a promoter, resulting in permanent expression of the RET gene. Furthermore, these genes have domains that induce RET activation by permanent dimerization; because of this fusion, the chimeric protein is localized in the cytoplasm and not in the plasma cell membrane.

Three major classes of RET/PTC have been identified:

1. RET/PTC, is formed by an intrachromosomal rearrangement fusing the RET tyrosine kinase domain to a gene designated H4 (D10S170), whose function is still unknown.
2. RET/PTC is formed by an interchromosomal rearrangement fusing the RET tyrosine kinase domain to a gene located on chromosome 17 encoding the RI regulatory subunit of protein kinase A.
3. RET/PTC is formed by an intrachromosomal rearrangement fusing the RET tyrosine kinase domain to a gene designated ELE1, whose function is still unknown.

Several variants of RET/PTC have been observed in post-Chernobyl thyroid tumors, including rearrangements formed by fusing the tyrosine kinase domain of the RET gene at other breakpoint sites or with other partners.

The frequency of RET/PTC rearrangements occurring in PTC patients without prior childhood neck irradiation varies between 2.5% and 35%. In these tumors, the frequencies of RET/PTC and RET/PTC were similar and that of RET/PTC was lower. The RET/PTC rearrangements were more frequently found (in 60% to 80% of cases) in PTC cases occurring either after external irradiation in childhood or in children after the Chernobyl accident. RET/PTC was more frequently found in aggressive tumors that occurred early after permanent dimerization; because of this fusion, the chimeric protein is localized in the cytoplasm and not in the plasma cell membrane.

Several additional oncogenes may occasionally be involved in PTC, including NTRK1 (also named TRKA), which codes for a neural growth factor receptor with a tyrosine kinase domain and which is activated by rearrangement in about 10% of PTCs. The receptor for hepatocyte growth factor is a transmembrane tyrosine kinase encoded by the MET oncogene; it is overexpressed in some patients with PTC, and low expression has been associated with the occurrence of DM.

A high incidence of PTC has been reported in patients with adenomatous polyposis coli and Cowden's disease (the multiple hamartoma syndrome), suggesting that the predisposing genes may play a role in the occurrence of papillary carcinoma. About 3% of cases of PTC are familial; their behavior is similar to or slightly more aggressive than that of nonfamilial cases. The gene predisposing to familial thyroid tumors with cellular oxyphilia has been mapped to chromosome 19q13.2, and in a family with PTC and renal carcinoma a separate gene was mapped to chromosome 1q21.1-2.
Although PTCs can occur at any age, most occur in patients between 30 and 50 years of age (mean age, 45 years). Women are affected more frequently (female predominance, 60% to 80%). Most primary tumors are 1 to 4 cm in size; they average about 2 to 3 cm in greatest diameter. Extrathyroidal invasion of adjacent soft tissues is present in about 15% (range 5% to 34%) at primary surgery, and about one third of PTC patients have clinically evident lymphadenopathy at presentation. About 35% to 50% of excised neck nodes have histologic evidence of involvement, and in patients 17 years of age or younger nodal involvement may be present in up to 90%. Only 1% to 7% of PTC patients have DM at diagnosis. Spread to superior mediastinal nodes is usually associated with extensive neck nodal involvement.

The TNM classification is a widely used system for tumor staging. Most PTC patients present with either stage I (60%) or stage II (22%). Patients aged 45 years or older with either nodal metastases or extrathyroidal extension (stage III) account for fewer than 20% of cases. As already noted, few (1% to 7%) of PTC patients present with DM and have stage IV disease (age 45 years or older with any T, any N, M1). Figure 13-8 (upper left) illustrates the distribution of TNM stages in 2284 PTC cases seen at the Mayo Clinic, and Figure 13-9 demonstrates survival by TNM stage in this cohort of PTC patients treated from 1940 to 1997.

### Recurrence and Mortality

Three types of tumor recurrence may occur with PTC:

- **Postoperative nodal metastases (NM)**
- **Local recurrence (LR)**
- **Postoperative distant metastases (DM)**

LR may be defined as “histologically confirmed tumor occurring in the resected thyroid bed, thyroid remnant, or other adjacent tissues of the neck (excluding lymph nodes)” after complete surgical removal of the primary tumor. Nodal or distant spread may be considered postoperative if the metastases are discovered within 180 or 30 days, respectively. Ideally, tumor recurrence should be considered only as it occurs in patients without initial DM who had complete surgical resection of the primary tumors.

Figure 13-10 illustrates rates of PTC recurrence at local, nodal, and distant sites in 2150 patients with PTC treated at one institution from 1940 to 1997. After 20 years of follow-up, postoperative NM had been discovered in 9%, and LR and DM occurred in 5% and 4%, respectively. Both LR and DM are less common in PTC than in FTC.

Cause-specific mortality (CSM) rates for differentiated thyroid cancer are shown in Figure 13-12. CSM rates for PTC were 2% at 5 years, 4% at 10 years, and 5% at 20 years. Among those with lethal PTC, 20% of deaths occurred in the first year after diagnosis, and 80% of the deaths occurred within 10 years. The 25-year cause-specific survival rate of 95% for PTC was significantly higher than the 79%, 71%, and 66% rates seen with MTC, Hürthle cell cancer (HCC), and FTC, respectively.

### Outcome Prediction

Only a fraction (15%) of patients with PTC are likely to experience relapse of disease, and even fewer (5%) have a lethal outcome. Exceptional patients, who have an aggressive course, tend to experience relapse early (Fig. 13-13), and the rare fatalities usually occur within 5 to 10 years of diagnosis. Multivariate analyses have been used to identify variables predictive of CSM. Increasing age of the patient and the presence of extrathyroidal invasion are independent prognostic factors in all studies. The presence of initial DM, although relevant to future nodal recurrence, does not influence CSM.

Several scoring systems based on these significant prognostic indicators have been devised. Each system allows one to assign the majority of PTC patients (80% or more) to a low-risk
Information obtained at surgery, the system probably should not be used to decide the extent of primary surgery.

Tumor surveillance and the appropriateness of adjunctive radioiodine therapy. Because the CIS (completeness of resection, invasion, and size) variables require information obtained at surgery, the system probably should not be used to decide the extent of primary surgery.
Follicular Thyroid Carcinoma

FTC is "a malignant epithelial tumor showing evidence of follicular cell differentiation but lacking the diagnostic features of papillary carcinoma." Such a definition excludes the follicular variant of PTC, and it is also customary to exclude both the poorly differentiated insular carcinoma and the rare mixed medullary and follicular carcinoma. The correct classification of tumors with predominant oncocyctic features (Hürthle cell carcinomas) is controversial. The WHO committee has taken the stance that this tumor is an oxyphilic variant of FTC. The AFIP monograph, by contrast, states that "the tumors made up of this cell type have gross, microscopic, behavioral, cytogenetic (and conceivably etiopathogenic) features that set them apart from all others and justify discussing them in a separate section." Thus categorized, FTC is a relatively rare neoplasm whose identification requires invasion of the capsule, blood vessel, or adjacent thyroid. In epidemiologic surveys, FTC constituted from 5% to 50% of differentiated thyroid cancers and tended to be more common in areas with iodine deficiency. Owing to a combination of changing diagnostic criteria and an increase in the incidence of FTC associated with dietary iodine supplementation, the diagnosis of FTC has decreased in frequency; in one North American experience, minimally invasive nonoxyphilic FTC made up fewer than 2% of thyroid malignancies.

The microscopic appearance of FTC varies from well-formed follicles to a predominantly solid growth pattern. Poorly formed follicles and atypical patterns (e.g., cribiform) may occur, and multiple architectural types may coexist. Mitotic activity is not a useful indicator of malignancy.

FTC is best divided into two categories on the basis of degree of invasiveness:

- Minimally invasive or encapsulated
- Widely invasive

There is little overlap between these two types.

Minimally invasive FTC is an encapsulated tumor whose growth pattern resembles that of a trabecular or solid, microfollicular, or atypical adenoma. The diagnosis of malignancy depends on the demonstration of blood vessel or capsular invasion, or both. The criteria for invasion must therefore be strict. Blood vessel invasion is almost never seen grossly.

Microscopically, the vessels "should be of venous caliber, be located in or immediately outside of the capsule and contain one or more clusters of tumor cells attached to the wall and protruding into the lumen." Interruption of the capsule must involve the full thickness to qualify as capsular invasion. Penetration of only the inner half of the presence of tumor cells embedded in the capsule does not qualify for the diagnosis of FTC. Foci of capsular invasion must be distinguished from the capsular rupture that can result from FNA. The acronym WHAFFT (worrisome histologic alterations following FNA of the thyroid) is applied to such changes.

In contrast, the rare, widely invasive form of FTC can be distinguished easily from benign lesions. Although the tumor may be partially encapsulated, the margins are infiltrative even on gross examination and vascular invasion is often less. The structural features are variable, with solid and trabecular areas, but a follicular element is always present. When follicular differentiation is poor or absent, the tumor may be classified as a poorly differentiated (insular) carcinoma.

Focal or extensive clear-cell changes can occur. A rare clear cell variant of FTC has been described in which glycogen accumulation or dilatation of the granular endoplasmic reticulum is responsible for the clear cells. When more than 75% of cells in an FTC exhibit Hürthle cell (or oncocytic) features, the tumor is classified as a Hürthle cell or an oncocytic carcinoma or an oxyphilic variant FTC.

Molecular Pathogenesis

There is still no accepted paradigm for the pathogenesis of follicular thyroid cancer. A multistep adenoma-to-carcinoma pathogenesis, similar to that for colon cancer and other adenocarcinomas, is not universally accepted because pathologists do not recognize follicular carcinoma in situ and documentation of the evolution of adenoma to carcinoma is rare. Nevertheless, several facts about the pathogenesis of FTC are firmly established.

First, most follicular adenomas and all FTCs are probably of monoclonal origin. Second, oncogene activation, particularly by point mutation of the RAS oncogene, is common both in follicular adenomas and in FTCs (40%), supporting a role in early tumorigenesis. Such RAS mutations are not specific for follicular tumors and also occur in PTC. The RET oncogene does not appear to be significantly involved in follicular tumors. Third, cytogenetic abnormalities and evidence of genetic loss are more common in FTC than in PTC and also occur in follicular adenomas. Losses in FTC are particularly associated with chromosomes 3, 10, 11, and 17.

Of the cytogenetic abnormalities described in FTC, the most common are deletions, partial deletions, and deletion-rearrangements involving the p arm of chromosome 3. Loss of heterozygosity (LOH) on chromosome 3p appears to be limited to FTC because no evidence for 3p LOH has been found in follicular adenomas or PTC. A translocation, t(2;3)(q13;p25), resulting in the fusion of the deoxyribonucleic acid (DNA) binding domains of the thyroid transcription factor PAX-8 to domains of the peroxisome proliferator-activated receptor (PPAR) 1, was detected in five of eight FTCs but not in follicular adenomas, PTCs, or multinodular hyperplasia. The chimeric protein may retard growth inhibition and follicular differentiation normally induced by PPAR 1.

Presenting Features

FTC tends to occur in older people, with the mean age in most studies being more than 50 years, about 10 years older than that for typical PTC. The average median age of patients with oxyphilic FTC (HCC) is about 60 years. As in most thyroid malignancies, women outnumber men by more than 2 to 1. Most patients with FTC present with a painless thyroid nodule, with or without background thyroid nodularity, and they rarely (4% to 6%) have clinically evident lymphadenopathy at presentation. Lymph node metastases to the neck in FTC are so exceptional that "wherever they are observed, the alternative possibilities of follicular variant papillary carcinoma, oncocyctic carcinoma, and poorly differentiated (insular) carcinoma should be considered."

In most series in which tumor sizes were reported, the average tumor in FTC (oxyphilic or nonoxyphilic) was larger than those seen with PTC. Direct extrathyroidal extension, by definition, does not occur with minimally invasive FTC but is not uncommon in the rare patient with invasive FTC. Between 5% and 20% of patients may have DM at presentation. The most common sites for DM in FTC are lung and bone. The bones most often involved are long bones (e.g., femur), flat bones (particularly the pelvis, sternum, and skull), and vertebrae. When a DM is the first manifestation of the disease, definitive proof of its thyroid origin...
should be obtained, usually by a biopsy of a metastasis, before performing any thyroid surgery. It is unusual for patients with FTC to have thyrotoxicosis caused by massive tumor burden.\footnote{315}

Most patients (53\% to 69\%) with FTC or HCC have pTNM stage II disease. Patients aged 45 years or older with nodal metastases or extrathyroidal extension (stage III) account for only 4\% of FTCs and 9\% of HCCs (see Fig. 13-8).\footnote{217} About 5\% of HCCs and 17\% or more of nonoxyphil FTCs have DM at the time of diagnosis (stage IV).

### Recurrence and Mortality

Nodal metastases are rare in typical FTC, and the nodal recurrence rate at 20 postoperative years is the lowest in differentiated thyroid carcinoma, being around 2\% (see Fig. 13-11).\footnote{221} About 6\% of patients with HCC have node involvement at presentation,\footnote{222} but within 25 years after primary surgery about 17\% of HCC patients have nodal recurrence.\footnote{223} When recurrences at either neck or distant sites are taken into consideration, patients with HCC (Fig. 13-17) have the highest numbers of tumor recurrences after 10 to 20 years. As illustrated by Figure 13-11, local recurrences at 20 years have occurred in 20\% of FTCs and 30\% of HCCs. Comparable DM rates are 23\% and 28\%, respectively.

CSM rates vary with the presenting TNM stage in both FTC (Fig. 13-18) and HCC. The death rates tend to parallel the curves for development of DM (see Fig. 13-11).\footnote{224} In more than five decades of experience at the Mayo Clinic, the mortality rate for FTC initially exceeds that of HCC, but by 20 to 30 postoperative years there are no significant differences in cause-specific survival rates between FTC and HCC (Fig. 13-19), both being around 80\% at 20 and 70\% at 30 postoperative years.\footnote{225}

### Outcome Prediction

The risk factors that predict outcome in FTC are largely the same as in PTC.\footnote{219} DM at presentation, increasing age of the patient, large tumor size, and the presence of local (extrathyroidal) invasion. To a lesser degree, increased mortality is associated with male sex and higher grade (less well-differentiated) tumors. In addition, vascular invasiveness, lymphatic involvement at presentation, DNA aneuploidy, and oxyphilic histology are potential prognostic variables unique to FTC.\footnote{220} The importance of vascular invasion is underscored by a study showing that FTC patients with minimal capsular invasion and no evidence of vascular invasion had 0\% CSM at 10-year follow-up.\footnote{224}

Prognostic scoring systems for FTC\footnote{236} allow stratification of patients into high-risk and low-risk categories. A multivariate analysis at the Mayo Clinic found that DM at presentation, patient's age greater than 50 years, and marked vascular invasion predict a poor outcome.\footnote{226} As illustrated by Figure 13-21, if two or more of these factors are present, the 5-year survival rate is only 47\%, and 20-year survival is 8\%. By contrast, if only one of these factors is present, 5-year survival is 99\%, and 20-year survival is 86\%.\footnote{227}

Systems developed to predict outcome in either PTC or FTC have been applied to FTC patients. Specifically, the pTNM as well as the AMES risk group categorization (age, metastasis, extent, size) is useful in FTC.\footnote{228} From a multivariate analysis of 228 patients with FTC treated at the Memorial Sloan Kettering Cancer Center, the independent adverse prognostic factors were identified as age older than 45 years, Hürthle cell histotype, extrathyroidal extension, tumor size exceeding 4 cm, and the presence of DM.\footnote{229} The prognostic importance of FTC of histologic grade was also confirmed,\footnote{230} and this factor was included in assignment of risk groups to low, intermediate, or high categories (Fig. 13-22).\footnote{231}

The AGES scheme, originally developed for PTC, has also been successfully applied to FTC.\footnote{232} It thus appears that scoring systems used in PTC may be cautiously applied in FTC as long as some of the unique features of this tumor, such as vascular invasiveness and the remarkable significance of DNA aneuploidy in HCC, are kept in mind.\footnote{233}

---

\footnote{219} Comparison of cause-specific survival in 1472 papillary thyroid carcinoma (PTC) and 250 follicular thyroid carcinoma (FTC) patients treated at the Mayo Clinic from 1940 to 1999. Numbers in parentheses represent the number of patients in each pTNM stage grouping.

\footnote{220} Deaths related to HCC occur gradually over the first 15 years; however, by 25 years, the average survivor of HCC is 84 years old, and by that time, almost 50\% of the treated cohort would be predicted by the actuarial curve to have died from all causes.

\footnote{221} Curve representing mortality from all causes differ in FTC and HCC. On average, patients with FTC are about 5 years younger, tend to die within the first 10 postoperative years, and have high all-cause mortality for 10 to 30 postoperative years.\footnote{222} (Fig. 13-20). Deaths related to HCC occur gradually over the first 15 years; however, by 25 years, the average survivor of HCC is 84 years old, and by that time, almost 50\% of the treated cohort would be predicted by the actuarial curve to have died from all causes.

\footnote{223} CSM rates vary with the presenting TNM stage in both FTC (Fig. 13-18) and HCC. The death rates tend to parallel the curves for development of DM (see Fig. 13-11).

\footnote{224} In more than five decades of experience at the Mayo Clinic, the mortality rate for FTC initially exceeds that of HCC, but by 20 to 30 postoperative years there are no significant differences in cause-specific survival rates between FTC and HCC (Fig. 13-19), both being around 80\% at 20 and 70\% at 30 postoperative years.

\footnote{225} Curves representing mortality from all causes differ in FTC and HCC. As illustrated by Figure 13-21, if two or more of these factors are present, the 5-year survival rate is only 47\%, and 20-year survival is 8\%. By contrast, if only one of these factors is present, 5-year survival is 99\%, and 20-year survival is 86\%.

\footnote{228} Systems developed to predict outcome in either PTC or FTC have been applied to FTC patients. Specifically, the pTNM as well as the AMES risk group categorization (age, metastasis, extent, size) is useful in FTC. From a multivariate analysis of 228 patients with FTC treated at the Memorial Sloan Kettering Cancer Center, the independent adverse prognostic factors were identified as age older than 45 years, Hürthle cell histotype, extrathyroidal extension, tumor size exceeding 4 cm, and the presence of DM. The prognostic importance of FTC of histologic grade was also confirmed, and this factor was included in assignment of risk groups to low, intermediate, or high categories.

\footnote{229} The AGES scheme, originally developed for PTC, has also been successfully applied to FTC. It thus appears that scoring systems used in PTC may be cautiously applied in FTC as long as some of the unique features of this tumor, such as vascular invasiveness and the remarkable significance of DNA aneuploidy in HCC, are kept in mind.
Poorly Differentiated (Insular, Solid, or Trabecular) Carcinoma

Poorly differentiated thyroid carcinoma has been defined as a tumor of follicular cell origin with morphological and biologic attributes intermediate between differentiated and anaplastic carcinomas of the thyroid. The most distinctive histologic feature is the presence of small cells with round nuclei and scant cytoplasm with a diffuse solid pattern or organized in round or oval nests (insulae) or in trabeculae. The predominant pattern of growth is solid, but microfollicles are also seen, some of which contain dense colloid. Extrathyroidal extension and blood vessel invasion are common. Most such tumors exhibit foci of necrosis, are larger than 5 cm in diameter at diagnosis, and have an invasive margin on gross examination.

The mean age at diagnosis is about 55 years, and the female/male ratio is about 2:1. Poorly differentiated carcinoma is aggressive and often lethal. Metastases are common in regional nodes and distant sites (lung, bone, brain). In one series,
Undifferentiated (Anaplastic) Carcinoma

Anaplastic carcinoma constitutes about 5% of all thyroid carcinomas, usually occurs after the age of 60 years, and is slightly more common in women (1.3:1 to 1.5:1). This carcinoma is highly malignant, nonencapsulated, and extends widely. Evidence of invasion of adjacent structures, such as the skin, muscles, nerves, blood vessels, larynx, and esophagus, is common. DM occur early in the course of the disease in lungs, liver, bones, and brain.

On histopathologic examination, the lesion is composed of atypical cells that exhibit numerous mitoses and form a variety of patterns. Spindle-shaped cells, multinucleate giant cells, and squamoid cells usually predominate. Areas of necrosis and polymorphonuclear infiltration are common, and the presence of PTC or FTC suggests that they may be the precursors of anaplastic carcinoma. Mutations of the p53 gene are present in many undifferentiated carcinomas but may not be found in the residual well-differentiated component, suggesting that these mutations occurred after the development of the original tumor and may have played a key role in tumor progression.

The usual clinical complaint is of a rapid, often painful enlargement of a mass that may have been present in the thyroid gland for many years. The tumor invades adjacent structures, causing hoarseness, inspiratory stridor, and difficulty in swallowing. On examination, the overlying skin is often warm and discolored. The mass is tender and is often fixed to adjacent structures. It is stony hard in consistency, but some areas may be soft or fluctuant. The regional lymph nodes are enlarged, and there may be evidence of DM. Anaplastic carcinomas do not accumulate iodine and do not typically produce thyroglobulin.

Treatment should be initiated rapidly to avoid death from locally infiltrative disease and possible suffocation. It consists of surgical resection of the tumor tissue present in the neck, when this is feasible, followed by a combination of external irradiation and chemotherapy. When the extent of disease is limited and when these protocols can be applied, local control may be obtained in about two thirds of the patients and long-term survival in about 20%.
Medullary Thyroid Carcinoma

MTC accounts for less than 10% of thyroid malignancies (see Chapter 36). It arises from the parafollicular or C cells of the thyroid gland, and the tumor cells typically produce an early biochemical signal (hypersecretion of calcitonin). MTC readily invades the intraglandular lymphatics and spreads to other parts of the gland, in addition to the pericapsular and regional lymph nodes. It also regularly spreads through the blood stream to the lungs, bone, and liver.

MTC tumors are firm and usually unencapsulated. On histopathologic examination, the tumor is composed of cells that vary in morphologic features and arrangement. Round, polyhedral, and spindle-shaped cells form a variety of patterns, which may vary from solid, trabecular to endocrine or glandular-like structures. An amyloid stroma is commonly present. Gross or microscopic foci of carcinoma may be present in other parts of the gland, and blood vessels may be invaded. The histopathologic appearance of the metastases resembles that of the primary lesion. In all cases, the diagnosis can be confirmed by positive immunostaining of tumor tissue for calcitonin and carciinoembryonic antigen (CEA).

MTC first appears either as a hard nodule or mass in the thyroid gland or as an enlargement of the regional lymph nodes. Occasionally, a metastatic lesion in a distant site is found first. The neck masses are frequently painful; they are sometimes bilateral and are often localized to the upper two thirds of each lobe of the gland, which reflects the anatomic location of the parafollicular cells.

The tumor occurs in both sporadic and hereditary forms, the latter making up about 20% of the total. The hereditary variety can be transmitted as a single entity, familial MTC, or it can arise as part of MEN syndrome type 2A or 2B. The hereditary form is typically bilateral and is usually preceded by a premalignant C cell hyperplasia. Total thyroidectomy at this premalignant stage can cure the disease in more than 90% of cases. RET proto-oncogene testing should be performed in all MTC patients. The finding of a germline mutation in this gene indicates a hereditary disease; the mutation should then be sought in all first-degree family members.

Early series of MTC mainly described sporadic cases, in which 80% of patients presented with TNM stage II or III. As more patients with familial MTC or MEN 2A have been diagnosed, more patients have curable (stage I) disease, and the survival rate has improved, a trend that should continue with widespread application of RET proto-oncogene testing. Patients with MTC now have outcomes similar to or better than those of patients with nonpapillary FCTC (see Fig. 13-10). The cause-specific survival curves for 218 consecutive MTC cases treated from 1940 to 1997 at the Mayo Clinic, according to TNM stage, are presented in Figure 13-23.

Prognostic factors relevant to outcome in MTC include (1) age at diagnosis, (2) male gender, (3) initial extent of the disease, such as NM and DM, (4) tumor size, (5) extrathyroidal invasion, (6) vascular invasion, (7) calcitonin immunoreactivity and amyloid staining in tumor tissue, (8) postoperative gross residual disease, and (9) postoperative plasma calcitonin levels.

In multivariate analysis, only the age of the patient at initial treatment and the stage of the disease remain significantly independent indicators of survival. This suggests that, in routine practice, clinicians attempting to predict outcome in MTC should take into account not only the presenting disease stage, as assessed by the pTNM system (see Fig. 13-23), but also the age of the patient at diagnosis.

In patients with MTC, Cushing's syndrome may occur because of secretion of corticotropin by the tumor. Prostaglandins, serotonins, kinins, and vasoactive intestinal peptide may also be secreted and are variously responsible for flushing and for the attacks of watery diarrhea that about one third of patients experience, usually at an advanced stage of the disease. In MEN-2A, hyperparathyroidism occurs late and is usually due to parathyroid hyperplasia rather than adenoma. Pheochromocytomas invariably occur later than MTC; they are often bilateral and may be clinically silent, and patients at risk should be screened with measurements of urinary metanephrine excretion. In MEN-2B, MTC and pheochromocytomas are associated with multiple mucosal neuromas (bumpy lip syndrome), a marfanoid habitus, and typical facies, but such patients do not regularly have hyperparathyroidism.

Differentiation of sporadic MTC from other types of thyroid nodule on clinical grounds alone may be difficult. In patients with a family history of thyroid cancer associated with hypertension or hyperparathyroidism, the MEN-2A syndrome should be suspected. FNAB has made it possible to diagnose MTC before surgery. In some patients, however, cytologic findings may be misleading because the type of carcinoma is difficult to determine and HCC may occasionally be confused with MTC.

Positive immunocytochemical staining for calcitonin allows confirmation of the diagnosis. Basal plasma calcitonin levels are elevated in virtually all patients with clinical MTC. Infusions of pentagastrin or calcium elicit secretion of calcitonin, and the response may be exaggerated in patients with either MTC or the antecedent C-cell hyperplasia; its use should be restricted to patients with an undetectable or borderline plasma calcitonin level (see Chapter 36).

When the diagnosis of MTC is made from calcitonin measurements or FNAB, patients should be evaluated for hyperparathyroidism and for pheochromocytoma. If these diagnoses are satisfactorily excluded, a total thyroidectomy with removal of regional nodes can safely be performed. In patients with MEN, surgery should be performed for pheochromocytomas before surgery for MTC is performed. First-degree relatives of patients with MEN or familial MTC should undergo DNA testing for the presence of the mutant RET gene (see Chapter 36). Gene carriers should undergo a prophylactic total thyroidectomy between 5 and 7 years of age.
Primary Malignant Lymphoma

Primary lymphomas of the thyroid are uncommon tumors, constituting fewer than 2% of all thyroid malignancies. The peak incidence is in the seventh decade, and the male/female ratio is 1:3.[237][238][239][240] Thyroid lymphomas are almost invariably seen as a rapidly enlarging, painless neck mass, fixed to surrounding tissues; they cause compressive symptoms and should be differentiated from anaplastic carcinoma. Unilateral or bilateral lymph node enlargement is present in about 50% of affected patients. Clinically evident distant disease is uncommon. The palpated mass is solid and, if studied by imaging, would be hypoechoic on ultrasonography and nonfunctioning on thyroid scintiscan. Most primary thyroid lymphomas arise in patients who have chronic autoimmune thyroiditis. Nonetheless, the disease is a rare complication of Hashimoto's thyroiditis.[241]

Primary thyroid lymphomas should be distinguished from generalized lymphomas with thyroid involvement. FNAB can be useful in distinguishing lymphoid proliferation from epithelial tumors. However, differentiating lymphoma from chronic autoimmune thyroiditis by thyroid cytology may be difficult.[242] Therefore, surgical specimens are needed for diagnosis. Immunohistochemical studies identify lymphoid proliferation if findings are positive for leukocyte common antigen.

Because chronic autoimmune thyroiditis reproduces the exact features of a mucosa-associated lymphoid tissue (MALT), most cases of thyroid lymphoma are considered MALT lymphomas.[243] Those small cell lymphomas are characterized by a low grade of malignancy, slow growth, and a tendency for recurrence in other MALT sites, such as the gastrointestinal or respiratory tract, the thymus, or the salivary glands.

A large proportion of clinical cases are large cell lymphomas and have an aggressive course. With immunohistochemistry, nearly all of them show B-cell markers. Monoclonality for light chain immunoglobulin is considered a strong indication of malignant lymphoma. Usually, immunohistochemistry is positive for BCL2 in small cell and negative in large cell lymphomas.

Although accurate staging is very important for planning treatment, patients are often elderly, in poor condition, or may require urgent therapy to relieve symptoms, thus making a full staging investigation before treatment impractical. Staging includes physical examination; complete blood count; serum lactate dehydrogenase and 2-microglobulin measurements; liver function tests; bone marrow biopsy; CT scanning of the neck, thorax, abdomen, and pelvis; and appropriate biopsies at sites where tumor is suspected. Involvement of Waldeyer's ring and of the gastrointestinal tract has been associated with thyroid lymphomas, and for this reason upper gastrointestinal radiography or endoscopy should be performed.

Disseminated disease necessitates chemotherapy. In patients with disease apparently confined to the neck, therapy is guided by the histologic features of the lymphoma. Chemotherapy with an anthracycline-based regimen and involved-field radiotherapy should be given to all patients with large cell thyroid lymphoma and in some series has provided long-term survival rates of nearly 100%. For small cell MALT lymphomas, radiation alone may be adequate if the disease is determined to be localized after accurate staging.[238][239][240]
SURGICAL TREATMENT OF THYROID CARCINOMA

The extent of surgery appropriate for thyroid malignancy is a matter of controversy. Factors that influence this decision include the histologic diagnosis, the size of the original lesion, the presence of DM, the patient's age, and the risk group category. Obviously, the surgeon must be appropriately skilled in thyroid surgery, and the goal of surgery should be to remove all the malignant neoplastic tissue present in the neck. Therefore, the thyroid gland and affected neck lymph nodes should all be carefully identified and adequately resected.

In the case of PTC and FTC, although some debate still exists regarding the extent of thyroid surgery, many favor a near-total (leaving no more than 2 to 3 g of thyroid tissue) thyroidectomy for all patients. Near-total thyroidectomy reduces the recurrence rate, compared with more limited surgery, because many PTCs are both multifocal and bilateral. Removal of most, if not all, of the thyroid gland facilitates postoperative remnant ablation with 131I.

For extremely low-risk patients (i.e., those with unifocal intra-thyroidal PTM and possibly small [≤2 cm] FTC with only capsular invasion), a lobectomy may be an appropriate primary surgical procedure. In patients who have undergone a previous unilateral lobectomy for a supposedly benign tumor that proves to be an aggressive FTC, a completion thyroidectomy is advisable because it facilitates future follow-up.

Surgery of lymph nodes is routinely performed in patients with PTC. It should include dissection of the central compartment (paratracheal and tracheoesophageal areas) and may also include dissection of the supravclicular area and the lower third of the jugulocarotid chain. A modified neck dissection is performed if palpable lymph node metastases are present in the jugulocarotid chain. Dissection is preferable to lymph node picking. Although this type of lymph node dissection has not been shown to improve the recurrence and survival rates, several arguments support its routine use in patients with papillary carcinomas. These include the fact that histologic evidence of lymph node metastases is present in about two thirds of PTC patients, of whom more than 80% have involvement of the central compartment, and metastases are difficult to detect by palpation in lymph nodes located behind the vessels or in the paratracheal groove. The knowledge of initial lymph node status, acquired by such a routine, helps in the interpretation of any cervical abnormality identified during the subsequent postoperative follow-up. In the case of FTC, lymph node metastases are less frequent, but a lymph node dissection should be performed if FTC has already been diagnosed and palpable lymph nodes are present.

MTC is usually treated by total thyroidectomy, with a dissection of the central compartment of the neck and the lower two thirds of the jugulocarotid chains. A modified neck dissection may be required for MTC affecting the lateral neck nodes.

Ideally, patients with anaplastic carcinoma should be treated with near-total thyroidectomy and lymph node dissection, but lesions are usually too extensive for any procedure but palliative surgery. In these cases, surgery may be performed later in the case of tumor regression after a combination of chemotherapy and external radiotherapy.

In recommending surgery, the endocrinologist should discuss potential operative complications with the patient. Unilateral lobectomy virtually never causes permanent hypocalcemia but can cause vocal cord paralysis in as many as 3% of patients. Near-total thyroidectomy causes temporary hypocalcemia in 7% to 10% of patients and permanent hypocalcemia in 0.5% to 1%; temporary vocal cord paralysis occurs in about 1% to 2%. A total extracapsular thyroidectomy may lead to hypoparathyroidism in as many as 30% of individuals, an unacceptable complication rate for patients with indolent malignancy. In addition, vocal cord paralysis is more common after such a procedure. The experience of the surgeon is important in terms of the finer technical points of thyroidectomy, including preservation of the external branch of the recurrent laryngeal nerve, which is important in the fine regulation of voice pitch.

A history of radiation in childhood increases the risk of both benign and malignant thyroid nodules in later life. The risk increases with a younger age at exposure and larger radiation dose. Several issues are relevant for the thyroidologist. First, given that surgical exploration may be required for patients with a history of thyroid radiation and suspicious thyroid nodules, what should the extent of initial surgery be and how should such patients be treated subsequently?

With respect to the extent of surgery, the protocol described previously should always be applied to patients with a thyroid carcinoma. In cases with benign lesions, individuals with bilateral nodular disease should have a near-total thyroidectomy; when the opposite lobe is macroscopically normal, one must weigh the relative risk of complications associated with a more extensive surgical procedure against the possibility of recurrence of thyroid nodules in the residual thyroid tissue.

In one irradiated population, both benign and malignant nodules recurred after previous subtotal thyroidectomy. The overall risk of recurrence in this study was approximately 20% and was lower in those who had more thyroid tissue removed than in those who had less extensive procedures. In those patients, suppression of TSH by thyroid hormone led to a reduction in recurrence from 35% to approximately 8%, but TSH suppression had no influence on the occurrence of malignant nodules.

Thus, the recommendations for such patients must take into account the estimated risk of developing a thyroid nodule and the experience of the operating surgeon. All irradiated patients who have had thyroid nodules removed should receive TSH-suppressive doses of levothyroxine regardless of the extent of surgery. The appearance of new thyroid nodules is, however, fairly common, and such patients should be monitored indefinitely for this possibility.

It is not clear whether this experience should be extrapolated to prescribe routine TSH suppression therapy for all irradiated patients, even if nodularity is not present, because its beneficial effects have not been quantified and the risks of long-term TSH suppression in women, especially vis-à-vis osteoporosis, have not been clearly defined and may be significant. At present, this approach cannot be recommended for all irradiated patients but can be recommended for patients at high risk of developing a thyroid nodule.
Iodine 131 Therapy

131 I is an effective agent for delivering high radiation doses to the thyroid tissue with low spillover to other portions of the body. The radiation dose to the thyroid tissue is related to the tissue concentration, the ratio between the total tissue uptake and the volume of functional tissue, and the effective half-life of 131 I in the tissue. Thyroid tissue is able to concentrate iodine only after TSH stimulation, but even after optimal TSH stimulation, iodine uptake in neoplastic tissue is always lower than in normal thyroid tissue and may not be detectable in about one third of cases.

131 I therapy is given postoperatively for three reasons. First, it destroys normal thyroid remnants, thereby increasing the sensitivity of subsequent 131 I total-body scanning and the specificity of measurements of serum Tg for the detection of persistent or recurrent disease. Second, it may destroy occult microscopic carcinoma, thereby potentially decreasing the long-term recurrence rate. Finally, it makes it possible to perform a postablative 131 I total-body scan, a sensitive tool for detecting persistent carcinoma.

It cannot be emphasized too strongly that postoperative 131 I therapy should be used selectively and that not all patients with a diagnosis of FCTC benefit from routine postoperative radiiodine ablative therapy. 131 I ablation requires that a dose of at least 300 Gy (30,000 rad) is delivered to thyroid remnants, and a dosimetric study can allow a more precise estimate of the dose to be administered. Obviously, the only patients eligible for such a protocol would be those selected high-risk patients with either PTC or FTC.

Postoperatively, no levothyroxine treatment is given for 4 to 6 weeks but levothyroxine can be substituted for at least 3 to 4 weeks and then discontinued for 2 weeks before radiiodine studies. At that time, the serum TSH level should be greater than 25 to 30 mU/L. Neck uptake may be measured with a tracer dose of 131 I; high uptake (>10%) should lead to completion surgery. 131 I therapy can be administered to the other patients, usually with 24-hour uptakes considerably less than 10%. A total body scan is performed 4 to 7 days after the treatment dose, and levothyroxine suppressive therapy is initiated. Total ablation (defined as no visible uptake) may be verified by an 131 I total-body scan 6 to 12 months later, typically with 2 to 5 mCi (74 to 185 MBq).

Total ablation is achieved after administration of either 100 mCi (3700 MBq) or 30 mCi (1100 MBq) in more than 80% of patients who had at least a near-total thyroidectomy. After less extensive surgery, ablation is achieved in only two thirds of patients with 30 mCi (1100 MBq). Therefore, a near-total thyroidectomy should be performed in all patients who are to be treated with 131 I. Total ablation requires that a dose of at least 300 Gy (30,000 rad) is delivered to thyroid remnants, and a dosimetric study can allow a more precise estimate of the dose to be administered. Obviously, the only patients eligible for such a protocol would be those selected high-risk patients with either PTC or FTC. 131 I ablation therapy does not play a regular role in the management of patients with anaplastic thyroid cancer, MTC, or thyroid lymphoma.

External Radiotherapy

External radiotherapy to the neck and mediastinum is indicated only for older patients with extensive PTC in whom complete surgical excision is impossible and in whom the tumor tissue does not take up $^{131}$I. Retrospective studies have shown that in these selected patients, external radiotherapy decreases the risk of neck recurrence.\[254\] The target volume encompasses the thyroid bed, bilateral neck lymph node areas, and the upper part of the mediastinum. Typically, 50 Gy (5000 rad) would be delivered in 25 fractions over 5 weeks.

In patients with MTC, this protocol may be applied after incomplete resection of the tumor and also after apparently complete surgery, when plasma calcitonin remains detectable in the absence of DM. In these patients, it may decrease the risk of neck recurrence by a factor of 2 to 4.\[254\]

In patients with anaplastic thyroid carcinoma, when the extent of disease is limited and surgery is feasible, accelerated external radiotherapy in combination with chemotherapy permits local control of the disease in two thirds of the patients and long-term survival in about 20%.\[153\]
Levothyroxine Treatment

The growth of thyroid tumor cells is controlled by TSH, and inhibition of TSH secretion with levothyroxine is thought to improve the recurrence and survival rates. Therefore, levothyroxine should be given to all patients with FCTC, whatever the extent of thyroid surgery and other treatment. The initial effective dose is about 2.5 µg/kg body weight in adults; children require a higher dose. The adequacy of therapy is monitored by measuring serum TSH 3 months after it is begun, the initial goal being a serum TSH concentration of 0.1 mU/L or less. In some centers, the serum free T3 concentration is also documented to be within the normal range. When these guidelines are followed, levothyroxine therapy does not have deleterious effects on the heart or bone.

In patients with anaplastic thyroid carcinoma, MTC, or thyroid lymphoma, a replacement dose of levothyroxine is given with the aim of obtaining a serum TSH level in the normal range.
FOLLOW-UP

In patients with PTC or FTC, the goals of follow-up after initial therapy are to maintain adequate levothyroxine suppressive therapy and to detect persistent or recurrent thyroid carcinoma. Most recurrences occur during the first years of follow-up, but some occur late. Therefore, follow-up is necessary throughout the patient’s life.

Early Detection of Recurrent Disease

Clinical and Ultrasonographic Examinations

Palpation of the thyroid bed and lymph node areas should be routinely performed at all follow-up visits in patients with thyroid cancer. Ultrasonography should be performed in patients at high risk of recurrence and in any patient with clinically suspicious findings. Palpable lymph nodes that are small, thin, or oval; in the posterior neck chains; and especially if they decrease in size after an interval of 3 months are considered benign. By contrast, round shape, hypoechogenicity and absence of a central echogenic line, microcalcifications, a cystic component, and hypervascularization on color Doppler ultrasonography are suspicious findings.

Serum Tg is undetectable in 20% of patients receiving levothyroxine treatment who have isolated lymph node metastases, and undetectable values do not exclude metastatic lymph node disease. If in doubt, ultrasound-guided node biopsy for cytology and Tg measurement in the fluid aspirate may be performed. Sensitive reverse transcriptasepolymerase chain reaction (RT-PCR) to amplify Tg mRNA appears to be even more sensitive but is not yet being used by commercial laboratories.

Radiographs

Bone and chest radiographs are no longer routinely obtained for patients with undetectable serum Tg concentrations. The reason is that virtually all patients with abnormal radiographs have readily detectable serum Tg concentrations.

Serum Thyroglobulin Determinations

Tg is a glycoprotein that is produced only by normal or neoplastic thyroid follicular cells. Methods used for serum Tg determination and serum interferences are detailed in Chapter 10. It should not be detectable in patients who have had total thyroid ablation, and its detection in that setting probably signifies the presence of persistent or recurrent disease (Table 13-7). In patients who are in complete remission after total thyroid ablation, serum Tg antibodies decline gradually to low or undetectable levels. Their persistence or reappearance during follow-up should be considered suspicious for persistent or recurrent disease.

Most serum thyroglobulin concentrations were above 10 ng/mL.

The production of Tg by both normal and neoplastic thyroid tissue is in part TSH dependent. When serum Tg is detectable during levothyroxine treatment, it increases after TSH stimulation obtained either after the treatment is discontinued or with injections of rhTSH. After rhTSH stimulation, the peak of serum Tg is usually obtained 3 days after the second injection. The serum Tg concentration is an excellent prognostic indicator. Most patients with undetectable serum Tg concentrations who were not receiving levothyroxine therapy remained free of relapse after more than 15 years of follow-up, and only 2% had a neck lymph node recurrence. Conversely, 60% to 80% of patients with serum Tg concentrations above 10 ng/mL after levothyroxine withdrawal and with no other evidence of disease had detectable foci of 131I uptake in the neck or at distant sites after administration of a large dose (3700 MBq, 100 mCi) of 131I.

Several researchers have developed sensitive RT-PCR assays to amplify circulating Tg mRNA. The technique appeared sensitive in that the test was positive in most patients with thyroid tissue, but results were not related to the extent of the disease. This technique may be useful in patients with Tg antibodies.
