The results of a 131I total-body scan depend on the ability of neoplastic thyroid tissue to take up 131I in the presence of high serum TSH concentrations, which are achieved by withdrawing levothyroxine for 4 to 6 weeks. However, the resulting hypothyroidism is poorly tolerated by some patients. This effect can be attenuated by substituting the more rapidly metabolized liothyronine for levothyroxine for 3 to 4 weeks and withdrawing it for 2 weeks or simply by reducing the dose of levothyroxine by 50%.

The serum TSH concentration should be above some arbitrary value (>25 to 30 mU/L) in patients treated in this way; if it is not, 131I administration should be delayed until it is. Intramuscular injections of rhTSH (0.9 mg for 2 consecutive days) are an alternative because levothyroxine treatment need not be discontinued and side effects are minimal. When combining serum Tg measurement and 131I total-body scanning, its efficiency is comparable to that of levothyroxine withdrawal in most patients.

| TABLE 13-8 -- Nonthyroidal Conditions Associated with 131I Accumulation |

Contamination
Consideration given to surgical reexploration if levothyroxine is discontinued or after rhTSH stimulation. If residual neck disease is found on sonography, the diagnosis should be confirmed by guided biopsy and performed annually; neck ultrasonography is frequently performed in case of doubt or in high-risk patients, but any other testing is unnecessary as long as the patient’s serum Tg concentration is undetectable and the patient does not produce an interfering anti-Tg autoantibody.

In low-risk patients considered cured, the dose of levothyroxine is decreased to maintain a low but detectable serum TSH concentration (0.1 to 0.5 mU/L). In high-risk patients, higher doses of levothyroxine are given, the goal being a serum TSH concentration less than 0.1 mU/L.

Follow-up Strategy

If the total-body scan performed after administration of 131I to destroy the thyroid remnants does not show any uptake outside the thyroid bed, physical examination is performed and serum TSH and Tg are measured during levothyroxine treatment 3 months later (Fig. 13-26). In most centers, the serum Tg level is measured and a diagnostic 131I total-body scan is done after thyroid hormone withdrawal or rhTSH stimulation 6 to 12 months later. Visible uptake in the thyroid bed that is too low to be quantified should not be considered evidence of disease in the absence of any other abnormality.

If any significant uptake is detected outside the thyroid bed, a therapeutic dose of 100 mCi (3700 MBq) of 131I is given. Serum Tg determination after TSH stimulation, obtained after either thyroid hormone withdrawal or injections of rhTSH, may help to select for scanning with a large amount of 131I those patients with negative diagnostic 131I total-body scans who have detectable serum Tg levels.

In low-risk patients considered cured, the dose of levothyroxine is decreased to maintain a low but detectable serum TSH concentration (0.1 to 0.5 mU/L). In high-risk patients, higher doses of levothyroxine are given, the goal being a serum TSH concentration less than 0.1 mU/L. Clinical and biochemical evaluations are performed annually; neck ultrasonography is frequently performed in case of doubt or in high-risk patients, but any other testing is unnecessary as long as the patient’s serum Tg concentration is undetectable and the patient does not produce an interfering anti-Tg autoantibody.

In patients receiving levotyroxine in whom serum Tg becomes detectable, neck ultrasonography is performed and serum Tg may be measured again after levotyroxine is discontinued or after rhTSH stimulation. If residual neck disease is found on sonography, the diagnosis should be confirmed by guided biopsy and consideration given to surgical reexploration.
of the neck. If there is no demonstrable neck disease but the stimulated serum Tg concentration increases above 10 ng/mL, even if no uptake is seen on a diagnostic $^{131}$I total-body scan performed with 2 to 5 mCi, consideration should be given to the administration of a therapeutic dose of 100 mCi of $^{131}$I. In the absence of $^{131}$I uptake, spiral CT of the neck and lungs, bone scintigraphy, and FDG PET scanning can be useful in localizing hitherto unrecognized sites of recurrent disease. In patients whose serum Tg levels are initially undetectable during levothyroxine treatment but later become detectable (levels $<$10 ng/mL) after TSH stimulation, another Tg determination should be obtained after TSH stimulation every 2 to 5 years, depending on Tg levels and on prognostic factors.

In low-risk PTC patients who have had a near-total thyroidectomy but who were not given $^{131}$I postoperatively, the intensity of the follow-up strategy depends largely on the serum Tg level. If the Tg is not detectable and a neck ultrasound is negative, $^{131}$I total-body scanning may be avoided. However, if despite adequate TSH suppression, the Tg is readily detectable, a $^{131}$I total-body scan may be performed 6 to 12 months after surgery. An ablative $^{131}$I treatment may rarely be necessary in some of those patients who have either an elevated serum Tg level or abnormal findings on $^{131}$I total-body scanning. The follow-up protocol previously described is then applied on the basis of serum Tg determinations.

In low-risk PTC patients who have initially undergone only a unilateral lobectomy for small ($<$15 mm) tumors, yearly follow-up should consist of a careful neck examination and serum Tg determination during levothyroxine treatment. With time, ultrasonography is likely to show focal nodular abnormalities in the remaining lobe in most patients with detectable Tg concentrations. Usually, biopsies of these lesions can be performed under sonographic guidance, and most prove to be cytologically benign. However, if recurrent PTC is found on biopsy, a completion thyroidectomy should be performed.

For MTC patients, the tumor marker for follow-up is the plasma calcitonin level. In more than 90% of young patients whose disease is treated at a preclinical stage on the basis of a RET oncogene mutation, the postoperative calcitonin level returns to normal and peak levels after stimulation with either pentagastrin or calcium are absent. In patients with a negative pentagastrin stimulation test after two follow-up evaluations are likely to be cured, despite the fact that about 5% of them have subsequent biologic recurrence of the disease.

In adults with sporadic MTC, who most often present with TNM stage III (node-positive) disease, postoperative calcitonin levels are rarely normal, and normal responsiveness to pentagastrin stimulation is unusual. In general, basal and stimulated calcitonin levels correlate with MTC tumor mass, but many MTC patients who have surgery with a curative intent still have postoperative elevations in calcitonin levels without clinical or imaging evidence of persistent disease. In these patients, the localization of neoplastic foci may be difficult and may require a venous sampling catheterization with calcitonin measurements. Reinterventions based on the results of selective venous sampling catheterization allow the removal of neoplastic foci in most patients, but they are not likely to improve the cure rate by more than 5% to 30%. Such a situation may exist for several postoperative years, and slowly rising calcitonin levels may not necessarily imply a prognosis worse than that indicated by the presenting stage of disease.

A second major tumor marker for MTC is CEA. In general, serum CEA levels are higher in more malignant MTC, whereas the plasma calcitonin level is higher in those with better differentiated tumors, leading some authorities to suggest that a rising CEA level postoperatively correlates better with the emergence of a potentially aggressive tumor recurrence.
Papillary and Follicular Thyroid Carcinoma

Locoregional Recurrences

Locoregional recurrences occur in 5% to 20% of patients with PTC and FTC. A recurrence that is palpable or easily visualized with ultrasonography or CT scanning should be excised. Total excision may be facilitated by total-body scanning 4 days after administration of 100 mCi (3700 MBq) of I, because additional tissue that should be excised may be identified. In some selected centers, surgery is performed 1 day later, typically using an intraoperative probe. The completeness of resection is verified 1 to 2 days after surgery by another total-body scan, and in one series this was achieved in 92% of cases. External radiotherapy is indicated only in FTC patients with soft tissue recurrences that cannot be completely excised and that do not take up I. Recently, it has been reported that patients with FTC who were not eligible for further surgery or I therapy have been treated for regional nodal recurrence with ultrasound-guided radiofrequency ablation or percutaneous ethanol injections (PEI). Both techniques appear promising in selected PTC patients with recurrent nodal disease that is not amenable to conventional retreatment with surgery, I, or external irradiation.

Distant Metastases

In a large group of patients with differentiated carcinoma (PTC, FTC, and HCC), only 9% developed DM. Mortality rates at 5 and 10 years after the diagnosis of metastasis were 65% and 75% for all patients with DM, and nearly 80% of the deaths were due to thyroid cancer. Thus, the development of DM in FTC portends an ominous prognosis. Lung metastases are more frequent in young patients with PTC, and the lung is almost the only site of distant spread in children. Bone metastases are more common in older patients and in those with FTC. Other less common sites are the brain, liver, and skin.

Clinical symptoms of lung involvement are uncommon. By contrast, pain, swelling, or fracture occurs in more than 80% of patients with bone metastases. The pattern of lung involvement may vary from macronodular to diffuse infiltrates. The latter, when not detected by chest radiography, are usually diagnosed with I total-body scan and may be confirmed by spiral CT; enlarged mediastinal lymph nodes are often present in patients with PTC, especially children. Bone metastases are osteolytic and are often difficult to visualize on radiographs. Skeletal scintigraphy may show decreased or moderately increased uptake, and bone involvement is better visualized by CT or MRI. Nearly all patients with DM have high serum Tg concentrations unless the lung metastases are not visible on radiographs, and two thirds of such patients have uptake in their sites of metastases.

Palliative surgery is required for bone metastases when there are neurologic or orthopedic complications or a high risk of such complications. Surgery may also be performed with a curative intent in patients with a single or a few bone metastases.

Patients with DM that take I should be treated with 100 to 150 mCi (3700 to 5550 MBq) every 4 to 6 months. Between I treatments, suppressive doses of levothyroxine are given. The radiation dose to the tumor tissue and outcome of I therapy are correlated. A radiation dose higher than 80 Gy (8000 rads) should be delivered to obtain cure; with radiation doses less than 35 Gy (3500 rads), there is little chance for success. For treatment to be effective in this clinical setting, appropriate levels of TSH stimulation and absence of iodine contamination are essential. For this reason, higher doses (200 mCi [7400 MBq] or more) have been advocated in patients with bone metastases, but their effectiveness remains to be demonstrated. Lower doses (1 mCi [37 MBq]/kg body weight) are given to children.

There is no limit to the cumulative dose of I that can be given to patients with DM, although the risk of leukemia rises slightly above a cumulative dose of 500 mCi (18,500 MBq). Furthermore, above this dose, further I therapy may rarely provide benefit. External radiotherapy is given to bone metastases visible on radiographs, even in the presence of iodine uptake. Alternatively, embolization or cement injection may be considered. Chemotherapy is poorly effective and should be given only to patients with progressing and nonfunctioning metastases. Retinoic acid analogues increased iodine uptake by neoplastic tissue and decreased its growth rate in several in vitro models. Further clinical trials are still warranted to assess the role of such therapies.

Complete responses have been obtained in about 45% of patients with DM showing avidity for I, and responses are even more frequent in younger patients and in those with small pulmonary metastases. It was shown by PET scanning that large DM with high FDG uptake almost never respond to I therapy. When response was judged to have been complete after I therapy, subsequent relapse rarely occurred even though serum Tg levels were persistently detectable in some patients.

Overall survival after the discovery of DM is more favorable in young patients with well-differentiated tumors that take up I and have metastases that are small when discovered. When the tumor mass is considered, the location of the DM, be it in the lungs or bone, has no independent prognostic influence. The poor prognosis of patients with bone metastases is linked to the large size of their lesions. The prognostic importance of the small size of the metastases at their discovery has led to the administration of 100-mCi (3700-MBq) doses of I to patients with elevated serum Tg concentrations and no other evidence of disease. Some believe that there is no conclusive evidence that I treatment of these asymptomatic patients meaningfully prolongs life. Others recently have reported a 33% complete remission rate in treated patients who had a positive post-I therapy total-body scan.

Complications of Treatment with Iodine 131

Acute side effects (nausea, sialadenitis) after treatment with I are common but are typically mild and resolve rapidly. Radiation thyroiditis is usually trivial, but if the thyroid remnant is large, the patient may have enough pain to warrant corticosteroid therapy for a few days. Tumor in certain locations, such as the brain, spinal cord, and paratracheal, may swell in response to TSH stimulation or after I therapy, causing compressive symptoms. Radiation fibrosis may develop in patients with diffuse lung metastases and can eventually prove fatal if high doses (>150 mCi [5550 MBq]) are administered at short intervals (<3 months).

Particular attention must be paid to avoid administration of I to pregnant women. After I treatment, spermatogenesis may be transiently depressed, and women may have transient ovarian failure. Genetic damage induced by exposure to I before conception has been a major subject of concern. However, the only anomaly reported to date is an increased frequency of miscarriages in women treated with I during the year preceding the conception. Therefore, it is recommended that conception be postponed for 1 year after treatment with I. There is no evidence that pregnancy affects tumor growth in women receiving adequate levothyroxine therapy. During pregnancy, the serum TSH level should be measured every 2 months, and this frequency leads to an increase in the daily dose of levothyroxine.

Mild pancytopenia may occur after I therapy, especially in patients with bone metastases also treated with external radiotherapy. The overall relative risk of leukemia was found to be increased only in patients treated with a high cumulative dose of I (>500 mCi [18,500 MBq]) or in association with external radiotherapy. In contrast, there is no significant increased risk of solid carcinoma in these patients.
Medullary Thyroid Carcinoma

For patients with locoregional recurrence of MTC, a complete diagnostic work-up should be obtained, principally to exclude DM. Surgery is performed when feasible and is typically followed by external radiotherapy.

DM are usually multifocal in each involved organ and frequently involve multiple organs, including liver, lungs, and bones. They may progress slowly and may be compatible with decades of survival. Systemic chemotherapy is poorly efficient and may be indicated only in cases of rapid tumor progression.

HISTORICAL MILESTONES

The anatomy of the adrenal glands was described almost 450 years ago by Bartholomeo Eustacius, and the zonation of the gland and its distinction from the medulla were elucidated shortly thereafter. However, a functional role for the adrenal glands was not accurately defined until the pioneering work of Thomas Addison, who described the clinical and autopsy findings in 11 cases of "Addison's disease" in his classical monograph in 1855. Just a year later, Brown-Séquard demonstrated that the adrenal glands were "organs essential for life" by performing adrenalectomies in dogs, cats, and guinea pigs. In 1896, William Osler first administered adrenal extract to a patient with Addison's disease, a feat that was repeated by others in both animal and human studies over the next 40 years. As a consequence, between 1937 and 1955 the adrenocorticosteroid hormones were isolated, their structures defined, and the hormones synthesized, notable breakthroughs being the discovery of cortisone and the clinical evaluation of its anti-inflammatory effect in patients with rheumatoid arthritis (Reichstein, Hench, Kendall, and Slocumb) and the isolation of aldosterone (Simpson and Tait). The control of adrenocortical function by a pituitary factor was demonstrated in the 1920s, and this led to the isolation of sheep adrenocorticotropic hormone (ACTH) in 1943. Such a concept was supported through clinical studies, notably in 1932 by Harvey Cushing, who associated his original clinical observations of 1912 (a "polyglandular syndrome" caused by pituitary basophilism) with adrenal hyperactivity. The neural control of pituitary ACTH secretion by corticotropin-releasing hormone (CRH) was defined by Harris and other workers in the 1940s, but CRH was not characterized and synthesized until 1981 in the laboratory of Wylie Vale. Jerome Conn described primary aldosteronism in 1956, and the control of adrenal aldosterone secretion by angiotensin II was confirmed shortly afterward. Advances in radioimmunoassays and particularly molecular biology have facilitated an exponential increase in our understanding of adrenal physiology and pathophysiology (Table 14-1).
ANATOMY

The adrenal cortex derives from mesenchymal cells attached to the coelomic cavity lining adjacent to the urogenital ridge. The fetal adrenal is evident from 6 to 8 weeks of gestation and rapidly increases in size so that by midgestation it is larger than its adjacent kidney. In fetal life and up to 12 months post partum two distinct zones are evident: an inner prominent fetal zone and an outer definitive zone that differentiates into the adult adrenal gland. Post partum the fetal zone regresses and the definitive zone containing an inner zona fasciculata and outer glomerulosa proliferates. The innermost zone, the zona reticularis, is evident after 1 year of life. The differentiation of the adrenal cortex into distinct zones has important functional consequences (discussed later) and is thought to be dependent upon the temporal expression of transcription factors including Pref-1/ZOG, inner zone antigen, and steroidogenic factor-1.

The adult gland is a pyramidal structure approximately 4 g in weight, 2 cm wide, 5 cm long, and 1 cm thick lying immediately above the kidney on its posteromedial surface. Beneath the capsule, the zona glomerulosa constitutes approximately 15% of the cortex (depending upon sodium intake). Cells are clustered in spherical nests and are small with smaller nuclei in comparison with other zones. The zona fasciculata makes up 75% of the cortex; cells are large and lipid laden and form radial cords between the fibrovascular radial network. The innermost zona reticularis is sharply demarcated from both the zona fasciculata and adrenal medulla. Cells here are irregular with little lipid content. The maintenance of normal adrenal size appears to involve a progenitor cell population lying between the zona glomerulosa and zona fasciculata; cell migration and differentiation occur within the fasciculata and senescence within the reticularis, but the factors regulating this important aspect of adrenal regeneration are unknown. ACTH administration results in glomerulosa cells adopting a fasciculata phenotype; in turn, the innermost fasciculata cells adopt a reticularis phenotype, which is reversible upon withdrawal of ACTH.

The vasculature of the adrenal cortex is complex. Arterial supply is conveyed by up to 12 small arteries from the aorta, inferior phrenic, renal, and intercostal arteries. These branch to form a subcapsular arteriolar plexus from which radial capillaries penetrate deeper into the cortex. In the zona reticularis, a dense sinusoidal plexus is created that empties into a central vein. The right adrenal vein is short, draining directly into the inferior vena cava; the longer left adrenal vein usually drains into the left renal vein.
ADRENAL STEROIDS AND STEROIDOGENESIS

Three main types of hormones are produced by the adrenal cortex: glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone [DOC]), and sex steroids (mainly androgens). All steroid hormones are derived from the cyclopananoperhydrophenanthrene structure, that is, three cyclohexane rings and a single cyclopentane ring (Fig. 14-2).

Steroid nomenclature is defined in two ways: either by trivial names (e.g., cortisol, aldosterone) or by the chemical structure as defined by the International Union of Pure and Applied Chemistry (IUPAC). The IUPAC classification is inappropriate for clinical use but does provide invaluable insight into steroid structure. The basic structure and trivial and IUPAC names of some common steroids are given in Figure 14-2 and Table 14-2. Estrogens have 18 carbon atoms (C₁₈ steroids), androgens have 19 carbon atoms (C₁₉), and glucocorticoids and progesterogens are C₂₁ steroid derivatives.

Cholesterol is the precursor for all adrenal steroidogenesis. Most of this cholesterol is provided from the circulation in the form of low-density lipoprotein (LDL) cholesterol. Uptake is by specific cell surface LDL receptors present on adrenal tissue; LDL is then internalized by receptor-mediated endocytosis, the resulting vesicles fuse with lysosomes, and free cholesterol is produced after hydrolysis. However, it is clear that this cannot be the sole source of adrenal cholesterol; patients with abetalipoproteinemia who have undetectable circulating LDL and patients with defective LDL receptors in the setting of familial hypercholesterolemia still have normal basal adrenal steroidogenesis. Cholesterol can be generated de novo within the adrenal cortex from acetyl coenzyme A. In addition, there is evidence that the adrenal can utilize HDL cholesterol after uptake through the putative HDL receptor, the class B, type I scavenger receptor (SR-BI).

The biochemical pathways involved in adrenal steroidogenesis are shown in Figure 14-3. The initial hormone-dependent rate-limiting step is the transport of intracellular cholesterol from the outer to the inner mitochondrial membrane for conversion to pregnenolone by cytochrome P450. Human experiments of nature have confirmed the importance of a 30-kd protein, steroidogenic acute regulatory protein (StAR), in mediating this effect (see later). StAR is induced by an increase in intracellular cyclic adenosine monophosphate after binding of ACTH to its cognate receptor, providing the first important rate-limiting step in adrenal steroidogenesis. Other transporters, including the peripheral benzodiazepine-like receptor, may be involved.

Steroidogenesis involves the concerted action of several enzymes, including a series of cytochrome P450 enzymes, all of which have been cloned and characterized (Table 14-3). Cholesterol side-chain cleavage enzyme and the CYPI1B enzymes are localized to the mitochondria and require an electron shuttle system, provided through adrenodoxinreductin reductase, to oxidize and hydroxylate steroids. 17-Hydroxylase and 21-hydroxylase are localized to the microsomalendoplasmic reticulum fraction and are dependent upon a distinct electron shuttle system involving a flavoprotein, cytochrome b₅. Mutations in the genes encoding these enzymes result in human disease, so some understanding of the underlying pathways and steroid precursors is required.

After uptake of cholesterol to the mitochondrion, cholesterol is cleaved by the P450 cholesterol side-chain cleavage enzyme to form pregnenolone. In the cytoplasm, pregnenolone is converted to progesterone by the type II isozyme of 3-hydroxysteroid dehydrogenase (3-HSD) by a reaction involving dehydrogenation of the 3-hydroxy group and isomerization of the double bond at C5. Progesterone is hydroxylated to 17-OHP through the activity of CYPI7-hydroxylase. 17-Hydroxylation is a prerequisite for glucocorticoid synthesis, and the zona glomerulosa does not express 17-hydroxylase. CYPI7 also possesses 17,20-lyase activity, which results in the production of the C₁₈ adrenal androgens, dehydroepiandrosterone (DHEA) and androstenedione. In humans, however, 17-OHP is not an efficient substrate for CYPI7, and there is negligible conversion of 17-OHP to androstenedione. Adrenal androstenedione secretion is dependent on the conversion of DHEA to androstenedione by 3-HSD; this enzyme also converts 17-hydroxy pregnenolone to 17-OHP, but the preferred substrate is pregnenolone.

21-Hydroxylation of either progesterone (zona glomerulosa) or 17-OHP (zona fasciculata) is carried out by the product of the CYPI1B2 gene, 21-hydroxylase, to yield DOC or 11-deoxycortisol, respectively. The final step in cortisol biosynthesis takes place in the mitochondria and involves the conversion of 11-deoxycortisol to cortisol by the enzyme CYPI1B1, 11-hydroxylase. In the zona glomerulosa, 11-hydroxylase may also convert DOC to corticosterone. However, the enzyme CYPI1B2 or aldosterone synthase may also carry out this reaction and, in addition, is required for the conversion of corticosterone to aldosterone through the intermediate 18-OH corticosterone. Thus, CYPI1B2 can carry out 11-hydroxylation, 18-hydroxylation, and 18-methyl oxidation to yield the characteristic C₁₁-18-hemisected structure of aldosterone.

Regulation of Adrenal Steroidogenesis

"Functional Zonation" of the Adrenal Cortex

Glucocorticoids are secreted in relatively high amounts (cortisol 10 to 20 mg/day) from the zona fasciculata under the control of ACTH, and mineralocorticoids are secreted in low amounts (aldosterone 100 to 150 µg/day) from the zona glomerulosa under the principal control of angiotensin II. As a class, adrenal androgens (DHEA, dehydroepiandrosterone sulfate [DHEAS], androstenedione) are the most abundant steroids secreted from the adult adrenal gland (>20 mg/day). In each case, this is facilitated through the expression of steroidogenic enzymes in a specific zonal manner. The zona glomerulosa cannot synthesize cortisol because it does not express 17-hydroxylase. In contrast, aldosterone secretion is confined to the outer zona glomerulosa through the restricted expression of CYPI1B2. Although CYPI1B1 and CYPI1B2 share 95% homology, the 5' promoter sequences differ and permit regulation of the final steps in glucocorticoid and mineralocorticoid biosynthesis by ACTH and angiotensin II, respectively. DHEA is sulfated only in the zona reticularis to form DHEAS.

In the fetal adrenal, steroidogenesis occurs primarily in the inner fetal zone. Because of a relative lack of 3-HSD and high sulfotransferase activity, the principal steroidogenic products are DHEA and DHEAS, which are then aromatized by placental trophoblast to estrogens. Thus, the majority of maternal estrogen across pregnancy is, indirectly, fetally derived. The control and ontogeny of human fetal steroidogenesis are discussed further in Chapter 21.

Classical endocrine feedback loops are in place to control the secretion of both hormones; cortisol inhibits the secretion of both CRF and ACTH from the hypothalamus and pituitary, respectively, and the aldosterone-induced sodium retention inhibits renal renin secretion.
ACTH is the principal hormone stimulating adrenal glucocorticoid biosynthesis and secretion. ACTH has 39 amino acids but is synthesized within the anterior pituitary as part of a much larger 241-amino-acid precursor, pro-opiomelanocortin (POMC). POMC is cleaved in a tissue-specific fashion to yield smaller peptide hormones. In the anterior pituitary this results in the secretion of -lipoprotein and pro-ACTH, the latter being further cleaved to an N-terminal peptide, joining peptide, and ACTH itself (Fig. 14-5). The functions of the N-terminal peptide and -lipoprotein are unknown, although they have weak steroidogenic activity of their own and may augment the effect of ACTH, particularly on stimulating adrenal growth. Indeed, recent studies have cloned a serine protease expressed in the outer adrenal cortex that leaves progamma MSH, releasing shorter fragments that promote adrenal growth.

The first 24 amino acids of ACTH are common to all species, and synthetic ACTH 1 to 24 (Synacthen) is available commercially for clinical testing of the hypothalamic-pituitary-adrenal (HPA) axis and assessment of adrenal glucocorticoid reserve. Melanocyte-stimulating hormones (MSHs, , , and ) are also cleaved products from POMC, but the increased pigmentation characteristic of Addison’s disease is thought to arise directly from increased ACTH concentrations binding to the melanocortin-2 receptor rather than the result of -MSH secretion.

POMC is also transcribed in many extrapituitary tissues, notably brain, liver, kidney, gonad, and placenta. In these normal tissues, POMC messenger ribonucleic acid (mRNA) is usually shorter than the pituitary 1200-bp species.
because of lack of exons 1 and 2 and the 5' region of exon 3. As a result, it is probable that this POMC-like peptide is neither secreted nor active. However, in ectopic ACTH syndrome, additional POMC mRNA species are described that are longer than normal pituitary 1200-bp POMC species (typically 1450 bp) because of the use of alternative promoters in the 5' region of the gene. This may in part explain the resistance of POMC secretion to glucocorticoid feedback in these tumors. Others factors, including interaction with tissue-specific transcription factors and POMC methylation, may explain the ectopic expression of ACTH in some malignant tissues. The cleavage of POMC is also tissue-specific and, at least in some cases of ectopic ACTH syndrome, it is possible that circulating ACTH precursors, notably pro-ACTH, may cross-react in current ACTH radioimmunoassays. The biologic activity of POMC itself upon adrenal function is thought to be negligible.

POMC expression within the hypothalamus and its cleavage appear to be of crucial importance in regulating hair pigmentation and appetite control (see later).

Figure 4C-6 Synthesis and cleavage of pro-opiomelanocortin (POMC) within the human anterior pituitary gland. Prohormone convertase enzymes sequentially cleave POMC to adrenocorticotropic hormone (ACTH). Shaded areas represent melanocyte-stimulating hormone (MSH) structural units. LPH, lipo-protein; LPH, lipo-protein; N-P0C, amino-terminal pro-opiomelanocortin.

Negative Feedback

An important aspect of CRH and ACTH secretion is the negative feedback control exerted by glucocorticoids themselves. Glucocorticoids inhibit POMC gene transcription in the anterior pituitary and CRH and AVP mRNA synthesis and secretion in the hypothalamus. This negative feedback effect is dependent upon the dose, potency, half-life, and duration of administration of the glucocorticoid and has important physiologic and diagnostic consequences. Suppression of the HPA axis by pharmacologic corticosteroids may persist for many months after cessation of therapy, and adrenocortical insufficiency should be anticipated.

The Adrenocorticotropic Hormone Receptor and ACTH Effects on the Adrenal

ACTH binds to a G protein-coupled, melanocortin-2 receptor, of which there are approximately 3500 on each adrenocortical cell. Signal transduction is mediated principally through the stimulation of adenyl cyclase and intracellular cyclic adenosine monophosphate, although both extracellular and intracellular Ca2+ play a role. Other factors synergize with or inhibit the effects of ACTH on the adrenal cortex, including angiotensin II, actinibin, interleukin, and cytokines (tumor necrosis factor and interleukin). Cell-to-cell communication through gap junctions is also important in mediating the effects of ACTH.
Aldosterone production, possibly because of receptor down-regulation or suppression of angiotensin II-stimulated secretion because of a mineralocorticoid effect of aldosterone, is principally by stimulating the early pathways of adrenal steroidogenesis (see earlier), but circulating levels increase by no more than 10% to 20% above baseline.

The effect of ACTH on aldosterone secretion is modest and differs in the acute and chronic situations. An acute bolus of ACTH increases aldosterone secretion, binding of angiotensin II to the surface angiotensin I receptor and activation of phospholipase C. The potassium effect is mediated through membrane depolarization and opening of calcium channels and the angiotensin II effect following calcimodulin kinases. Angiotensin II and potassium stimulate aldosterone secretion principally by increasing the transcription of CYP11B2 through common intracellular signaling pathways.

Prostaglandins also play a role in modulating renin secretion, and indomethacin inhibits renin release. In patients with hypertension, ectopic ACTH syndrome, and renal disease (see Chapter 15), aldosterone is generated through the renin-angiotensin system (Fig. 14-8). Angiotensinogen is an α 2-globulin produced by the liver. Angiotensin I is converted into biologically active angiotensin II by angiotensin-converting enzyme (ACE), mainly in the lung. Angiotensin II increases peripheral vascular resistance, and, together with angiotensin III, stimulates aldosterone (ALDO) secretion, which results in sodium retention and increased plasma volume.

Angiotensin II is generated through the renin-angiotensin system (Figs. 14-8, 14-13). Angiotensinogen is an α 2-globulin synthesized within the liver and is cleaved by renin to form angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in lung and many other peripheral tissues; further cleavage to angiotensin III may also occur. Angiotensin I has no apparent biologic activity, but both angiotensin II and angiotensin III are potent in stimulating aldosterone secretion. In addition, angiotensin III is a potent vasconstrictor.

Hypokalemia increases and hyperkalemia decreases renin secretion; in addition, potassium exerts a direct effect on the adrenal cortex to increase aldosterone secretion. The sensitivity of the renin-angiotensin system to changes in circulating potassium is high, with changes in potassium concentrations of only 0.1 to 0.5 mmol/L producing marked changes in aldosterone concentrations. Potassium concentrations also determine the sensitivity of the aldosterone response to a given infusion of angiotensin II, with high potassium intake increasing responsiveness.

Norepinephrine increases renin secretion, and -blockers inhibit renin release. In the clinical assessment of the renin-angiotensin-aldosterone axis, -blockers have a minimal effect on endogenous renin levels and can be given concomitantly if required to control hypertension so that renin and aldosterone concentrations can be measured. Prostaglandins also play a role in modulating renin secretion, and indomethacin inhibits renin release.

Angiotensin II and potassium stimulate aldosterone secretion principally by increasing the transcription of CYP11B2 through common intracellular signaling pathways. Cyclic adenosine monophosphate response elements in the S region of the CYP11B2 gene are activated after an increase in intracellular Ca 2+ and activation of calmodulin kinases. The potassium effect is mediated through membrane depolarization and opening of calcium channels and the angiotensin II effect following binding of angiotensin II to the surface aldosterone I receptor and activation of phospholipase C.

The effect of ACTH on aldosterone secretion is modest and differs in the acute and chronic situations. An acute bolus of ACTH increases aldosterone secretion, principally by stimulating the early pathways of adrenal steroidogenesis (see earlier), but circulating levels increase by no more than 10% to 20% above baseline values. ACTH has no effect on CYP11B2 gene transcription or enzyme activity. Chronic continual ACTH stimulation has either no effect or an inhibitory effect on aldosterone production, possibly because of receptor down-regulation or suppression of angiotensin II-stimulated secretion because of a mineralocorticoid effect of cortisol, DOCC, or angiotensin II. Dopamine and atrial natriuretic peptide inhibit aldosterone secretion, as does heparin.

The separate control of glucocorticoid biosynthesis through the HPA axis and mineralocorticoid synthesis through the renin-angiotensin system has important clinical consequences. Patients with primary adrenal failure invariably have both cortisol and aldosterone deficiency, whereas patients with ACTH deficiency related to
pituitary disease have glucocorticoid deficiency but normal aldosterone concentrations because the renin-angiotensin system is intact.

**Adrenal Androgen Secretion**

Adrenal androgens represent an important component (>50%) of circulating androgens in premenopausal females. In males this contribution is much smaller because of the testicular production of androgens, but adrenal androgen excess even in males may be of clinical significance, notably in patients with CAH. The adult adrenal secretes DHEA at approximately 4 mg/day, DHEAS at 7 to 15 mg/day, androstenedione at 1.5 mg/day, and testosterone at 0.05 mg/day. DHEA is a weak sex steroid but can be converted to androgens and estrogens through the activities of 3-HSD, a superfamily of 17-HSD isozymes, and aromatase, expressed in peripheral target tissues, and this is of clinical importance in many diseases.

ACTH stimulates androgen secretion; DHEA (but not DHEAS because of its increased plasma half-life) and androstenedione demonstrate a similar circadian rhythm to cortisol. However, there are many discrepancies between adrenal androgen and glucocorticoid secretion, which has led to the suggestion of an additional androgen-stimulating hormone (Table 14-4). Many putative androgen-stimulating hormones have been proposed including POMC derivatives such as joining peptide, prolactin, and insulin-like growth factor-I (IGF-I), but conclusive proof is lacking. Adrenal androgen steroidogenesis is dependent upon the relative activities of 3-HSD and 17-hydroxylase and in particular upon the 17.20-lyase activity of 17-hydroxylase. Factors that determine whether 17-hydroxylated substrates, 17-hydroxypregnenolone and 17-OHP, undergo 21-hydroxylation to form glucocorticoid or side-chain cleavage by 17-hydroxylase to form DHEA and androstenedione are unresolved and seem likely to be important in defining the activity of any putative androgen-stimulating hormone.

CORTICOSTEROID HORMONE ACTION

Receptors and Gene Transcription

Both cortisol and aldosterone exert their effects after uptake of free hormone from the circulation and binding to intracellular receptors, termed the glucocorticoid and mineralocorticoid receptors (GR and MR). These are both members of the thyroid/steroid hormone receptor superfamily of transcription factors comprising a C-terminal ligand-binding domain, a central deoxyribonucleic acid (DNA) binding domain interacting with specific DNA sequences on target genes, and an N-terminal hypervariable region. In both cases, although there is only a single gene encoding the GR and MR, splice variants have been described resulting in and variants.

Glucocorticoid hormone action has been studied in more depth than mineralocorticoid action. The binding of steroid to the GR in the cytosol results in activation of the steroid-receptor complex through a process that involves the dissociation of heat shock proteins (HSP 90 and HSP 70). After translocation to the nucleus, gene transcription is stimulated or repressed following binding of dimerized GR-ligand complexes to specific DNA sequences in the promoter regions of target genes. This glucocorticoid response element is invariably a palindromic CGTACAnnnTGTACT sequence that binds with high affinity to two loops of DNA within the DNA binding domain of the GR (zinc fingers). This stabilizes the RNA polymerase II complex, facilitating gene transcription. The GR variant may act as a dominant negative regulator of GR transactivation.

Naturally occurring mutations in the GR (as seen in patients with glucocorticoid resistance, discussed later) and GR variants generated in vitro have highlighted critical regions of the receptor responsible for binding and transactivation. But numerous others factors are also required (coactivators, corepressors) that may confer tissue specificity of response. This is a rapidly evolving field and is reviewed in Chapter 4. However, the interactions between GR and two particular transcription factors are important in mediating the anti-inflammatory effects of glucocorticoids and explain the effect of glucocorticoids on genes that do not contain obvious glucocorticoid response elements in their promoter regions. Activator protein-1 (AP-1) comprises Fos and Jun subunits and is a proinflammatory transcription factor induced by a series of cytokines and phorbol ester. The GR-ligand complex can bind to Jun and prevent interaction with the AP-1 site to repress AP-1 and GR trans-activation functions. Similarly, functional antagonism exists between the GR and nuclear factor B (NF-B). NF-B is a ubiquitously expressed transcription factor that activates a series of genes involved in lymphocyte development, inflammatory response, host defense, and apoptosis. In keeping with the diverse array of actions of cortisol, many hundred glucocorticoid-responsive genes have been identified. Some glucocorticoid-induced genes and repressed genes are given in Table 4-1.

In contrast to the diverse actions of glucocorticoids, mineralocorticoids have a more restricted role, principally to stimulate epithelial sodium transport in the distal nephron, distal colon, and salivary glands. This stimulation is mediated through the induction of the apical sodium channel (comprising three subunits, and ) and the , and subunits of the basolateral Na+. K+-adenosine triphosphatase through transcriptional regulation of an aldosterone-induced gene, serum and glucocorticoid-induced kinase (SGK). Aldosterone binds to the MR, principally in the cytosol (although there is evidence for expression of the unliganded MR in the nucleus), followed by translocation of the hormone-receptor complex to the nucleus through the "prereceptor" metabolism of cortisol through the enzyme 11-HSD, which inactivates cortisol and corticosterone to inactive 11-keto metabolites, enabling aldosterone to bind to the MR.

For both glucocorticoids and mineralocorticoids there is accumulating evidence for so-called nongenomic effects involving hormone responses obviating the genomic GR or MR. A series of responses have been described within seconds or minutes of exposure to corticosteroids and are thought to be mediated by as yet uncharacterized membrane-coupled receptors.
Cortisol-Binding Globulin and Corticosteroid Hormone Metabolism

Over 90% of circulating cortisol is bound, predominantly to the \( \alpha \)-globulin cortisol-binding globulin (CBG). This 383-amino-acid protein is synthesized in the liver and binds cortisol with high affinity. Affinity for synthetic corticosteroids (except prednisolone, which has an affinity for CBG about 50% of that of cortisol) is negligible. Circulating CBG concentrations are approximately 26 mg/dL (700 nmol/L); levels are increased by estrogens and in some patients with chronic active hepatitis but reduced by glucocorticoids and in patients with cirrhosis, nephrosis, and hyperthyroidism. The estrogen effect can be marked, with levels increasing twofold to threefold during pregnancy, and this should also be taken into account when measuring plasma "total" cortisol in pregnancy and in women taking estrogens.

bFGF, basic fibroblast growth factor; CRH, corticotropin-releasing hormone; C/EBP/\( \alpha \), CAAT-enhancer binding protein-beta; GR, glucocorticoid receptor; GHRH, growth hormonereleasing hormone; ICAM, intercellular adhesion molecule; IFN, interferon; IGF-BP, insulin-like growth factorbinding protein; IB, inhibitory kappa B; iNOS, inducible nitric oxide synthase; NFB, nuclear factor B; NGF, nerve growth factor; PEPCK, phosphoenolpyruvate carboxykinase; POMC, proopiomelanocortin; PPAR, peroxisome proliferatoractivated receptor; PTHrP, parathyroid hormone-related protein; RXR, retinoid X receptor; SGK, serum and glucocorticoid-induced kinase; TCR, T-cell receptor; TNF-, tumor necrosis factor-alpha; VIP, vasoactive intestinal peptide.

Inherited abnormalities in CBG synthesis are much rarer than those described for thyroid-binding globulin but include elevated CBG, partial and complete deficiency of CBG, or CBG variants with reduced affinity for cortisol. In each case, alterations in CBG concentrations change total circulating cortisol concentrations accordingly but free cortisol concentrations are normal. Only this free circulating fraction is available for transport into tissues for biologic activity. The free cortisol excreted through the kidneys is termed urinary free cortisol and represents only 1% of the total cortisol secretion rate.

The circulating half-life of cortisol varies between 70 and 120 minutes. The major steps for cortisol metabolism are depicted in **Figure 14-12**. These
The interconversion of the 11-hydroxyl (cortisol, Kendall's compound F) to the 11-oxo group (cortisone, compound E) through the activity of 11-HSD (EC 1.1.1.146). The metabolism of cortisol and cortisone then follow similar pathways.

2. Reduction of the C4-C5 double bond to form dihydrocortisol or dihydrocortisone followed by hydroxylation of the 3-oxo group to form tetrahydrocortisol (THF) and tetrahydrocortisone (THE). The reduction of the C4-C5 double bond can be carried out by either 5-reductase or 5-reductase to yield, respectively, 5-THF (THF) or 5-THF (allo-THF). In normal subjects the 5 metabolites predominate (5:5-THF 2:1). THF, allo-THF, and THE are rapidly conjugated with glucuronic acid and excreted in the urine.

Further reduction of the 20-oxo group by either 20HSD or 20-HSD to yield - and -cortols and cortolones from cortisol and cortisone, respectively. Reduction of the C20 position may also occur without A ring reduction, giving rise to 20-hydroxycortisol and 20-hydroxycortisone.

4. Hydroxylation at C6 to form 6-hydroxycortisol.

Cleavage of THF and THE to the C21 hydroxyl group followed by either 20HSD or 20-HSD to yield - and -cortols and cortolones from cortisol and cortisone, respectively.

Further reduction of the 20-oxo group by either 20HSD or 20-HSD to yield - and -cortols and cortolones from cortisol and cortisone, respectively. Reduction of the C20 position may also occur without A ring reduction, giving rise to 20-hydroxycortisol and 20-hydroxycortisol.

6. Oxidation of the C21 position of cortols and cortolones to form the extremely polar metabolites cortolic and cortolonic acids.

Approximately 50% of secreted cortisol appears in the urine as THF, allo-THF, and THE; 25% as cortols and cortolones; 10% as C11 steroids; and 10% as corticotropic and corticosterone acids. The remaining metabolites are free, unconjugated steroids (cortisol, cortisone, 6- and 20-20-metabolites of THF and THE).

The principal site of cortisol metabolism has been considered to be the liver, but many of the preceding enzymes have been described in the mammalian kidney, notably in the inactivation of cortisol to cortisone by 11-HSD. Quantitatively, the interconversion of cortisol to cortisone by 11-HSD is also the most important pathway. Furthermore, the bioactivity of glucocorticoids is in part related to the hydroxyl group at C11; cortisone with a C11 oxo group is an inactive steroid so that 11-HSD expressed in peripheral tissues plays a crucial role in regulating corticosteroid hormone action. Two distinct 11-HSD isozymes have been reported: a type 1 oxoreductase dependent on reduced nicotinamide adenine dinucleotide phosphate and expressed principally in the liver, which confers bioactivity upon orally administered cortisone by converting it to cortisol, and a type 2, nicotinamide adenine dinucleotide-dependent dehydrogenase. It is 11-HSD2, coexpressed with the MR in the kidney, colon, and salivary gland, that inactivates cortisol to cortisone and permits aldosterone to bind to the MR in vivo. If this enzyme-protective mechanism is impaired, cortisol is able to act as a mineralocorticoid; this explains some forms of endocrine hypertension (apparent mineralocorticoid excess, licorice ingestion; see Chapter 15) and the mineralocorticoid excess state that characterizes the ectopic ACTH syndrome (see later).

Hyperthyroidism results in increased cortisol metabolism and clearance and hypothyroidism the converse, principally because of an effect of thyroid hormone on hepatic 11-HSD and 5/5-reductases. IGF-I increases cortisol clearance by inhibiting hepatic 11-HSD (conversion of cortisone to cortisol), and 6-Hydroxylation is normally a minor pathway, but cortisol itself induces 6-hydroxylation so that 6-hydroxycortisol excretion is markedly increased in patients with Cushing's syndrome. Furthermore, some drugs, notably rifampicin and phenytoin, increase cortisol clearance through this pathway. Patients with renal disease have impaired cortisol clearance because of reduced renal conversion of cortisol to cortisone. These observations have clinical implications for patients with thyroid disease, acromegaly, and renal disease and for patients taking cortisol replacement therapy. Adrenal crisis has been reported in steroid-replaced Addisonian patients given rifampicin, and hydrocortisone replacement therapy may need to be increased in treated patients in whom hyperthyroidism develops.

Aldosterone is also metabolized in the liver and kidneys. In the liver it undergoes tetrahydro reduction and is excreted in the urine as a 3-glucuronide tetrahydroaldosterone derivative; however, glucuronide conjugation at the 18 position occurs directly in the kidney, as does 3 and 5/5 metabolism of the free steroid. Because of the aldehyde group at the C18 position, aldosterone is not metabolized by 11-HSD. Hepatic aldosterone clearance is reduced in patients with cirrhosis, ascites, and severe congestive heart failure.
Effects of Glucocorticoids (Fig. 14-13)

Carbohydrate, Protein, and Lipid Metabolism

Glucocorticoids increase blood glucose concentrations through their action on glycogen, protein, and lipid metabolism. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilizing enzyme glycogen phosphorylase. Hepatic glucose output increases through the activation of key enzymes involved in gluconeogenesis, principally glucose-6-phosphatase and phosphoenolpyruvate carboxykinase.

In peripheral tissues (muscle, fat), cortisol inhibits glucose uptake and utilization. In adipose tissue lipolysis is activated, resulting in the release of free fatty acids into the circulation. An increase in total circulating cholesterol and triglycerides is observed, but HDL cholesterol levels fall. Glucocorticoids also have a permissive effect on other hormones including catecholamines and glucagon. The resultant effect is to cause insulin resistance and an increase in blood glucose concentrations at the expense of protein and lipid catabolism.

Glucocorticoids stimulate adipocyte differentiation, promoting adipogenesis through the transcriptional activation of key differentiation genes including lipoprotein lipase, glycerol-3-phosphate dehydrogenase, and leptin. Chronically, the effects of glucocorticoid excess on adipose tissue are more complex, at least in humans, in whom the deposition of visceral or central adipose tissue is stimulated, providing a useful discriminatory sign for the diagnosis of Cushing's syndrome. The explanation for the predilection for visceral obesity may be related to the increased expression of both the GR and type 1 isozyme of 11-HSD (generating cortisol from cortisone) in omental compared with subcutaneous adipose tissue.

Skin, Muscle, and Connective Tissue

In addition to inducing insulin resistance in muscle tissue, glucocorticoids cause catabolic changes in muscle, skin, and connective tissue. In the skin and connective tissue, glucocorticoids inhibit epidermal cell division and DNA synthesis and reduce collagen synthesis and production. In muscle, glucocorticoids cause atrophy (but not necrosis), and this seems to be specific for type II or "phasic" muscle fibers. Muscle protein synthesis is reduced.

Salt and Water Homeostasis and Blood Pressure Control

Glucocorticoids increase blood pressure by a variety of mechanisms involving actions on the kidney and vasculature. In vascular smooth muscle they increase sensitivity to pressor agents such as catecholamines and angiotensin II while reducing nitric oxide-mediated endothelial dilation. In the kidney, depending on the activity of the type 2 isozyme of 11-HSD, cortisol can act on the distal nephron to cause sodium retention and potassium loss (mediated by the MR). Elsewhere across the nephron, glucocorticoids increase glomerular filtration rate, proximal tubular epithelial sodium transport, and free water clearance. The last effect involves antagonism of the action of vasopressin and explains the dilutional hyponatremia seen in patients with glucocorticoid deficiency.

Anti-Inflammatory Actions and the Immune System

Glucocorticoids suppress immunologic responses, and this has been the stimulus to develop a series of highly potent pharmacologic glucocorticoids to treat a variety of autoimmune and inflammatory conditions. The inhibitory effects are mediated at many levels. In the peripheral blood, glucocorticoids reduce lymphocyte counts acutely (T lymphocytes > B lymphocytes) by redistributing lymphocytes from the intravascular compartment to spleen, lymph nodes, and bone marrow. Conversely, neutrophil counts increase after glucocorticoid administration. Eosinophil counts fall rapidly, an effect that was used historically as a bioassay for glucocorticoids.

The immunologic actions of glucocorticoids involve direct actions on both T and B lymphocytes that include inhibition of immunoglobulin synthesis and stimulation of lymphocyte apoptosis. Inhibition of cytokine production from lymphocytes is mediated through inhibition of the action of NF-B. NF-B plays a crucial and generalized role in inducing cytokine gene transcription; glucocorticoids can bind directly to NF-B to prevent nuclear translocation and can induce NF-B inhibitor, which sequesters NF-B in the cytoplasm, thereby inactivating its effect.

Additional anti-inflammatory effects involve inhibition of monocyte differentiation into macrophages and macrophage phagocytosis and cytotoxic activity.
Glucocorticoids reduce the local inflammatory response by preventing the action of histamine and plasminogen activators. Prostaglandin synthesis is impaired through the induction of lipocortins, which inhibit phospholipase A₂ activity. Prostaglandin synthesis is impaired through the induction of lipocortins, which inhibit phospholipase A₂ activity.

Central Nervous System and Mood

Clinical observations of patients with glucocorticoid excess and deficiency reveal that the brain is an important target tissue for glucocorticoids, with depression, euphoria, psychosis, apathy, and lethargy being important manifestations (see the following). Both glucocorticoid and mineralocorticoid receptors are expressed in discrete regions of the rodent brain including hippocampus, hypothalamus, cerebellum, and cortex. Glucocorticoids cause neuronal death notably in the hippocampus, and this may underlie the interest in glucocorticoids and cognitive function, memory, and neurodegenerative diseases such as Alzheimer’s. In the eye, glucocorticoids act to raise intraocular pressure through an increase in aqueous humor production and deposition of matrix within the trabecular meshwork, which inhibits aqueous drainage. Steroid-induced glaucoma appears to have a genetic predisposition, but the underlying mechanisms are unknown.

Gut

Chronic but not acute administration of glucocorticoids increases the risk of developing peptic ulcer disease. Pancreatitits with fat necrosis is reported in patients with glucocorticoid excess. The GR is expressed throughout the gastrointestinal tract and the MR in the distal colon, and these mediate the corticosteroid control of epithelial ion transport.

Endocrine: Replacement therapy (Addison’s disease, pituitary disease, congenital adrenal hyperplasia), Graves’ ophthalmopathy

Skin: Dermatitis, pemphigus

Hematology: Leukemia, lymphoma, hemolytic anemia, idiopathic thrombocytopenic purpura

Gastrointestinal: Inflammatory bowel disease (Ulcerative colitis, Crohn’s disease)

Liver: Chronic active hepatitis, transplantation, organ rejection

Renal: Nephrotic syndrome, vasculitides, transplantation, rejection

Central nervous system: Cerebral edema, raised intracranial pressure

Respiratory: Angioedema, anaphylaxis, asthma, sarcoidosis, tuberculosis, obstructive airway disease

Rheumatology: Systemic lupus erythematosus, polyarteritis, temporal arteritis, rheumatoid arthritis

Muscle: polymyalgia rheumatica, myasthenia gravis

excess. The GR is expressed throughout the gastrointestinal tract and the MR in the distal colon, and these mediate the corticosteroid control of epithelial ion transport.

Growth and Development

Although glucocorticoids stimulate growth hormone (GH) gene transcription in vitro, glucocorticoids in excess inhibit linear skeletal growth, probably as a result of catabolic effects on connective tissue, muscle, and bone and inhibition of the effects of IGF-I. Experiments on mice lacking the GR gene emphasize the role of glucocorticoids in normal fetal development. In particular, glucocorticoids stimulate lung maturation through the synthesis of surfactant proteins (SP-A, SP-B, SP-C) and mice lacking the GR die shortly after birth as a result of hypoxia from lung atelectasis. Glucocorticoids also stimulate the enzyme phenylethanolamine N-methyltransferase, which converts norepinephrine to epinephrine in adrenal medulla and chromaffin tissue. Mice lacking the GR do not develop an adrenal medulla.

Endocrine Effects

Glucocorticoids suppress the thyroid axis, probably through a direct action on thyroid-stimulating hormone (TSH) secretion. In addition, they inhibit 5’ deiodinase activity, mediating the conversion of thyroxine to active triiodothyronine. Glucocorticoids also act centrally to inhibit gonadotropin-releasing hormone pulsatility and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (see later).
THERAPEUTIC CORTICOSTEROIDS

Since the dramatic anti-inflammatory effect of cortisol was first demonstrated in the 1950s, a series of synthetic corticosteroids have been developed for therapeutic purposes. These are used to treat a diverse variety of human diseases and rely principally on their anti-inflammatory and immunologic actions (Table 14-6). The main corticosteroids used in clinical practice, together with their relative glucocorticoid and mineralocorticoid potencies, are listed in Table 14-7.

The structures of common synthetic steroids are depicted in Figure 14-14. Biologic activity of a corticosteroid is dependent upon a 4-3-keto, 11-hydroxy, 17,21-trihydroxyl configuration. Conversion of the C11 hydroxyl group to a C11 keto group (cortisol to cortisone) inactivates the steroid. The addition of a 1,2 unsaturated bond to cortisol results in prednisolone, which is four times more potent than cortisol in classical glucocorticoid bioassays such as hepatic glycogen deposition, suppression of eosinophils, and anti-inflammatory actions. Prednisone is the "cortisone equivalent" of prednisolone and relies upon conversion by 11-HSD type 1 in the liver for bioactivity. Potency is further increased by the addition of a 6-methyl group to prednisolone (methylprednisolone). Fludrocortisone is a synthetic mineralocorticoid that has 125-fold greater potency than cortisol in stimulating sodium reabsorption. This is achieved through the addition of a 9-fluoro group to cortisol. Interestingly, fludrocortisone also has glucocorticoid potency (12-fold greater than cortisol), and the addition of a 16-methyl group and 1,2 saturated bond to fludrocortisone results in dexamethasone, a highly potent glucocorticoid (25-fold greater than cortisol) but with negligible mineralocorticoid activity. Betamethasone has the same structure but with a 16-methyl group and is widely used in respiratory and nasal aerosol sprays.

Corticosteroids are given orally, parenterally, and by numerous topical routes (e.g., eyes, skin, nose, inhalation, rectal suppositories). Unlike hydrocortisone, which has a high affinity for CBG, most synthetic steroids have low affinity for this binding protein and circulate as free steroid (30%) or bound to albumin (70%). Circulating half-lives vary depending upon individual variability and underlying disease, particularly renal and hepatic impairment. Cortisone acetate should not be used parenterally as it requires metabolism by the liver to active cortisol.

It is beyond the consideration of this chapter to describe which steroid should be given and by which route for the nonendocrine conditions listed in Table 14-6. The acute and chronic administration of corticosteroid therapy in patients with hypoadrenalism and CAH is discussed in these sections. In addition to the undoubted benefit that corticosteroids provide, there is increasingly a misuse of corticosteroid therapy, particularly in patients with respiratory or rheumatologic disease, to such an extent that up to 0.5% of the population is now prescribed chronic corticosteroid therapy. Because of their established euphoric effect, corticosteroids often make patients feel better but without any objective measures of improvements in underlying disease parameters. In view of the long-term sequelae of chronic glucocorticoid excess, decisions regarding treatment should be evidence-based and subject to constant review for efficacy and side effects. The endocrinologic consequences, notably suppression of the HPA axis, are an important aspect of modern clinical practice. Endocrinologists need to be aware of the effects of chronic therapy and advise on steroid withdrawal.

**Chronic Corticosteroid Therapy, Hypothalamic-Pituitary-Adrenal Axis Suppression, and Steroid Withdrawal**

The negative feedback control of the HPA axis by endogenous cortisol has already been detailed. Synthetic corticosteroids similarly suppress the function of the HPA axis through a process that is dependent on both dose and duration of treatment. As a result, sudden cessation of corticosteroid therapy may result in adrenal failure. This may also occur after treatment with high doses of the synthetic progestagen medroxyprogesterone acetate, which possesses glucocorticoid agonist activity in patients taking any steroid dose for less than 3 weeks, clinically significant suppression of the HPA axis is rarely a problem and patients can withdraw from steroids suddenly with no ill effect. The possible exception to this is the patient who receives frequent short courses of corticosteroid therapy; for example, patients with recurrent episodes of severe asthma. Conversely, suppression of the HPA axis is invariably in patients taking the equivalent of 15 mg or more of prednisolone.

**TABLE 14-8 -- Duration of Glucocorticoid Treatment**
per day chronically. In patients taking lower doses of corticosteroid chronically (prednisolone 5 to 15 mg/day or equivalent), suppression of the HPA axis is variable. Defects in response of the HPA axis to insulin-induced hypoglycemia or exogenous ACTH have been reported in patients taking prednisolone doses as low as 5 mg/day, but clinically significant suppression at these doses is debatable. Alternate-day therapy is associated with less suppression of the HPA axis.

All patients treated chronically with corticosteroids should be treated in a similar fashion to patients with chronic ACTH deficiency; they should carry steroid cards and be offered Steroid Alert bracelets or necklaces. In the event of an intercurrent stress (infection, surgery), supplemental steroid cover should be given, equivalent to hydrocortisone at 100 to 150 mg/day. If the patient is unable to take drugs orally, parenteral therapy is required. Recovery from suppression may take 6 to 9 months. CRH secretion returns to normal, and within a few weeks ACTH levels begin to increase and indeed rise above normal values until adrenal steroidogenesis recovers. In the interim, and without replacement therapy, patients may experience symptoms of glucocorticoid deficiency including anorexia, nausea, weight loss, arthralgia, lethargy, skin desquamation and postural dizziness (see Glucocorticoid Insufficiency). To avoid symptoms of glucocorticoid deficiency, steroids should be withdrawn cautiously over a period of months. Assuming the underlying disease permits steroid reduction, doses should be reduced from pharmacologic levels to physiologic levels (equivalent to prednisolone at 7.5 mg/day) over a few weeks. Thereafter doses should be reduced by 1 mg/day prednisolone every 2 to 4 weeks depending on the patient's well-being. An alternative approach is to change to hydrocortisone at 20 mg/day and reduce the daily dose by 2.5 mg/day every week to 10 mg/day. Doses at nighttime should be avoided as they result in greater suppression of early morning ACTH secretion. After 2 to 3 months of these reduced doses of corticosteroids, endogenous function of the HPA axis can be assessed through a corticotropin (ACTH, Synacthen) stimulation test or an insulin-induced hypoglycemia test (see later). A pass response to these tests indicates adequacy of function of the HPA axis, and corticosteroid therapy can be safely withdrawn. In patients taking physiologic doses of prednisolone (less than 5 to 7.5 mg/day) or equivalent, a corticotropin stimulation test 12 to 24 hours after having omitted steroid therapy will provide an immediate answer on whether sudden or gradual withdrawal of steroid therapy is indicated (Table 14-8).

Iatrogenically induced Cushing's syndrome occurs in patients taking suppressive doses of corticosteroids for more than 3 weeks. The rapidity of onset of clinical features is dependent upon the administered dose but can occur within 1 month of therapy.

ADRENOCORTICAL DISEASES

Adrenocortical diseases are relatively rare, but their importance lies in their morbidity and mortality if untreated coupled with the relative ease of diagnosis and the availability of effective therapy. The diseases are most readily classified on the basis of whether there is hormone excess or deficiency (Table 14-9).

Glucocorticoid Excess

In 1912 Harvey Cushing first described a 23-year-old woman with obesity, hirsutism, and amenorrhea and 20 years later postulated that this “polyglandular syndrome” was due to a primary pituitary abnormality causing adrenal hyperplasia. Adrenal tumors were shown to cause the syndrome in some cases but ectopic ACTH production was not characterized until much later in 1962. The term Cushing’s syndrome is used to describe all causes, and Cushing’s disease is reserved for cases of pituitary-dependent Cushing’s syndrome.

Cushing’s syndrome comprises the symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoids (Fig. 14-15). The term glucocorticoid in the definition covers both endogenous (cortisol) and exogenous (e.g., prednisolone, dexamethasone) excess (Table 14-10). Ectopic Cushing’s syndrome is most common occurring to some degree in the majority of patients taking chronic corticosteroid therapy. Endogenous causes of Cushing’s syndrome result in loss of the normal feedback mechanism of the HPA axis and the normal circadian rhythm of cortisol secretion and are rare.

The incidence of pituitary-dependent Cushing’s syndrome is estimated to be 5 to 10 cases per million population per year. The incidence of ectopic ACTH syndrome parallels that of bronchogenic carcinoma, and although 0.5% of lung cancer patients have ectopic ACTH syndrome, the rapid progression of the underlying disease often precludes an early diagnosis. Cushing’s disease and adrenal adenomas are four times commoner in women, and ectopic ACTH syndrome is commoner in men.

Clinical Features of Cushing’s Syndrome

The classical features of Cushing’s syndrome with centripetal obesity, moon face, hirsutism, and plethora are well known.

following Cushing’s initial descriptions in 1912 and 1932 (Fig. 14-15 and Fig. 14-16). However, this gross clinical picture is not always present and a high index of suspicion is required in many cases. When the normal physiologic effects of glucocorticoids are appreciated (see Fig. 14-13), the clinical features of glucocorticoid excess are easier to define. These are summarized in Table 14-11 together with the most discriminatory features that assist in distinguishing Cushing’s syndrome from simple obesity.

Obesity

Weight gain and obesity are the commonest sign, and at least in adults this is invariably centripetal in nature. Indeed, generalized obesity is commoner in the general population than in patients with Cushing’s syndrome. One exception to this is childhood, in which glucocorticoid excess may result in generalized obesity. In addition to centripetal obesity, patients develop fat depots over the thoracocervical spine (“buffalo hump”), in the supraclavicular region, and over the cheeks and temporal regions, giving rise to the rounded “moon-like” facies. The epicardial space is another site of abnormal fat deposition, and this may lead to neurologic deficits.

Reproductive Dysfunction

Gonadal dysfunction is common, with menstrual irregularity in females and loss of libido in both sexes. Hirsutism is frequently found in female patients, as is acne. The commonest form of hirsutism is vellous hypertrichosis on the face and should be distinguished from darker terminal differentiated hirsutism, which may...

Psychiatric Abnormalities

Psychiatric abnormalities occur in approximately 50% of patients with Cushing's syndrome regardless of cause. Agitated depression and lethargy are among the commonest problems, but paranoia and overt psychosis are also well recognized. Memory and cognitive function may also be affected, and increased irritability may be an early feature. Insomnia is common, and both rapid eye movement and delta wave sleep patterns are reduced. Lowering of plasma cortisol by medical or surgical therapy usually results in a rapid improvement in the psychiatric state.

Bone

In childhood the commonest presentation is with poor linear growth and weight gain; as discussed earlier, glucocorticoids have profound effects on growth and development. Many patients with long-standing Cushing's syndrome have lost height because of osteoporotic vertebral collapse. This can be assessed by measuring the patient's height and comparing it with the patient's span; in normal subjects these measurements should be equal. Pathologic fractures, either spontaneous or after minor trauma, are not uncommon. Rib fractures, in contrast to those of the vertebral, are often painless. The radiographic appearances are typical, with exuberant callus formation at the site of the healing fracture. In addition, aseptic necrosis of the femoral and humeral heads, a recognized feature of high-dose exogenous corticosteroid therapy, can occur in endogenous Cushing's syndrome (Fig. 14-17) (Figure Not Available). Hypercalciuria may lead to renal calculi, but hypercalcemia is not a feature.

Skin

Hypercortisolism results in skin thinning, separation, and exposure of the subcutaneous vascular tissue. On examination, wrinkling of the skin on the dorsum of the hand may be seen resulting in a "cigarette paper" appearance (Liddle's sign). Minimal trauma may result in bruising, which frequently resembles the appearance of "senile purpura." The plethoric appearance of the patient with Cushing's syndrome is secondary to the thinning of the skin combined with loss of facial subcutaneous fat and is not due to true polycythemia. Acne and papular lesions may occur over the face, chest, and back.

The typical, almost pathognomonic red-purple livid striae greater than 1 cm in diameter are most frequently found on the abdomen but may also be present on the upper thighs, breasts, and arms. They are common in younger patients and less so in those older than 50 years. They must be differentiated from the paler, less pigmented striae that occur post partum (striae gravidarum) or in association with rapid weight loss.

Increased skin pigmentation is rare in Cushing's disease but common in the ectopic ACTH syndrome and arises because of overstimulation of melanocyte receptors by ACTH.

Myopathy and bruising are two of the most discriminatory features of the syndrome. The myopathy of Cushing's syndrome

Lack of "cure" after pituitary stalk section

Pituitary Theory

[Note: The full context and discussion around the pituitary stalk section and its implications are not provided in the given text.]

Etiology.

When iatrogenic causes are excluded, the commonest cause of Cushing's syndrome is Cushing's disease, accounting for approximately 70% of cases. The adrenal glands in these patients show bilateral adrenocortical hyperplasia with widening of the zona fasciculata and zona reticularis.

Cushing's Disease

The condition is most readily classified into ACTH-dependent and ACTH-independent causes. This can be diagnosed by documenting an increase in the ratio of urinary cortisol to cortisone metabolites. In addition, hepatic 5-reductase activity is inhibited, resulting in greater excretion of 5-cortisol metabolites.

Cardiovascular

Hypertension is another prominent feature, occurring in up to 75% of cases; even though epidemiologic data show a strong association between blood pressure and obesity, hypertension is much more common in patients with Cushing's syndrome than in those with simple obesity. This, together with the established metabolic consequences of the disease (diabetes, hyperlipidemia; see the following), is thought to explain the increased cardiovascular mortality in untreated cases. In addition, thromboembolic events may be commoner in Cushing's patients.

Infections

Infections are more common in patients with Cushing's syndrome. In many instances these are asymptomatic and occur because the normal inflammatory response is suppressed. Reactivation of tuberculosis has been reported and has even been the presenting feature in some cases. Fungal infections of the skin (notably tinea versicolor) and nails may occur, as may opportunistic fungal infections. Bowel perforation is commoner in patients with extreme hypercortisolism, and the hypercortisolism may mask the usual symptoms and signs of the condition. Wound infections are commoner and contribute to poor wound healing.

Eye

Ocular effects include raised intraocular pressure and exophtalmos (in up to one third of patients in Cushing's original series), the latter occurring because of increased retro-orbital fat deposition. Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon except as a complication of diabetes. In the author's experience chemosis is a sensitive and underreported feature of Cushing's syndrome.

Classification and Pathophysiology of Cushing's Syndrome

The condition is most readily classified into ACTH-dependent and ACTH-independent causes (see Table 14-10).

Adrenocorticotropic Hormone (ACTH) Dependent Causes

Cushing's Disease

When iatrogenic causes are excluded, the commonest cause of Cushing's syndrome is Cushing's disease, accounting for approximately 70% of cases. The adrenal glands in these patients show bilateral adrenocortical hyperplasia with widening of the zona fasciculata and zona reticularis.

Etiology.

Cushing himself raised the question of whether this disease was a primary pituitary condition or secondary to an abnormality in the hypothalamus, and there has been an ongoing debate on this issue ever since. The hypothalamic theory states that ACTH-secreting adenomas arise because of dysfunctional regulation of corticotrophs through chronic stimulation by CRH (or AVP), but other studies provide data to support a primary pituitary defect as the cause of the condition (Table 14-12).

Ocular effects include raised intraocular pressure and exophtalmos (in up to one third of patients in Cushing's original series), the latter occurring because of increased retro-orbital fat deposition. Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon except as a complication of diabetes. In the author's experience chemosis is a sensitive and underreported feature of Cushing's syndrome.

Classification and Pathophysiology of Cushing's Syndrome

The condition is most readily classified into ACTH-dependent and ACTH-independent causes (see Table 14-10).
The hypothalamic may have an initiating role, and overwhelming evidence is that, at presentation, the condition is pituitary-dependent. In 85% to 90% of cases the disease is due to a pituitary adenoma of mononuclear origin; basophil hyperplasia alone is found in 9% to 33% of pathologic series. On clinical grounds, this condition can be divided into two entities, cases occurring in the setting of highly malignant tumors such as small cell carcinoma of bronchus (Table 14-13) and more indolent cases occurring in patients with underlying neuroendocrine tumors such as bronchial carcinoids. In the former case, the clinical presentation more commonly resembles Addison's disease than Cushing's syndrome. Circulating ACTH concentrations and cortisol secretion rates can be extremely high. As a result, the duration of symptoms from onset to presentation is short (<3 months); patients are commonly pigmented, and the metabolic manifestations of glucocorticoid excess are often rapid and progressive. Weight loss, myopathy, and glucose intolerance are prominent symptoms and signs. The association of these features with hypokalemic alkalosis and peripheral edema should alert the clinician to the diagnosis.

The distinction of pituitary-dependent Cushing's from these indolent causes of ectopic ACTH syndrome is challenging. A key biochemical hallmark of the disease is a relative resistance of ACTH secretion to normal glucocorticoid feedback inhibition. ACTH-secreting pituitary adenomas function at a higher than normal set-point for cortisol feedback. In Cushing's disease the predominant finding is an increase in ACTH pulse amplitude with loss of normal circadian rhythm, but ACTH pulse frequency is also increased in some cases (see Fig. 14-7).

</tbody>
</table>

The majority of tumors (usually bronchial carcinoids, but larger macroadenomas occur in up to 10% of cases and usually signify a more invasive tumor. Selective surgical removal of a macroadenoma results in cure with a low recurrence rate. However, it is possible, particularly in cases with no identifiable pituitary adenoma, that Cushing's disease may be heterogeneous with different subtypes.

Ectopic Adrenocorticotropic Hormone Syndrome

In 15% of cases, Cushing's syndrome may be associated with nonpituitary tumors secreting ACTH and the ectopic ACTH syndrome. On clinical grounds, this condition can be divided into two entities, cases occurring in the setting of highly malignant tumors such as small cell carcinoma of bronchus (Table 14-13) and more indolent cases occurring in patients with underlying neuroendocrine tumors such as bronchial carcinoids. In the former case, the clinical presentation more commonly resembles Addison's disease than Cushing's syndrome. Circulating ACTH concentrations and cortisol secretion rates can be extremely high. As a result, the duration of symptoms from onset to presentation is short (<3 months); patients are commonly pigmented, and the metabolic manifestations of glucocorticoid excess are often rapid and progressive. Weight loss, myopathy, and glucose intolerance are prominent symptoms and signs. The association of these features with hypokalemic alkalosis and peripheral edema should alert the clinician to the diagnosis.

Depending on local referral practice, approximately 20% of cases of ectopic ACTH syndrome are explained by indolent tumors, such as benign bronchial carcinoids that produce ACTH. In these cases, symptoms and signs are commonly present for 18 months from onset to clinical presentation. Such patients present with the typical features of Cushing's syndrome and may be biochemically similar to patients with Cushing's disease. This, once a diagnosis of Cushing's syndrome is established, the principal diagnostic dilemma is in establishing the distinction of pituitary-dependent Cushing's from these indolent causes of ectopic ACTH syndrome.

### Etiology

POMC is expressed in normal peripheral extrapancreatic tissues and many tumors (lung, testis) irrespective of the presence of Cushing's syndrome, raising the appropriateness of the term "ectopic" ACTH syndrome. Tumors most commonly associated with ectopic ACTH syndrome arise from neuroendocrine tissues, the cells of which have the ability to take up and decarboxylate amine precursors (APUD cells). However, in the case of small cell lung cancer, only 0.5% to 1% of tumors are associated with ectopic ACTH syndrome and the explanation for the development of ACTH secretion remains unclear. POMC mRNA transcripts are usually shorter in tumors not associated with ectopic ACTH syndrome, whereas those with the syndrome express larger POMC mRNA species in addition to the "pituitary" size transcript. In addition to aberrant transcriptional regulation of the POMC gene, interaction with tissue-specific transcription factors or methylation status of the POMC gene may be involved (see earlier). Once secreted, POMC is cleaved in the pituitary by specific serine endopeptidases to produce ACTH precursors; in ectopic ACTH syndrome, aberrant peripheral processing of POMC may lead to increased circulating ACTH precursor concentrations (pro-ACTH, amino-terminal POMC [N-POMC]). In contrast to ACTH-secreting pituitary adenomas, ectopic POMC or ACTH production is not responsive to normal glucocorticoid feedback because of a defective GR or GR signaling mechanism. However, this sensitivity to glucocorticoid feedback is far from clear-cut, which is one reason why the differential diagnosis of ACTH-dependent Cushing's syndrome can be challenging.

### Ectopic Corticotropin-Releasing Hormone Production

This is a rare cause of pituitary-dependent Cushing's syndrome. A number of cases have been described in which a tumor (usually bronchial carcinoid, medullary thyroid, or prostate carcinoma) has been shown to contain CRH but not ACTH. However, CRH is also produced by many normal tissues. Where available, pituitary histology reveals corticotroph hyperplasia but not adenoma formation. Biochemically, these patients usually are similar to patients with ectopic ACTH syndrome with loss of the normal negative glucocorticoid feedback mechanism; 50% are resistant to high-dose dexamethasone therapy. It has been suggested that ectopic CRH production may explain the suppression of cortisol secretion after high-dose dexamethasone found in some patients with the ectopic ACTH syndrome.

### Macronodular Adrenal Hyperplasia

In 10% to 40% of patients with Cushing's disease, there is bilateral adrenocortical hyperplasia associated with one or more nodules that may be up to several centimeters in diameter. Patients tend to be older and have had symptoms for a longer time but otherwise present with the classical clinical features of Cushing's syndrome. Pathologically, the nodules are lobulated and can be markedly enlarged, but interstitial adrenal hyperplasia is invariably found. Macronodular adrenal hyperplasia is thought to result from long-standing adrenal ACTH stimulation that leads to autonomous adenoma formation. Thus, the adrenals in a patient with Cushing's disease become more hyperplastic, they secrete more cortisol for a given ACTH level and the ACTH may ultimately lead to autorepression. Individual clinical cases support this hypothesis, and macronodular adrenal hyperplasia should be regarded as an ACTH-dependent form of Cushing's syndrome, even though...
ACTH levels may be relatively low and dexamethasone suppressibility

less marked than in other cases of Cushing's disease. The adrenals can be a trap for the unwary as they may be mistaken for primary adrenal tumors.

Adrenocorticotropin Hormone-independent Causes

Cortisol-secreting Adrenal Adenoma and Carcinoma

With the exclusion of iatrogenic Cushing's syndrome, adrenal adenomas are responsible for about 10% to 15% of cases and carcinomas for less than 5%. By contrast, in children 65% of cases of Cushing's syndrome have an adrenal etiology (15% adenomas, 50% carcinoma). Onset of clinical features is gradual in patients with adenomas but often rapid in adrenal carcinoma. In addition to the features of hypercortisolism, patients may complain of loin or abdominal pain and a tumor may be palpable. The tumor may secrete other steroids, such as androgens or mineralocorticoids. Thus, in females, there may be features of virilization, with hirsutism, clitoromegaly, breast atrophy, deepening of the voice, temporal recession, and severe acne. With "pure" cortisol-secreting adenomas, hirsutism is uncommon. Subclinical Cushing's syndrome has been reported in patients with adrenal "incidentalomas" (see later).

Primary Pigmented Nodular Adrenal Hyperplasia and Carney Complex

About 100 cases of ACTH-independent Cushing's syndrome have been reported in association with bilateral, small pigmented adrenal nodules. Pathologically, these nodules are usually 2 to 4 mm in diameter (but can be larger) and black or brown on cut section. Adjacent adrenal tissue is strophic, distinguishing this condition from macronodular adrenal hyperplasia. Presentation is with typical features of Cushing's syndrome but is always before 30 years of age and before 15 years of age in 50% of cases. Cases of primary pigmented nodular adrenocortical disease (PPNAD) have been reported without Cushing's syndrome. Bilateral adrenalec-tomy is curative.

In 20% of cases, there is a family history, and it is known that PPNAD forms part of the familial autosomal dominant condition called Carney complex (Table 14-14). This comprises mesenchymal tumors (especially atrial myxomas), spotty skin pigmentation, peripheral nerve tumors, and various tumors including breast lesions and testicular and GH-secreting pituitary tumors.

In this condition, fibrous dysplasia and cutaneous pigmentation may be associated with pituitary, thyroid, adrenal, and gonadal hyperfunction. The commonest manifestation is with sexual precocity and GH excess, but Cushing's syndrome has been reported. The underlying abnormality is a somatic mutation in the subunit of the stimulatory G protein that is linked to adenyl cyclase. The mutation results in the G protein being constitutively activated, mimicking constant ACTH stimulation at the level of the adrenal. ACTH levels are suppressed, and adrenal adenomas may occur.

McCune-Albright Syndrome

Although macronodular hyperplasia commonly occurs in patients with ACTH-dependent Cushing's syndrome (see earlier), truly ACTH-independent macronodular disease is also recognized as a distinct entity. The nodules are nonpigmented and over 5 mm in diameter; occasionally the adenals may be massively enlarged. The pathogenesis is unknown in many cases, but in one kindred activating mutations of the ACTH receptor-coupled receptor may have caused the phenotype. It is likely that many cases may be explained on the basis of aberrant receptor expression within the adrenal cortex. Patients have been described with macronodular hyperplasia, ACTH-independent Cushing's syndrome, and enhanced adrenal responsiveness to gastric inhibitory polypeptide (GIP). Biochemically, plasma cortisol levels are subnormal in the morning and rise after food because of the normal increase in GIP after eating. The adenocortical tissue of these patients responded in vitro to low doses of GIP, whereas there was no such effect in normal adrenal cortex, suggesting that adrenal GIP receptors are linked to steroidogenesis in these patients. It remains to be seen whether abnormalities of adrenal sensitivity to GIP play a subtle role in other types of Cushing's syndrome. Similarly, Cushing's syndrome related to a cortisol-secreting adrenal adenoma has been attributed to aberrant expression of receptors for interleukin-1.

Iatrogenic Cushing's Syndrome

The basis for this condition is discussed under "Therapeutic Corticosteroids." Development of the features of Cushing's syndrome depends on the dose, duration, and potency of corticosteroid used in clinical practice. ACTH is rarely prescribed but chronically also results in cushingoid features. Some features such as increased intraocular pressure, cataracts, benign intracranial hypertension, aseptic necrosis of the femoral head, osteoporosis, and pancreatitis are commoner in iatrogenic compared with endogenous Cushing's syndrome, whereas other features, notably hypertension, hirsutism, and oligomenorrhea or amenorrhea, arerarer.

Special Features of Cushing's Syndrome

Cyclic Cushing's Syndrome
Of particular clinical interest has been a group of patients with cyclic Cushing's syndrome, characterized by periods of excess cortisol production interspersed with intervals of normal cortisol production. Some of these patients demonstrate a paradoxical rise in plasma ACTH and cortisol when treated with dexamethasone, and occasional patients show benefit with dopamine agonist (bromocriptine) or serotonin antagonist (cyproheptadine) therapy. The majority of cases have been thought to have pituitary-dependent disease, and in many of these patients basophil adenomas have been removed, some with long-term cure. However, cortisol secretion may show some evidence of cyclicity in patients with an ectopic source of ACTH syndrome.

Children

In children, in addition to the preceding features, growth arrest is almost invariably. The dissociation between height and weight on the growth chart is obvious. If the patient is growing along the same centile line, the diagnosis of Cushing's syndrome is highly unlikely. In addition to glucocorticoid-induced growth arrest, androgen excess may result in precocious puberty. Adrenal causes account for 65% of all cases.

Pregnancy

Pregnancy is rare in women with Cushing's syndrome because of associated amenorrhea related to androgen excess or hypercortisolism. However, approximately 100 such cases have been reported, 50% of which were due to adrenal adenomas. A few cases of true pregnancy-induced Cushing's syndrome have been described with regression post partum. In these cases, the etiology is unknown. Establishing a diagnosis and cause can be difficult; clinically, striae, hypertension, and gestational diabetes are common features in pregnancy, yet hypertension and diabetes are the commonest signs of Cushing's syndrome in pregnant women (70% and 30% of all cases, respectively). Furthermore, biochemically, normal pregnancy is associated with a threefold increase in plasma cortisol because of increased cortisol production rates and increases in CBG. Urinary free cortisol also rises, and dexamethasone does not suppress plasma cortisol to the same degree as in the nonpregnant state. Untreated, the condition results in high maternal and fetal morbidity and mortality. Adrenal or pituitary adenomas should be excised. Metyrapone, which is not teratogenic, has been effective in many cases in controlling the hypercortisolism.

Pseudo-Cushing's Syndromes

A pseudo-Cushing's state can be defined as some or all of the clinical features of Cushing's syndrome together with some evidence for hypercortisolism. Resolution of the underlying cause results in disappearance of the cushingoid state. Several causes have been described.

Alcohol

In the original description of this syndrome, urinary and plasma cortisol levels were elevated and not suppressed by dexamethasone. Plasma ACTH has been found to be normal or suppressed. The condition is rare but should be suspected in a patient with an ongoing history of heavy alcohol intake and biochemical or clinical evidence of chronic liver disease. The pathogenesis of this condition remains unknown, but a "two-hit" hypothesis has been put forward to explain its etiology. Chronic liver disease of any cause is associated with impaired cortisol metabolism, but in alcoholics this is associated with an increase in cortisol secretion rate rather than concomitant suppression in the presence of impaired metabolism. In some studies, alcohol has directly stimulated cortisol secretion; alternatively, vasopressin levels are elevated in patients with decompensated liver disease and may stimulate the HPA axis. With abstinence from alcohol the biochemical abnormalities rapidly revert to normal.

Depression

Although the cause is unknown, it is recognized that patients with depression may exhibit the hormonal abnormalities of patients with Cushing's syndrome. These abnormalities are reversible on correction of the psychiatric condition. Conversely, patients with Cushing's syndrome are frequently depressed, and a careful clinical and endocrinologic assessment is required.

Obesity

Although one of the commonest referrals to a clinical endocrinologist is to exclude an underlying endocrine cause in a patient with obesity, the diagnosis of Cushing's syndrome in such patients should not cause difficulties. Patients with obesity have mildly increased cortisol secretion rates, and the data suggest that this is due to activation of the hypothalamo-pituitary axis. However, circulating cortisol concentrations are invariably normal and urinary free cortisol concentrations are either normal or only slightly elevated. The stimulus for the increased secretion rate appears to be increased peripheral metabolism and hence clearance of cortisol (principally reduced hepatic conversion of cortisone to cortisol by 11-HSD type 1 and increased conversion of cortisol to 5-reduced derivatives).

Investigation of Suspected Cushing's Syndrome

There are two stages in the investigation of suspected Cushing's syndrome. (1) Does the patient have Cushing's syndrome? (2) If the answer is yes, then what is the cause? Unfortunately, many investigators fail to make this distinction and ill-advisedly use tests that are relevant to question 2 to try to answer question 1. In particular, it is essential that radiologic investigations not be undertaken until Cushing's syndrome has been confirmed biochemically. The major tests are listed in Table 14-15 and their application in Figure 14-19.

Circadian Rhythm of Plasma Cortisol

In normal subjects, plasma cortisol levels are at their highest first thing in the morning and reach a nadir at about midnight (<50 nmol/L (2 µg/dL) in a nonstressed subject). This circadian rhythm is lost in patients with Cushing's syndrome so that in the majority of patients the 9 AM plasma cortisol is normal but nocturnal levels are raised. Random morning plasma cortisol levels are therefore of little value in making the diagnosis, and a midnight cortisol level greater than

Note: The above information is a simplified representation of the content provided in the document. For a comprehensive understanding, please refer to the original source.
Certain drugs (phenytoin, rifampicin) may increase the metabolic clearance rate of dexamethasone and lead to false-positive results. Simultaneous measurement of true-positive rate and a false-positive rate less than 1% every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% sensitivity.

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and 48 hours later following dexamethasone given at a dose of 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% true-positive rate and a false-positive rate less than 1%. Sensitivity is higher if plasma rather than urinary cortisol is measured.

Urinary cortisol/creatinine ratio
Corticosteroid excretion
In normal subjects, the administration of a supraphysiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing's syndrome of any cause there is failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given. Various doses of dexamethasone have been used, but 1 mg of dexamethasone is usually given at midnight. A normal response is a plasma cortisol less than 140 nmol/L (5 µg/dL) between 8 and 9 AM the following morning. A dose of 1.5 or 2 mg gives a 30% false-positive rate, whereas after 1 mg this is reduced to 12.5% with a false-negative rate less than 2%. In addition, sensitivity can be improved by reducing the plasma cortisol cutoff value; a postdexamethasone cortisol value of less than 50 nmol/L (2 µg/dL) effectively excludes Cushing's syndrome. Thus, the outpatient overnight test has high sensitivity (95%) but low specificity, and further investigation is often required.

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and 48 hours later following dexamethasone given at a dose of 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% true-positive rate and a false-positive rate less than 1%. Sensitivity is higher if plasma rather than urinary cortisol is measured.

Low-Dose and Overnight Dexamethasone Suppression Tests

In normal subjects, the administration of a supraphysiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing's syndrome of any cause there is failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given. Various doses of dexamethasone have been used, but 1 mg of dexamethasone is usually given at midnight. A normal response is a plasma cortisol less than 140 nmol/L (5 µg/dL) between 8 and 9 AM the following morning. A dose of 1.5 or 2 mg gives a 30% false-positive rate, whereas after 1 mg this is reduced to 12.5% with a false-negative rate less than 2%. In addition, sensitivity can be improved by reducing the plasma cortisol cutoff value; a postdexamethasone cortisol value of less than 50 nmol/L (2 µg/dL) effectively excludes Cushing's syndrome. Thus, the outpatient overnight test has high sensitivity (95%) but low specificity, and further investigation is often required.

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and 48 hours later following dexamethasone given at a dose of 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% true-positive rate and a false-positive rate less than 1%. Sensitivity is higher if plasma rather than urinary cortisol is measured.

Low-Dose and Overnight Dexamethasone Suppression Tests

In normal subjects, the administration of a supraphysiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing's syndrome of any cause there is failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given. Various doses of dexamethasone have been used, but 1 mg of dexamethasone is usually given at midnight. A normal response is a plasma cortisol less than 140 nmol/L (5 µg/dL) between 8 and 9 AM the following morning. A dose of 1.5 or 2 mg gives a 30% false-positive rate, whereas after 1 mg this is reduced to 12.5% with a false-negative rate less than 2%. In addition, sensitivity can be improved by reducing the plasma cortisol cutoff value; a postdexamethasone cortisol value of less than 50 nmol/L (2 µg/dL) effectively excludes Cushing's syndrome. Thus, the outpatient overnight test has high sensitivity (95%) but low specificity, and further investigation is often required.

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and 48 hours later following dexamethasone given at a dose of 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% true-positive rate and a false-positive rate less than 1%. Sensitivity is higher if plasma rather than urinary cortisol is measured.
In patients with depression, urinary free cortisol concentrations may be elevated and overlap those seen in patients with true Cushing's syndrome. Compared with patients with Cushing's disease, depressed patients have greater suppressibility after dexamethasone and a reduced response to CRH, but neither of these tests is diagnostic. However, by performing a CRH test after the standard 2-day low-dose dexamethasone suppression test, separation of true versus pseudo-Cushing's syndrome has been possible. In normal subjects and in patients with endogenous depression, insulin-induced hypoglycemia results in a rise in ACTH and cortisol levels, a response that is usually not seen in Cushing's syndrome. Finally, loperamide lowers cortisol values in patients with pseudo-Cushing's but not in true Cushing's syndrome.

When the biochemical diagnosis has been made, a series of investigations are required to determine the cause of the Cushing's syndrome.

### Plasma ACTH

Ideally, ACTH should be measured using a modern two-site immunoradiometric assay, which differentiates ACTH-dependent from ACTH-independent causes. In Cushing's disease, 50\% of patients have a 9 AM ACTH within the normal reference range (2 to 12 pmol/L [9 to 54 pg/mL]); in the remainder it is modestly elevated. ACTH levels in the ectopic ACTH syndrome are high (usually > 20 pmol/L [90 pg/mL]) but nevertheless overlap values seen in Cushing's disease in 30\% of cases and cannot therefore be used to differentiate these two conditions. The most discriminatory time of day to measure ACTH is actually between 11 AM and 1 AM, when ACTH-cortisol secretion is at a nadir, and in our practice ACTH is usually measured with cortisol in the circadian rhythm studies. A midnight ACTH result greater than 5 pmol/L (23 pg/mL) in a patient with biochemical hypercortisolism confirms that the underlying disease is ACTH-dependent. The measurement of ACTH precursors (pro-ACTH, POMC) is not routinely available but may be more useful in detecting an ectopic source of ACTH; more data are required on patients with occult tumors causing the syndrome.

In patients with adrenal tumors, plasma ACTH is invariably undetectable (<1 pmol/L [4.5 pg/mL]). This can also occur with degradation of ACTH; as a result, nonhemolyzed blood samples should be taken on ice and immediately separated.

### Plasma Potassium

Hypokalemic alkalosis is present in more than 95\% of patients with the ectopic ACTH syndrome but is present in fewer than 10\% of patients with Cushing's disease. As discussed earlier ("Metabolic and Endocrine"), the etiology of this mineralocorticoid excess state is now established. Patients with the ectopic syndrome usually have higher cortisol secretion rates that saturate the renal protective 11-HSD type 2 enzyme, resulting in cortisol-induced, mineralocorticoid hypertension (see Chapter 15). In addition, these patients have higher levels of the ACTH-dependent mineralocorticoid DOC, which are not suppressed.

### High-Dose Dexamethasone Suppression Test

The rationale for this test is that in Cushing's disease there is a resetting of the negative feedback control of ACTH to a higher level than normal. Thus, cortisol levels are low normal or intermittently detectable. This may occur in macronodular hyperplasia. The danger is that in some patients the asymmetry of the nodular hyperplasia may lead to a diagnosis of adrenal adenoma, the plasma ACTH is ignored, and an inappropriate adrenalectomy is performed. Conversely, in some patients with this syndrome an autonomous adrenal tumor develops and, despite detectable ACTH, unilateral adrenalectomy is required.

### Metyrapone Test

Metyrapone blocks the conversion of 11-deoxycortisol to cortisol and DOC to corticosterone by inhibiting 11-hydroxylase. This effect lowers plasma cortisol and, through negative feedback control, increases plasma ACTH. This, in turn, stimulates an increase in the secretion of adrenal steroids proximal to the block. When metyrapone is given in doses of 750 mg every 4 hours for 24 hours, patients with Cushing's disease exhibit an exaggerated rise in plasma ACTH with 11-deoxycortisol levels at 24 hours exceeding 1000 pmol/L (35 pg/dL). In most patients with the ectopic ACTH syndrome there is little or no response, but occasional patients (possibly those producing both ACTH and CRH) have an 11-deoxycortisol response that may be similar to that observed in Cushing's disease.

The metyrapone test was originally used to distinguish patients with Cushing's disease from those with a primary adrenal cause. However, these can be more reliably distinguished by measuring plasma ACTH and subsequent computed tomographic (CT) scanning of the adrenals. As indicated, the test does not reliably distinguish between Cushing's disease and the ectopic ACTH syndrome, and the value of this test in modern endocrine practice has been questioned. It should be reserved for patients when the results of other tests are equivocal.

---

**Figure 14-20** Plasma adrenocorticotropic hormone (ACTH) concentrations in patients with Cushing's disease and Cushing's syndrome associated with adrenocortical tumors and ectopic ACTH syndrome. To convert values to pmol/L, multiply by 0.2202. (From Besser GM, Edwards CRW. Cushing's syndrome. Clin Endocrinol Metab 1972; 1:451-490.)
CRH is a 41-amino-acid peptide identified by Vale in 1981 from ovine hypothalamus. The ovine sequence differs by seven amino acid residues from that of the human but, despite this, is slightly more effective in stimulating the release of ACTH in humans. The test involves the intravenous injection of either ovine or human CRH in a dose of 1 µg/kg body weight or a single dose of 100 µg. In some centers CRH is combined with AVP, which results in an augmented ACTH response. The test can be performed in the morning or afternoon, and, after basal sampling, blood samples for ACTH and cortisol are taken every 15 minutes for 1 to 2 hours following the administration of CRH.

In normal subjects, CRH produces a rise in ACTH and cortisol (approximately 15% to 20%), but this response is exaggerated in Cushing’s disease, where typically an ACTH rise greater than 50% and a cortisol rise greater than 20% over baseline values are seen. No response is seen in the ectopic ACTH syndrome, but false-positive results have been reported. In distinguishing pituitary-dependent Cushing’s from the ectopic ACTH syndrome, the response of ACTH and cortisol to CRH has a specificity and sensitivity of approximately 90%. However, using an ACTH increase of 100% or a cortisol rise of 50% over baseline values, a positive response effectively eliminates a diagnosis of ectopic ACTH syndrome, and this is the real benefit of this test. Up to 10% of patients with Cushing’s disease do not respond to CRH.

**Inferior Petrosal Sinus Sampling and Selective Venous Catheterization**

The most robust test to distinguish Cushing’s disease from the ectopic ACTH syndrome is inferior petrosal sinus sampling (IPSS). As blood from each half of the pituitary drains into the ipsilateral inferior petrosal sinus, catheterization and venous sampling of both sinuses simultaneously can distinguish a pituitary from an ectopic source. In virtually all patients with the ectopic ACTH syndrome, the ratio of ACTH concentrations between the inferior petrosal sinus and simultaneously drawn peripheral venous level is less than 1.4:1. In contrast, in Cushing’s disease this ratio is elevated at greater than 2.0. However, because of the problem of intermittent ACTH secretion, it is useful to make measurements before and at intervals (for example, 2, 5, and 15 minutes) after intravenous injection of 100 µg of synthetic ovine CRH. Using this approach, an ACTH petrosal sinus/peripheral ratio greater than 3.0 after CRH has a sensitivity of 97% and specificity of 100% in diagnosing Cushing’s disease.

IPSS may also be of value in lateralizing a pituitary tumor in a patient in whom imaging techniques have failed to demonstrate a microadenoma, although other centers have found that this is of little value in predicting tumor location. Coadministration of desmopressin with CRH may help in localizing the tumor. However, it should be remembered that many tumors are central and may drain into both sinuses; current evidence suggests that it would unwise to base the surgical procedure on the results of IPSS studies alone.

IPSS is a useful technique for establishing the differential diagnosis of ACTH-dependent Cushing’s syndrome. However, it is technically demanding, has been associated with complications (referred aural pain, thomboembolism), and is expensive. In our practice, it is reserved for cases in which the differential diagnosis is still in doubt after conducting the preceding tests.

Rarely, selective catheterization of vascular beds may be required to identify the source of ectopic ACTH secretion, for example, from a small pulmonary carcinoid or thymic tumor.

**Tumor Markers**

Many tumors responsible for the ectopic ACTH syndrome also produce peptide hormones other than ACTH or its precursors.

**Imaging**

High-resolution, thin-section contrast-enhanced imaging using either CT or magnetic resonance imaging (MRI) has revolutionized the investigation of Cushing’s syndrome. However, the results of any imaging technique must always be interpreted alongside the biochemical results if mistakes are to be avoided. In imaging the adrenals, asymmetric nodular hyperplasia may lead to a false diagnosis of adrenal adenoma. Because of the presence of pituitary incidentalomas, pituitary CT or MRI scanning may produce false-positive results, particularly for lesions less than 5 mm in diameter.

Pituitary MRI is the investigation of choice when the biochemical tests suggest Cushing’s disease, with a sensitivity of 70% and specificity of 87%. About 90% of ACTH-secreting pituitary tumors are microadenomas (i.e., less than 10 mm in diameter). The classical features of a pituitary microadenoma are a hypodense lesion after contrast, associated with deviation of the pituitary stalk and a convex upper surface of the pituitary gland. With such small tumors it is not surprising that the sensitivity of CT scanning is relatively low (20% to 60%) with a similar specificity.

By contrast, for adrenal imaging, CT rather than MRI is the investigation of choice, offering better spatial resolution, but MRI scanning may provide diagnostic information in patients with suspected adrenal carcinoma. Once again, it is stressed that adrenal incidentalomas are present in up to 5% of normal subjects (see later), and thus adrenal imaging should not be performed unless biochemical investigation suggests a primary adrenal cause (undetectable ACTH concentrations). Adrenal carcinomas are large and often associated with metastatic spread at presentation.

In patients with occult ectopic ACTH syndrome, high-definition CT or MRI scanning of thorax, abdomen, and pelvis...
with images every 0.5 cm may be required to detect small ACTH-secreting carcinoid tumors (Fig. 14-26) (Figure Not Available).

### Scintigraphy Studies

Scintigraphy is of value in certain patients with primary adrenal pathology. The most commonly used agent is $^{131}$I-labeled 6-Iodomethyl-19-norcholesterol. This is a marker of adrenocortical cholesterol uptake. In patients with adenomas, the isotope is taken up by the

![Image](image_url)

### Treatment of Cushing's Syndrome

#### Adrenal Causes

Adrenal adenomas should be removed by unilateral adrenalectomy, which has a 100% cure rate. With the increasing experience of laparoscopic adrenalectomy in most tertiary centers, this has now become the surgical treatment of choice for unilateral tumors, reducing surgical morbidity and postoperative hospital stay compared with traditional open approaches. After operation it may take many months or even years for the contralateral suppressed adrenal to recover. It is wise, therefore, to give slightly suboptimal replacement therapy with dexamethasone at 0.5 mg in the morning, with intermittent measurement of morning plasma cortisol before taking dexamethasone. When the morning plasma cortisol is above 180 nmol/L (6 µg/dL), dexamethasone can be stopped. A subsequent negative dexamethasone suppression test confirms adrenal recovery. In the interim, all patients should carry a Steroid Alert card and increase their dose of replacement therapy in the event of an intermittent illness (see earlier).

### Adrenal Carcinomas

Adrenal carcinomas have a poor prognosis, and most patients are dead within 2 years of diagnosis. It is usual practice to try to remove the primary tumor even though metastases may be present so as to enhance the response to the adrenolytic agent $p,p'$-dichlorodiphenyldichloroethane ($p,p'$-DDD, mitotane, see later). Radiotherapy to the tumor bed and to some metastases, such as those in the spine, may be of limited value.

### Pituitary-Dependent Cushing's Syndrome

The treatment of Cushing's disease has been significantly enhanced through transsphenoidal surgery conducted by an experienced surgeon. Before the selective removal of a pituitary microadenoma, the treatment of choice was bilateral adrenalectomy. This had an appreciable mortality even in the best centers (up to 4%) and significant morbidity. The major risk was the subsequent development of Nelson's syndrome (postadrenalectomy hyperpigmentation with a locally aggressive pituitary tumor) [Fig. 14-27]. This is often attributed to loss of any negative feedback after adrenalectomy. In an attempt to avoid this, pituitary radiation was often carried out at the time of bilateral adrenalectomy. In addition, these patients required lifelong replacement therapy with dexamethasone at 0.5 mg in the morning, with intermittent measurement of morning plasma cortisol before taking dexamethasone. When the morning plasma cortisol is above 180 nmol/L (6 µg/dL), dexamethasone can be stopped. A subsequent negative dexamethasone suppression test may then demonstrate whether the response to stress is normal. In the interim, all patients should carry a Steroid Alert card and increase their dose of replacement therapy in the event of an intermittent illness (see earlier).

The surgical outcome for transsphenoidal hypophysectomy is center-dependent and related to surgical expertise. Because of the hazards of untreated Cushing's disease and potential complications of surgery, the endocrinologist should refer cases only to a recognized surgical specialist where outcome data have been established. In optimal centers, cure rates are 80% to 90% for microadenomas and 50% for macroadenomas. Rates for hypopituitarism and permanent diabetes insipidus postoperatively depend on how aggressive the surgeon has been in removing pituitary tissue. The ideal outcome is a cured patient with intact pituitary function, but this may not be possible in a patient with Cushing's disease in whom a pituitary adenoma was not identified preoperatively or during the
operation itself.

At the time of surgery, patients should be treated with corticosteroids as for any other potential or confirmed deficit of the HPA axis (see later). Postoperatively, hydrocortisone can be withdrawn to maintenance replacement doses, usually within 3 to 7 days. On day 5 postoperatively, plasma cortisol should be measured at 9 AM with the patient having omitted hydrocortisone for 24 hours. After selective removal of a microadenoma, the surrounding corticotrophs are normally suppressed (Fig. 14-28). In these cases plasma cortisol levels are less than 30 nmol/L (1 µg/dL) postoperatively and glucocorticoid replacement therapy is required. Using the dexamethasone regimen described earlier after removal of an adenoma, there is usually (but not invariably) gradual recovery of the HPA axis (Fig. 14-29). A nonsuppressed plasma cortisol postoperatively suggests that the patient is not cured even though cortisol secretion may have fallen to normal or subnormal values. The recurrence rate in patients with an established cure after pituitary surgery is 2%, but this value is higher in children (up to 40%). A detailed assessment of residual pituitary function is required in each case, and close follow-up of such individuals is warranted.

In the past, pituitary radiation was often used in the treatment of Cushing's disease. However, the improvements in pituitary surgery have resulted in far fewer patients being so treated. In children, pituitary radiation appears to be more effective. Radiotherapy is not recommended as a primary treatment but is reserved for patients who do not respond to pituitary microsurgery, those in whom bilateral adrenalectomy has been performed, or patients with established Nelson's syndrome.

Ectopic Adrenocorticotropic Hormone Syndrome

Treatment of the ectopic ACTH syndrome depends on the cause. If the tumor can be found and has not spread, then its removal can lead to cure (e.g., bronchial carcinoid or thymoma). However, the prognosis for small cell lung cancer associated with the ectopic ACTH syndrome is poor. The cortisol excess and associated hypokalemia and diabetes mellitus can be ameliorated by medical therapy. The treatment of the small cell tumor itself also, at least initially, produces improvement. Sometimes, if the ectopic source of ACTH cannot be found, it may be necessary to perform bilateral adrenalectomy and then observe the patient carefully (sometimes for several years) before the primary tumor becomes apparent.

Medical Treatment of Cushing's Syndrome

Several drugs have been used in the treatment of Cushing's syndrome. Metyrapone inhibits 11-hydroxylase and has been most commonly given, often to lower cortisol concentrations prior to definitive therapy or while awaiting benefit from pituitary radiation. The daily dose has to be determined by measuring either plasma or urinary free cortisol. The aim should be to achieve a mean plasma cortisol of about 300 nmol/L (11 µg/dL) during the day or a normal urinary free cortisol. The drug is usually given in doses ranging from 250 mg twice daily to 1.5 g every 6 hours. Nausea is a side effect that can be helped (if it is not due to adrenal insufficiency) by giving the drug with milk.

Aminoglutethimide is a more toxic drug that, in high doses, blocks earlier enzymes in the steroidogenic pathway and thus affects the secretion of steroids other than cortisol. In doses of 1.5 to 3 g daily (start with 250 mg every 8 hours) it commonly produces nausea, marked lethargy, and a high incidence of skin rash. It is commonly prescribed as combination therapy with metyrapone.

Trilostane, a 3-HSD inhibitor, is ineffective in Cushing's disease, as the block in steroidogenesis is overcome by the rise in ACTH. However, it can be effective in patients with adrenal adenomas.

Ketokonazole is an imidazole that has been widely used as an antifungal agent but causes abnormal liver function tests in about 15% of patients. Ketokonazole blocks a variety of steroidogenic cytochrome P450-dependent enzymes and thus lowers plasma cortisol levels. For effective control of Cushing's syndrome, 400 to 800 mg daily has been required.

Mitotane is an adrenolytic drug that is taken up by both normal and malignant adrenal tissue, causing adrenal atrophy and necrosis. Because of its toxicity, it has been used mainly in the management of adrenal carcinoma. Doses of up to 10 to 20 g/day are required to control glucocorticoid excess, although evidence that it causes tumor shrinkage or improves long-term survival is lacking. The drug also produces mineralocorticoid deficiency, and concomitant glucocorticoid and mineralocorticoid replacement therapy may be required. Side effects are common and include fatigue, skin rashes, and gastrointestinal disturbance.

Prognosis of Cushing's Syndrome

Studies carried out before the introduction of effective therapy indicated that 50% of patients with untreated Cushing's syndrome died within 5 years, principally from vascular disease. Even with modern management, an increased prevalence...
Figure 14-29 Gradual recovery of function of the hypothalamic-pituitary-adrenal axis after removal of a pituitary adrenocorticotropic hormone-secreting microadenoma. The insulin hypoglycemia test (I.H.T.) eventually demonstrated the return of a normal stress response.
Glucocorticoid Resistance

A small number of patients have been described who have increased cortisol secretion but without the stigmata of Cushing's syndrome. These patients are resistant to suppression of cortisol with low-dose dexamethasone but respond to high doses. ACTH levels are elevated and lead to increased adrenal production of androgens and DOC. Thus, patients may present with the features of androgen or mineralocorticoid excess, or both. Treatment with a dose of dexamethasone adequate to suppress ACTH (usually 3 mg/day) results in a fall in adrenal androgens and often return of plasma potassium and blood pressure to normal levels. Many of these patients have been found to have point mutations in the steroid-binding domain of the GR, with consequent reduction of glucocorticoid-binding affinity, but this is not invariable. A useful clinical discriminatory test to differentiate this condition from Cushing's syndrome is to measure bone mineral density; this is preserved in patients with glucocorticoid resistance or even increased in female patients because of the androgen excess. In addition, circadian rhythm for ACTH and cortisol is preserved in patients with glucocorticoid resistance.
Glucocorticoid Deficiency

Primary and Secondary Hypoadrenalism

Primary hypoadrenalism refers to glucocorticoid deficiency occurring in the setting of adrenal disease; secondary hypoadrenalism arises because of deficiency of ACTH (Table 14-16). A major distinction between these two is that mineralocorticoid deficiency invariably accompanies primary hypoadrenalism but does not occur in secondary hypoadrenalism because only ACTH is deficient; the renin-angiotensin-aldosterone axis is intact. A further important cause of adrenal insufficiency where there may be dissociation of glucocorticoid and mineralocorticoid secretion is congenital adrenal hyperplasia (CAH) (see later).

Primary Hypoadrenalism

Addison's Disease

Thomas Addison described this condition in his classical monograph published in 1855.

Etiology.

This is a rare condition with an estimated incidence in the developed world of 0.8 cases per 100,000 and prevalence of 4 to 11 cases per 100,000 population. It is associated with significant morbidity and mortality, but when the diagnosis is made it can be easily treated. The causes of Addison's disease are listed in Table 14-16.

Autoimmune Adenititis.

In the Western world, autoimmune adrenalitis accounts for over 70% of all cases. Pathologically, the adrenal glands are atrophic, with loss of most of the cortical cells, but the medulla is usually intact. In 75% of cases adrenal autoantibodies can be detected. Fifty percent of patients with this form of Addison's disease have an associated autoimmune disease (Table 14-17), thyroid disease being the commonest. Conversely, only 1% to 2% of patients with commoner autoimmune diseases such as insulin-dependent diabetes mellitus or thyrotoxicosis have antialdrenal autoantibodies and adrenal disease. This figure is higher in patients with autoimmune hypoparathyroidism (16%).

These autoimmune polyendocrine syndromes (APS) I and II have been classified into two distinct variants. APS type I is inherited as an autosomal recessive condition and comprises Addison's disease, chronic mucocutaneous candidiasis, and hypoparathyroidism. Also called autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy

dysplasia (APECED) (Table 14-18), the condition is rare and is usually seen in childhood with either candidiasis or hypoparathyroidism. Other autoimmune conditions such as pernicious anemia, thyroid disease, chronic active hepatitis, and gonadal failure may occur but are rare (see also Chapter 37). The adrenal autoantibodies characterizing PGA type I are to the steroidogenic enzymes side-chain cleavage and 17-hydroxylase but not to 21-hydroxylase. The disease has been mapped to chromosome 21q22.3, and mutations in a transcription regulation gene designated AIRE (autoimmune regulator) have been defined.

APS II is commoner and comprises Addison’s disease, autoimmune thyroid disease, diabetes mellitus, and hypogonadism (see Table 14-18). The condition has an inherited basis with linkage to the human leukocyte antigen (HLA) major histocompatibility complex, notably HLA DR3 and HLA DR4. Autoantibodies to 21-hydroxylase are usually present and are predictive of the development of adrenal destruction.

Other autoimmune conditions such as pernicious anemia, thyroid disease, chronic active hepatitis, and gonadal failure may occur but are rare (see also Chapter 37). The condition has an inherited basis with linkage to the human leukocyte antigen (HLA) major histocompatibility complex, notably HLA DR3 and HLA DR4. Autoantibodies to 21-hydroxylase are usually present and are predictive of the development of adrenal destruction.

Other features may accompany APS I and APS II (see Table 14-18). Patients

with APS are more likely to be female (70%); conversely, patients presenting with isolated autoimmune adrenalitis are usually male.

Infections.

Worldwide, infectious diseases are the commonest cause of primary adrenal insufficiency and comprise tuberculosis, fungal infections (histoplasmosis, cryptococcosis), and cytomegalovirus infection. Adrenal failure may also occur in the acquired immunodeficiency syndrome.

Tuberculous Addison’s disease results from hematogenous spread of the infection from elsewhere in the body, and extra-adrenal disease is usually evident. The adrenals are initially enlarged with extensive epithelioid granulomas and caseation, and both the cortex and the medulla are affected. Fibrosis ensues, and the adrenals become normal or smaller in size with calcification evident in 50% of cases.

The adrenals are frequently involved in patients with acquired

</table>
immunodeficiency syndrome (AIDS); adrenalitis may occur after infection with cytomegalovirus or atypical mycobacterium, and Kaposi's sarcoma may result in adrenal replacement. The onset is often insidious, but if tested, over 10% of patients with AIDS demonstrate a subnormal cortisol response following a short Synacthen test. Adrenal insufficiency may be precipitated through the concomitant administration of appropriate anti-infectives such as ketoconazole (inhibits cortisol synthesis) or rifampin (increases cortisol metabolism). Rarely, patients with AIDS and features of adrenal insufficiency are found to have elevated circulating ACTH and cortisol concentrations that are not suppressed normally by low-dose dexamethasone administration. This is thought to reflect an acquired form of glucocorticoid resistance related to reduced GR affinity, but the underlying cause remains unknown.

Miscellaneous.

With the exception of tuberculosis and autoimmune adrenal failure, other causes of Addison's disease are rare (see Table 14-16). Adrenal metastases (commonest primary being lung and breast) are often found at postmortem examination, but adrenal insufficiency resulting from these is uncommon, perhaps because over 90% of the adrenal cortex needs to be compromised before symptoms and signs become apparent. Necrosis of the adrenals related to intra-adrenal hemorrhage should be considered in any severely sick patient, particularly those with underlying infection, trauma, or coagulopathy. Intra-adrenal bleeding may be found with any cause of severe septicemia, particularly in children, in whom a common cause is infection with Pseudomonas aeruginosa. When Addison's disease is caused by meningococcus, the association with adrenal insufficiency is known as the Waterhouse-Friderichsen syndrome. Adrenal replacement may also occur with amyloidosis and hemochromatosis.

Adrenal hypoplasia congenita is an X-linked disorder comprising congenital adrenal insufficiency and hypogonadotropic hypogonadism. The condition is caused by mutations in the dosage-sensitive sex reversal, adrenal hypoplasia congenita, X-chromosome factor (DAX-1) gene, a member of the nuclear receptor family of unknown function that is expressed in the adrenal cortex, gonads, and hypothalamus. Mutations in another transcription factor, steroidogenic factor-1, also result in adrenal insufficiency related to lack of development of a functional adrenal cortex. The transcriptional regulation of many P450 steroidogenic enzymes is dependent upon steroidogenic factor-1. Congenital adrenal hypoplasia may also occur in association with glycogen kinase deficiency and muscular dystrophy.

Adrenoleukodystrophy has a prevalence of 1 in 20,000 and is a cause of childhood adrenal insufficiency in association with demyelination within the nervous system related to a failure of beta oxidation of fatty acids within peroxisomes because of reduced activity of very-long-chain acyl-CoA synthetase (VLCs). Increased accumulation of very-long-chain fatty acids occurs in many tissues, and serum assays can be used diagnostically. Only males have the fully expressed condition, and carrier females are usually normal. Several forms are recognized: a childhood cerebral form (30% to 40% of cases), adult adrenomyeloneuropathy (40% of cases), and Addison's disease only (7% of cases).

The childhood-onset form occurs at 5 to 10 years of age with eventual progression to a blind, mute, and severely spastic tetraplegic state. Adrenal insufficiency is usually present but does not appear to correlate with the neurologic deficit. Nevertheless, this is the commonest form of adrenal insufficiency in a child younger than 7 years. Adrenoleukomyelopathy, by contrast, arises later in life with the gradual development of spastic paresis and peripheral neuropathy. Both the childhood and adult conditions result from mutations in a gene on chromosome Xq28 that encodes a peroxisomal membrane protein with homology to the adenosine triphosphatase-binding membrane transporter proteins. At present, there are no genotype-phenotype correlations and it is uncertain how these mutations affect the activity of VLCs. Treatment is unsuccessful. Monounsaturated fatty acids that block the synthesis of the saturated very-long-chain fatty acids have been used. A combination of erucic acid and oleic acid (Lorenzo's oil) has led to normal levels of very-long-chain fatty acids, but this has not altered the rate of neurologic deterioration. However, more promising results have been obtained after bone marrow transplantation.

Familial glucocorticoid deficiency is a rare, autosomal recessive cause of hypothalamic adenohypophyseal dysfunction that is usually seen in childhood. The renin-angiotensin-aldosterone axis is intact, and children usually present either with neonatal hypoglycemia or later with increasing pigmentation, often with enhanced growth velocity. Patients have glucocorticoid deficiency with very high plasma ACTH levels; this occurs because of mutations in the melanocortin-2 or ACTH receptor (MC2R) on chromosome 18p11.2 in some but not all cases. A variant is called triple A or Allgrove's syndrome and refers to the triad of adrenal insufficiency related to ACTH resistance, achalasia, and alacrima. It is not caused by mutations in the MC2R; studies have mapped this disease to chromosome 12q13, and mutations in a novel gene have been reported.

Secondary Hypoadrenalism (Adrenocorticotropic Hormone Deficiency)

This is a common clinical problem and is most often due to sudden cessation of exogenous glucocorticoid therapy. Such therapy suppresses the hypothalamic-pituitary-adrenal axis with consequent adrenal atrophy, and this may last for months after stopping glucocorticoid treatment. Adrenal atrophy and subsequent deficiency should be anticipated in any subject who has taken more than the equivalent of 30 mg of hydrocortisone per day orally (7.5 mg/day prednisolone or 0.75 mg/day dexamethasone) for more than 3 weeks. In addition to the magnitude of the dose of glucocorticoid, the timing of administration of the dose may affect the degree of adrenal suppression. Thus, prednisolone in a dose of 5 mg given last thing at night and 2.5 mg in the morning produces more marked suppression of the hypothalamic-pituitary-adrenal axis than 2.5 mg at night and 5 mg in the morning because the larger evening dose blocks the early morning surge of ACTH. Secondary hypothalamic dysfunction may also occur after failure to give adequate glucocorticoid replacement therapy for intercurrent stress in a patient who has received long-term glucocorticoid therapy. Other causes of secondary adrenal insufficiency (see Table 14-16) reflect inadequate ACTH production from the anterior pituitary gland. In many of these, other pituitary hormones are deficient in addition to ACTH and the patient presents with partial or complete hypopituitarism. The clinical features of hypopituitarism make a relatively easy diagnosis (see also Chapter 8). Isolated ACTH deficiency is rare but a difficult diagnosis to make. It may occur in patients with lymphocytic hypophysitis. A rare but fascinating cause is related to a defect in the normal post-translational processing of POMC to ACTH by the prohormone convertase enzymes (PC1 and PC2). Such patients may have more generalized defects in peptide processing (e.g., cleavage of proinsulin to insulin) giving rise to diabetes mellitus. Patients have also been reported with mutations in the POMC gene that interrupt the synthesis of ACTH and causes ACTH deficiency. The elucidation of the phenotype of these cases, however, has uncovered a novel role for POMC peptides in regulating appetite and hair color. A central role for -MSH in regulating food intake through the hypothalamic

melandocortin-4 receptor has been established. Thus, in addition to adrenal insufficiency, mutations in the POMC gene result in severe obesity and red hair pigmentation. In recombinant mice lacking the POMC gene, the obese phenotype can be reversed by giving an -MSH agonist peripherally.

Secondary hypothalamic dysfunction is also observed in patients with Cushing's disease after successful and selective removal of the ACTH-secreting pituitary adenoma. The function of adjacent "normal" pituitary corticotrophs is suppressed and may remain so for many months after surgery.

Patients have primary adrenal failure usually have both glucocorticoid and mineralocorticoid deficiency. In contrast, those with secondary adrenal insufficiency have an intact renin-angiotensin-aldosterone system. This accounts for differences in salt and water balance in the two groups of patients, which in turn result in different

Clinical Features of Adrenal Insufficiency

clinical presentations. The most obvious feature that differentiates primary from secondary hypoadrenalism is skin pigmentation (Table 14-19 and Fig. 14-30), which is nearly always present in primary adrenal insufficiency (unless of short duration) and absent in secondary insufficiency. The pigmentation is seen in sun-exposed areas, recent rather than old scars, axillae, nipples, palmar creases, pressure points, and in mucous membranes (buccal, vaginal, vulval, anal). The cause of the pigmentation has long been debated, but it is thought to reflect increased stimulation of the melanocortin-2 receptor by ACTH itself. In autoimmune Addison’s disease there may be associated vitiligo (see Fig. 14-30).

The clinical features are related to the rate of onset and severity of adrenal deficiency. In many cases, the disease has an insidious onset and a diagnosis is made only when the patient presents with an acute crisis during an intercurrent illness. Acute adrenal insufficiency or an adrenal or addisonian crisis is a medical emergency manifesting as hypotension and

Acute circulatory failure (Table 14-20). Anorexia may be an early feature, which progresses to nausea, vomiting, diarrhea, and sometimes abdominal pain. Fever may be present, and hypoglycemia may occur. Patients presenting acutely with adrenal hemorrhage have hypotension; abdominal, flank, or lower chest pain; anorexia; and vomiting. The condition is difficult to diagnose, but evidence of occult hemorrhage (rapidly falling hemoglobin), progressive hyperkalemia, and shock should alert the clinician to the diagnosis.

Alternatively, the patient may present with vague features of chronic adrenal insufficiency: weakness, tiredness, weight loss, nausea, intermittent vomiting, abdominal pain, diarrhea or constipation, general malaise, muscle cramps, arthralgia, and symptoms suggestive of postural hypotension (see Table 14-19). Salt craving may be a feature, and there may be a low-grade fever. Supine blood pressure is usually normal, but almost invariably there is a fall in blood pressure on standing. Although adrenal androgen secretion is lost, this is clinically more apparent in women, who may complain of loss of axillary and pubic hair. Psychiatric symptoms may occur in long-standing cases and include memory impairment, depression, and psychosis. Patients may be inappropriately diagnosed as suffering from chronic fatigue syndrome or anorexia nervosa. These features regress upon treatment with replacement corticosteroids.

In secondary adrenal insufficiency associated with hypopituitarism, the presentation may be related to deficiency of hormones other than ACTH, notably LH or FSH (infertility, oligomenorrhea or amenorrhea, poor libido) and TSH (weight gain, cold intolerance). Fasting hypoglycemia occurs because of loss of the gluconeogenic effects of cortisol. It is rare in adults unless there is concomitant alcohol abuse or additional GH deficiency. However, hypoglycemia is a common presenting feature of ACTH or adrenal insufficiency in childhood. In addition, patients with ACTH deficiency present with malaise, weight loss, and other features of chronic adrenal insufficiency. Rarely, the presentation may be more acute in patients with pituitary apoplexy.

Investigation of Hypoadrenalism

Routine Biochemical Profile

In established primary adrenal insufficiency, hyponatremia is present in about 90% of cases and hyperkalemia in 65%. The blood urea concentration is usually elevated. Hyperkalemia occurs because of aldosterone deficiency and is therefore usually absent in patients with secondary adrenal failure. Hyponatremia may be depletional in an addisonian crisis, but in addition vasopressin levels are elevated, resulting in increased free water retention. Thus, in secondary adrenal insufficiency there may be a dilutional hyponatremia with normal or low blood urea. Reversible abnormalities in liver transaminases frequently occur. Hypercalcemia occurs in 6% of all cases and may be particularly marked in patients with coexisting thyrotoxicosis. However, free thyroxine concentrations are usually low or normal but TSH values are frequently moderately elevated. This is a direct effect of glucocorticoid deficiency and reverses with replacement therapy. Persistent elevation of TSH in association with positive thyroid autoantibodies suggests concomitant autoimmune thyroid disease.

Mineralocorticoid Status

In primary hypoadrenalism, mineralocorticoid deficiency usually occurs with elevated plasma renin activity and either low or low normal plasma aldosterone. The investigation of zona glomerulosa activity is frequently neglected in Addison’s...
Clinical suspicion of the diagnosis should be confirmed with definitive diagnostic tests. Basal plasma cortisol and urinary free cortisol levels are often in the low normal range and cannot be used to exclude the diagnosis. However, a basal cortisol value greater than 400 nmol/L (15 µg/dL) invariably indicates an intact HPA axis. In practice, rather than waiting for results of insensitive basal tests, all patients suspected of having adrenal insufficiency should have an ACTH stimulation test, although in patients with an Addisonian crisis treatment should be instigated immediately and stimulation tests conducted at a later stage.

The ACTH stimulation test involves intramuscular or intravenous administration of 250 µg of tetracosactrin (Synacthen), comprising the first 24 amino acids of normally secreted ACTH 1 to 39. Plasma cortisol levels are measured at 0 and 30 minutes after ACTH, and a normal response is defined by a peak plasma cortisol level greater than 525 nmol/L (19 µg/dL). This value equates to the fifth percentile response in normal subjects but is assay-dependent, with different cortisol radioimmunoassays giving different results. Incremental responses (i.e., the difference between peak and basal values) are of no value in defining a pass response and should not be used. Response is unaffected by the time of day of the test, and the test can be performed in patients who have commenced corticosteroid replacement therapy provided this is of short duration and does not include hydrocortisone (which would cross-react in the cortisol assay).

A prolonged ACTH stimulation test, involving the administration of depot or intravenous infusions of tetracosactrin for 24 to 48 hours, differentiates primary from secondary hypoadrenalism. In normal subjects the plasma cortisol at 4 hours is greater than 1000 nmol/L (36 µg/dL), and beyond this time there is no further increase. Patients with secondary hypoadrenalism show a delayed response with usually a much higher value at 24 and 48 hours than at 4 hours, but in primary hypoadrenalism there is no response at either time. However, the test is now rarely required if plasma ACTH has been appropriately measured at baseline. In primary adrenal insufficiency the ACTH level is disproportionately elevated in comparison with plasma cortisol.

Although there is agreement about the investigation of suspected primary adrenal failure, the diagnosis of secondary hypoadrenalism, notably in patients with existing hypothalamic or pituitary disease, is contentious. Based on correlations with the response of circulating cortisol to surgery, the insulin-induced hypoglycemia test or insulin tolerance test was introduced over 30 years ago as a laboratory test to assess the integrity of the HPA axis and should be considered the "gold standard" in this regard. It should not be performed in patients with ischemic heart disease (always check an electrocardiogram before the test), epilepsy, or severe hypopituitarism (that is, < 9 µg plasma cortisol less than 180 nmol/L [6 µg/dL]). The test involves intravenous administration of soluble insulin in a dose of 0.1 to 0.15 U/kg body weight with measurement of plasma glucose at 0, 30, 45, 60, 90, and 120 minutes. Adequate hypoglycemia (blood glucose less than 39 µg/dL [2.2 mmol/L] with signs of neuroglycopeniasweating and tachycardia) is essential. In normal subjects the peak plasma cortisol exceeds 500 nmol/L (19 µg/dL).

However, the cortisol response to hypoglycemia can be reliably predicted by the response to acute ACTH stimulation (see earlier), a safer, cheaper, and quicker test. This test relies on the principle that the cortisol response to an exogenous bolus of ACTH is determined by the endogenous ACTH trophic drive to the adrenal cortex, impaired ACTH secretion from the anterior pituitary resulting in an impaired cortisol response after Synacthen. However, the ACTH test should not be used to diagnose secondary hypoadrenalism in patients with a recent pituitary insult (surgery, apoplexy). Total hypophysectomy would result in a failed cortisol response to an insulin tolerance test immediately thereafter, but it takes 2 to 3 weeks for the adrenal cortex to readjust to the reduced level of ACTH secretion; in the interim, a false-positive cortisol response would be seen.

The short Synacthen test should also be avoided in patients with a primary diagnosis of Cushing's disease, in whom an exaggerated cortisol response to ACTH may persist. In clinical practice, if the ACTH test is normal, insulin hypoglycemia testing is not necessary in the vast majority of cases unless there is also a need to document endogenous GH reserve in a patient with pituitary disease. In our practice, an insulin tolerance test is performed if, in a patient with suspected hypopituitarism, there is a subnormal response to ACTH. Some patients have an inadequate response to ACTH but then respond normally to hypoglycemia. They do not require corticosteroid replacement therapy. This approach is open to debate, and even taking into account the preceding caveats, false-positive results have been reported for the short Synacthen test; although these are rare (<2% of cases) this should be noted, particularly in patients with ongoing symptoms and signs indicative of hypoadrenalism.

A low-dose ACTH stimulation test giving only 1 µg of ACTH has been proposed as a screen for adequacy of function of the HPA axis with the suggestion that it may be more sensitive than the conventional 250-µg test. Further validation of this test is required to support such a concept.

Two other tests have been advocated to assess adequacy of function of the HPA axis, but their use in modern clinical practice should be restricted to difficult diagnostic cases. In the overnight metyrapone test, metyrapone is given at 30 mg/kg (maximum 3 g) at midnight and plasma cortisol and 11-deoxycortisol are measured at 8 AM the following morning. In patients with an intact axis, ACTH levels rise after the blockade of cortisol synthesis by metyrapone and a normal result is signified by a peak 11-deoxycortisol value greater than 200 nmol/L (7 µg/dL). The CRH stimulation test has been used to diagnose adrenal insufficiency and, unlike the metyrapone test, differentiates primary from secondary causes. Patients with primary adrenal failure have high ACTH levels that rise further after CRH. Conversely, patients with secondary adrenal failure have low ACTH levels that fail to respond to CRH. Patients with hypothalamic disease show a steady rise in ACTH levels after CRH.

Other Tests

Radioimmunoassays to detect autoantibodies such as those against the 21-hydroxylase antigen are now available and should be analyzed in patients with primary adrenal failure. In autoimmune Addison's disease, it is also important to look for evidence of other organ-specific autoimmune disease. A CT scan may reveal enlarged or calcified adrenals, suggesting an infective, hemorrhagic, or malignant diagnosis.
For patients with both primary and secondary adrenal failure, beneficial effects of adrenal androgen replacement therapy with DHEA at 25 to 50 mg/day have been observed. Every patient receiving glucocorticoid therapy should be advised to register for a Medic Alert bracelet or necklace and must carry a Steroid Alert card.

For acute adrenal insufficiency, beneficial effects of adrenal androgen replacement therapy with DHEA at 25 to 50 mg/day have been observed. Every patient receiving glucocorticoid therapy should be advised to register for a Medic Alert bracelet or necklace and must carry a Steroid Alert card.

Chronic Replacement Therapy

The aim is to give replacement doses of hydrocortisone to mimic the normal cortisol secretion rate (Table 14-22). Initially, this was thought to be approximately 25 to 30 mg/day, but stable isotope studies indicate lower normal cortisol production rates of 22 to 41 µmol/day (8 to 15 mg/day). Increasingly, most patients can cope with less than 84 µmol/day (30 mg/day) (usually 15 to 25 mg/day in divided doses). Doses are usually given on waking, with a smaller dose in the late afternoon, but some patients may feel better with doses three times daily. In primary adrenal failure, cortisol day curves with simultaneous ACTH measurements may provide some insight into the adequacy of replacement therapy, but unfortunately there are no good objective tests in secondary adrenal failure. Decisions about doses of replacement therapy are largely based on crude but nevertheless important end points such as weight, well-being, and blood pressure. Bone mineral density may be reduced with conventional hydrocortisone doses of 30 mg/day, highlighting the need to strive for minimally effective but safe doses.

In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone (or 9-fluorinated hydrocortisone) at 0.05 to 0.2 mg/day. The mineralocorticoid activity of this is about 125 times that of hydrocortisone. After the acute phase has passed, the adequacy of mineralocorticoid replacement should be assessed by measuring electrolytes and supine and erect blood pressure and plasma renin activity; too little fludrocortisone may cause postural hypotension with elevated plasma renin activity and too much may cause the converse. Mineralocorticoid replacement therapy is all too frequently neglected in patients with adrenal failure.

Emergency Measures

1. Establish intravenous access with a large-gauge needle.
2. Draw blood for stat serum electrolytes and glucose and routine measurement of plasma cortisol and ACTH. Do not wait for laboratory results.
3. Infuse 2 to 3 L of 154 mmol/L NaCl (0.9% saline) solution or 50 g/L (5%) dextrose in 154 mmol/L NaCl (0.9% saline) solution as quickly as possible. Monitor for signs of fluid overload by measuring central or peripheral venous pressure and listening for pulmonary rales. Reduce infusion rate if indicated.
4. Inject intravenous hydrocortisone (100 mg immediately and every 6 hr)
5. Use supportive measures as needed.

ACTH, adrenocorticotropic hormone.

Patients receiving glucocorticoid replacement therapy should be advised to double the daily dose in the event of intercurrent febrile illness, accident, or mental stress such as an important examination. If the patient is vomiting and cannot take medication by mouth, parenteral hydrocortisone must be given urgently, as indicated earlier. For minor surgery, 50 to 100 mg of hydrocortisone hemisuccinate is given with the premedication. For major operations, this is then followed by the same regimen as for acute adrenal insufficiency (see Table 14-22). Pregnancy proceeds normally in patients taking replacement therapy, but daily doses of hydrocortisone are usually increased modestly (5 to 10 mg/day) in the last trimester. During labor, patients should be well hydrated with a saline drip and receive hydrocortisone at 50 mg intramuscularly every 6 hours until delivery. Thereafter, doses can be rapidly tapered off to usual maintenance regimens.

For patients receiving glucocorticoid therapy who are not receiving corticosteroid therapy, beneficial effects of adrenal androgen replacement therapy with DHEA at 25 to 50 mg/day have been observed.
reported. To date, the reported benefit is principally confined to female patients and includes improvement in sexual function and well-being.
Congenital Adrenal Hyperplasia

These inherited syndromes are caused by deficient adrenal corticosteroid biosynthesis. In each case, there is reduced negative feedback inhibition of cortisol and, depending on the steroidogenic pathway involved, alteration in adrenal mineralocorticoid and androgen secretion (Table 14-23).

21-Hydroxylase Deficiency

Ninety percent of cases of CAH are due to 21-hydroxylase deficiency. In Western societies the incidence varies from 1 in 5000 to 1 in 15,000 live births, but in isolated communities the incidence may be much higher (1 in 300 in Alaskan Eskimos, for example). The condition arises because of defective conversion of 17-hydroxyprogesterone to 11-deoxycortisol. Reduced cortisol biosynthesis results in reduced negative feedback drive and increased ACTH secretion; as a consequence, adrenal androgens are produced in excess (Fig. 14-32). Seventy-five percent of cases have mineralocorticoid deficiency because of failure to convert progesterone to DOC in the zona glomerulosa. Clinically, several distinct variants of 21-hydroxylase deficiency have been recognized (Table 14-24).

Simple Virilizing Form

The enhanced ACTH drive to adrenal androgen secretion in utero leads to virilization of an affected female fetus. Depending on the severity, clitoral enlargement, labial fusion, and development of a urogenital sinus may occur, leading to sexual ambiguity at birth and even inappropriate sex assignment. Rarely, the diagnosis is not made in the neonatal period, especially in boys, who may be phenotypically normal at birth. Such

| Table 14-22 — Treatment of Chronic Primary Adrenal Insufficiency |
|------------------|------------------|
| **Maintenance Therapy** |
| **Glucocorticoid Replacement** |
| Hydrocortisone 1520 mg on awakening and 510 mg in early afternoon. |
| Monitor clinical symptoms and morning plasma ACTH. |
| **Mineralocorticoid Replacement** |
| Fludrocortisone 0.1 (0.050.2) mg orally. |
| Liberal salt intake. |
| Monitor lying and standing blood pressure and pulse, edema, serum potassium, and plasma renin activity. |
| Educate patient about the disease, how to manage minor illnesses and major stresses, and how to inject steroid intramuscularly. |
| Obtain Medic Alert bracelet/necklace, Emergency Medical Information Card. |
| **Treatment of Minor Febrile Illness or Stress** |
| Increase glucocorticoid dose twofold to threefold for the few days of illness; do not change mineralocorticoid dose. |
| Contact physician if illness worsens or persists for more than 3 days or if vomiting develops. |
| No extra supplementation is needed for most uncomplicated, outpatient dental procedures under local anesthesia. General anesthesia or intravenous sedation should not be used in the office. |
| **Emergent Treatment of Severe Stress or Trauma** |
| Inject contents of prefilled dexamethasone (4-mg) syringe intramuscularly. |
| Get to physician as quickly as possible. |
| **Steroid Coverage for Illness or Surgery in Hospital** |
| For moderate illness give hydrocortisone 50 mg twice a day orally or intravenously. Taper rapidly to maintenance dose as patient recovers. |
| For severe illness give hydrocortisone 100 mg intravenously every 8 hr. Taper dose to maintenance level by decreasing by half every day. Adjust dose according to course of illness. |
| For minor procedures under local anesthesia and most radiologic studies, no extra supplementation is needed. |
| For moderately stressful procedures, such as barium enema, endoscopy, or arteriography, give a single 100 mg intravenous dose of hydrocortisone just before the procedure. |
| For major surgery, give hydrocortisone 100 mg intravenously just before induction of anesthesia and continue every 8 hr for first 24 hr. Taper dose rapidly, decreasing by half per day, to maintenance level. |

B, corticosterone; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; 18-OHB, 18-hydroxycorticosterone.

Figure 14-32 Congenital adrenal hyperplasia related to 21-hydroxylase deficiency. The normal synthesis of cortisol is impaired, and adrenocorticotropic hormone (ACTH) levels increase because of loss of normal negative feedback inhibition resulting in an increase in adrenal steroid precursors proximal to the block. The results are cortisol deficiency, variable mineralocorticoid deficiency, and excessive secretion of adrenal androgens. DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; HSD, hydroxysteroid dehydrogenase; StAR, steroidogenic acute regulatory protein.

Patients may present in early childhood with sexual precocity and pubic hair development. Initially, linear growth is accelerated because of premature androgen excess, but if left untreated this stimulates epiphyseal closure and final adult height is invariably diminished. \[472\] \[473\]

Salt-Wasting Form

Seventy-five percent of cases in both sexes also have concomitant aldosterone deficiency. In addition to the preceding features, neonates may present within the first week of life with a salt-wasting crisis and hypotension. Indeed, this may alert the clinician to the diagnosis in a male, but unfortunately the diagnosis is still delayed in many cases and the condition carries a significant neonatal mortality rate.

Cryptic or “Late-Onset” 21-Hydroxylase Deficiency

Patients present in childhood or early adulthood with premature pubarche or with a phenotype that may masquerade as polycystic ovary syndrome (PCOS). \[471\] \[474\] Indeed, late-onset CAH is a recognized secondary cause of PCOS and appears to be commoner than the classical variety. \[474\] In some series from tertiary referral centers, late-onset 21-hydroxylase deficiency may account for up to 12% of all patients with PCOS, but more realistic prevalence rates are probably 1% to 3%. Females present with hirsutism, primary or secondary amenorrhea or anovulatory infertility. \[472\] Androgenic alopecia and acne may be other presenting features. Males may develop enlargement of the testes related to adrenal rests, that is, ectopic adrenal tissue within the testes that regresses after glucocorticoid suppression of ACTH secretion. \[472\]

Heterozygote Deficiency

Salt-wasting, simple virilizing, and late-onset 21-hydroxylase deficiencies are all caused by homozygous or compound heterozygous mutations in the human \(CYP21A2\) gene, whereas in the carrier, heterozygote state, only one allele is mutated. The clinical significance of the heterozygote state is uncertain; it does not appear to affect reproductive capability but may cause signs of hyperandrogenism in women. \[471\]

Two \(CYP21A2\) genes are located within 50 kb of the short arm of chromosome 6 within the major histocompatibility locus, a 3' \(CYP21A2\) (Fig. 14-33). These two genes are closely homologous, and at least 25% of cases of 21-hydroxylase deficiency arise because of unequal crossover and genetic recombination of these two genes at meiosis. Although mutations have been identified within the \(CYP21A2\) gene in affected kindreds (point mutations, gene conversions, and deletions \[472\] \[479\]), the relationship between genotype and phenotype is complex. \[479\] Severe mutations within the gene do not correlate with a severe phenotype either within families or in individual

ACTH, adrenocorticotropic hormone; SD, standard deviation.
A diagnosis of 21-hydroxylase deficiency should be considered in any newborn infant with genital ambiguity, salt wasting, or hypotension. Hypernatremia and hyperkalemia with raised plasma renin activity are found in salt wasters. In later life, adrenal androgen excess (DHEAS, androstenedione) is found in patients presenting with sexual precocity or a PCOS-like phenotype. 17-Hydroxyprogesterone (17-OHP) is invariably elevated, and clinically useful nomograms have been developed comparing circulating concentrations of 17-OHP before and 60 minutes after exogenous ACTH. This separates patients with classical and nonclassical 21-hydroxylase deficiency from heterozygote carriers and normal subjects, but there is some overlap between values seen in heterozygotes and normal people. 17-OHP is measured basally and then 60 minutes after 250 μg of Synacthen. Stimulated values are invariably grossly elevated in patients with classical and nonclassical varieties (in excess of 35 nmol/L [11 µg/dL]). Heterozygote patients usually have stimulated values between 10 and 30 nmol/L (3 to 9 µg/dL). 

Prenatal diagnosis of 21-hydroxylase deficiency has been advocated because treatment of an affected female may prevent masculinization in utero. 17-OHP can be assayed in amniotic fluid, but the most robust approach is the rapid genotyping of fetal cells obtained by chorionic villus sampling in early gestation. Unlike hydrocortisone, which is inactivated by placental 11-HSD, maternally administered dexamethasone can cross the placenta to suppress the fetal HPA axis. One approach is to advocate dexamethasone therapy as soon as pregnancy is confirmed in high-risk cases and to continue this until the diagnosis is excluded in the fetus. If the fetus is affected, only those of female sex require dexamethasone therapy during gestation. Therapy must be initiated before 8 to 10 weeks of gestation to be effective. However, because only one in eight cases treated in this way has an affected female fetus, the use of steroid therapy in this setting has been questioned. Dexamethasone can lead to maternal cushingoid effects in pregnancy and may in turn have long-term, deleterious effects on the fetus. In patients with known cases requesting fertility (be they male or female), determination of 17-OHP levels through a Synacthen test in the partner before conception uncovers late-onset or heterozygote cases and provides the endocrinologist or geneticist with some assignment of risk before pregnancy.

In the absence of any evidence-based data, there are no prescriptive steroid regimens to treat patients with CAH at any age, and as a result many individualized approaches are used. The overall goal is to replace glucocorticoid and mineralocorticoid, thereby preventing further salt-wasting crises, but also to suppress adrenal androgen secretion so that normal growth and skeletal maturation can proceed. Accurate replacement is essential; glucocorticoids in excess suppress growth, and inadequate replacement results initially in accelerated linear growth but ultimately in short stature because of premature epiphyseal closure. Response is best monitored through growth velocity and bone age, with biochemical markers (17-OHP, DHEAS, testosterone) being useful adjuncts. In difficult cases, a day curve study as described for patients with primary adrenal failure, but measuring the ACTH and 17-OHP response before and after corticosteroid replacement, may confirm overreplacement or underreplacement. Corrective surgery is frequently required (clitoral reduction, vaginoplasty) during childhood.

In late childhood and adolescence, appropriate replacement therapy is equally important. Overtreatment may result in obesity and delayed menarche or puberty with sexual infantilism, whereas underreplacement results in sexual precocity. Compliance with regular medication is often an issue through adolescence. Although much has been written about adequate control in childhood, adults with CAH often provide an ongoing dilemma for the endocrinologist. The follow-up of such patients should involve multidisciplinary clinics, initially with transition adolescence clinics to facilitate transfer from pediatric to adult care. Problems in adulthood are related to fertility concerns, hirsutism and menstrual irregularity in women, obesity and impact of short stature, sexual dysfunction, and psychological problems; counseling is often required in addition to endocrine support.

In women with hyperandrogenism and untreated late-onset CAH, there is no evidence that final height is affected. In this setting, glucocorticoid suppression in isolation rarely controls hirsutism and additional antiandrogen therapy is often required (cyproterone acetate, spironolactone, flutamide together with an oral estrogen contraceptive pill). However, ovulation induction rates with gonadotropin therapy are improved after suppression of nocturnal ACTH levels with 0.25 to 0.5 mg of dexamethasone. Once final height is achieved in adult males, strict control is required only for patients with adrenal rests within the testes or to ensure fertility; inadequate replacement therapy may result in adrenal androgen excess suppressing pituitary FSH secretion and lowering sperm counts.
reported for 21-hydroxylase deficiency, there remains a poor correlation between genotype and phenotype. There is loss of negative cortisol feedback and enhanced ACTH-mediated adrenal androgen excess (Fig. 14-35). Clinical features are therefore similar to those reported in the simple virilizing form of CAH (virilized female fetus, sexual ambiguity), and again milder cases can present later in childhood or even young adulthood. The principal difference compared with 21-hydroxylase deficiency is hypertension, and this is thought to be secondary to the mineralocorticoid effect of DOC excess (see Table 14-23). However, there is a poor correlation between DOC secretion and the presence of hypertension; furthermore, unexplained salt wasting has been reported in a few cases.

On this clinical background, the diagnosis can be made by demonstrating a plasma ACTH-stimulated 11-deoxycorticisol value that is more than three times the 95th percentile for an age-matched normal group. Although established heterozygotes do not demonstrate a rise in 11-deoxycorticisol above normal after Synacthen (unlike the 17-OHP response observed in heterozygote 21-hydroxylase patients), exaggerated ACTH-stimulated responses have been observed in patients with hirsutism and in patients with essential hypertension. Suggesting partial defects in 11-hydroxylase activity. As reported for 21-hydroxylase deficiency, treatment is with replacement glucocorticoid therapy; with suppression of DOC secretion, plasma renin activity (suppressed at baseline) increases into the normal range.

17-Hydroxylase Deficiency

Fewer than 150 cases of 17-hydroxylase deficiency have been reported. Mutations within the CYP17 gene result in the failure to synthesize cortisol (17-hydroxylase activity), adrenal androgens (17,20-lyase activity), and gonadal steroids (Fig. 14-36). Thus, in contrast to 21-hydroxylase and 11-hydroxylase deficiencies, 17-hydroxylase deficiency results in adrenal and gonadal insufficiency. A single enzyme is expressed in adrenal and gonadal tissue that is capable of producing both 17-hydroxylation and 17,20-lyase activities, but patients with isolated deficiency in the hydroxylation of 17-OHP or 17,20-lyase deficiency have rarely been reported. Loss of negative feedback results in increased secretion of steroids proximal to the block, and mineralocorticoid synthesis is enhanced. However, aldosterone levels are variable and the mineralocorticoid excess state that characterizes this condition is thought to be induced by DOC excess in over 80% of cases.

The genetic basis of the disease has been established in many cases, involving point mutations, gene deletions, and conversions in the CYP17 gene. Relative hydroxylase and lyase activities of mutant CYP17 complementary DNAs vary in in vitro transfection assays, but correlations with clinical phenotype are lacking. Thus, patients with clinically pure 17,20-lyase deficiency may have mutant CYP17 complementary DNAs that exhibit compromised 17-hydroxylase activity.

The diagnosis is usually made at the time of puberty when patients present with hypertension, hypokalemia, and hypogonadism, the latter occurring because of lack of CYP17 expression within the gonad and impaired gonadal steroidogenesis. As a result, LH and FSH levels are elevated. Female patients (XX) have primary amenorrhea with absent sexual characteristics, and males (46,XY) have complete pseudohermaphroditism with female external genitalia but absent uterus and fallopian tubes. The intra-abdominal testes should be removed, and such patients are usually reared as female.

Glucocorticoid replacement reverses the DOC-induced suppression of the renin-angiotensin system and lowers blood pressure. Additional sex steroid replacement is required from puberty onward.

3-Hydroxysteroid Dehydrogenase Deficiency

In this rare form of CAH, the secretion of all classes of adrenal and ovarian steroids is impaired because of mutations within the HSD3B2 gene encoding 3-HSDII. Patients usually present in early infancy with adrenal insufficiency. Loss of mineralocorticoid secretion results in salt wasting, although this is absent in 30% to 40% of cases (Fig. 14-37). As with 21-hydroxylase deficiency, absence of salt wasting may delay the presentation into childhood or puberty. The correlation between genotype and phenotype is once again poor; identical mutations have been found in the HSD3B2 gene in both salt wasters and nonsalt wasters. The spectrum of genital development is variable in both sexes. In males, because the 3-HSDII enzyme is also expressed within the gonad, male pseudohermaphroditism may occur with female external genitalia. In milder cases, hypospadias may be found or even normal male genitalia. In females, genital development can be normal but there is usually evidence of mild virilization, presumably because of enhanced adrenal secretion of DHEA, which is converted peripherally to testosterone. A late-onset form has been described in patients with premature pubarche and a PCOS-like phenotype (hirsutism, oligomenorrhea, amenorrhea). Because activity of the 3-HSDII enzyme present in skin and other peripheral tissues is intact, circulating 4 steroid levels (progesterone, 17-hydroxyprogesterone, androstenedione) may be normal (or even increased). However, a diagnosis is established by demonstrating an increased ratio of 5 steroids (pregnenolone, 17-hydroxyprogrenolone, DHEA) to 4 steroids in plasma or urine. ACTH stimulation may be required to detect a late-onset presentation. Treatment is with replacement glucocorticoids, fludrocortisone (if indicated), and sex steroids from puberty onward.

Steroidogenic Acute Regulatory Protein Deficiency

Mutations in the gene encoding STAR result in a failure of transport of cholesterol from the outer to the inner mitochondrial membrane.
membrane in steroidogenic tissues; as a result, there is deficiency of all adrenal and gonadal steroid hormones. Presentation is with acute adrenal insufficiency in the neonatal period, and males exhibit pseudohermaphroditism because of absent gonadal steroids. The condition is fatal in infancy in two thirds of all cases. The adrenal glands are often massively enlarged and full of lipid; prior to the characterization of STAR, the condition was termed congenital "lipoid" hyperplasia and the candidate gene was thought to be cholesterol side-chain cleavage (CYP11A1). In fact, to date, no mutations have been reported in the CYP11A1 gene; such mutations are thought to be lethal in utero. This clinical phenotype is endorsed by recombinant mouse models lacking the STAR gene.

**Apparent Cortisone Reductase Deficiency**

In this condition, adrenal glands become hyperplastic because of ACTH stimulation resulting from a defect in cortisol metabolism rather than an inherent defect within the gland itself. Patients with apparent cortisone reductase deficiency have a defect in the conversion of cortisone to cortisol, suggesting inhibition of 11-oxoreductase activity and, by implication, inhibition of the type 1 isozyme of 11-hydroxysteroid dehydrogenase (11-HSD1). Eight cases have been described; with one exception, all are female. Cortisol clearance is increased, and ACTH secretion is elevated to maintain normal circulating cortisol concentrations but at the expense of adrenal androgen excess. As a consequence, patients described are usually young women who present with hirsutism, menstrual irregularity, or androgenic alopecia.

Dexamethasone treatment to suppress ACTH has been used with some success to control the hyperandrogenism in these cases. Urinary tetrahydro metabolites of cortisol and cortisone show almost exclusively THE with little or no detectable THF or allo-THF (ratio of THF + allo-THF to THE less than 0.05, reference range 0.8 to 0.045).

DHEAS, dehydroepiandrosterone sulfate; allo-THF, 5-tetrahydrocortisol; THE, tetrahydrocortisone; THF, 5-tetrahydrocortisol.

been described; with one exception, all are female (Table 14-25). Cortisol clearance is increased, and ACTH secretion is elevated to maintain normal circulating cortisol concentrations but at the expense of adrenal androgen excess. As a consequence, patients described are usually young women who present with hirsutism, menstrual irregularity, or androgenic alopecia.

Dexamethasone treatment to suppress ACTH has been used with some success to control the hyperandrogenism in these cases. Urinary tetrahydro metabolites of cortisol and cortisone show almost exclusively THE with little or no detectable THF or allo-THF (ratio of THF + allo-THF to THE less than 0.05, reference range 0.8 to 1.3). Further studies have also shown impaired plasma cortisol concentrations after an oral dose of cortisone acetate. Despite this biochemical evidence implicating a defect in 11-HSD1, investigations have revealed no mutations to date in the HSD11B1 gene in affected cases.

Patients with PCOS share many of the same clinical characteristics as those with apparent cortisone reductase deficiency. Although there is evidence to support increased cortisol secretion rates in PCOS, perhaps indicative of a defect in conversion of cortisone to cortisol, there remains to be a consensus with respect to THF + allo-THF/TESTH ratios. Both normal and reduced ratios have been reported in the literature.
Mineralocorticoid Deficiency

These syndromes are listed in Table 14-26. They can be divided into those that are congenital and others that are acquired. Mineralocorticoid deficiency may occur in some forms of CAH and with other causes of adrenal insufficiency (e.g., Addison’s disease and congenital adrenal hypoplasia) (see preceding).

Primary Defects in Aldosterone Biosynthesis: Aldosterone Synthase Deficiency

Failure of conversion of corticosterone to 18-hydroxycorticosterone or of 18-hydroxycorticosterone to aldosterone usually results in a salt-wasting crisis in neonatal life. Hyperkalemia, metabolic acidosis, dehydration, and hypotension are found. The condition has been called corticosterone methyl oxidase (CMO) deficiency, but this was before the final enzyme or enzymes involved in the conversion of DOC to aldosterone were characterized and cloned. In fact, a single enzyme, aldosterone synthase, carries a multistep reaction involving 11-hydroxylation of DOC to corticosterone and 18-hydroxylation of corticosterone to 18-hydroxycorticosterone followed by 18-dehydrogenation to aldosterone (see Fig. 14-3).

Two variants of CMO deficiency are described: CMO I is characterized by low 18-hydroxycorticosterone and aldosterone levels, whereas patients with CMO II deficiency have hypoaldosteronism but high 18-hydroxycorticosterone levels. In both cases, mutations in the gene encoding aldosterone synthase have been described and the discrepant 18-hydroxycorticosterone levels seem likely to be explained on the basis of variable 18-hydroxylase activity of the related CYP45011-hydroxylase enzyme.

CMO II is much more common in Iranian Jews than the white population.

Defects in Aldosterone Action: Pseudohypoaldosteronism

Pseudohypoaldosteronism type I may occur in neonatal life with respiratory difficulties but is usually found in infancy with severe salt wasting and failure to thrive, with very high plasma aldosterone and plasma renin activity levels and inappropriate urinary sodium loss. The MR appears to be defective, as judged by studies evaluating the binding of aldosterone to monocytes, but molecular studies have failed to show any abnormality in the MR itself. Rather, inactivating mutations in the , and subunits of the epithelial sodium channel have been shown to explain the condition. Acquired forms of pseudohypoaldosteronism can occur in patients after renal transplantation, following obstructive uropathy, and in premature infants.

Pseudohypoaldosteronism type II or Gordon’s syndrome is an autosomal dominant disorder characterized by hyperkalemia

but not salt wasting, in contrast to the type I condition. Patients have resistance to the mineralocorticoid effects of aldosterone on tubular potassium transport but not to those of sodium and chloride transport. As a result, affected individuals have hyperkalemia, hypertension, and suppression of plasma renin activity. Recently, deletions in the WNK4 gene (a member of the WNK family of serine-threonine kinases) have been described in affected cases.

Angiotensin II is a key stimulus to aldosterone secretion, and damage or blockade of the renin-angiotensin system may result in mineralocorticoid deficiency. Various renal conditions have been associated with damage to the juxtaglomerular apparatus and hence renin deficiency. These include systemic lupus erythematosus, myeloma, amyloid, AIDS, and use of nonsteroidal anti-inflammatory drugs, but the most common (greater than 75% cases) is diabetic nephropathy.

The usual picture is of an elderly patient with hyperkalemia, acidosis, and mild to moderate impairment of renal function. Plasma renin activity and aldosterone are low and fail to respond to sodium depletion, the erect posture, or furosemide administration. In contrast to those with adrenal insufficiency, patients have normal or elevated blood pressure and no postural hypotension. Muscle weakness and cardiac arrhythmias may also occur. Other factors may contribute to the hyperkalemia, including the use of potassium-sparing diuretics, potassium supplementation, insulin deficiency, and -adrenoceptor blocking drugs and prostaglandin synthetase inhibitors, which inhibit renin release.

Treatment of primary renin deficiency is with fludrocortisone in the first instance together with dietary potassium restriction. However, these patients are not salt depleted and may become hypertensive with fludrocortisone. In such a scenario, the addition of a loop-acting diuretic such as furosemide is appropriate. This increases acid excretion and improves the metabolic acidosis.
Adrenal Adenomas, Incidentalomas, and Carcinomas

Etiology of Adrenal Tumors

The underlying basis for adrenal tumorigenesis is unknown. Clonal analysis suggests progression from a normal to adenomatous to carcinomatous lesion, but the molecular pathways involved remain obscure. Several factors have been associated with malignant transformation including genes encoding p53, p7 cyclin-dependent kinase, menin, IGF-II, MC2R, and inhibin-βA. Mice lacking the inhibin-βA gene develop adrenal tumors through a process that is also gonadotropin-dependent.

Adenomas

Cortisol-secreting adrenal adenomas have been discussed in detail (“Cortisol-Secreting Adrenal Adenoma and Carcinoma”), and aldosterone-secreting adenomas (Conn’s syndrome) are discussed in Chapter 15.

Pure virilizing benign adrenal adenomas are rare, with approximately 50 cases reported in the literature. The majority of cases occur in women; male cases are restricted to childhood, when presentation is with sexual precocity and accelerated bone age. In females, the majority of cases arise before the menopause with marked hirsutism, deepening of the voice, and amenorrhea. Clitoromegaly is found in 80% of cases. Testosterone is usually strikingly elevated, but gonadotropin levels may not be suppressed. By definition, urinary free cortisol is normal. Tumors vary in size and should be treated surgically. Postoperatively, clinical features invariably improve and normal menses return.

Incidentalomas

Autopsy series have defined the prevalence of adrenal adenomas more than 1 cm in diameter to be between 1.5% and 7%. It is perhaps not surprising, therefore, that with the advent of high-resolution imaging procedures (CT, MRI), incidentally discovered adrenal masses have become a common clinical problem. An adrenal mass is uncovered in up to 4% of patients imaged for nonadrenal pathology. Incidentalomas are uncommon in patients younger than 30 years but increase in frequency with age; they occur equally in males and females. In more than 85% of cases these lesions are nonfunctioning, benign adenomas. Occasionally they may represent myelolipomas, hamartomas, or granulomatous infiltrations of the adrenal and result in a characteristic CT or MRI appearance (Fig. 14-38). Functioning tumors (pheochromocytomas or those secreting cortisol, aldosterone, or sex steroids) and carcinomas make up the remainder.

In addition, it is established that some incidentalomas may cause abnormal hormone secretion without obvious clinical manifestations of a hormone excess state; the best example of this is “preclinical” Cushing’s syndrome, which may occur in up to 20% of all cases. This may explain why incidentalomas appear to be common in patients with obesity and diabetes mellitus. As a result, all patients with incidentally discovered adrenal masses should undergo appropriate endocrine screening tests. These should comprise 24-hour urinary catecholamine collection, 24-hour urinary free cortisol, and overnight dexamethasone suppression tests. Because of the reported poor sensitivity of serum potassium measurements in detecting primary aldosteronism, our practice has been to measure supine circulating plasma renin activity and aldosterone levels. DHEAS should be measured as a marker of adrenal androgen secretion. Low levels may occur in patients with suppressed ACTH concentrations related to autonomous cortisol secretion from the adenoma, and it is important that DHEAS not be measured during the overnight dexamethasone study. Some studies have also documented high levels of 17-OHP after ACTH stimulation tests, suggesting partial defects in 21-hydroxylase in some tumors.

The possibility of malignancy should be considered in each case. In patients with a known extra-adrenal primary, the incidence of malignancy is obviously much higher (up to 20% of patients with lung cancer, for example, have adrenal metastases on CT scanning). In those with no evidence of malignancy, adrenal carcinoma is rare; in one study, only 26 of 630 incidentalomas were found to be adrenal carcinomas. In true incidentalomas, size appears to be predictive of malignancy; a lesion less than 5 cm in diameter is unlikely to be malignant. The majority of nonfunctioning lesions less than 5 cm can therefore be treated conservatively and patients followed up with annual imaging. Even incidentalomas larger than 5 cm are more likely to be benign than malignant, but because of an increased risk of malignancy many centers recommend removal of tumors more than 5 cm in diameter, preferably by laparoscopic adrenalectomy. Additional characteristic MRI appearances or scintigraphy studies may aid in differentiating malignant from nonmalignant lesions. CT-guided biopsy is useful in differentiating adrenal from nonadrenal tissue in the case of a suspected metastasis but is poor in differentiating benign adenomas from malignant adrenal lesions.

Carcinomas

Primary adrenal carcinoma is rare, with an incidence of 1 per million population per year. Women are more commonly affected than men (2:1); mean age of onset is 40 to 50 years, although men tend to be older at presentation. Eighty percent of tumors are functional, most commonly secreting glucocorticoids alone (45%), glucocorticoids and androgens (45%), or androgens alone (10%). Less than 1% of all cases secrete aldosterone. Patients present with features of the hormone excess state (glucocorticoid or androgen excess, or both), but abdominal pain, weight loss, anorexia, and fever occur in 25% of cases. An abdominal mass may be palpable.

Current treatments for what is often an aggressive tumor are poor. Surgery offers the only chance of cure for patients with local disease, but metastatic spread is evident in 75% of cases at presentation. Radiotherapy is ineffective, as are most chemotherapeutic regimens. Mitotane in high doses offers transient benefit in reducing tumor growth in 25% to 30% of cases and controlling hormonal hypersecretion in 75% of cases. Overall, the prognosis is poor, with 5-year survival rates of less than 20%.

Hypertension is a common disorder, occurring in approximately 20% of the United States population. The great majority of hypertensive subjects have the diagnosis of essential or primary hypertension. Essential hypertension is a heritable syndrome reflecting a variety of pathophysiologic abnormalities that can lead, independently or together, to an elevated arterial blood pressure. Although secondary causes exist in a smaller percentage (10%) of hypertensive subjects, they still represent a large number of patients.

Broadly speaking, the secondary causes of hypertension can be divided into renal causes (e.g., parenchymal or renovascular disease) and endocrine causes. In some disorders, many cases can be diagnosed by an astute clinician because the signs and symptoms are often distinct (e.g., pheochromocytoma and Cushing's syndrome). In addition, hypertension refractory to antihypertensive treatment may prompt the physician to screen for secondary causes. The age and sex of the hypertensive patient may also be helpful in the diagnosis of disorders with the secondary etiologies. For example, fibromuscular hyperplasia and Cushing's syndrome are more commonly seen in younger females, whereas primary hypothyroidism most commonly occurs in older female patients. Finally, making a diagnosis of a secondary disorder is gratifying because it may lead to significant amelioration or in some instances cure of the elevated blood pressure.
PHYSIOLOGY OF THE SYMPATHOADRENAL SYSTEM AND PHEOCHROMOCYTOMA

The autonomic nervous system consists of the parasympathetic nervous system and the sympathoadrenal system. The neurotransmitter in the parasympathetic nervous system is primarily acetylcholine, and the neurotransmitters in the sympathoadrenal system include norepinephrine at sympathetic nerve endings in the periphery and central nervous system and epinephrine, which is secreted by the adrenal medulla into the systemic circulation. Another catecholamine, dopamine, acts primarily as a neurotransmitter in the central nervous system but is also secreted from peripheral sympathetic nerve endings. The sympathetic nervous system is under direct control of the central nervous system, allowing rapid onset of actions of short duration as a result of the abbreviated half-lives of catecholamines.

Structure and Organization of the Sympathoadrenal System

The sympathoadrenal system, which is composed of the ganglia of the sympathetic nervous system and the adrenal medulla, is embryologically derived from neural crest tissue. The precursor sympathogonia differentiate into neuroblasts, ultimately giving rise to the paravertebral and preaortic ganglion cells. Sympathetic preganglionic axons arise in large part from cells located in the thoracolumbar spinal cord. These preganglionic sympathetic neurons in turn have synapses with descending tracks from neurons in the pons, medulla, and hypothalamus, allowing regulation of sympathetic activity by the brain (Fig. 15-1; see also Fig. 15-16). Thus, the limbic system and cortex can also regulate sympathetic activity by connections with central nuclei in the hypothalamus and medulla. In turn, these central nervous system neurons that influence sympathetic activity are regulated by a variety of factors including substrates (glucose) and hormones (corticotropin-releasing hormone).

The axons of the preganglionic neurons synapse with postganglionic cell bodies located in the paravertebral and preaortic ganglia as well as neurons in the celiac and superior and inferior mesenteric ganglia (Fig. 15-2). Postganglionic axons from the cell bodies located in these ganglia in turn innervate the visceral organs. The splanchnic outflow of the lower thoracic and lumbar preganglionic axons also directly innervates the cells of the adrenal medulla (see Fig. 15-2). Acetylcholine is the neurotransmitter at the ganglionic synapses and at the adrenal medullary neurons. In different tissues, the postganglionic sympathetic innervation can be cholinergic or noradrenergic, or both. For example, at arteriolar synapitc clefts norepinephrine is released from postganglionic nerve terminals, and sweat glands have sympathetic cholinergic innervation. Adrenergic nerves also contain other mediators including the peptide substance P, neuropeptide Y, somatostatin, and chromogranin A. These substances, which are released in peripheral and central adrenergic nerves, may have synergistic or direct actions with norepinephrine on effector cells. On the other hand, the adrenal medullary cells that secrete epinephrine into the systemic circulation are innervated by the splanchnic outflow of cholinergic preganglionic neurons.

The arterial blood supply to the adrenal gland is derived from the aorta (middle adrenal artery), the inferior phrenic artery, and the renal artery. Adrenal blood flow drains centrally toward the medulla, eventually forming a single adrenal vein, which drains into the renal vein on the left and into the vena cava on the right. Although the existence of a corticomedullary portal system remains controversial, it is likely that local high concentrations of glucocorticoids influence the biosynthesis of epinephrine by induction of the enzyme phenylethanolamine N-methyltransferase (PNMT).
Catecholamines

All naturally occurring catecholamines contain a catechol nucleus (Fig. 15-3). Epinephrine is synthesized and stored in the adrenal medulla and released into the systemic circulation. Norepinephrine is synthesized and stored at peripheral nerve endings. Dopamine acts primarily as a neurotransmitter in the central nervous system, although epinephrine and norepinephrine also act as central nervous system neurotransmitters.

Catecholamines act widely in the body and affect many cardiovascular and metabolic processes. Specific catecholamine receptors mediate the biologic actions of these compounds. The amount of endogenous catecholamines released at peripheral nerve endings and the plasma concentration of epinephrine are the main determinants of the physiologic responses to activation of the sympathetic nervous system. Identification of -adrenergic and -adrenergic receptors and their receptor subtypes (1, 2, 3, and 4) in target tissue has led to an understanding of the physiologic responses to exogenous and endogenous administration of catecholamines.

Moreover, the pharmacologic development of selective - and -adrenergic antagonists has added a wide range of treatments for a variety of clinical disorders. For example, -agonists (terbutaline and albuterol), among their actions, can cause bronchial smooth muscle relaxation and are commonly prescribed in aerosol formulation for the treatment of bronchial asthma. On the other hand, -antagonists (such as atenolol and metoprolol) are considered standard therapies for angina pectoris, hypertension, and cardiac arrhythmias. The - and -adrenergic receptors on cell surfaces reciprocally increase or decrease in response to the receptor-specific agonist concentration. Inhibition or stimulation of the intracellular adenylate cyclase (cyclic adenosine monophosphate [cAMP]) system mediates the majority of responses to receptor subtypespecific agonists.

Catecholamine Synthesis

Catecholamines are formed from the amino acid tyrosine by a process of hydroxylation and decarboxylation (see Fig. 15-3). This process of amine precursor uptake and decarboxylation (APUD) is a feature of neuroendocrine tissues that have a common origin. Most reactions occur in the cytoplasm except for hydroxylation of dopamine into norepinephrine, which occurs in the secretory vesicle.

The rate-limiting step in catecholamine biosynthesis is the conversion of tyrosine to 3,4-dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase (TH). The reaction requires tyrosine as substrate and oxygen, iron (Fe2+), and tetrahydrobiopterin as cofactors. Tyrosine hydroxylase is expressed only in neuronal tissues that synthesize catecholamines, and several factors regulate its activity. The intraneuronal or intracellular transport of tyrosine may be affected by other amino acids or drugs that compete for transport or act as competitive inhibitors of the transport system, such as -methylparatyrosine. Increased intracellular levels of catechols down-regulate the activity of the enzyme. As catechols are released from secretory granules in response to a stimulus, cytoplasmic catecholamines are depleted and the feedback inhibition of tyrosine hydroxylase is released. Four isoforms of tyrosine hydroxylase exist. Transcription is stimulated by glucocorticoids, cAMP-dependent protein kinases, Ca2+ dependent protein kinase, and Ca2+ -calmodulin-dependent protein kinase.

Aromatic L-amino acid decarboxylase (AADC) catalyzes the decarboxylation of dopa to dopamine, a process that can occur in any APUD tissue in which dopa is present. AADC is not specific for dopa. For example, decarboxylation of 5-hydroxytryptophan produces serotonin. Pyridoxal 5-phosphate is the cofactor required.

Catecholamine Uptake and Release

Catecholamines are taken up into storage vesicles by active transport using an H+ + ATP-driven proton pump and carrier proteins, vesicular monoamine transporters (VMATs). The ATP-driven pump maintains a steep electrical gradient. For every monoamine transported, ATP is hydrolyzed and two hydrogen ions are transported from the vesicle into the cytosol. Calcium is also maintained in high concentration within the vesicle. Labeled 131Iodoamphetamine (131I-MIBG) appears to be imported by VMATs into the storage vesicles in the adrenal medulla, which makes imaging with MIBG useful for evaluation of pheochromocytomas.
Catecholamine uptake, as well as MIBG, is inhibited by reserpine.  

Acetylcholine originating from preganglionic sympathetic fibers stimulates nicotinic cholinergic receptors and causes depolarization of the adrenomedullary chromaffin cell. Depolarization leads to activation of voltage-gated Ca\(^{2+}\) channels resulting in exocytosis of secretory vesicle contents. A Ca\(^{2+}\)-sensing receptor appears to be involved in the process of exocytosis. During exocytosis, all of the granular contents are released into the extracellular space.

**Catecholamine Metabolism**

Metabolism of catecholamines occurs through two enzyme pathways (Fig. 15-4). Catechol-O-methyltransferase (COMT) is found primarily outside neuronal tissue and converts epinephrine to metanephrine and norepinephrine to normetanephrine by meta-\(\text{O}\)-methylation. S-Adenosylmethionine is used as the methyl donor, and Ca\(^{2+}\) is required.

Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid (VMA) by oxidative deamination. MAO may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by COMT to VMA. MAO is located on the outer membrane of mitochondria. In the storage vesicle, norepinephrine is protected from metabolism by MAO. MAO action may play an important role in regulating the metabolism of norepinephrine and dopamine. Intravesical stores of norepinephrine increase when MAO is inhibited.
Pheochromocytoma

Incidence and Importance

Pheochromocytomas are tumors of neuroectodermal origin arising from chromaffin cells. They are named for the dark staining reaction that is caused by the oxidation of intracellular catecholamine stores on exposure to dichromate salts. Although pheochromocytomas are a rare cause of hypertension, failure to recognize and treat a pheochromocytoma could prove a fatal oversight. Reportedly, less than 1% of patients who are evaluated for hypertension have pheochromocytomas, but this may be an underestimate. In one series, the incidence rate was calculated to be 0.8 per 100,000 person-years. In an autopsy series, approximately half of the pheochromocytomas were diagnosed at postmortem examination, demonstrating that this disorder is frequently not recognized.

Tumors that arise from chromaffin cells of the adrenal medulla are referred to as pheochromocytomas, and those that arise in paraganglia are termed paragangliomas or extra-adrenal pheochromocytomas. The paraganglia are collections of specialized neural crest cells that have migrated to their final destination throughout the body. Tumors can arise from sympathetic ganglia located from the neck to the bladder as well as the carotid body, vagal body, mediastinum, aorta, organs of Zuckerkandl, and pelvis (the most common site). It is commonly believed that the malignant potential is higher for extra-adrenal tumors than intra-adrenal tumors. However, some studies suggest that disease-free survival is similar for patients with extra-adrenal and intra-adrenal tumors.

Clinical Manifestations

Hypertension is the most common clinical manifestation of pheochromocytoma and is present in 90% to 100% of patients. Sustained hypertension is seen in approximately half, paroxysmal hypertension in a third, and normal blood pressure in less than a fifth of patients. In children, sustained hypertension occurs most frequently.

Patients with pheochromocytoma frequently present with paroxysmal episodes or spells that include the classic triad of severe headaches, palpitations, and diaphoresis. These episodes may occur daily or as frequently as every few months. More than 90% of patients present with at least two of the three symptoms in the classic triad. The headaches are typically abrupt in onset, throbbing, and bilateral and diminish within an hour. The headaches may be associated with pallor or nausea, may be brief, or may persist over a week. The presence of palpitations, anxiety, or tremulousness may suggest the predominant secretion of epinephrine. Less common symptoms include tremor, angina, nausea, Raynaud's phenomenon, livedo reticularis, and mass effect from the tumor.

Increased total peripheral resistance causes the hypertension in patients with pheochromocytoma, as in patients with essential hypertension. Heart rate is variably increased in patients with pheochromocytoma.

Normal cardiac output is maintained by a decreased stroke volume resulting from intravascular volume depletion.

Lability of blood pressure is caused by a combination of the following: (1) episodic catecholamine release, (2) impaired sympathetic reflexes, and (3) unrecognized chronic volume depletion. Altered sympathetic vascular regulation may underlie the orthostatic hypotension often seen in pheochromocytoma. In rare cases of pheochromocytoma with predominant secretion of epinephrine, dopamine, or dopamine, orthostatic hypotension may be the presenting symptom. Patients with pheochromocytoma who are asymptomatic despite high circulating levels of catecholamines may have adrenergic receptor desensitization related to chronic stimulation.

Other cardiovascular manifestations of pheochromocytomas include dilated cardiomyopathy resulting from catecholamine excess or hypertrophic cardiomyopathy. Both forms have been reported to be reversible with tumor resection. Myocarditis has also been described in patients with pheochromocytoma with a pathology characterized by infiltration of inflammatory cells, specifically perivascularly, and focal conduction band necrosis.

Patients may also present with features of acute myocardial infarction including chest pain or electrocardiographic abnormalities including ST segment elevation or depression or inversion of T waves, or both. Other electrocardiographic manifestations of pheochromocytoma include left ventricular hypertrophy, sinus tachycardia, T-wave inversion, and rhythm disturbances such as supraventricular tachycardia or supraventricular ectopic beats.

Hereditary Pheochromocytoma

The majority of pheochromocytomas are sporadic. However, approximately 10% or more occur in association with a familial disorder such as multiple endocrine neoplasia type 2A or 2B (MEN-2A or MEN-2B), von Hippel-Lindau (VHL) disease, or neurofibromatosis (see Chapter 36). The MEN-2 syndromes and VHL disease are inherited in an autosomal dominant pattern with age-related penetrance. MEN-2A (Siepe's syndrome) is characterized by pheochromocytoma, medullary carcinoma of the thyroid, and multiple mucosal neuromas, often in association with a marfanoid habitus. Germ line mutations of the RET proto-oncogene have been described in the MEN-2 syndromes, and the MEN-2A gene has been localized to chromosome 10q11.2. The mutation confers constitutive activation of the tyrosine kinase receptor leading to unregulated hyperplasia and increased susceptibility to malignant transformation.

The VHL disease phenotype includes pheochromocytoma, cerebellar and retinal hemangioblastomas, renal carcinoma, and renal and pancreatic cysts. The VHL disease suppressor gene has been cloned to chromosome 3p25-p26. A loss-of-function mutation leads to tumor formation with different kindreds demonstrating varied clinical manifestations related to different types of mutations. Missense mutations are thought to be more commonly associated with pheochromocytoma.

A low percentage (0.1% to 5.7%) of patients with von Recklinghausen's neurofibromatosis have pheochromocytoma. However, a much higher percentage (50%) of pheochromocytoma is seen in such patients who have hypertension. The majority of patients with von Recklinghausen's disease have solitary pheochromocytomas, whereas bilateral disease is often seen in other hereditary syndromes. Inactivating mutations in the neurofibromatosis F1 (NF1) gene, a tumor suppressor gene on
Hereditary pheochromocytomas are typically intra-adrenal and bilateral. In one series, up to 83% of the patients with familial pheochromocytoma had bilateral tumors. Patients with hereditary pheochromocytoma typically present at younger ages than those with sporadic pheochromocytoma. The mean age of diagnosis of familial pheochromocytoma was 38 ± 11 years, compared with 47 ± 16 years for patients with sporadic tumors. Sporadic pheochromocytoma cases usually present with hypertension; in contrast, many cases of the familial syndrome are diagnosed earlier as a result of biochemical surveillance or genetic testing, often before hypertension is detected.

The MEN-2 and VHL tumors make up most of the hereditary pheochromocytomas, but about 25% apparently sporadic patients may have germline mutations. It has been shown that MEN-2 tumors typically produce metanephrine, the metabolite of epinephrine, whereas tumors in patients with VHL disease produce normetanephrine, the metabolite of norepinephrine. These specific biochemical phenotypes demonstrate that unique mutation-dependent differential gene expression is probably involved in catecholamine synthesis. PNMT has been reported to be overexpressed in the MEN-2 tumors providing the epinephrine metabolism profile, whereas PNMT is under-expressed in VHL tumors providing the norepinephrine metabolism profile.

MEN-2 pheochromocytomas also appear to have increased tyrosine hydroxylase activity, which accounts for the greater concentration of catecholamine metabolites measured and clinical symptoms seen in MEN-2 patients compared with VHL patients. Patients with MEN-2 typically demonstrate episodic symptoms of hypertension. On the other hand, a pattern of sustained hypertension is seen in VHL patients. Thus, the biochemical phenotypes in these syndromes appear to be associated with particular patterns of catecholamine synthesis and release. Measurement of plasma-free metanephrines has been used to distinguish between MEN-2 and VHL disease and to reveal the presence of pheochromocytoma prior to clinical symptoms with greater sensitivity and specificity than urine testing (see later).

Hereditary paragangliomas of the neck (glomus tumors) are associated with germline mutations in a mitochondrial complex II gene, succinyl dehydrogenase subunit D (SDHD), which encodes an enzyme that is involved in oxidative phosphorylation. Somatic and germline mutations of the SDHD gene may also be associated with non-syndromic, sporadic, familial and familial pheochromocytoma.

**Diagnosis**

**Differential Diagnosis**

Pheochromocytoma may be suspected when a crisis, the physiologic consequence of abrupt catecholamine release, is precipitated by factors such as exertion, trauma, certain drugs, anesthesia, surgery, or surgical manipulation of the tumor. Tricyclic antidepressants, droperidol, glucagon, metoclopramide, phenothiazines, and naloxone have all been reported to induce hypertensive episodes. Foods or beverages, such as certain aged cheeses or red wine that contain tyramine, may precipitate a crisis. The β-blockers may cause a paradoxical rise in blood pressure. Several disorders may mimic the symptoms of pheochromocytoma and also cause elevations in catecholamines. Abrupt withdrawal from medications such as clonidine or from alcohol may produce such a picture. Cerebral events such as cerebral vasculitis, preeclampsia, subarachnoid hemorrhage, migraine, and intracranial lesions associated with increased intracranial pressure may mimic pheochromocytoma. Agents such as amphetamines, ephedrine, pseudoephedrine, isoproterenol, phenylpropanolamine, cocaine, phenylcyclidine (PCP), and lysergic acid diethylamide (LSD) also lead to excess catecholamine levels.

On the other hand, the symptoms of pheochromocytoma may be mistaken for those of panic attacks, hypoglycemic episodes, or accelerated hypertension of other etiologies. Lastly, disorders such as mastocytosis and the carcinoid syndrome, which are characterized by spells and episodic symptoms, may also mimic pheochromocytoma. However, hypertensive crises, which often occur with pheochromocytoma, are notably absent in these disorders. In fact, episodic hypotension may occur with mastocytosis or the carcinoid syndrome as a result of peripheral vasodilation.

**Indication for Screening**

Because pheochromocytomas do not occur frequently, physicians must appreciate when screening for the disorder is appropriate. The following are reasonable indications for screening:

1. Hypertension with episodic features suggesting pheochromocytoma (the classic triad of headaches, palpitations, and diaphoresis)
2. Refractory hypertension
3. Prominent lability of blood pressure
4. Severe pressor response during anesthesia, surgery, or angiography
5. Unexplained hypotension during anesthesia, surgery, or pregnancy
6. Family history of pheochromocytoma or a familial disorder such as MEN-2, VHL disease, neurofibromatosis, or glomus tumors
7. Incidentally discovered adrenal masses
8. Idiopathic dilated cardiomyopathy

**Biochemical Assessment**

In pheochromocytoma, enzyme activity involved in synthesis of catecholamines is augmented and enzyme activity involved in catabolism is decreased. Because the catecholamine excess cannot be effectively stored, the hormones spill into the peripheral circulation. Biochemical measurement of excessive catecholamine production by the tumor confirms the diagnosis of pheochromocytoma (see later). However, because catecholamines are normally constitutively produced by the sympathoadrenal system, it is the magnitude of the elevation that is diagnostic of pheochromocytoma.

**Screening**

The diagnosis is made with the demonstration of elevated circulating or urinary catecholamines or metabolites (see Fig. 15-3). Screening methods include (1) 24-hour urine collection for excretion of unmetabolized or so-called free catecholamines (epinephrine and norepinephrine) or catecholamine metabolites (metanephrine, normetanephrine, and vanillylmandelic acid) and (2) determination of plasma metanephrines and catecholamines (Fig. 15-5). Pheochromocytomas are heterogeneous in hormone metabolism and secretion. Therefore, there is no one optimal test for screening and there is disagreement about the preferred test for diagnosis. For example, as catecholamines have short half-lives and are secreted episodically, a
random plasma measurement may miss the peak catecholamine levels. On the other hand, plasma levels are particularly helpful when samples are collected during a paroxysm. Although the 24-hour urine collection has the advantage of integration of the catecholamine secretion over time, it is more cumbersome for patients and may yield a false-negative result if the collection is performed in absence of symptoms or hypertension in patients with episodic catecholamine secretion. The urinary methanephrine-to-creatinine ratio can be useful in compensating for overcollection (false-positives) or undercollection (false-negatives). 12 Overnight measurements of urine catecholamines have also been used to diagnose pheochromocytoma but involve an increased risk of both false-positive and false-negative results. 13

In the initial evaluation of a patient suspected of having a pheochromocytoma, we recommend a 24-hour urine collection for free or unmetabolized catecholamines (epinephrine and norepinephrine), total methanephrines, and creatinine (see Fig. 15-5). Of the different metabolites that can be detected in a 24-hour urine collection, methanephrines are the most sensitive and specific. 14 There are less data concerning the appropriate use of plasma measurements. However, more experience with the measurement of plasma methanephrines is accruing, and it is considered by some to be a highly sensitive method for biochemical diagnosis, especially for hereditary pheochromocytoma (sensitivity 97%, specificity 96%). 15 Because pheochromocytomas secrete primarily metabolized catecholamines, plasma methanephrines may be more useful than plasma catecholamines.

Measurement of plasma-free methanephrines as opposed to the conjugated or sulfated forms is particularly helpful because free fraction levels result from the actions of COMT on tumor catecholamine production. As a result, plasma-free methanephrines may show larger increases above normal than plasma catecholamines in pheochromocytoma. On the other hand, although plasma methanephrines are highly sensitive in detecting pheochromocytoma, a high number of false-positives may occur, particularly in older patients. Accordingly, the sensitivities and specificities of urine and plasma biochemical tests remain under investigation. As a result, some centers advocate urine testing as the initial screening test whereas others suggest plasma-free methanephrine levels. It is important to remember that the current technology for measuring plasma methanephrines requires that the patient abstain from acetaminophen for 3 to 5 days before testing 16 (see Fig. 15-5).

Typically, a measurement of urinary catecholamines or metabolites that is two or three times above the upper limit of normal is considered diagnostic of pheochromocytoma. For example, the upper limit of normal for total urinary catecholamines is approximately 100 µg per 24 hours, and a measurement above 250 µg per 24 hours is obtained in most patients with pheochromocytoma. Urine collections should include measurement of urinary creatinine to verify the adequacy of collection. A strong acid (such as 6 N HCl) is added to a sealed container. The optimal system for plasma catecholamine determination includes having the patient fast overnight and lie comfortably in a supine position with a heparin lock inserted 20 to 30 minutes before collection for withdrawing the blood.

Certain precautions should be taken in interpreting catecholamine or methanephrine values. For example, iodinated contrast dyes can interfere with some biochemical measurements. Labelato can give falsely elevated results when the following assays are employed: fluorometric methods of analysis used for catecholamine measurements, spectrophotometric methods used for methanephrine measurements, or radioenzymatic assays used for urinary-free catecholamine measurements. 17 Tricyclic antidepressants, prochlorperazine (Compazine), reserpine, clonidine, and clofibrate may interfere with urinary catecholamines and metabolite measurements. 18 Such medications should be discontinued, preferably 2 weeks before collection. Blood pressure should be controlled with agents such as dihydropyridine calcium channel blockers that do not interfere with the assays.

To provide better resolution against interfering substances, many laboratories use a reverse-phase high-performance liquid chromatography method with electrochemical detection. Measurement of these compounds by mass spectroscopy, which eliminates the problem of interfering substances, and use of immunoassay techniques are future directions. Stresses associated with serious illnesses, such as myocardial infarction, cerebral vascular accidents, or congestive heart failure, cause elevation in catecholamine levels. In renal insufficiency, plasma and urinary levels may be falsely elevated and urinary collections should be expressed in milligrams of creatinine. 19 In these circumstances, other diagnostic tests including imaging modalities are required for evaluation.

Chromogranin A is a soluble protein stored and secreted with catecholamines in chromaffin tissue. This biochemical marker is not specific for pheochromocytoma, and elevations may be seen with other neuroendocrine tumors. Plasma chromogranin A levels are elevated in more than 80% of patients with pheochromocytomas. 20 This assay is most often utilized in the postoperative surveillance of patients after resection of catecholamine-secreting tumors (see "Medical and Surgical Management"). Chronic renal failure is also associated with elevated chromogranin A levels.

Stimulation and Suppression Tests

The clonidine and glucagon tests are dynamic tests that are not routinely performed but are usually used when the suspicion of pheochromocytoma is high but the basal catecholamine levels are not diagnostic or are equivocal. Clonidine is a centrally acting α2-adrenoceptor agonist that normally suppresses the release of catecholamines from neurons but does not affect the autonomous release of catecholamines from a neoplasm. 21 In patients without pheochromocytoma, a decrease in basal plasma catecholamines by 50% or less than 3 nmol/L (500 pg/mL) is expected 2 to 3 hours after 0.3 mg of clonidine is administered. 22

Provocative testing is utilized when clinical suspicion of pheochromocytoma is not supported by the biochemical testing. Patients with pheochromocytomas typically demonstrate a threefold increase in plasma catecholamine levels or a concentration greater than 12 nmol/L (2000 pg/mL) 2 minutes after administration of 1.0 mg of intravenous glucagon. The glucagon provocative test is considered highly specific but poorly sensitive, whereas the clonidine test is considered highly sensitive with poor specificity. If both tests are negative, the diagnosis of pheochromocytoma may be reasonably excluded. 23 24

Imaging Techniques

After the diagnosis of pheochromocytoma is confirmed by biochemical testing, imaging techniques are employed for tumor location. Localization techniques include magnetic resonance imaging (MRI), computed tomography (CT), and MIBG or octreotide scintigraphy. Pheochromocytomas are typically large tumors (2 to 5 cm in diameter) and may contain areas of hemorrhage or necrosis. Pheochromocytomas in hereditary syndromes tend to be bilateral and smaller. 25 The latter feature is probably related to early detection as the result of periodic surveillance.

Approximately 98% of pheochromocytomas are intra-abdominal, and 90% originate within the adrenal gland. However,
Somatic serotonin receptor scintigraphy is another localization technique because somatostatin receptors are normally expressed in adrenomedullary and paraganglionic tissues. The receptor density is increased on pheochromocytoma tissue, which enables imaging with the somatostatin analogue octreotide. Octreotide, which binds to somatostatin receptor subtypes 2 and 5, is labeled with 111 In-DTPA. As with MIBG, octreotide scanning is best employed for detection of pheochromocytomas of extra-adrenal origin and of metastases from malignant pheochromocytoma. Some malignant tumors down-regulate the expression of somatostatin receptors. As a result, lack of uptake by octreotide may be a poor prognostic indicator in such patients.

In contrast to MIBG or octreotide scintigraphy, which requires 24 to 48 hours for optimal visualization, a promising new technology that can immediately image a pheochromocytoma is 6-[18 F]Fluorodopamine positron emission tomography. The uptake and retention of this radiopharmaceutical in chromaffin cells with subsequent imaging by emission scanning may provide a useful diagnostic test in patients with pheochromocytoma.

Finally, venous sampling has been utilized in the past to confirm or rule out the diagnosis of pheochromocytoma. The adrenal sampling effluent has a norepinephrine/epinephrine ratio less than 1. Higher ratios suggest the presence of pheochromocytoma.

Medical and Surgical Management

Preoperative Management

Surgical excision of a pheochromocytoma is the treatment of choice, but it involves a risk of morbidity as high as 40% and a risk of mortality of 2% to 4%. Surgical outcomes have improved with preoperative treatment such as -blocker blockade and volume expansion. Volume expansion is initially achieved with a high-sodium diet (150 to 200 mEq/L [150 to 200 mmol/dl]) unless contraindicated by congestive heart failure or renal insufficiency. Phenoxbenzamine, a noncompetitive -blocker, has traditionally been used for preoperative preparation. Phenoxbenzamine is titrated to reduce blood pressure to normal levels or orthostasis, or both. The starting dose, 10 mg/day by mouth, is titrated upward every 2 days. Most patients require 80 to 100 mg daily given in divided doses.

When -blockade is established, -blockade may be initiated if the patient is tachycardic or has arrhythmias. Without prior -blockade, -blockade alone can lead to unopposed -receptor stimulation and further elevation of blood pressure. Because phenoxbenzamine blocks catecholamine binding to receptors, it minimizes the risk of a hypertensive crisis during intubation, during induction with anesthesia, or during exploration and tumor manipulation. A noncompetitive -blocker is theoretically preferred to a competitive inhibitor because catecholamine levels, which can increase 500-fold, may overcome a competitive inhibitor. However, complete -blockade can mask the dramatic fall in blood pressure seen after tumor resection that signals to the surgeon that the pheochromocytoma is resected. Phenoxbenzamine may also lead to postoperative hypotension because of its prolonged half-life of 24 hours.

Calcium channel blockers, in particular nicardipine from the dhydropyridine class, are increasingly popular. These agents improve intraoperative systemic vascular resistance by blunting catecholamine-mediated arterial vasoconstriction during tumor manipulation, and they have few side effects. The selective, -inhibitor doxazosin has been effective in preoperative management without causing tachycardia or other serious side effects. The oral formulation of labetalol, an -blocker, might be ideal for preparation for surgery because the -blockade is weaker than that of phenoxbenzamine. As a result, additional vasodilators may be required intraoperatively in labetalol-treated subjects. Finally, metyrosine, which inhibits catecholamine synthesis, has been used in combination with -blockade for preoperative management.

Tradition and experience have guided the length of preoperative therapy with volume expansion and -blockade. Patients are typically treated for 10 to 14 days, although this time course has not been consistently associated with better operative and postoperative outcomes. Unfortunately, there are no reliable features that predict a smooth surgical course. Thus, each patient must be evaluated on an individual basis when selecting antihypertensive medicines.

Surgical Management

The surgical approach is dictated by the clinical situation. In patients with familial pheochromocytoma, a transabdominal incision allows adequate visualization and bilateral adrenalectomy if required. The flank approach offers better exposure and reduced blood loss for the patient with a solitary tumor. Surgeons are gaining experience with laparoscopic adrenalectomy performed when the tumor is smaller than 6 cm. The patient with pheochromocytoma should be referred to a surgeon who has experience in the management of pheochromocytoma and who collaborates with an experienced anesthesiologist to establish a smooth team effort.

Intraoperative hypotension is managed initially with volume expansion and then with intravenous pressor agents if necessary. Postoperative hypoglycemia, which may be due to reactive hyperinsulinemia, should be anticipated and warrants routine screening of glucose monitoring in the early postoperative hours. Surgical outcomes have been improved by intraoperative hemodynamic monitoring, the combination of fast-acting intravenous vasodilators and -blockers (sodium nitroprusside and esmolol, respectively), and the use of intravenous vasoconstrictors (norepinephrine or epinephrine).

The following is an approach followed in our institution to prepare the patient for surgery. As soon as the diagnosis of pheochromocytoma is established, -blockade is started and titrated upward (see earlier). Five days before surgery, if not earlier, a high-sodium (150 to 200 mEq/L [150 to 200 mmol]) diet is initiated; therapy with -blockade is continued, and daily weights and vital signs are monitored. Admission for volume expansion with intravenous saline is considered, depending on the patient's status. One day before surgery, the patient is transferred to a monitored intensive care setting with intravenous arterial and Swan-Ganz catheters. Isotonic saline is administered to achieve a pulmonary capillary wedge pressure greater than 10 mm Hg. If systemic vascular resistance is elevated (>1000 dyne second/cm 2/m2), intravenous sodium nitroprusside at 0.5 to 2 µg/kg per minute is initiated and increased as needed (500 to 1000 mg/minute may be required). On the day of surgery, the patient is given two separate intravenous lines, one for administration of pressors and the other for administration of vasodilators. Sodium nitroprusside, esmolol, epinephrine, and norepinephrine infusions are on standby in the event that they are required.

When surgery is performed, the catecholamine levels usually return to normal in approximately 2 weeks. If hypertension persists despite normal catecholamine levels and patient condition is good, reexploration should be considered.

Pregnancy

Management of pheochromocytoma in pregnancy is especially challenging. The mortality rate for mother and fetus is reported to be approximately 50%. Diagnosis before term improves these rates considerably. Clinical symptoms are similar to those in nonpregnant individuals, but unique features can occur. For example, the gravid uterus may compress the pheochromocytoma, causing paroxysms in the supine position with normal blood pressure in the erect posture.

Pheochromocytomas may also be easily misdiagnosed as preeclampsia, especially later in pregnancy. The diagnosis is typically made by evaluation of the urinary collection of catecholamines and metanephrines. Methyldopa should be discontinued before collection because of interference in catecholamine measurements. MRI is the preferred imaging modality because there is no ionizing radiation, and MIBG is contraindicated. Surgery is typically performed before 20 to 24 weeks of gestation. Thereafter, medical therapy is attempted, depending on the maternal status, and cesarean section is planned followed by tumor resection. Phenoxbenzamine has been used during pregnancy, but it does cross the placental barrier; as a result, calcium channel blockers may be preferable to control blood pressure.
Malignant Pheochromocytoma

Malignant pheochromocytoma occurs in 3% to 13% of all cases. The 5-year survival rate is 23% to 44%, compared with 97% 5-year survival in benign pheochromocytoma. These tumors typically grow slowly, and evidence of malignancy may not be seen for several years. Malignancy is defined by direct local invasion of sites that do not typically have chromaffin tissue. Malignant tumors most commonly metastasize to the lungs, bone, liver, or lymph nodes or may recur locally. Surgical removal or debulking is the treatment of choice.

After surgery, treatment goals are palliative to control the symptoms related to excess catecholamines. To achieve this end, -blockade followed by -blockade has most often been used (as discussed earlier). However, use of other antihypertensive treatments, such as dihydropyridine calcium channel blockers, is increasing. Unfortunately, the response to chemotherapeutic agents has been disappointing, but they may be tried in combination with antihypertensive treatment. Chemotherapeutic agents such as vincristine, cyclophosphamide, and dacarbazine have been used, often in combination. Although the response rate is suboptimal, the experience with high-specific-activity 131I-labeled MIBG is increasing, sometimes in combination with chemotherapy. External beam radiation has been attempted for palliation of bone metastases. Tumor embolization is another approach when surgery is not possible.
RENIN-ANGIOTENSIN-ALDOSTERONE AXIS

Several different mechanisms can lead to an increase in blood pressure in patients with essential hypertension and are similar to the mechanisms that cause an increase in blood pressure in individuals with secondary forms. A leading candidate for one of these mechanisms is a derangement in the renin-angiotensin system.\[1\]

Components

Components of the renin-angiotensin system are shown in Figure 15-7.\[1\]

Re nib

Renin is an enzyme produced in a number of cells in the body, principally in the juxtaglomerular apparatus of the kidney. In tissues that produce renin, it is stored in granules and released in response to specific secretagogues. It is a member of the aspartyl proteinase family of enzymes and is synthesized as a pre-proprotein. In humans, the gene that encodes renin is located on the short arm of chromosome 1 (1q21q22). In the rat the gene is located on chromosome 13, and in the mouse it is located on chromosome 1\[1\] (the mouse has two renin genes). In each species, the nucleotide sequence is approximately 12 kb, with 10 exons and 9 introns. The transcript production is a 1.5-kb messenger ribonucleic acid, and the initial protein consists of 340 amino acids, of which the first 43 are a prosegment cleaved to produce the active enzyme.

Renin is termed a double-domain enzyme because the N-terminal and C-terminal halves are similar.\[1\] Each domain contains a single aspartic acid residue critical for its catalytic activity. The three-dimensional structure of the enzyme has been characterized. A number of factors can regulate the transcription of the renin gene; consensus elements are present in the 5-flanking region of the gene, including those for cAMP and a number of steroid receptors (estrogen, progesterone, and glucocorticoids).\[1\] [1]

Angi tensinogen

Angiotensinogen is the only known substrate for renin and is catabolized to angiotensin peptides. The interaction between enzyme and substrate appears to be species specific because minor structural variations in the substrate render it relatively inactive in different species.\[1\] Human angiotensinogen belongs to the serpin superfamily of proteins and is encoded by a gene on chromosome 1q24.3 near the renin gene.\[1\] The angiotensinogen gene consists of five exons and four introns and is approximately 13 kb long. The transcript encodes a protein of 485 amino acids, 33 of which constitute a presegment that is cleaved after secretion. Angiotensin I is composed of the first 10-amino-acid sequence following the presegment. The 5 promotor region has consensus sequences for control by glucocorticoids, estrogens, and cytokines.\[1\] [1]

Angiotensin-Converting Enzyme

Angiotensin-converting enzyme (ACE), a second enzyme involved in the final production of angiotensin II (see Fig. 15-7), is a dipeptidyl carboxyl zinc metallopeptidase usually found bound to cell membranes.\[1\] It is also present in intracellular granules in certain tissues that produce angiotensin II. Its molecular weight is considerably greater than that of renin and it consists of two homologous domains, suggesting that there are two active sites in each molecule. In humans, the ACE gene is located on chromosome 17q23 and consists of 26 exons and 25 introns. Two molecular forms of ACE are products of a single gene but have separate promoter regions. One product is a somatic, or endothelial, ACE that consists of 1306 amino acids, and the second is a germinal ACE with a promoter region upstream from the 13th exon.\[1\]

Angiotensin Receptors

In humans, the two primary forms of the angiotensin receptor are termed AT\[1\] and AT\[2\]. A single gene on chromosome 3 encodes the angiotensin receptor in humans; rats have two genes. The S-flanking region contains three putative glucocorticoid response elements. The receptor has seven transmembrane regions, with a disulphide bridge linking the first and fourth extracellular segments. The principal signaling mechanism involved in the AT\[1\] receptor operates through a \(G_\alpha\) protein-mediated activation of phospholipase C.\[1\] However, some data suggest a linkage to protein tyrosine kinase.\[1\] [1] \[1\] The AT\[2\] receptor gene has three exons and two introns and a seven-transmembrane-domain structure.\[1\] [1]

Angiotensin Peptides

At least four angiotensin-like peptides have biologic activity (Table 15-1).\[1\] [1] The action of renin on angiotensinogen produces angiotensin I, a decapeptide that does not appear to have biologic activity. Angiotensin II is formed by cleavage of the two carboxyl-terminal peptides by ACE.\[1\] [1] and has full biologic activity. Amino peptidase A can remove the aminoterminal aspartic acid to produce the heptapeptide, angiotensin III. Angiotensin II and angiotensin III have equivalent efficacy in promoting aldosterone secretion and modifying renal blood flow. However, angiotensin III has less pressor activity. Amino peptidase B can cleave an additional amino acid from angiotensin III to form angiotensin IV (angiotensin 38).\[1\] The function of this peptide is not clear, but it may be involved in the regulation of cerebral circulation and may produce vasodilation rather than vasoconstriction. A fourth biologically active compound is produced from angiotensin I by the action of a propyl...
endopeptidase to form angiotensin 17, whose function is unclear.
Functions of Angiotensin II

The effects of the renin-angiotensin system can be mediated by local paracrine effects or through endocrine action. The endocrine system primarily involves renin from the juxtaglomerular apparatus of the kidney and angiotensinogen from the liver. In the circulation, the concentrations of each are such that variations in the angiotensinogen levels can modify angiotensin I generation. The half-life in the circulation of angiotensin II is short (probably less than a minute). Although circulating levels of angiotensin II are in the picomolar range, its affinity for its receptor is in the nanomolar range, suggesting that some angiotensin II effects may actually be mediated not by the circulating peptide but by its local generation.

Elements of the renin-angiotensin system are present in the adrenal, the kidneys, the heart, and the brain. For example, the adrenal glomerulosa cells contain the proteins needed to produce and secrete angiotensin II. Other tissues contain one or more components of the renin-angiotensin system and require other cells or circulating components, or both, to generate angiotensin II. For example, fat cells synthesize angiotensinogen but not renin or ACE, but they can generate angiotensin II locally. An increasing body of evidence suggests that many of the functions of angiotensin II are mediated by these paracrine effects. In some tissues, such as the heart, the angiotensin II may be generated by a nonrenin system the chymase system.

Angiotensin II functions through the AT₁ receptor to maintain normal extracellular volume and blood pressure in five ways: (1) constriction of vascular smooth muscle, thereby increasing blood pressure and reducing renal blood flow; (2) release of norepinephrine and epinephrine from the adrenal medulla; (3) enhancement of the activity of the sympathetic nervous system by increasing central sympathetic outflow, thereby increasing norepinephrine discharge from sympathetic nerve terminals; (4) promotion of the release of vasopressin; and (5) increasing aldosterone secretion.

Other functions of angiotensin II mediated through the AT₁ receptor include (1) central nervous system effects, including modification of thirst or the sense of well-being, or both; (2) modification of the release of corticotropin from the pituitary gland; (3) possible effects on placental and ovarian function; (4) activation of plasminogen activator inhibitor type 1, thereby contributing to the coagulation cascade; and (5) modification of growth of the heart, kidneys, and vascular smooth muscle.

In many respects, the action of angiotensin II through the AT₂ receptor antagonizes its effects through the AT₁ receptor. Thus, AT₂-receptor activation results in vasodilation, renal sodium loss, and apoptosis (thereby antagonizing the growth-promoting effects of AT₁ receptor activation). AT₂ receptors are highly expressed in fetal compared with adult tissue unless the adult tissue is damaged.
Functions of Aldosterone

Aldosterone's classical functions are twofold: regulation of extracellular volume and control of potassium homeostasis. These effects are mediated by binding to the mineralocorticoid receptor in the cytosol of epithelial cells, principally in the renal collecting duct. Transport to the nucleus and binding to specific binding domains on targeted genes lead to their increased expression. Although not all the genes have been identified, serum and glucocorticoid-induced kinase appears to be a key intermediary. Its increased expression leads to modification of the apical sodium channel and the basal lateral Na⁺,K⁺-adenosine triphosphatase (ATPase), resulting in increased sodium ion transport across the cell membrane (see Chapter 14). Glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor. Specificity of action is provided in many tissues by the presence of a glucocorticoid-degrading enzyme, 11-hydroxysteroid dehydrogenase, which prevents glucocorticoids from interacting with the receptor (see Chapter 14).

A second protective mechanism for untoward mineralocorticoid action is "escape" from its renal sodium-retaining effect. This usual occurs within 3 to 5 days of continued administration. Several mechanisms contribute to this escape, including renal hemodynamic factors and an increase in atrial natriuretic peptide.

In addition to these classical genomic actions, mediated by aldosterone binding to cytosolic receptors, an increasing body of data suggests that mineralocorticoids have acute, nongenomic actions secondary to activation of an unidentified cell surface receptor. This action involves a G protein signaling pathway and probably a modification of the sodium-hydrogen exchange activity. In both epithelial and nonepithelial cells (e.g., myocytes and leukocytes) this effect has been demonstrated.

There are additional nonclassical effects of aldosterone primarily on nonepithelial cells. These actions, although probably genomic and therefore mediated by activation of the cytosolic mineralocorticoid receptor, do not include modification of sodium-potassium balance. Aldosterone-mediated actions include the expression of several collagen genes; genes controlling tissue growth factors, such as transforming growth factor \( eta \); and plasminogen activator inhibitor type 1; or genes mediating inflammation. The resultant actions lead to microangiopathy, necrosis (acutely), and fibrosis in a variety of tissues, such as heart, the vasculature, and kidney. Increased levels of aldosterone are not necessary to cause this damage. Rather, an imbalance between the volume or sodium balance state and the level of aldosterone appears to be the critical factor.
Regulation

Renin

The release of renin into the circulation from the kidneys is controlled by four factors: (1) the macula densa, a specialized group of distal convoluted tubular cells that function as chemoreceptors for monitoring the sodium and chloride loads present in the distal tubule; (2) juxtaglomerular cells acting as miniature pressure transducers that sense renal perfusion pressure; (3) the sympathetic nervous system, which modifies the release of renin, particularly in response to upright posture in humans; and (4) humoral factors including potassium, angiotensin II, and atrial natriuretic peptides. The tissue renin-angiotensin systems are not necessarily regulated in the same manner as the circulating renin-angiotensin system. For example, a high potassium intake reduces renal renin release and increases adrenal renin secretion.

Aldosterone

The action of angiotensin II on aldosterone involves a negative feedback loop that also includes extracellular fluid volume (Fig. 15-8) (Figure Not Available). The major function of this feedback loop is to modify sodium homeostasis and, secondarily, to regulate arterial pressure. Thus, sodium restriction activates the renin-angiotensin-aldosterone axis. The effects of angiotensin II on both the adrenal cortex and the renal vasculature promote renal sodium conservation. Conversely, with suppression of renin release and suppression of the level of circulating angiotensin, aldosterone secretion is reduced and renal blood flow is increased, thereby promoting sodium loss.

In addition to the usual internal regulation of this negative feedback loop, a secondary fine-tuning component is related to the level of dietary sodium intake. Most endocrine negative feedback loops are not particularly sensitive to environmental factors. In contrast, the renin-angiotensin-aldosterone loop is exquisitely sensitive to dietary sodium intake. Sodium excess enhances the renal and peripheral vasculature responsiveness and reduces the adrenal responsiveness to angiotensin II (Fig. 15-9). Sodium restriction has the opposite effect. Thus, sodium intake modifies, or modulates, target tissue responsiveness to angiotensin II, a fine tuning that appears to be critical to maintaining normal sodium homeostasis without modifying blood pressure, particularly chronically. The mechanism or mechanisms by which dietary sodium intake induces these changes in the adrenal is unclear, but in the vascular system the effects are a consequence of angiotensin II down-regulation of the target tissue responsiveness to its agonists.
ESSENTIAL HYPERTENSION

The renin-angiotensin system has a powerful influence on both vasoconstrictor activity and volume regulation. Thus, defects in its regulation could lead to a rise in blood pressure by either or both of these mechanisms. Two other hormonal systems are implicated in the pathogenesis of essential hypertension: insulin (either directly or mediated by selective insulin resistance) and the calcium regulating systems.

Role of the Renin-Angiotensin System in the Pathogenesis of Essential Hypertension

In the late 1960s and early 1970s, Laragh and colleagues developed a classification of hypertension based on the level of circulating renin activity. By controlling dietary sodium and potassium intake, they classified patients into those whose values were low, normal, or high and used this information to define whether an individual case of hypertension was more volume-dependent or vasoconstrictor-dependent. The model predicted that individuals with low plasma renin activity (PRA) levels would have a volume-sensitive form of hypertension and those with high plasma levels would have a vasoconstrictor form of hypertension. It was presumed that classifying patients in this manner would lead to a more rational treatment program.

However, several concerns have been raised. First, age modifies the level of renin activity, older subjects having lower renin levels regardless of volume status. Second, race modifies the level of renin activity (whites, in general, have higher levels than blacks). Finally, in individuals who consume a relatively large amount of sodium (more than 175 mmol/day) low, normal, and high PRA levels are difficult to distinguish from each other. However, the concept of subclassification of hypertensive patients on the basis of the level of renin activity was useful in the development of better approaches to subclassifying patients.
Pathophysiologic Mechanisms in Low-Renin Essential Hypertension

Several mechanisms are thought to cause volume expansion and suppress renin activity in some patients with essential hypertension. Adrenal mechanisms may be involved in some subjects with low-renin hypertension because spironolactone (a mineralocorticoid antagonist) and aminoglutethimide (an inhibitor of steroid hormone biosynthesis) substantially reduce their blood pressure. Wisgerhof and Brown reported that the adrenal response to angiotensin II is enhanced in some patients with low-renin essential hypertension and that the enhanced responsiveness alters the renin-angiotensin-aldosterone negative feedback loop, allowing restoration of normal sodium homeostasis with decreased PRA and angiotensin II levels. However, with normal to high sodium intake, this enhanced adrenal response could result in a scenario in which aldosterone secretion would not be suppressed adequately, promoting sodium retention and an increase in blood pressure. The frequency of this abnormality is unclear because no population-based studies have been reported. However, even some patients with so-called normal renin essential hypertension appear to have a similar defect.
Nonmodulating Hypertension: Salt Sensitivity and Normal to High Renin Levels

Some patients with normal or high renin levels have a peculiar form of salt-sensitive hypertension in which increased sodium intake fails to change the vascular and the adrenal response to angiotensin II. These patients, termed nonmodulators, appear to be a subset of the essential hypertensive population, as documented by a bimodal distribution of several of their biochemical features. Patients with these features have been reported from Argentina, Brazil, Japan, The Netherlands, France, Italy, and the United States. In whites, between 25% and 30% of hypertensive subjects are nonmodulators, and in black hypertensives the frequency is likely to be greater.

Nonmodulators share several features with low-renin essential hypertensive patients: (1) they both have salt-sensitive hypertension, and (2) they tend to be older than the rest of the hypertensive population. However, nonmodulators have several features that are not similar to those of low-renin hypertension, including (1) fasting hyperinsulinemia, (2) a positive family history of hypertension and myocardial disease, (3) elevated levels of cholesterol and triglycerides, and (4) a decreased adrenal response to angiotensin II as assessed with a sodium-restricted intake. Finally, and perhaps most important, the characteristics associated with nonmodulation distribute in a bimodal fashion in the hypertensive population, suggesting a discrete subgroup.

In nonmodulators, target tissue responsiveness to angiotensin II does not change when sodium intake is modified. Two functional tests have been used to distinguish them from the rest of the hypertensive population. One measures the aldosterone response to an angiotensin II infusion of 3 ng/kg per minute with a low-salt (10 mEq) diet. The other approach is to measure the renal blood flow response to the same dose of angiotensin II with a high-salt (200 mEq) diet. Unless the dietary sodium intake is precisely controlled, a hypertensive subject can be misclassified. The correlation between these two criteria is 70% to 80%. Thus, if feasible, the best approach is to require both criteria to be positive in defining a nonmodulator. Other characteristics of this subset include failure of renal blood flow to increase when dietary sodium intake is changed from low to high and an enhanced response of atrial natriuretic peptide to infused angiotensin II.

Nonmodulators appear to have an inherited form of hypertension, as evidenced by (1) bimodality of the distribution of the nonmodulating characteristic in the hypertensive population, (2) the presence of the nonmodulating characteristic in normotensive subjects, (3) a strong family history of hypertension in nonmodulators (approximately 80%, compared with about 30% for the rest of the hypertensive population), (4) familial aggregation of nonmodulating characteristics with hypertension, and (5) the association of the nonmodulating phenotype with individuals who are homozygous for the angiotensinogen 235T genotype (Fig. 15-11). Data also support the involvement of the ACE and aldosterone synthase (CYP11B2) genes. Nonmodulators are twice as likely as the rest of the hypertensive population to be homozygous for the angiotensinogen 235T genotype, four times as likely if they have both the angiotensinogen and ACE dd genotypes, and nearly six times as likely if they have the angiotensinogen, ACE, and CYP11B2-344T genotypes.

A defect in the renin-angiotensin system is likely to underlie nonmodulating hypertension. It is probably a defect in the local renal and adrenal renin-angiotensin systems, as evidenced by the following: (1) the previously cited genetic data involving genes of the renin-angiotensin-aldosterone system; (2) low renal blood flow with a high-sodium diet and a reduced renal vascular response to infused angiotensin II, suggesting inappropriately high local renal angiotensin II levels; (3) correction of the renal blood flow defect by administration of a converting enzyme inhibitor; and (4) correction of the nonmodulating adrenal defect by a converting enzyme inhibitor.

The effect of sodium intake on blood pressure in nonmodulators has been extensively evaluated. Either short-term (3 days) or chronic (2 weeks) salt loading increases blood pressure in nonmodulators but not in other normal or high-renin hypertensive patients. The salt sensitivity of the hypertensive is due to the tendency for nonmodulators to retain more of a salt load both acutely and chronically. The abnormality in sodium handling is probably due to the alteration in renal hemodynamics with salt loading described previously and secondary to an inappropriately high local angiotensin II level. Support for this conclusion comes from correction of salt-sensitive hypertension in nonmodulators by converting enzyme inhibitors.

In summary, nonmodulators are a distinct subgroup of the essential hypertensive population and may constitute as much as 30% of that population. They have a sodium-sensitive form of hypertension, probably owing to a derangement of the local renin-angiotensin system in the kidney and the adrenal. These patients also have insulin resistance, hypercholesterolemia, a family history positive for myocardial infarction.
and an association with a specific allelic variant of the angiotensinogen gene. Finally, the defect appears to be correctable by the administration of converting enzyme inhibitors.
Insulin Resistance and Hypertension

Noninsulin-dependent diabetes mellitus (NIDDM), hypertension, and obesity are commonly associated, and the frequency of this association may be greater than their occurrence in the general population (see the review by Hopkins and colleagues). There is a common etiology. In support of this possibility is the fact that insulin resistance and hypertension can coexist without obesity or other stigmata of NIDDM. There may be a genetic component of this interaction. For example, in whites of European descent there is a strong relation between insulin resistance and blood pressure, whereas in normotensive blacks or Pima Indians there is no such relationship. However, most hypertensive blacks are insulin resistant.

Causative Role of Insulin in Hypertension

Several mechanisms have been proposed to explain the insulin-resistant state, including abnormalities in insulin binding to its receptor, defects in glucose transport, changes in the signal transduction pathway within insulin-sensitive cells, and metabolic abnormalities in glycolysis, glucose oxidation, or glucagon synthesis. Yet little is known concerning the cause of insulin resistance in essential hypertension. (Fig. 15-14) Several features are relevant. First, insulin resistance is common in essential hypertension whether defined by fasting or postglucose load insulin levels or by euglycemic, hyperinsulinemic clamps. Second, obesity cannot explain all cases of insulin resistance. Third, insulin directly stimulates the calcium pump in insulin-sensitive tissues and promotes calcium loss from the cell, and raising cytosolic calcium levels in an adipocyte can induce insulin resistance. If a cell is resistant to insulin, the insulin-induced calcium loss from cells would be decreased, and in vascular smooth muscle cells the resultant increase in intracellular calcium would enhance responsiveness to vasoconstrictors and increase blood pressure.

Two other mechanisms have been proposed to explain the linkage between insulin resistance and hypertension: increased activity of the adrenergic nervous system and increased renal sodium retention. Underlying both these hypotheses is the assumption that insulin resistance in a hypertensive subject may be selective. Accordingly, insulin resistance in the skeletal muscle or liver, or both, would induce a rise in circulating insulin levels. However, there would be little, if any, resistance at the renal tubule or adrenergic nervous system. Finally, for the vasoconstrictor hypothesis to be correct, there would have to be an imbalance between insulin's direct vasodilator effect and the vasoconstriction induced by activation of the adrenergic nervous system.

A hyperinsulinemic response to glucose loading has been described in salt-sensitive but not in salt-resistant normotensive subjects. This salt sensitivity also extends to metabolic abnormalities that are often associated with insulin resistance, such as increased levels of circulating low-density lipoprotein cholesterol in salt-sensitive hypertensives compared with salt-resistant hypertensives. Thus, salt sensitivity of blood pressure is associated with lipid and glucose metabolic abnormalities and increased cardiovascular risk. Impaired insulin sensitivity and hyperlipidemia have been described in healthy volunteers with normal to high plasma renin levels compared with those with low renin levels. Thus, the data derived from these sources are inconsistent. Individuals who are salt-sensitive, as noted earlier, are likely to have low PRA. Yet salt-sensitive subjects as a group also have an increased risk of carbohydrate and lipid abnormalities.

In summary, insulin resistance occurs in some patients with essential hypertension who do not have obesity or NIDDM. Several lines of evidence suggest that insulin resistance per se or hyperinsulinemia, or both, could result in increased sodium reabsorption, enhanced vascular tone, and activation of the adrenergic nervous system. Alternatively, this state could be associated with abnormal regulation of the renin-angiotensin system. Environmental factors can exacerbate this defect. For example, if patients with insulin resistance gain weight or receive drugs that increase insulin resistance, such as diuretics or beta-blockers, the hypertension may be worsened. However, it is still unclear whether the insulin resistance is a marker for some other abnormality or a primary defect in these patients.
Calcium and Hypertension

In 1982 McCarron and co-workers\(^2\) reported that dietary calcium intake in humans with hypertension was lower than in normotensive control subjects, and the inverse relation between blood pressure and calcium intake has been confirmed in epidemiologic studies. \(^3\) These studies also suggest an association between the level of calcium intake and the degree of sensitivity of the blood pressure to sodium intake. In part, this may not be surprising given the known relationship between the reabsorption of calcium and that of sodium by the proximal tubule of the kidney. Blood pressure, in part, may also correlate with magnesium intake, at least in women.\(^4\) Indeed, the relative risk of developing hypertension was 0.65 when both magnesium (<200 mg/day) and calcium (<400 mg/day) intakes were lower. There appears to be a critical threshold for the effect of calcium intake on blood pressure, the effect not being evident unless calcium intake is less than 700 to 800 mg/day.\(^5\) Thus, increasing calcium intake above this threshold may not modify blood pressure.

Clinical trials designed to evaluate the validity of these observational data have provided equivocal results. However, a meta-analysis of these trials suggests that high calcium intake causes a minimal reduction of blood pressure in the general population and a modest reduction in individuals who already have hypertension. In one meta-analysis\(^6\) of results for 2412 subjects, high calcium intake reduced systolic blood pressure \(1.33\) mm Hg in the general population and \(4.3\) mm Hg in hypertensive patients. Hypertensive subjects also had a significant reduction in diastolic blood pressure \(1.5\) mm Hg. A second meta-analysis involving \(1231\) individuals did not demonstrate as large an effect.\(^7\)

Pathophysiologic Mechanisms

The mechanisms responsible for the impact of calcium intake on blood pressure are uncertain. Some studies have shown that parathyroid hormone (PTH) levels, on average, are higher in hypertensive subjects compared with normal control subjects, suggesting a potential role for PTH in mediating hypertension. However, PTH levels in hypertensive patients are still within the normal range and are not inappropriate for the level of ionized calcium. Thus, it is unclear whether the elevated PTH causes an increase in blood pressure or is simply a reflection of a modest change in calcium homeostasis. Furthermore, when infused, PTH is a vasodilator.\(^8\) and PTH inhibits contraction of vascular smooth muscle, presumably by inhibiting calcium entry.\(^9\)

Pang and Lewanczuk\(^10\) have suggested that there is a specific hypertensive factor from the parathyroid gland, distinct from PTH, that is increased in some patients with essential hypertension. Several studies in experimental hypertension suggest that the plasma level of the factor is elevated and that it can modify vascular smooth muscle function by increasing cytosolic calcium levels.\(^11\) In some patients with hyperparathyroidism and hypertension, parathyroid hypertensive factor is said to be elevated and becomes undetectable after parathyroidectomy as blood pressure decreases.\(^12\) However, only a single group has reported on the presence of such a factor.

PTH-related protein (PTHrP), a peptide with a structure similar to that of PTH but derived from a different gene, appears to share with PTH an ability to produce vasodilation. It has been suggested that a deficiency in PTHrP could lead to an elevated blood pressure, as this substance may be produced to counteract the effect of vasoconstrictors.\(^13\)

Finally, the active metabolite of vitamin D \((1,25\text{-dihydroxycholecalciferol})\) increases calcium uptake in cardiac and vascular smooth muscle cells, induces vascular contractions, and exerts a myotropic effect on vascular smooth muscle.\(^14\) Patients with low-renin or salt-sensitive hypertension tend to have an increase in both PTH and \(1,25\text{-dihydroxycholecalciferol}\) levels. With sodium loading, levels of both hormones increase further as the blood pressure increases. However, as with the changes in PTH levels, it is difficult to determine a cause-and-effect relationship. For example, the increase in \(1,25\text{-dihydroxycholecalciferol}\) levels in these patients may be secondary to the higher PTH level because PTH stimulates 1-hydroxylase activity.

In brief, epidemiologic and experimental evidence suggests that calcium and calcium-regulating hormones play a role in the control of vascular tone. Meta-analyses of clinical trials support a blood pressure-lowering effect of a high calcium intake, particularly in patients with essential hypertension. However, the mechanism or mechanisms involved and the relationship of the effects of calcium intake to the effects of sodium intake on blood pressure are still unclear. Finally, it is uncertain how many of these associations are primary versus secondary events.
Summary

Several lines of evidence suggest that many patients with essential hypertension have an endocrine basis for elevated blood pressure. Increased circulating hormone levels, changes in the responsiveness of target tissues to these hormones, and abnormalities in vascular tone can all contribute to the pathogenesis of the hypertension. Whether these endocrine abnormalities are primary or secondary events is unclear. Intriguingly, most do not fit the classical endocrine pattern for disease because hormonal overproduction is rare. Rather, there is a change in the response of target tissues to specific hormones, with associated adaptive responses probably the major contributor to the hypertensive process. Finally, a number of the abnormalities appear to have a major genetic component. This fact makes possible a more precise dissection of subgroups or phenotypes of hypertensive patients with the use of genetic markers.
RENIN-ANGIOTENSIN SYSTEM AND SECONDARY HYPERTENSION

In addition to its involvement in primary hypertension, the renin-angiotensin system is a major factor in the most common cause of secondary hypertension: renal disease. Indeed, many insights into the renin-angiotensin system have come from the study of patients with renal disease.

Renal Vascular Hypertension

Goldblatt and colleagues described the pathologic role of excess renin production in the hypertension associated with constriction of a renal artery, and 4 years after their observations, a nephrectomy in a hypertensive patient with a small kidney led to correction of the hypertension. Thus, renal vascular hypertension is defined as hypertension associated with either unilateral or bilateral ischemia. Unilateral renal vascular disease is likely to be the cause of elevated blood pressure in approximately 1% of the hypertensive population, and bilateral renal parenchymal disease is causative in another 2% to 4%.

It is important to distinguish between renal vascular disease and renal vascular hypertension. Perhaps 50% or more of subjects older than 60 years have renal vascular disease, only a minority of whom also have hypertension. This discrepancy is not surprising when one considers Goldblatt's original experiment, which documented that the lumen of the renal artery needs to be reduced to less than 30% of its original size before hypertension develops. Documentation of a functional abnormality in association with a radiologically defined renal arterial lesion is a critical diagnostic maneuver before therapeutic intervention.

Blacks and patients with diabetes mellitus seem to have a lower frequency of renal vascular hypertension, even though in both groups the incidence of renal vascular disease is higher than in the nondiabetic white population. Most patients with renal vascular disease have either atherosclerotic plaques or fibromuscular disease, and in 10% of the cases the lesion may not be in the main renal artery but in a segmental or branch artery.

Pathophysiology

The initiating event in the hypertension in subjects with renal disease is a reduction in perfusion pressure to the affected kidney, which stimulates the release of renin. The increased production of renin leads to increased angiotensin II levels and increased aldosterone secretion (secondary aldosteronism; see Fig. 15-6, Figure Not Available). As a consequence of the hyper-aldosteronism, sodium is retained and potassium is lost. The combination of angiotensin II-induced vasoconstriction and sodium retention increases blood pressure and leads to a natriuresis through the contralateral kidney. The increased levels of renin, elevated blood pressure, and sodium retention all act in concert to suppress renin production from the contralateral kidney, an important feature in the diagnostic evaluation of these patients. With bilateral renal arterial disease, the vasculature to both kidneys is compromised. Thus, the ability of the kidneys to excrete sodium is reduced, a gradual volume expansion occurs, and circulating renin levels are suppressed.

In long-standing unilateral renal artery stenosis, the contralateral kidney may become damaged secondary to the elevated blood pressure. Thus, the affected kidney is protected by the stenotic lesion and may ultimately suffer less damage, except for the ischemia induced by the stenosis. In these cases correction of the renal artery stenosis may not correct the elevated blood pressure, which can be sustained by the diffusely damaged contralateral kidney. Paradoxically, in this circumstance repair of the renal artery stenosis and removal of the contralateral kidney may normalize blood pressure.

Although renal vascular hypertension occurs in all age groups, the etiology varies. In individuals younger than 50 years, renal vascular hypertension is more common in women and is usually secondary to fibromuscular dysplasia of the renal artery. After the age of 50 it is more likely to be secondary to atherosclerosis and therefore more common in men. In addition to unilateral or bilateral vascular insufficiency, generalized renal ischemia can result from renal compression, such as in hydrocephalus. Initially the kidney is enlarged, but over time cortical atrophy develops.

Diagnosis

Renal vascular hypertension should be suspected in a normotensive individual of any age who has sudden onset of hypertension, in a known hypertensive subject with an acute acceleration of blood pressure, or in an individual younger than 30 years who has significant hypertension. Other clinical features are suggestive of this condition (Fig. 15-15). In general, if the hypertension is mild to moderate (diastolic blood pressure 105 mm Hg) with an onset between ages 30 and 60 years, the probability of renal vascular hypertension is low. In these patients, a detailed search for renal vascular hypertension is probably not warranted.

The diagnosis of renal vascular hypertension rests on two criteria: (1) the identification of a significant arterial obstruction and (2) evidence of excess renin secretion by one or both kidneys. The following tests are particularly useful in patients with fibromuscular dysplasia whose hypertension is renin-dependent and often cured by revascularization. In elderly individuals with renal artery stenosis that is probably secondary to atherosclerosis, consideration of the therapeutic options may modify the extent of testing.

Noninvasive Testing

Gadolinium-Enhanced Magnetic Resonance Angiography

This procedure is useful for defining anatomic lesions of one or both renal arteries. In some centers it is becoming the screening procedure of choice. Because gadolinium is not nephrotoxic, it may be particularly useful for individuals with renal insufficiency. The reported sensitivity (90% to 100%) and specificity (90% to 95%) are excellent for detecting a stenosis greater than 50%. Limitations of this technique include the requirement for breath holding, overestimation of stenosis,
inadequate visualization of segmental and accessory renal arteries, low availability of MR angiography, and cost. With future development, rapid imaging techniques may permit the acquisition of hemodynamic data by visualization of the vascular phases.

**Captopril Renography**

This is a functional test. Captopril, a converting enzyme inhibitor, is administered 30 to 60 minutes before the renogram. This test takes advantage of the dependence of the hemodynamics of the renal vasculature on angiotensin II because both the efferent and afferent arterioles are highly sensitive to the vasoconstrictor actions of angiotensin II. Indeed, balanced constriction of these two vessels maintains a normal glomerular filtration rate with a variety of changes in renal blood flow, so-called renal autoregulation. An increase in angiotensin II levels secondary to unilateral stenosis of a renal artery leads to vasoconstriction of the afferent and efferent arterioles in both kidneys. Because of the stenotic lesion on the affected side, blood flow to the glomerulus, and therefore glomerular pressure, on this side is determined primarily by the structural lesion.

When a converting enzyme inhibitor (which reduces intrarenal angiotensin II levels) is given, angiotensin II-induced afferent arteriolar constriction is reduced in both kidneys. In the unaffected contralateral kidney there is a concomitant reduction in efferent arteriolar tone, an increase in blood flow, and no change in glomerular filtration rate. However, in the stenotic kidney, where perfusion of the glomeruli is restricted by the stenosis, a reduction in efferent arteriolar tone results in a fall in glomerular filtration rate and reduced uptake and delayed excretion of the isotopic tracer as assessed by the renogram. The sensitivity (80% to 90%) and specificity (65% to 80%) of the captopril renogram are somewhat less than those of the MR angiogram, particularly in patients with renal insufficiency.

**Digital Subtraction Angiography**

This procedure is used in some centers, but because of the cost and the need for arterial rather than venous injection, its role as a screening test is limited.

**Renal Duplex Ultrasonography**

This test provides both a functional (Doppler) and an anatomic (B-mode imaging) evaluation of the renal artery and renal perfusion. Intrarenal ultrasonography measures the pulsatility index and blood flow acceleration during early systole. Its sensitivity (85% to 95%) and specificity (70% to 85%) fall between those of the captopril renogram and the MR angiogram. Although in theory this may be an ideal screening test, in practice its validity is dependent on the skills of the radiologist. Depending on operator availability, it is the procedure of choice in some centers.

**Invasive Testing**

The definitive test for a correctable renal vascular lesion is the combination of bilateral renal vein renin sampling and a selective renal arteriogram. As noted earlier, the renal arteriogram alone defines structural lesions but does not provide insight into their functional significance. Simultaneous bilateral renal vein renin measurement provides a valuable adjunct for predicting whether therapeutic intervention will modify the hypertension. When one kidney is ischemic and the other is normal, nearly all the circulating renin is produced by the affected side. As a result, the venous concentration of renin from the ischemic kidney is at least 1.5 times greater than that from the contralateral kidney. Theoretically, the renin concentration from the contralateral kidney should be the same as that in the peripheral circulation. Unfortunately, in many circumstances there is a varying degree of damage to the contralateral kidney, and therefore total suppression of renin from that kidney does not occur.

Some administer captopril before renal vein sampling to exaggerate the renin release from the stenotic side; all agents that suppress renin secretion, such as β-blockers, should be withheld before the study. If feasible, the patient should also have a low sodium intake to enhance renin release from the affected kidney. If these procedures are followed, approximately 80% of subjects with unilateral renin elevations that fulfill the preceding criteria have a beneficial response to therapeutic intervention.

**Treatment**

The treatment of choice in renal artery stenosis secondary to fibromuscular disease is renal angioplasty with or without insertion of a stent. Lesions at the ostium of the renal artery often do not respond well to angioplasty alone, but the addition of a stent may improve the outcome. Surgical revascularization, previously the primary approach, is used less frequently in older adults with atherosclerotic lesions because the surgical risk is high in these individuals. The same reservation may apply to angioplasty or stenting, or both, in comparison with medical treatment. Thus, surgery is usually reserved for individuals in whom angioplasty has proved unsuccessful.

Medical management to control blood pressure may be appropriate in elderly individuals, those who are not candidates for definitive corrective procedures, or those in whom these procedures have failed. Converting enzyme inhibitors or an angiotensin II receptor antagonist would be the treatment of choice, given the pathophysiology of the disease. However, for the reasons outlined earlier, these agents may worsen ischemia in the affected kidney. Converting enzyme inhibitors should be used with great caution in individuals who may have bilateral renal artery disease or arterial disease in a solitary kidney because these agents may reduce the glomerular filtration rate, cause renal hypoxia, and precipitate renal failure. Finally, a more aggressive therapeutic approach to preserve renal function may require invasive techniques.
Primary Reninism

Rarely, juxtaglomerular cell tumors of the kidney or ectopic tumors secrete renin. Individuals with such tumors have typical features of renal vascular hypertension: hypertension, elevated renin levels, hypokalemia, and hyponatremia. Most, however, are young and have high circulating levels of renin in the blood and also severe hypertension at the time of diagnosis. When a mass lesion is discovered in the kidney, there is unilateral renin secretion but no evidence of renal artery stenosis. Radiologic evaluation with CT scanning is invaluable. Surgical removal of the tumor cures the hypertension and the hyperreninemia.
Renal Parenchymal Disease

A variety of conditions can cause hypertension associated with renal parenchymal disease, the most common of which are hypertension per se, diabetes mellitus, and autoimmune disease (e.g., systemic lupus erythematosus). In these patients there is the potential, depending on the level of sodium intake, for a shift from a vasoconstrictor (angiotensin II) form of hypertension to a volume-sensitive hypertension secondary to decreased capacity for renal sodium excretion. The local (intrarenal) renin-angiotensin system is activated to a variable degree in these subjects. This activation results in an elevation of hydraulic pressure in the glomeruli (so-called glomerular hypertension) secondary to the vasoconstrictor effect of angiotensin II on the efferent arteriole as noted earlier.慢性 elevation of glomerular pressure leads to glomerular sclerosis and progressive loss of functioning nephron units.

The administration of converting enzyme inhibitors can slow the progression of renal damage in both diabetic and nondiabetic renal parenchymal disease. This effect appears to be an added action of converting enzyme inhibitors beyond their ability to lower systemic blood pressure, probably because they also selectively reduce renal glomerular pressure. Thus, agents that produce a decrease in systemic blood pressure equivalent to that accomplished by converting enzyme inhibitors do not afford the same degree of protection of renal function.

However, caution should be exercised in administering converting enzyme inhibitors to patients who may have an increased risk of bilateral renal artery stenosis. In such circumstances, instead of improvement, converting enzyme inhibitors would cause a sudden deterioration of renal function. Interestingly, the renal protective actions of converting enzyme inhibitors work in advanced diabetic nephropathy, a condition usually associated with hyporeninemic hypoaldosteronism. Because of the possible further reduction of aldosterone production with converting enzyme inhibitors in such patients, frequent measurement of serum potassium levels is mandatory, with institution of appropriate measures to reduce potassium levels if hyperkalemia occurs (e.g., low-potassium diet, potassium-wasting diuretics). In some instances, the converting enzyme inhibitor may have to be discontinued.
Hypertension during Pregnancy

Pregnancy-induced hypertension (PIH), or gestational hypertension, is defined as de novo hypertension arising during the second half of pregnancy. The literature regarding the prevalence and pathophysiological abnormalities in this disorder is clouded by studies that have often included pregnant patients with chronic hypertension. The classification of hypertensive disorders of pregnancy developed by the American College of Obstetricians and Gynecologists has been adopted by the National Institutes of Health:

1. Chronic hypertension: blood pressure greater than 140/90 mm Hg before pregnancy or before the 20th week of pregnancy
2. Preeclampsia: a systolic blood pressure increase of at least 30 mm Hg or a diastolic blood pressure increase of at least 15 mm Hg over prepregnancy or early pregnancy values combined with proteinuria (300 mg per 24 hours) or edema, or both
3. Preeclampsia superimposed on chronic hypertension: the same criteria as for item 2 but occurring in women with preexisting hypertension
4.Transient hypertension: a blood pressure increase similar to that in preeclampsia but without proteinuria or edema

Preeclampsia may also progress to eclampsia, defined as the occurrence of convulsions. As viewed according to the preceding classification, PIH includes preeclampsia and transient hypertension of pregnancy. However, the prognosis for each is different. The preeclampsia form of PIH is self-limited and usually does not occur in subsequent pregnancies, whereas...

### Risk Factors for Pregnancy-Induced Hypertension

PIH arises in approximately 5% of nulliparous pregnant women, and the prevalence appears to be related to both environmental and genetic factors. For example, the prevalence of PIH is double in indigent, inner-city pregnant women. Other risk factors include nulliparity, low dietary calcium intake, multiple gestations, black race, chronic hypertension, increasing age, inherited and acquired coagulation disorders such as protein S and protein C deficiencies and antiphospholipid antibodies, and a history of a mother who had this syndrome.

### Pathophysiology

Pathophysiological abnormalities in PIH should be divided into those in preeclampsia and those in transient hypertension of pregnancy. In normal pregnancy, plasma volume increases by 40%, associated with a reduction in peripheral vascular resistance (40% to 80%) and a rise in cardiac output, renal blood flow, and glomerular filtration rate. The renin-angiotensin-aldosterone system is activated despite the increase in plasma volume. This activation is believed to be related to prostaglandins, for example, prostacyclin and prostaglandin E₂, direct effects of estrogen; or an antiinflammatory action of progesterone.

A number of alterations have been reported in subjects with PIH, although many investigations do not clearly distinguish between patients with preeclampsia and those with transient hypertension of pregnancy. Table 15-3 presents the findings in preeclampsia compared with normotensive pregnancy. Plasma volume is reduced in preeclampsia and systemic vascular resistance is increased. Paradoxically, the hormonal markers of volume are consistent with a volume-expanded state, relative suppression of the renin-angiotensin-aldosterone system, and increased levels of atrial natriuretic peptide and digitalis-like factor. This apparent paradox is unexplained unless these hormonal changes induce the volume changes or there is a misperception of extracellular fluid volume in this disorder. On the other hand, elevated levels of digitalis-like factor, an inhibitor of the Na⁺,K⁺-ATPase pump, could increase intracellular sodium levels, as reported in red blood cells in patients with PIH. The role of digitalis-like factor is controversial, however, because of disparate findings for digoxin-like immunoreactivity versus measurement by bioassay, that is, inhibition of Na⁺,K⁺-ATPase.

Enhanced maternal vascular reactivity is also seen in PIH with increased pressor sensitivity to infused angiotensin II even in normotensive phases of pregnancies, before patients progress to PIH. In contrast, in normal pregnancies pressor responsiveness to angiotensin II is blunted. One important hypothesis that could explain these observations includes decreased production of vasodilatory prostaglandins, such as prostaglandin E₁, and prostacyclin; in fact, decreased prostacyclin production may precede the appearance of hypertension in PIH. Others propose a relative increase in the vasocostriction prostaglandin, thromboxane, and subnormal nitric oxide. Reported cation abnormalities include increased intracellular calcium and enhanced responses of intracellular calcium to vasopressin in platelets of patients with PIH. These findings suggest that parallel changes might occur in vascular smooth muscle, where intracellular calcium is a major determinant of peripheral vascular resistance. It is unclear whether the abnormalities in PIH reflect initiating events or are secondary alterations that sustain the elevation of blood pressure.

One unifying hypothesis to explain PIH is uteroplacental hyperperfusion. Perhaps secondary to structural abnormalities in the spiral arteries supplying the uterus, uterine blood flow is impaired. Through unknown mechanisms, prostaglandin production is reduced and there is generalized endothelial damage (endothelin levels are elevated in PIH). Subsequently, platelet aggregation is enhanced, fibrin is deposited in the glomeruli, and proteinuria occurs. Although this is an attractive hypothesis, a number of links need to be established.

### Treatment

There is little evidence that sodium restriction improves the outcome of pregnancy in women with PIH or is effective for prophylaxis against PIH. On the other hand, some studies suggest that volume expansion may improve both blood pressure and outcome in preeclampsia. It now appears that a moderate to liberal...
sodium diet should be recommended to pregnant women and that the diet should be adequate in calcium. Bed rest with lateral recumbency is commonly recommended for women with PIH and is believed to result in hemodynamic improvements, including increased renal and uterine blood flow and reduced peripheral vascular resistance with lowering of systemic blood pressure.

Low-dose aspirin (50 to 100 mg/day) may reduce the incidence of PIH, although the results of several large trials remain controversial. The rationale for low-dose aspirin is to restore the balance between vasodilator and vasoconstrictor prostaglandins (primarily by reducing thromboxane A₂ but without affecting prostacyclin levels). Antihypertensive agents are usually given when diastolic blood pressure exceeds 100 mm Hg. Traditional agents include methyldopa and hydralazine. β-Blockers, such as prazosin, and calcium channel blockers, primarily nifedipine, are being used with increased frequency because of their greater efficacy. These agents also appear to have acceptable safety profiles, although they have not been used as long as the traditional drugs. ACE inhibitors and angiotensin receptor antagonists are contraindicated in PIH because of adverse effects on kidney development in the fetus.
PRIMARY MINERALOCORTICOID EXCESS STATES

Primary mineralocorticoid excess states are characterized by suppressed PRA and hypokalemia and include primary aldosteronism.

- Ectopic corticotropin production
- Liddle's syndrome

Deoxycorticosterone (DOC)-secreting tumors, and inherited diseases (Table 15-4).

**Primary Aldosteronism**

Primary aldosteronism, the cause of approximately 0.05% to 2.2% of all unselected cases of hypertension, was first described in 1955 by Conn in conjunction with an aldosterone-producing adrenal adenoma (APA). Other etiologies include idiopathic bilateral hyperplasia (idiopathic hyperaldosteronism) and inherited entities. Its prevalence may be as high as 10% in hypertensive patients, depending on the study population and the criteria used. The prevalence of tumors remains fairly constant. However, the prevalence of bilateral hyperplasia can vary greatly.

#### Clinical Features

The clinical symptoms of primary aldosteronism are nonspecific and result from potassium depletion. Neuromuscular symptoms (weakness, periodic paralysis, cramps, or tetany), fatigue, and paresthesias are not uncommon; polyuria and nocturia probably result from a hypokalemia-induced renal concentrating defect. Despite the continuous high levels of aldosterone, patients rarely exhibit edema, presumably owing to escape, in which the sodium-retaining effects of chronic mineralocorticoid excess are lost. Intracellular potassium depletion can also impair insulin secretion and cause glucose intolerance or overt diabetes mellitus. Resetting of the osmostat can occur in primary aldosteronism, as evidenced by slightly higher than normal serum sodium levels. This is a useful clinical point because there is a tendency for a reduced serum sodium level in states of secondary aldosteronism.

The hypertension associated with primary aldosteronism is usually moderate to severe with mean blood pressures (± standard deviation) of 184 ± 8/112 ± 16 mm Hg. However, some patients have malignant hypertension, and others have normal or only mildly elevated blood pressure. Individuals with APA tend to have higher blood pressures than those with idiopathic hyperaldosteronism (IIA). Patients with primary aldosteronism may be refractory to conventional antihypertensive agents and may experience severe hypokalemia after institution of potassium-wasting diuretics such as hydrochlorothiazide. Although it would be expected that the hypertension is related to volume expansion, measurements of extracellular sodium spaces in patients with APA are usually normal while peripheral resistance is increased.

End-organ damage with primary aldosteronism is variable. In general, the left ventricular hypertrophy is disproportionate to the level of blood pressure when compared with the situation in essential hypertension.

With removal of an aldosteronoma, its regression occurs even if blood pressure does not become normal. In addition, structural damage to the kidney, cerebral circulation, and retinal vasculature occurs more frequently than would be assumed on the basis of the duration and level of blood pressure. As many as 50% of patients with primary aldosteronism may have proteinuria, and renal failure may occur in as many as 15%. Thus, it is probable that, independent of aldosterone's effect on blood pressure, its excess production induces cardiovascular damage.

Mineralocorticoid excess states are associated with vascular remodeling that results in perivascular fibrosis and vascular wall thickening. Cardiac fibrosis has also been reported in postmortem studies of patients with adrenal adenoma with mineralocorticoid hypertension. An excessive number of renal cysts has also been noted in association with hypokalemia and hyperaldosteronism (in as many as 60% of cases). However, other studies reported a prevalence of renal cysts similar to that in the normal population.

Etiologies of primary aldosteronism are shown in Table 15-5.

**Aldosterone-Producing Adenoma**

The solitary APA is the most common cause of primary aldosteronism and accounts for approximately 65% of cases. These lesions are usually less than 2 cm in
Idiopathic Hyperaldosteronism

Idiopathic hyperplasia (bilateral adrenal hyperplasia) is the cause of approximately 30% of cases of primary aldosteronism. Microscopically, the glands show hyperplasia of the zona glomerulosa accompanied by adrenocortical nodules. The aldosterone excess in IHA is usually milder than in APA; as a result, the biochemical abnormalities such as hypokalemia and suppression of PRA are usually less severe than in APA.

Because the plasma aldosterone response to infused angiotensin II is exaggerated compared with that in normal individuals or patients with APA, IHA has been hypothesized to represent a syndrome of enhanced responsiveness to angiotensin II. Others suggest that IHA is a form of essential hypertension representing one end of the distribution of aldosterone production in essential hypertension and is therefore related to low-renin essential hypertension, in which an enhanced aldosterone response to angiotensin II is seen (see earlier).

Glucocorticoid-Remediable Aldosteronism (GRA)

See later.

Regulation of Aldosterone Secretion

The renin-angiotensin system is suppressed in primary aldosteronism and does not contribute to the regulation of aldosterone production. In this sense, aldosterone production is "autonomous." However, studies in patients with APA, for example, demonstrate that the adenomas are regulated by corticotropin and potassium. Thus, autonomy is defined by the failure of aldosterone production to respond to maneuvers that normally activate (upright posture) or suppress (sodium loading) the renin-angiotensin system. A variant form of APA has been described in which the adenomas are renin responsive (see later). Moreover, in IHA aldosterone production is usually responsive to stimuli that activate the renin-angiotensin system. On the other hand, adrenal carcinomas are truly resistant to all secretagogues.

Diagnosis

Screening Tests

Spontaneous hypokalemia is commonly present. Some patients may have normal potassium levels, possibly because of self-selected dietary sodium restriction, because aldosterone-induced renal potassium wasting is diminished by decreased sodium delivery to the distal nephron. When potassium-wasting diuretics are given as antihypertensive agents, hypokalemia is more frequent and more severe. Serum potassium measurement is not a good screening test in GRA because many patients have normal potassium levels.

PRA is suppressed in almost all patients (<1.0 ng/mL per hour [<0.8 nmol/L per hour]) and does not increase appropriately (>2 ng/mL per hour [>1.6 nmol/L per hour]) after dietary sodium restriction or after acute diuretic administration with furosemide followed by 90 to 120 minutes of upright posture. Although a subset of patients with essential hypertension (25%) also have low PRA, documentation of a normal or high stimulated PRA level excludes primary aldosteronism.

Given the high prevalence of suppressed PRA levels in essential hypertension, documentation of a concomitant elevation of plasma aldosterone (PA) makes the diagnosis of primary aldosteronism more likely (Fig. 15-16). Thus, a PA:PRA ratio greater than 30 is suggestive and a ratio of 50 or more is virtually diagnostic of primary aldosteronism (when PRA is expressed as ng/mL per hour and PA as ng/dL). To improve the accuracy of this test, salt intake should not be restricted and serum aldosterone levels should be greater than 500 pmol/L (>15 ng/dL). Because a number of drugs (ACE inhibitors, β-blockers, and spironolactone) alter PRA levels, such antihypertensives should be withdrawn for 2 to 4 weeks if possible (6 to 8 weeks for spironolactone) before determining the PA:PRA ratio. Hypokalemia reduces aldosterone levels, and diagnostic studies should be performed with patients in a potassium-repleted state. Specimens should be obtained after 2 hours of upright posture because stimulated ratios have been shown to have better diagnostic accuracy than supine values.

The captoril test can also be used to diagnose primary aldosteronism. One protocol is to administer 50 mg orally at 9:00 AM; blood samples are obtained before and 90 minutes later. In normotensive individuals or essential hypertensives, acute inhibition of ACE decreases angiotensin-regulated aldosterone production. However, in primary aldosteronism aldosterone levels fail to decline because the renin-angiotensin system is suppressed and aldosterone production is autonomous. A postcaptopril aldosterone reduction of more than 20%, usually to less than 410 pmol/L (<15 ng/dL), is considered a normal response. Although the sensitivity of this test ranges from 90% to 100%, the specificity is significantly less (50% to 80%).

Diagnosis of Autonomus Aldosterone Production

Oral sodium loading for 3 days followed by a 24-hour urine collection for determination of aldosterone excretion can discriminate primary aldosteronism from essential hypertension with excellent sensitivity and specificity (96% and 93%, respectively). A 24-hour urinary aldosterone excretion rate greater than 28 to 39 nmol/day (10 to 14 µg/day) in the presence of urinay sodium excretion greater than 250 mmol/day is considered diagnostic of primary aldosteronism. Autonomous aldosterone production can also be demonstrated by acute intravenous volume expansion with isotonic saline. Isotonic saline is administered intravenously at a rate of 500 mL/hour for 4 to 6 hours. Postsaline plasma aldosterone levels greater than 280 pmol/L (>10 ng/dL) or more stringent value of greater than 140 to 220 pmol/L (>5 to 8 ng/dL) has also been proposed to confirm the diagnosis of autonomous aldosterone production.
Hormonal testing provides supportive data, especially if radiography fails to show a solitary tumor. The posture test is the most common study used in the differential diagnosis of primary aldosteronism. Samples are collected for PRA and plasma aldosterone when the subject is recumbent and after 2 to 4 hours of standing or walking. The response in normal subjects and those with essential hypertension is an increase in plasma aldosterone levels of at least 50% compared with recumbent levels. Before testing, hypokalemia should be corrected with oral potassium supplementation. The accuracy of the test is enhanced by simultaneous measurement of recumbent and upright cortisol levels.  

In patients with APA, aldosterone levels generally decline in parallel with the circadian secretion of cortisol, the so-called anomalous postural response. This is because the renin-angiotensin system is suppressed in patients with APA, and therefore changes in posture do not stimulate increased production of aldosterone. In contrast, in IHA there is usually an increase in renin and aldosterone levels in response to assumption of the upright posture. The predictive value of the posture test in distinguishing between APA and IHA approaches 90%; however, the specificity of this test is reduced in variant forms of APA and IHA (see later). A postural decline in plasma aldosterone is also seen in GRA because aldosterone secretion is regulated solely by corticotropin in this disorder. Blood levels of 18-OH-corticosterone, an intermediate of the aldosterone biosynthetic pathway, are generally greater than 2800 nmol/L (100 ng/dL) in subjects with APA, whereas patients with IHA have lower levels.  

Documentation of the unique hybrid 18-oxygenated cortisol compounds 18-oxocortisol and 18-OH-cortisol in a 24-hour urine collection can be used to make the diagnosis of GRA and also differentiate APA from IHA (see later). In contrast to modest elevations in APA and normal levels in IHA, levels of these compounds are 10-fold above normal in GRA. A major drawback is the lack of general availability of assays for these compounds.

Radiologic Studies

Tomography using spiral CT techniques is the imaging modality of first choice. It is critical to make a biochemical diagnosis before imaging the adrenal because of the 2% to 10% incidence of nonfunctioning adrenal masses in CT studies of the abdomen. The use of adrenal scintigraphy with NP-59 (I-131 I-iodomethyl-19-norcholesterol) can differentiate APA from IHA because lateralization is seen in the former disorder. However, a lateralizing scan lacks specificity because it may also be seen with adrenal adenomas that do not produce aldosterone.

Adrenal venous sampling, which should be reserved for cases in which diagnostic imaging and biochemical studies are inconclusive, is the most sensitive means of differentiating APA from IHA. In most cases of APA, the ratio of the ipsilateral to the contralateral aldosterone concentration is greater than 10:1. This procedure is diagnostic in more than 95% of cases when catheterization of the right adrenal vein is successful. However, the incidence of unsuccessful procedures can be as high as 25%. Furthermore, adrenal venous sampling is invasive and is associated with a small but significant risk of venous thrombosis, adrenal hemorrhage, or adrenal insufficiency.

Nonclassical Variants of Primary Aldosteronism

The aldosterone-producing renin-responsive adenoma (APRA) and primary adrenal hyperplasia are variants of primary aldosteronism that represent important exceptions in terms of both diagnosis and treatment. In contrast to findings in APA, the changes in plasma renin (features characteristically considered diagnostic of IHA) after upright posture in subjects with APRA cause an increase in aldosterone levels. Thus, in patients diagnosed with primary aldosteronism the importance of adrenal imaging in documenting a solitary lesion is emphasized by this unusual entity.

Primary unilateral adrenal hyperplasia is another variant form of primary aldosteronism. The biochemical features resemble those in APA: no increase or a decline in aldosterone levels in response to upright posture and elevated levels of urinary 18-OH-cortisol and 18-oxocortisol. The syndrome can be ameliorated by unilateral adrenalectomy or a reduction in adrenal mass.

Therapy

Surgery is the treatment of choice for patients with APA, APRA, and primary adrenal hyperplasia. Cure rates (defined as blood pressure less than 140/90 without medications 6 to 12 months after surgery) vary between 35% and 50%. All patients should receive medical treatment before surgery to control blood pressure and replete potassium stores (see later). Persistent postoperative hypertension may be related to the chronicity or severity of hypertension, the presence of endorgan changes, or concurrent essential hypertension. On the other hand, the hypertension in IHA responds poorly to bilateral adrenalectomy, although the potassium-wasting state is reversed. Pharmacologic treatment is the therapy of choice for IHA, for preoperative management of APA, or when the patient is not a surgical candidate. A sodium-restricted diet (sodium < 2 g/day) is also prescribed in conjunction with pharmacologic treatment to minimize potassium wasting and lower the blood pressure.

Spironolactone, a competitive antagonist of aldosterone, has traditionally been the drug of first choice, with doses of 100 to 500 mg/day usually being required. Spironolactone also blocks testosterone biosynthesis and action, resulting in erectile dysfunction, decreased libido, and gynecomastia in men; menstrual irregularities are seen in women. Amiloride blocks the apical sodium channel in the distal nephron and is an alternative to spironolactone; it is given in divided doses starting at 5 mg twice daily with a maximal dose of 15 mg twice daily.

The sustained-release formulation of the calcium channel blocker nifedipine (dose range 30 to 90 mg/day) has also been used in the medical management of primary aldosteronism because this compound inhibits aldosterone biosynthesis in vitro. However, the antihypertensive response to this agent alone in primary aldosteronism is disappointing, and nifedipine should be viewed as a second-line agent. ACE inhibitors and angiotensin II receptor antagonists may also have a role in the medical management of IHA because the response to angiotensin II may be exaggerated in this disorder.
Genetic Basis for Mineralocorticoid Excess States

Glucocorticoid-remediable aldosteronism (GRA) is the commonest heritable form of hyperaldosteronism. In the following syndromes, the steroids responsible for the mineralocorticoid excess states include DOC and cortisol. As a result of the suppression of the renin-angiotensin system, the aldosterone levels are lownot elevated as in the previously described syndromes. Some forms of congenital adrenal hyperplasia have a mineralocorticoid component.

Other genetic causes include a mutation in enzymes not in the biosynthetic pathway or ion channels important in mediating or mimicking the action of aldosterone.

Hypermineralocorticoidism/Suppressed Plasma Renin Activity

Congenital Adrenal Hyperplasia

DOC excess is seen in several hypertensive forms of congenital adrenal hyperplasia or rarely in neoplasms (adenoma or carcinoma) that overproduce DOC. Congenital adrenal hyperplasia results from a deficiency in cortisol biosynthesis (see Chapter 14). Deficiencies in both 11-hydroxylase (CYP11B) and 17-hydroxylase (CYP17) are associated with hypertension and hypokalemia. In 11-hydroxylase deficiency, the impaired conversion of 11-DOC to corticosterone results in accumulation of DOC, a potent mineralocorticoid. Mineralization in females, usually occurring in children, results from shunting into the androgen pathway. Blood levels of DOC, 11-deoxycorticol, and adrenal androgens are characteristically elevated. This form of congenital adrenal hyperplasia is more prevalent in Middle Eastern Moslems and Jews.

17-Hydroxylase deficiency is characterized by hypogonadism, hypokalemia, and hypertension. As with 11-hydroxylase deficiency, this disorder is a result of decreased production of cortisol with shunting into the unblocked mineralocorticoid pathway. Because 17-hydroxylase is required for the biosynthesis of gonadal testosterone and estrogen, a defect in this enzyme in both sexes is associated with sexual immaturity, high gonadotropin levels, and low urinary 17-ketosteroid excretion. Females have primary amenorrhea and lack of development of secondary sexual characteristics. Males may have ambiguous external genitalia or a female phenotype (male pseudohermaphroditism). Blood levels of 17-oxo-progesterone are low, and corticosterone and DOC levels are elevated.

The elevated blood pressure and hypokalemia in both syndromes result from elevated levels of DOC, a potent mineralocorticoid; excessive sodium retention and hypertension result and lead to suppression of PRA and low levels of aldosterone. The genetic lesions causing 11-hydroxylase deficiency are in the gene that encodes CYP11B. A large number of mutations in the CYP17 gene can cause 17-hydroxylase deficiency.

Glucocorticoid suppression with dexamethasone or prednisone restores normal levels of DOC and reverses the mineralocorticoid excess state in these adrenal hyperplasia syndromes. Caution must be exercised to avoid overdosing and induction of Cushing’s syndrome.

Glucocorticoid-Remediable Aldosteronism

This syndrome is inherited in an autosomal dominant fashion and is probably responsible for fewer than 3% of cases of primary aldosteronism. GRA is characterized by hypertension of early onset that is usually severe and refractory to conventional antihypertensive therapies. Prospective screening of GRA pedigrees has revealed that many affected individuals are not hypokalemic. The sine qua non of GRA is aldosterone production that is solely under the control of corticotropin. As a result, the syndrome can be mitigated by exogenous glucocorticoid therapy.

GRA is caused by a chimeric gene duplication that results from unequal crossing over between the highly homologous 11-hydroxylase (CYP11B) and aldosterone synthase (CYP17) genes. This chimeric gene contains 3 corticotropic-responsive portion of the promoter from the 11-hydroxylase gene fused to the 5 coding sequence of the aldosterone synthase gene. The result is ectopic expression of aldosterone synthase activity in the cortisol-producing zona fasciculata. Thus, mineralocorticoid production is regulated by corticotropin instead of the normal secretagogue, angiotensin II. This mutation results in overproduction of aldosterone and also the characteristic hybrid steroids 18-oxocortisol and 18-OH-cortisol, which can be measured in the urine to make the diagnosis.

Genetic Testing

The diagnosis of GRA was initially based on the family history and the clinical response to dexamethasone suppression. Subsequently, GRA was diagnosed by demonstrating markedly elevated levels of 18-oxocortisol and 18-OH-cortisol in a 24-hour urine collection. However, the discovery of the genetic basis of GRA by Lifton and co-workers made it possible to make a genetic diagnosis from a peripheral blood sample with the use of Southern blotting techniques. Genetic testing is a sensitive and specific means of diagnosing GRA and obviates the need to measure the urinary levels of 18-oxocortisol and 18-OH-cortisol or to perform dexamethasone suppression testing. Genetic analysis can be arranged by calling the International GRA Registry (617-732-5011). Because some individuals with GRA do not have hypokalemia and have only mild hypertension, other clues that may indicate the need for a genetic test include suppressed plasma renin levels and juvenile-onset hypertension, a history of early-onset hypertension in first-degree relatives, and a history of early hemorrhagic stroke in the subject or relative.

Therapy

GRA is unique among the syndromes of primary aldosteronism in that the underlying pathophysiologic abnormality is the regulation of aldosterone production solely by corticotropin. As a result, glucocorticoid treatment usually reverses the syndrome. Of great importance is an awareness of the potential toxicity (Cushing’s syndrome) of excessive doses of glucocorticoids, especially with the use of dexamethasone in children. When a decision to use glucocorticoids is made, the smallest effective dose of shorter-acting agents such as prednisone or hydrocortisone should be prescribed in relation to body surface area (hydrocortisone, 10 to 12 mg/m² per day). Target blood pressure in children should be guided by age-specific blood pressure percentiles. Children should be monitored by pediatricians with expertise in glucocorticoid therapy, with careful attention paid to preventing retardation of linear growth by overtreatment. Therapeutic alternatives in treating hypertension in GRA are mineralocorticoid antagonists, which also avoid the adverse effects of chronic glucocorticoid therapy. Amiloride and spironolactone are effective as monotherapies in most patients with GRA.

Increased Mineralocorticoid Action/Low Plasma Renin Activity

Apparent Mineralocorticoid Excess

This syndrome is the result of impaired activity of the enzyme 11-hydroxysteroid dehydrogenase (11-HSD), which normally inactivates cortisol in the kidney by converting it to cortisone. As a result of the enzyme deficiency, high levels of cortisol accumulate in the kidney. The characteristic abnormal urinary cortisol metabolite profile seen in apparent mineralocorticoid excess also reflects decreased 11-HSD activity (ratio of cortisol to cortisone increased 10-fold compared with the normal ratio of approximately 1). As a result of elevated intrarenal levels, cortisol binds to mineralocorticoid receptors in the distal tubule, which are normally sites of aldosterone binding.

Underlying the pathogenesis of apparent mineralocorticoid excess is the nonselectivity of renal mineralocorticoid receptors, which in vitro bind cortisol with affinity equal to that of aldosterone. Thus, 11-HSD normally excludes physiologic glucocorticoids from nonselective mineralocorticoid receptors by converting them to the inactive 11-keto compound, cortisone. 11-HSD has bidirectional activity in different tissues, acting primarily as a reductase in the liver and a dehydrogenase in the
kidney. These different activities are the consequence of two isoenzymes that are expressed in liver and kidney, respectively.

Decreased 11-HSD activity may be hereditary or secondary to pharmacologic inhibition of enzyme activity by glycyrrhetinic acid, the active principle of licorice root and some chewing tobaccos. The hereditary form contains mutations in the gene coding for isoenzyme 2. The phenotype of patients with apparent mineralocorticoid excess includes hypertension, low PRA levels, hypokalemia, normal plasma cortisol levels, and low plasma aldosterone levels.

Treatment has been difficult, although some success has been achieved with use of a high-potency glucocorticoid to suppress endogenous cortisol production. Although the synthetic steroid can also bind to the mineralocorticoid receptor, its concentration is far less than that of the endogenous cortisol. Alternatively, the mineralocorticoid receptor antagonist spironolactone could be given. However, its antiandrogenic and progestational side effects limit its long-term use, particularly in children.

The mineralocorticoid excess state commonly seen in patients with the ectopic corticotropin syndrome is believed to be related to the high rates of cortisol production that cause a relative deficiency of 11-HSD activity. However, DOC levels are high and could account for the hypokalemia in this disorder.

**Liddle’s Syndrome**

This syndrome is inherited as an autosomal dominant disorder in which affected subjects present with hypertension, suppressed PRA, low aldosterone levels, and usually hypokalemia. The hypokalemic state cannot be corrected by administration of the antimineralocorticoid spironolactone but is ameliorated by triamterene or amiloride, agents that block renal sodium reabsorption and potassium secretion by mineralocorticoid receptor-independent mechanisms. This disorder is caused by mutations in the subunits of the renal sodium epithelial channel. The amiloride-sensitive epithelial channel, considered the rate-limiting step for sodium absorption in the distal nephron, is composed of three subunits \( \alpha \), \( \beta \), \( \gamma \); mutations have been found in two of these subunits. As a result of these mutations, constitutive activity of the epithelial channel leads to increased sodium absorption and volume expansion.

**Hypermineralocorticoidism**

Occasionally, hyperaldosteronism occurs without edema or hypertension (Bartter’s and Gitelman’s syndromes). Bartter’s syndrome is usually characterized by severe hyperaldosteronism with hypokalemic alkalosis, substantial increases in PRA, hypercalcuria, no edema, normal blood pressure, and onset usually in childhood. The pathogenesis results from a defect in renal sodium or chloride conservation, or both. The hyperaldosteronism-induced hypokalemia can be accentuated by an additional defect in renal potassium conservation in some individuals. In many cases, Bartter’s syndrome is caused by a mutation in the renal Na-K-2Cl cotransporter gene.

Gitelman’s syndrome is an autosomal recessive trait also characterized by renal sodium wasting. As a result, as with Bartter’s syndrome, there is activation of the renin-angiotensin-aldosterone system. Affected subjects therefore have low serum potassium and magnesium levels, high serum bicarbonate, and low blood pressure. In contrast to that in Bartter’s syndrome, urinary calcium excretion is reduced. Gitelman’s syndrome results from mutations that lead to loss of function of the renal thiazide-sensitive Na-Cl cotransporter.
OTHER ENDOCRINE DISORDERS ASSOCIATED WITH HYPERTENSION

Glucocorticoid Excess (Cushing's Syndrome)

Cushing's syndrome, characterized by hypersecretion of cortisol, is associated with elevations in blood pressure in more than 80% of cases (see Chapter 14). Diastolic blood pressure exceeds 100 mm Hg in more than 50% of patients with endogenous Cushing's syndrome. On the other hand, the incidence of hypertension is lower and more variable in patients treated with exogenous glucocorticoids. Nevertheless, hypertension and associated metabolic abnormalities (diabetes mellitus and hyperlipidemia) probably account for the atherosclerotic cardiovascular morbidity and mortality seen in spontaneous Cushing's syndrome.

Mineralocorticoid production is usually normal in endogenous Cushing's syndrome. In Cushing's disease, commonly secondary to corticotropin hypersecretion from a pituitary microadenoma, aldosterone and renin levels are usually normal and DOC levels are normal or increased modestly. On the other hand, in ectopic corticotropin syndrome, increased mineralocorticoid activity and hypokalemia are the rule as a result of elevated levels of DOC and mineralocorticoid effects of high levels of cortisol. In adrenal carcinomas, DOC and aldosterone may also be elevated. Thus, in adrenal carcinomas and in ectopic corticotropin secretion, mineralocorticoid production may contribute to the hypertension; in such situations, PRA is usually suppressed.

The elevation of blood pressure by cortisol and synthetic glucocorticoids (which have minimal mineralocorticoid activity) is mediated by multiple mechanisms. Glucocorticoids increase cardiac output and activate the renin-angiotensin system by increasing the hepatic production of angiotensinogen. Other actions of glucocorticoids include reduction of the synthesis of vasodilatory prostaglandins secondary to inhibition of phospholipase A₂, thus blocking the release of arachidonic acid from phospholipids. There is also evidence for reduction of the components of the kallikrein-kinin system as well as enhanced pressor sensitivity to endogenous vasoconstrictors (epinephrine and angiotensin II). Glucocorticoids may also promote sodium influx into vascular smooth muscle cells.

The screening for endogenous cortisol excess is accomplished by measuring the response of plasma cortisol to the 1-mg dexamethasone suppression test or by the measurement of elevated levels of free cortisol in a 24-hour urine collection. Further studies to determine the etiology of the cortisol excess state are outlined in Chapter 14.
Thyroid Disease

Hypothyroidism

Hypothyroidism may account for 1% to 2% of cases of diastolic hypertension in the general population. In a large series of patients screened for the secondary forms of hypertension by age, the prevalence of hypothyroidism was 3%. In that study, hypothyroidism was thought to be a significant cause of secondary hypertension, especially in women older than 70 years. That hypothyroidism can actually cause hypertension was shown by Streeten and colleagues in another study in which 32% of hypertensive hypothyroid patients had a fall in diastolic blood pressure to 90 mm Hg or less after replacement levothyroxine treatment and withdrawal of all hypertensive drugs. Postulated mechanisms for the elevation of blood pressure include extracellular volume expansion and elevation in systemic vascular resistance.

Hyperthyroidism

In contrast to the diastolic hypertension associated with hypothyroidism, hyperthyroidism usually causes elevated systolic blood pressure. Thyrotoxic patients usually have tachycardia, high cardiac output, increased stroke volume, and decreased peripheral vascular resistance (see Chapter 11). These hemodynamic alterations are usually ameliorated by -blocker therapy. In elderly patients, atrial fibrillation may be the sole manifestation of thyrotoxicosis.
Acromegaly

Hypertension occurs in one third of patients with acromegaly (see Chapter 8), presumably owing to sodium retention with resultant extracellular volume expansion. This retention of sodium, in the context of an increase in glomerular filtration rate and low PRA, is the consequence of uncharacterized antinatriuretic actions of growth hormone. Sodium retention is also a complication of exogenous administration of growth hormone. The prevalence of primary aldosteronism in acromegaly appears to be increased. As previously discussed, in primary aldosteronism, plasma renin levels are suppressed and aldosterone levels are increased. In acromegaly, plasma renin levels also are suppressed owing to volume expansion but aldosterone levels are not increased.
Hyperparathyroidism

In contrast to the overall incidence of 0.1% of primary hyperparathyroidism in the general population, this disorder occurs in approximately 1% of hypertensive patients (see Chapter 26). Conversely, approximately, 30% to 40% of individuals with hyperparathyroidism are hypertensive. The mechanisms are unclear because there is no direct correlation with the elevated PTH or calcium levels. Hypertension may or may not remit after successful parathyroidectomy.

Because the blood pressure response to correction of primary hyperparathyroidism is variable and hypertension is not a clear-cut manifestation of the hyperparathyroid state, hypertension is considered a minor criterion for recommending surgery to patients with mild asymptomatic primary hyperparathyroidism. On the other hand, surgery may cause regression of myocardial hypertrophy in normotensive patients with hyperparathyroidism and may also reverse the increased mortality associated with hyperparathyroidism in subjects younger than 70 years. The hypertension associated with hyperparathyroidism can also result as a complication of hypercalcemia-induced renal impairment or when this disorder is part of a MEN syndrome that includes pheochromocytoma or primary aldosteronism.
Exogenous Treatments

Treatment with certain hormones or pharmacologic agents can elevate blood pressure (Table 15-6). Fludrocortisone, a potent mineralocorticoid used in the treatment of primary adrenal insufficiency, can cause hypertension when administered in supraphysiologic doses, as to patients with orthostatic hypotension, to cause volume expansion. Licorice and chewing tobacco abuse can result in hypokalemia, sodium and water retention, and blood pressure elevation, as noted earlier. The administration of growth hormone in pharmacologic doses to patients who have received transplants or to severely catabolic hospitalized subjects for its protein-sparing actions can raise blood pressure.

The hypertension associated with cyclosporine treatment appears to be related to renal vasospasm and secondary volume expansion. Glucocorticoid treatment in supraphysiologic doses for inflammatory and allergic disorders frequently elevates blood pressure, as noted earlier, but less commonly than in endogenous Cushing’s syndrome. Oral contraceptive preparations containing higher dose estrogen-progesterone formulations are known to induce hypertension. It is not known whether current lower dose formulations cause hypertension. However, postmenopausal estrogen replacement therapy does not elevate blood pressure. Androgens in pharmacologic doses can also produce volume expansion and arterial hypertension.

Finally, as with the hypertension in pheochromocytoma, ingestion of sympathomimetic amines or substances that potentiate endogenous sympathetic nervous system activity (e.g., cocaine inhibits reuptake of catecholamines at adrenergic nerve endings) produces increased cardiac output, increased peripheral arteriolar vasoconstriction, and hypertension.

Chapter 16 - The Physiology and Pathology of the Female Reproductive Axis

Serdar E. Bulun
Eli Y. Adashi

REPRODUCTIVE PHYSIOLOGY

Tightly coordinated functions of the hypothalamus, pituitary gland, ovaries, and endometrium give rise to cyclic, predictable menses that indicate regular ovulation. Regular ovulation also requires normal functioning of other endocrine units such as the thyroid and adrenal glands. For example, patients with hypothyroidism or hyperthyroidism, Cushing's syndrome, or glucocorticoid resistance may present with anovulation. Thus, it is imperative for the clinician to have a thorough knowledge of the functions of the hypothalamus, pituitary, ovaries, and uterus as well as interactions of these tissues with other systems in order to diagnose correctly reproductive disorders and generate treatment strategies.

The most obvious reproductive function of the hypothalamus is the pulsatile secretion of luteinizing hormonereleasing hormone (LHRH). Negative feedback effects of a number of factors including ovarian steroids (Fig. 16-1) regulate hypothalamic LHRH secretion into the portal vessels. Dopamine, norepinephrine, serotonin, and opioids produced in the brain may mediate the regulation of LHRH secretion by ovarian hormones or other stimuli. In response to LHRH, the anterior pituitary cells secrete follicle-stimulating hormone (FSH) and LH. Ovarian steroids and peptides of ovarian origin (e.g., inhibin) modify secretion of FSH and LH (see Fig. 16-1). LH stimulates androstenedione production in theca cells of the ovary, whereas FSH regulates estradiol production in the granulosa cells and follicular growth. Release of an egg from the mature follicle is dependent on a sudden rise in LH levels in midcycle. After ovulation, the follicle transforms into a corpus luteum that secretes both estradiol and progesterone under the control of LH and FSH. Endometrium, the mucosal lining of the uterine cavity, has extremely high levels of nuclear receptors for estrogen and progesterone and is extremely sensitive to these hormones. Estrogen induces the growth of endometrium, whereas progesterone limits this estrogenic effect and enhances differentiation. Sloughing off the functional portion (functionalis) of the endometrium follows withdrawal of estrogen or progesterone. The remaining basal layer (basalis) is capable of full regeneration in response to estrogen.

Ovaries remain quiescent until puberty because the hypothalamus is immature in prepubertal children and FSH and LH do not stimulate the ovaries. The entire reproductive function and most of the endocrine function of the ovaries cease after menopause because ovaries have lost all oocytes and surrounding stromal cells at this time. These prepubertal and postmenopausal states, characterized by the absence of ovarian function, are associated with the lack of menses.

In summary, the female reproductive function from puberty to menopause can be viewed as an extremely delicate ticking clock. The normal function of this apparatus is dependent on coordinate actions of the hypothalamus, pituitary, ovaries, and endometrium. The end result is regular menses every 24 to 35 days. Any disorder of these tissues or disorders of other systems that affect these reproductive units secondarily may result in anovulation and consequent irregular uterine bleeding.

Reproductive Functions of the Hypothalamus

Luteinizing Hormone-Releasing Hormone

LHRH is a 10-amino-acid peptide that is synthesized primarily in specialized neuronal bodies of the arcuate nucleus of the medial basal hypothalamus. Axons from LHRH neurons project to the median eminence and terminate in the capillaries that drain into the portal vessels. The portal vein is a low-flow transport system that descends along the pituitary stalk and connects the hypothalamus to the anterior pituitary. The direction of the blood flow in this hypothyseal portal circulation is from the hypothalamus to the pituitary. Thus, LHRH originating in the neurons of the arcuate nucleus is secreted at the median eminence into the portal circulation, which delivers this hormone to the anterior pituitary (Fig. 16-2). The mature decapeptide LHRH is derived from the posttranslational processing of a large precursor molecule, pre-pro-LHRH (see Fig. 16-2). This precursor peptide is the product of a gene located in the short arm of chromosome 8. The pre-pro-LHRH consists of 92 amino acids and contains four parts (from the N-terminal to the C-terminal): (1) a 23-amino-acid signal domain, (2) the LHRH decapeptide, (3) a 3-amino-acid proteolytic processing site, and (4) a 56-amino-acid domain called LHRH-associated peptide (GAP). The cleavage products of this precursor, LHRH and GAP, are transported to the nerve terminals and secreted into the portal circulation (see Fig. 16-2). A physiologic role of GAP has not been established.

In humans, LHRH neurons are located primarily in the arcuate nucleus of the medial basal hypothalamus and the preoptic area of the anterior hypothalamus. The population of LHRH-producing neurons is relatively limited and is in the range of 1000 to 3000. The neurons that produce LHRH originate from the olfactory area during embryogenesis. These cells migrate during embryogenesis along cranial nerves connecting the nose and forebrain to the hypothalamus. A neuronal cell-surface glycoprotein that probably mediates cell-to-cell adhesion appears to be an important migratory determinant. Mutation of the gene that encodes this adhesion molecule is associated with X-linked isolated gonadotropin deficiency (Kallmann's syndrome) characterized by anosmia, LHRH deficiency, and hypogonadotropic hypogonadism.
A long-acting depot formulation of an LHRH agonist gives rise eventually to down-regulation of the gonadotropin-gonadal axis within 1 to 3 weeks. The initial create a large reserve pool of gonadotropins. The most prominent agonistic response is observed during the early follicular phase, when the combined effects of LHRH agonist and elevated levels of estradiol receptors.

Position 6 gives rise to metabolic stability, whereas replacement of the C-terminal glycinamide residue by an ethylamide group increases strikingly the affinity for the peptides has been attributed to their high binding affinity to LHRH receptors and reduced susceptibility to enzymatic degradation. An amino acid substitution at bonds between amino acids 5 and 6, 6 and 7, and 9 and 10. Analogues of LHRH with different properties have been synthesized by altering amino acids at these positions

The half-life of LHRH is short (2 to 4 minutes) because it is degraded rapidly by peptidases in the hypothalamus and pituitary gland.

Luteinizing HormoneReleasing Hormone Analogues

Luteinizing HormoneReleasing Hormone Agonists

A number of LHRH agonists were generated by substitution of amino acids at the 6 or 10 position. The increased biologic activity of agonistic peptides has been attributed to their high binding affinity to LHRH receptors and reduced susceptibility to enzymatic degradation. An amino acid substitution at position 6 gives rise to metabolic stability, whereas replacement of the C-terminal glycaminide residue by an ethylamide group increases strikingly the affinity for the receptors.

LHRH agonists are administered subcutaneously, intranasally, or intramuscularly. Thus far, many agonistic and antagonistic LHRH analogues with various biologic effects have been produced. These peptidases cleave the bonds between amino acids 5 and 6, 6 and 7, and 9 and 10. Analogues of LHRH with different properties have been synthesized by altering amino acids at these positions

The variations in LHRH pulse frequency are achieved, at least in part, by gonadal steroid feedback. Estradiol increases LHRH pulse frequency, whereas elevated progesterone levels decrease LHRH pulsatility. Therefore, it is conceivable that increased progesterone levels may cause a decrease in LHRH pulse frequency and thereby lead to the preferential biosynthesis and secretion of FSH that is observed in the late luteal phase.

LHRH pulsatility is also modulated by the action of locally released neurotransmitters. Norepinephrine stimulates LHRH release, whereas dopamine exerts an inhibitory effect. Endorphin and other opioids may also serve to suppress the hypothalamic release of LHRH.

The variations in LHRH pulse frequency are achieved, at least in part, by gonadal steroid feedback. Estradiol increases LHRH pulse frequency, whereas elevated progesterone levels decrease LHRH pulsatility. Therefore, it is conceivable that increased progesterone levels may cause a decrease in LHRH pulse frequency and thereby lead to the preferential biosynthesis and secretion of FSH that is observed in the late luteal phase. LHRH pulsatility is also modulated by the action of locally released neurotransmitters. Norepinephrine stimulates LHRH release, whereas dopamine exerts an inhibitory effect. Endorphin and other opioids may also serve to suppress the hypothalamic release of LHRH. The gonadal steroids modify endogenous opioid activity, and the negative feedback of steroids on gonadotropins appears to be mediated, at least in part, by endogenous opioids. Thus, it was proposed that sex steroids enhance the activity of endogenous opioids that in turn exert an inhibitory effect on LHRH secretion. The negative effect of opioids on LHRH secretion is also clinically explicable because the reduced LHRH secretion is associated with hypothalamic amenorrhea may be mediated by an increase in endogenous opioid inhibitory tone.

The half-life of LHRH is short (2 to 4 minutes) because it is degraded rapidly by peptides in the hypothalamus and pituitary gland. These peptidases cleave the bonds between amino acids 5 and 6, 6 and 7, and 9 and 10. Analogues of LHRH with different properties have been synthesized by altering amino acids at these positions (Table 16-1). Thus far, many agonistic and antagonistic LHRH analogues with various biologic effects have been produced.

A number of LHRH agonists were generated by substitution of amino acids at the 6 or 10 position (see Table 16-1). The increased biologic activity of agonistic peptides has been attributed to their high binding affinity to LHRH receptors and reduced susceptibility to enzymatic degradation. An amino acid substitution at position 6 gives rise to metabolic stability, whereas replacement of the C-terminal glycaminide residue by an ethylamide group increases strikingly the affinity for the receptors. LHRH agonists are administered subcutaneously, intranasally, or intramuscularly. An initial agonistic action (i.e., the flare effect) is associated with an increase in the circulating levels of LH and FSH.

The most prominent agonistic response is observed during the early follicular phase, when the combined effects of LHRH agonist and elevated levels of estradiol create a large reserve pool of gonadotropins. Desensitization and down-regulation of the pituitary produce hypogonadotropic hypogonadism. The administration of a long-acting depot formulation of an LHRH agonist gives rise eventually to down-regulation of the gonadotropin-gonadal axis within 1 to 3 weeks. The initial

LHRH, luteinizing hormone-releasing hormone.

down-regulation effect is due to desensitization, whereas the sustained response is due to loss of receptors and the uncoupling of the receptor from its effector system. In addition, LHRH agonists may cause ovarian quiescence by the secretion of biologically inactive gonadotropins.

Thus far, the Food and Drug Administration has approved the use of these agonists for the treatment of LHRH-dependent precocious puberty, endometriosis, and prostate cancer. Another indication is preoperative hematologic improvement of patients with anemia caused by uterine leiomyomas. Off-label indications of LHRH agonists include the down-regulation of the pituitary during ovulation induction, induction of endometrial atrophy before endometrial ablation surgery, and the prevention of menstrual bleeding in patients with coagulation defects. LHRH agonists have also been used to suppress ovarian steroidogenesis in hirsute patients. \[^{29}\]

The most prominent side effects of long-term use of depot LHRH agonist formulations are caused by estrogen deficiency. Depot LHRH induces a menopause-like state characterized by hot flashes, vaginal dryness, bone resorption, and osteopenia. Osteopenia is reversible in young women if treatment is maintained for no more than 6 months. \[^{30}\] \[^{31}\] Therefore, the risk-benefit ratio must be considered carefully before LHRH agonist treatment is extended for longer durations. Add-back regimens employing low-dose estrogens or progestins, or both, administered along with LHRH agonists have provided a means to overcome these side effects and permit extending the length of agonist therapy. \[^{32}\]

Luteinizing Hormone-Releasing Hormone Antagonists

Multiple amino acid substitutions also permit the synthesis of LHRH antagonists (see Table 16-1). These include modifications of the pyroglutamic and glycine termini at positions 1 and 10 or deletion and substitution of hydrophobic amino acids at positions 2 and 3. \[^{27}\] LHRH antagonists bind to the LHRH receptor and provide competitive inhibition for the naturally synthesized LHRH. LHRH antagonists have the advantage of inducing an immediate decrease in circulating gonadotropin levels with rapid reversal. \[^{33}\] The early antagonists either lacked potency or were associated with undesirable side effects related to histamine release. Newer LHRH antagonists are at various stages of development. \[^{34}\] \[^{35}\] \[^{36}\] \[^{37}\] \[^{38}\] \[^{39}\] \[^{40}\] These new antagonists are slightly more potent in the down-regulation of ovaries and do not cause histamine release (see Table 16-1).
Reproductive Functions of the Anterior Pituitary

Gonadotroph

Gonadotrophs are specialized cell types of the anterior pituitary that synthesize and secrete LH and FSH. These cells constitute 7% to 15% of the total number of anterior pituitary cells and are detected in this location from early fetal life. The majority of the gonadotrophs are capable of synthesizing both LH and FSH. LH and FSH are each composed of two distinct, noncovalently associated protein subunits called and . In the gonadotroph, the subunit genes are transcribed into messenger ribonucleic acids (mRNAs), which are in turn translated into the subunit precursors. Gonadotrophs contain cell-surface LH-RH receptors that mediate the action of LH-RH. These receptors belong to the seven-transmembrane-domain and G protein-coupled receptor family.

Luteinizing Hormone/Releasing Hormone Receptor

LH-RH is transported from the hypothalamus to the pituitary through the portal circulation and binds to the LH-RH receptor on the cell surface of the gonadotroph with high affinity. The number of LH-RH receptors on the cell surface of the gonadotroph is regulated by varying LH-RH pulse frequencies and other hormonal factors. Changes in LH-RH receptor concentration on the surface of the gonadotroph are often correlated with alterations in gonadotroph response to LH-RH. The concentration of LH-RH receptors in the pituitary gland is highest with an LH-RH pulse frequency of 30 minutes. Markedly low concentrations are observed with an LH-RH pulse frequency of 2 hours. Such changes in the levels of LH-RH receptors are correlated with cyclic synthesis and release of LH and FSH during an ovulatory cycle. The difference in the quantity of LH-RH receptors observed between high-frequency and low-frequency LH-RH pulses is twofold to threefold.

The complementary deoxyribonucleic acid (DNA) for human LH-RH receptor has been cloned and characterized. The single-copy human LH-RH receptor gene is approximately 25 kb in size, contains three exons, and is found on the long arm of chromosome 4. LH-RH binds to a specific seven-transmembrane-domain receptor that is coupled to Gq and sequentially activates phospholipase C. Products of phospholipase C activity then mobilize intracellular pools of Ca and provide lipid-derived messenger molecules.

Luteinizing Hormone and Follicle-Stimulating Hormone

Each gonadotropin is a heterodimer. Both LH and FSH are made of two peptide subunits termed and . The subunits and are associated with noncovalent bonds. The

FSH, Follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

subunits of human LH, FSH, thyroid-stimulating hormone (TSH), and human chorionic gonadotropin (hCG) have an identical polypeptide structure. In contrast, the subunit of each hormone has a unique amino acid sequence and confers the specific activity of heterodimer. Each subunit is cysteine-rich and contains multiple disulfide linkages. Each subunit also contains multiple carbohydrate moieties that play important roles in the biologic activity and metabolism of these hormones. The identical subunit contains 92 amino acids. The subunits of human FSH, LH, and hCG contain 117, 121, and 145 amino acids, respectively.

Upon binding of LH-RH to its receptor, the biosynthesis of the gonadotropins proceeds by transcription of the subunit genes, translation of the subunit mRNAs, post-translational modifications of the precursor subunits and subunit folding and combination, mature hormone packaging, and hormone secretion.

The human subunit gene is located on the short arm of chromosome 6. The encoded precursor polypeptide contains a 24-amino-acid leader sequence that is cleaved post-translationally to produce the mature 92-amino-acid subunit.

The human LH and hCG subunit genes are located in chromosome 19q13.3, which contains a cluster of seven subunit-like genes. Five of these sequences are noncoding pseudogenes arranged in groups of tandem and inverted pairs. Only LH and hCG subunit genes give rise to two distinct and functional mRNA species. The LH subunit mRNA encodes a 145-amino-acid precursor protein that is later cleaved to produce a 24-amino-acid leader peptide and a 121-amino-acid biologically active mature peptide. The hCG subunit mRNA also encodes a 145-amino-acid protein. This protein, however, is not processed post-translationally and functions as the biologically active hCG subunit. The amino acid sequences of the human LH and hCG subunits are 82% homologous. These two subunits confer identical biologic activities when associated with the subunit.

A single gene located on the short arm of chromosome 11 encodes FSH subunit, which is 117 amino acids long. Complementary DNA encoding human FSH-, LH-, or hCG-in combination with the complementary DNA of subunit was expressed in mammalian cells in culture. These cells can synthesize these proteins, modify them after translation, glycosylate and combine the subunits, and secret them as intact FSH, LH, or hCG. These recombinant gonadotropins are currently used clinically to stimulate gonadal function.

Regulation of Circulating Levels of Follicle-Stimulating Hormone and Luteinizing Hormone

The molecular mechanisms responsible for formation and combination of the and subunits of FSH and LH are not completely understood. Production rates of both and subunits are regulated at least in part by negative feedback of estrogen, which is mediated by the pulsatile release of LH-RH from the hypothalamus. The pituitary always contains more subunit than subunit mRNA, and readily detectable levels of free subunit are present in serum. The free subunit, on the other hand, is present at relatively low levels in pituitary and is rarely found in serum or urine. Thus, the specific subunit may be the rate-limiting factor in the synthesis of these glycoprotein hormones.

Serum levels of gonadotropins are proportional to their secretion rates and serum half-lives, which are regulated by the amount of carbohydrate residues. The higher the content of carbohydrate residues, especially the sialic acid residues, the lower the rate of metabolism and the higher the serum half-life. The sialic acid content of gonadotropic hormones and other glycoproteins has a marked effect on their rate of clearance and also influences their apparent molecular size. The higher content of sialic acid in FSH compared with LH is responsible for slower clearance of FSH from the circulation; LH has the most rapid clearance rate. The hCG is highly sialylated and has the longest half-life.
Ovary

The ovary is essential for periodic release of oocytes and the production of the steroid hormones estradiol and progesterone. These activities are integrated into the cyclic repetitive process of follicular maturation, ovulation, and formation and regression of the corpus luteum. Thus, the ovary fulfills two major objectives: (1) the generation of a fertilizable ovum and (2) the preparation of the endometrium for implantation through the sequential secretion of estrogen and progesterone. The ovarian follicle comprising the egg and surrounding granulosa and theca cells constitutes the fundamental functional unit of the ovary.

Adult human ovaries are oval bodies with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. The combined weight of normal ovaries during the reproductive years is 10 to 20 g (average 14 g). The ovaries lie in approximation to the posterior and lateral pelvic wall and are attached to the posterior surface of the broad ligament by the peritoneal fold, termed the mesovarium. Blood vessels, nerves, and lymphatics traverse the mesovarium and enter the ovary at the hilum.

The ovary consists of three structurally distinct regions: (1) an outer cortex containing the surface germinal epithelium and the follicles, (2) a central medulla consisting of stroma, and (3) a hilum around the area of attachment of the ovary to the mesovarium. The functional anatomy of the adult ovary is illustrated in Figure 16-5 (Figure Not Available). The hilum is the point of attachment of the ovary to the mesovarium. It contains nerves, blood vessels, and hilus cells, which have the potential to become active in steroidogenesis or to form androgen-secreting tumors. These cells are similar to the testis producing Leydig cells of the testes. The outermost portion of the cortex, called the tunica albuginea, is covered by a single layer of surface cuboidal epithelium termed the germinal epithelium. The oocytes, enclosed in complexes called follicles, are in the inner part of the cortex, embedded in stromal tissue (see Fig. 16-5) (Figure Not Available). One

Ovarian differentiation and folliculogenesis depend on coordinate expression and interaction of a multitude of genes. Targeted gene disruption or insertion in mice has made it possible to inquire about the function of specific genes in ovarian differentiation and folliculogenesis. Figure 16-6 (Figure Not Available) summarizes the biologic roles of some of these genes. Transgenic mice represent a first step in attempting to understand in vivo the various gene interactions that result in a functional ovary. Indeed, ovarian pathologic conditions in transgenic mice closely resemble disorders observed in mutant human homologues, as exemplified in cases involving the FSH- subunit and FSH receptor. Many mouse models of ovarian pathologic conditions are available. In general, these can be divided into mice with prenatal ovarian failure with disordered gonad formation and diminished number of germ cells or absent germ cells and mice with postnatal ovarian failure as a result of defects at various stages of folliculogenesis (see Fig. 16-6) (Figure Not Available).

These models should lead to the identification of genetic and molecular mechanisms responsible for the development and function of the human ovary.

Ontogeny of the Ovary

The Oocyte

The primordial germ cells are known to originate outside the embryo proper, from the endoderm of the yolk sac. At this site, they can be identified as early as the end of the third week of gestation by alkaline phosphatase staining. Germ cells migrate to cross a remarkably long distance from the yolk sac to the genital ridge by ameboid movements with the aid of pseudopodia. This long route of migration along the dorsal mesentery of the hindgut is interrupted only by the required lateral curving of the coelomic angle at the level of the genital ridge (Fig. 16-7). Some chemotaxis is operational, but the precise cellular mechanisms underlying the guidance of germ cells to the genital ridge remain uncertain. Germ cells appear unable to persist outside the genital ridge, which may thus be viewed as the only region competent to sustain gonadal development. By the same token, germ cells play an indispensable role in the induction of gonadal development. In fact, no functional gonad is to be expected in the absence of germ cells.

On arrival at the genital ridge by the fifth week of gestation, the premeiotic germ cells are referred to as oogonia. During the subsequent 2 weeks of intrauterine life (weeks 5 to 7 of gestation or the "indifferent" stage), the primordial gonadal structure constitutes no more than a bulge on the medial aspect of the urogenital ridge (see Fig. 16-7). This protuberance is created by proliferation of surface (coelomic) germinal epithelium, by growth of the underlying mesenchyme, and by oogonial multiplication. The oogonia total 10,000 by about 6 to 7 weeks of intrauterine life. Because meiosis and oogonial atresia are not operational, the actual number of germ cells is dictated by mitotic division at this time.

It is during this indifferent phase that the gonadal cortex and medulla are first delineated. However, short of cytogenetic evidence, the precise sexual identity of the gonadal ridge cannot be ascertained at this point. Nevertheless, the absence of testicular development beyond 7 weeks of gestation is generally considered presumptive evidence of ovarian formation. Additional clues to the sexual identity of the gonad can be derived from the detection of oogonial meiosis at about 8 weeks of gestation because no comparable process is observed in the testis until puberty. The sexual identity of the gonadal ridge is histologically clear by 16 weeks of
gestation, when the first primordial follicles can be visualized.

By about 8 weeks of intrauterine life, persistent mitosis increases the total number of oogonia to 600,000 (Fig. 16-8). From this point on, the oogonal endowment is subject to three simultaneous ongoing processes: mitosis, meiosis, and oogonal atresia. Stated differently, the onset of oogonal meiosis and oogonal atresia is now superimposed on oogonal mitosis. As a result of the combined impact of these processes, that is, mitosis counterbalanced by meiosis and oogonal atresia, the number of germ cells peaks at 6 to 7 × 10^6 by 20 weeks of gestation (see Fig. 16-8). At this time, two thirds of the total germ cells are intramictic primary oocytes; the remaining third can still be viewed as oogonal. The midgestational peak and the postpeak decline are accounted for, if only in part, by the progressively decreasing rate of oogonal mitosis, a process destined to end entirely by about 7 months of intrauterine life. Equally relevant is the increasing rate of oogonal atresia, which peaks at about month 5 of gestation (see Fig. 16-8). During this period, regulation of the ovarian developmental process is complex and probably involves a diverse group of genes (see Fig. 16-7).

From midgestation onward, relentless and irreversible attrition progressively diminishes the germ cell endowment of the gonad. Ultimately, some 50 years later, this is finally exhausted. For the most part, this is accomplished through follicular atresia rather than oogonal atresia, begins around month 6 of gestation, and continues throughout life (see Fig. 16-8). In contrast, oogonal atresia is destined to end at 7 months of intrauterine life as follicular atresia sets in. Follicular atresia has a profound effect on germ cell endowment, given that only 1 to 2 × 10^5 germ cells are present at birth (see Fig. 16-8). Remarkably, this dramatic depletion of the germ cell mass occurs during a period as short as 20 weeks. No similar rate of depletion occurs earlier or subsequently. Consequently, newborn females enter life still far from realizing reproductive potential, having lost as much as 80% of their germ cell endowment. This decreases further to approximately 300,000 by the onset of puberty. Of these follicles, only 400 to 500 (i.e., less than 1% of the total) ovulate in the course of a reproductive life span.

Between weeks 8 and 13 of fetal life, some of the oogonia depart from the mitotic cycle to enter the prophase of the first meiotic division. This change marks the conversion of these cells to primary oocytes well before actual follicle formation. Meiosis (beginning at about 8 weeks of gestation) provides temporary protection from oogonial atresia, thereby allowing the germ cells to invest themselves with granulosa cells and to form primordial follicles. Accordingly, oogonia that persist beyond the seventh month of gestation and have not entered meiosis are subject to oogonal atresia. Consequently, no oogonia are usually present at birth.

Once formed, the primary oocyte persists in prophase of the first meiotic division until the time of ovulation, when meiosis is resumed and the first polar body is formed and extruded.
Unlike the testicular seminiferous tubule, the ovary does not constitute an immunologically privileged site. Thus, resident ovarian mononuclear phagocytes constitute the outermost layer of the membrana granulosa and abut the basement layer. High intracellular levels of steroidogenic enzymes and LH receptors in follicular cells suggest that these cells account for the majority of steroidogenesis in the follicle. (Fig. 16-12) (Figure Not Available) . Mural granulosa cells constitute the outermost layer of the membrana granulosa and abut the basement layer. High intracellular levels of steroidogenic enzymes and LH receptors in fetal granulosa cells do not have a direct blood supply. The first sign of follicular recruitment is cuboidal differentiation in the spindle-shaped cells inside the basal lamina, which thereafter undergo successive mitotic divisions to form a multilayered granulosa cell zone. The oocyte enlarges and secretes a glycoprotein-containing mucoid substance called the zona pellucida, which surrounds the oocyte and separates the granulosa cells from the oocyte. This structure is a primary follicle. The secondary follicle is formed by further proliferation of granulosa cells and by the final phase of oocyte growth, in which the oocyte reaches 120 μm in diameter, coincident with proliferation of layers of cells immediately outside the basal lamina to constitute the theca. The portion of the theca adjacent to the basal lamina is termed the theca interna. The theca externa is the outermost layer of the follicle. The theca externa acquires an independent blood supply consisting of one or more arterioles that terminate in a capillary bed at the basal lamina. Capillaries do not penetrate the basement membrane, and the granulosa and oocyte remain avascular. The tertiary follicle is characterized by further hypertrophy of the theca and the appearance of a fluid-filled space among the granulosa cells, named the antrum. The fluid in the antrum consists of a plasma transudate and secretory products of granulosa cells, some of which (estradiol) are found there in strikingly higher concentrations than in peripheral blood. The follicle rapidly increases in size under the influence of gonadotropins to form the mature or graafian follicle. In the graafian follicle, the granulosa and oocyte remain encased by the basal lamina and are devoid of direct vascularization. The antral fluid increases in volume, and the ovum, surrounded by an accumulation of granulosa cells (the cumulus oophorus), occupies a polar, eccentric position within the follicle. The mature graafian follicle is ready to release the ovum by the process of ovulation. (Adapted from Erickson GF, Magoffin DA, Dyer CA. The ovarian androgen producing cells: a review of structure-function relations. Endocr Rev 1985; 6:371-379. Copyright © 1985 by The Endocrine Society.)
are present within the ovarian stroma near perifollicular capillaries. Lymphocytes and polymorphonuclear leukocytes, on the other hand, are observed in the follicle and corpus luteum in varying quantities during the follicular development, corpus luteum formation, and follicular atresia.  

The significance of the preceding observations may be that resident ovarian representatives of the white blood cell series constitute potential in situ modulators of ovarian function, acting through direct local secretion of regulatory cytokines.  

Because the flow of information is probably multidirectional, the same cells are probably targeted for steroid and peptidergic input. Moreover, immune cells are endowed with steroidogenic capabilities that could, in their own right, affect steroid economy.  

Follicles

The follicle represents the most important functional unit in the ovary with respect to germ cell development and steroid production. The follicles are embedded in loose connective tissue of the ovarian cortex and can be subdivided into two functional types: nonmaturing (or primordial) and growing. The majority of follicles (90% to 95%) are nonmaturing throughout reproductive life. Recruitment of a primordial follicle initiates dramatic changes in growth, structure, and function. The growing follicles are divided into four stages: primary, secondary, tertiary, and graafian (see Fig. 16-12) (Figure Not Available). The first three stages of growth can occur in the absence of the pituitary and therefore appear to be controlled by intraovarian mechanisms (Fig. 16-14) . The follicle destined to ovulate is recruited in the first few days of the current cycle.  

The early growth of follicles occurs over the span of several preceding menstrual cycles, but the ovulatory follicle is one of a cohort recruited at the time of transition from the previous cycle's luteal phase and the current cycle's follicular phase (see Fig. 16-14). The total time to achieve preovulatory status is approximately 85 days (see Fig. 16-14). The majority of this period of development is FSH-independent. Eventually, this cohort of follicles reaches a stage at which, unless recruited by FSH, the next step is atresia. Thus, a cohort of follicles measuring 2 to 5 mm is continuously available for a response to FSH (Fig. 16-15) . The late luteal increase in FSH is the critical feature in rescuing this cohort of follicles from atresia, eventually allowing a dominant follicle to emerge and pursue a path to ovulation (see Fig. 16-15) . In addition, maintenance of this increase in FSH for a critical duration of time is essential.  

Recruited primordial follicles either develop into dominant, mature graafian follicles destined to ovulate or degenerate as a result of atresia (see Fig. 16-16). The average time for development of a selected follicle to the point of ovulation is 10 to 14 days (see Fig. 16-15). If a follicle is not recruited, it goes through a process called atresia during which the oocyte and granulosa cells within the basal lamina die and are replaced by fibrous tissue. In contrast, the thecal cells outside the basal lamina do not die but dedifferentiate and return to the pool of cells consisting of ovarian interstitial or stromal cells.  

The process of atresia is generally thought to result from lack of the hormones or growth factors that are formed by the mature dominant follicle through intrinsic intraovarian mechanisms. There is general agreement that atresia of follicles is due to apoptosis.  

Apoptosis is an active and regulated process triggered by a cascade of caspase proteases that lead to characteristic fragmentation of DNA and blebbing of membranes.  

Ovulation

There is a dramatic rise in circulating estradiol level as midcycle approaches (see later). This increase in estradiol is followed by a striking LH and to a lesser extent an FSH surge. This triggers the dominant follicle to ovulate. During each menstrual cycle, usually one follicle ovulates and gives rise to a corpus luteum. In the human, either LH or its surrogate hCG is essential to stimulate the rupture of the mature follicle. It was proposed that increased local prostaglandin biosynthesis in the follicle might mediate the ovulatory effect of LH.  

Ovulation consists of rapid follicular enlargement followed by protrusion of the follicle from the surface of the ovarian cortex. This is followed by the rupture of the follicle and extrusion of an egg-cumulus complex into the peritoneal cavity (Fig. 16-16) (Figure Not Available) . Follicular rupture or ovulation occurs predictably 34 to 36 hours from the start of the LH surge. Elevation of a conical "stigma" on the surface of the protruding follicle precedes rupture (see Fig. 16-16) (Figure Not Available) . Rupture of this stigma is accompanied by a gentle rather than explosive expulsion of the ovum and antral fluid. The gonadotropin-dependent production of proteases acting locally on protein substrates in the basal lamina may play an important role in stigma formation and follicular rupture.  

In particular, plasminogen activator levels increase in the follicle before rupture.  

Thus, plasminogen activatormediated conversion of plasminogen to plasin may contribute to the proteolytic digestion of the follicular wall, which is a prerequisite for follicular rupture.  

Corpus Luteum

After ovulation, the dominant follicle reorganizes to become the corpus luteum (Fig. 16-17) (Figure Not Available). After rupture of the follicle, capillaries and fibroblasts from the surrounding stroma proliferate and penetrate the basal lamina. This rapid vascularization of the corpus luteum may be guided by angiogenic factors, some of which are detected in the follicular fluid.  

Vascular endothelial growth factor has been isolated from corpora lutea and has been postulated, along with basic fibroblast growth factor, to be a potential angiogenic agent in corpora lutea.  

Concurrently, the granulosa and theca cells undergo morphologic changes collectively referred to as luteinization. The granulosa cells become granulosa-lutein cells (large cells), and the theca cells are transformed into theca-lutein cells (small cells; see Fig. 16-17 B) (Figure Not Available) . The so-called K cells, scattered throughout the corpus luteum, are believed to be macrophages.  

The corpus luteum is the endocrine gland that serves as the major source of sex steroid hormones secreted by the ovary during the postovulatory phase of the cycle.  

The human corpus luteum secretes as much as 40 mg of progesterone per day during the midluteal phase of the ovarian cycle.  

In view of the small size of the corpus luteum, it is the most active steroidogenic tissue in humans. An important aspect of corpus luteum formation is the penetration of the follicle basement membrane by blood vessels, which provides the granulosalutein cells with low-density lipoprotein (LDL).  

As stated earlier, LDL cholesterol serves as the substrate for corpus luteum progesterone production.  

A key regulator of steroidogenesis in the corpus luteum is LH. In humans, the LH receptor is maintained throughout the functional life span of corpora lutea and not down-regulated during the maternal recognition of pregnancy.  

The ratelimiting step in LH-mediated progesterone formation in luteinized granulosa cells is the entry of cholesterol into the mitochondria, which is regulated by steroidogenic acute regulatory protein (STAR; see later).  

Thus, the availability of LDL cholesterol and the STAR-mediated mitochondrial entry of cholesterol seem to be the two critical factors that account for the production of large amounts of progesterone in the corpus luteum.
The functional life span of the corpus luteum is normally 14 to 2 days. Thereafter, the corpus luteum spontaneously regresses. It is replaced, unless pregnancy occurs, by an avascular scar referred to as the corpus albicans.

Factors that may regulate luteal life span include hormones such as hCG, maintenance of luteal vascularization, and immune cells. There is little doubt about the central role of LH in the maintenance of corpus luteum function. Withdrawal of LH support in a variety of experimental circumstances has almost invariably resulted in luteal regression. In pregnancy, however, the LH surrogate hCG, secreted by the gestational trophoblast, maintains the ability of the corpus luteum to elaborate progesterone; this stimulus helps to maintain the early gestation until the luteoepithelial shift. Accordingly, the corpus luteum doubles in size (compared with the pregnancy size) during the first 6 weeks of gestation (see Fig. 16-17) (Figure Not Available). This increase is due to proliferation of connective tissues and blood vessels, along with hypertrophy of the luteinized granulosa and theca cells. This early hypertrophy is later followed by regression. The corpus luteum at term is only half the size of that during the menstrual cycle.

Hormones such as estrogens and prostaglandins have been suggested as important factors in the promotion of luteal demise. Immune factors may influence luteal life span because corpus luteal regression is associated with a progressive infiltration of lymphocytes and macrophages.

Apoptosis may be the end-point mechanism by which human corpora lutea are deleted. Corpora lutea during the early luteal phase of the menstrual cycle and corpora lutea of early pregnancy show no evidence of apoptotic DNA fragmentation. DNA fragmentation, on the other hand, is detected in midluteal and late luteal corpora. Thus, it is hypothesized that apoptosis is a major mechanism for the demise of the corpus luteum. LH or hCG inhibits apoptosis in the corpus luteum. In the absence of these trophic factors, apoptosis ensues. The remaining corpus luteum is composed of dense connective tissue and is termed the corpus albicans.

Ovarian Follicle-Stimulating Hormone and Luteinizing Hormone Receptors

The FSH receptor is expressed exclusively by granulosa cells. The LH-hCG receptor is expressed primarily by the theca-interstitial cells of all follicles and by granulosa cells of large preovulatory follicles.

Granulosa cells in primary or secondary follicles that are in the early developmental stages before antrum formation (i.e., preantral follicles) primarily bind FSH but not LH. In these preantral follicles, the binding of LH and hCG is confined to theca-interstitial cells. Granulosa cells in more mature tertiary follicles with an antrum appear capable of binding both LH and FSH. Thus, FSH receptors are found in granulosa cells from follicles of all sizes, but LH receptors are found only in granulosa cells of large preovulatory follicles.

The receptors for the glycoprotein hormones have related structures (Fig. 16-18) (Figure Not Available). The receptors belong to the large family of G protein-coupled receptors, whose members all have a transmembrane domain that consists of seven membrane-traversing -helices connected by three extracellular and three intracellular loops (see Fig. 16-18) (Figure Not Available). The glycoprotein hormone receptors form a separate subgroup within this large family by virtue of their large extracellular hormone-binding domain at the N-terminus. FSH binds to the FSH receptor, and LH and hCG both bind to the same LH receptor. Both LH and FSH receptor genes are located on chromosome 2 at the p21 region. The relationship of the glycoprotein hormone receptors to the other G protein-coupled receptors is indicated by their sequence homology in the C-terminal half of the receptor. This domain, encoded by a single, last exon, contains the seven transmembrane segments and the G-proteincoupling domain. The unusually large extracellular domain of the glycoprotein hormone receptors is encoded by the first 9 or 10 exons (Fig. 16-19).

Role of Follicle-Stimulating Hormone in Ovarian Function

As indicated by its name, FSH is the main promoter of follicular maturation. Given that FSH receptors have been exclusively localized to granulosa cells, it is generally presumed that FSH action in the ovary involves the granulosa cells. The ability of FSH to orchestrate follicular growth and differentiation depends on its ability to exert multiple actions concurrently.

Phenotypes of women with mutations that disrupt the function of the FSH+ subunit gene are in good agreement and demonstrate that FSH is necessary for normal follicular development, ovulation, and fertility. Likewise, pubertal development is hampered in the absence of sufficient numbers of later stage follicles with the granulosa cells needed for adequate estrogen production. Treatment of at least one of these patients with exogenous FSH resulted in follicular maturation, ovulation, and normal pregnancy. The presenting phenotype of FSH- subunit deficiency is practically identical to that caused by inactivating mutations of the FSH receptor. Women with FSH receptor mutations are clinically similar to patients with gonadal dysgenesis, with absent or poorly developed secondary sexual characteristics and high serum levels of FSH and LH. The notable difference was the presence of follicular cells in cases with FSH receptor mutation, consistent with the FSH independence of primordial follicle recruitment and early follicular growth and development. In contrast, total absence of all follicles, including those in the primordial stage, was observed in the cases in which the FSH receptor mutation could not be detected. Thus, the ovarian phenotype of FSH receptor deficiency is distinct from the common form of gonadal dysgenesis as found in Turner's syndrome with streak gonads and absence of growing follicles.

In vivo rodent studies suggest that FSH is capable of increasing the number of its own receptors in the granulosa cell. Whereas estradiol by itself may be without effect on the distribution, number, or affinity of granulosa cell FSH receptors, estradiol has been shown to synergize with FSH to enhance the overall number of granulosa cell FSH receptors. Consequently, changes in the production of estradiol by preantral follicles could increase their response to FSH through the regulation of granulosa cell-surface FSH receptors. This interaction between FSH and estradiol in follicular development has been well established in rodents. It appears that estradiol enhances the activity of ER and may mediate the estrogenic effect on ovarian follicular development and growth. On the other hand, it is not clear at this time whether a similar relationship exists in the human ovary. ER is not detected in the human ovary in significant quantities. The demonstration of ER in the human ovary, however, suggests an interaction between FSH and estrogen in the regulation of normal follicle development and ovulation in women.

One of the major actions of FSH is the induction of granulosa cell aromatase activity. Thus, little or no estrogen can be produced by FSH-unprimed granulosa cells even if they are supplied with aromatizable androgen precursors. On the other hand, treatment with FSH enhances the aromatization capability of granulosa cells, an effect related to enhancement of the granulosa cell aromatase content.

Treatment with FSH has also been shown to induce LH receptors in granulosa cells. The ability of FSH to induce LH receptors is augmented by the concomitant presence of estradiol. Furthermore, progestins, androgens, and LH itself may also induce LH receptors. Once induced, the granulosa cell LH receptor requires the continued presence of FSH for its maintenance.

Circumstantial evidence, as deduced from studies of women with disrupting mutations of the genes that encode FSH and LH receptors and aromatase P450 (P450 arom), indicates that FSH action, but not estrogen or LH action, is essential for follicular growth in humans. In women with deficient LH action or estrogen...
biosynthesis, follicular growth and development up to the antral stage were observed, although these individuals were anovulatory. On the other hand, women with mutations of the FSH- subunit or FSH receptor had only primordial follicles in their ovaries. These data indicate that estrogen or LH is not critical for follicular development at least until the tertiary stage (see Fig. 16-12 (Figure Not Available) and Fig. 16-14). It should be kept in mind, however, that FSH by itself is not sufficient to achieve normal follicular development and ovulation.

Role of Luteinizing Hormone in Ovarian Function

LH is essential for ovulation (follicular rupture) and the sustenance of corpus luteum function. In addition, LH plays other important roles in follicular function. First, it is likely that LH plays a major role in the promotion of theca-interstitial cell androgen production. Moreover, LH may well synergize with FSH in the more advanced phases of follicular development. Last, small and sustained increments in the circulating levels of LH are both necessary and sufficient to cause small antral follicles to grow and develop to the preovulatory stage.

It is presumed that LH acts on theca-interstitial cells of small follicles, where it promotes the biosynthesis of C₁₈ steroids. The consequent increase in estrogen production is presumed to contribute to the growth and development of the follicles. Treatment with small doses of LH also presumably results in an increase in LH receptor content as well as in induction of the key steroidogenic proteins such as STAR, side-chain cleavage P450 (P450sc), 3-hydroxysteroid dehydrogenase type II (3-HSD-II), and 17 hydroxylase (P450ør).

The role of LH action in human ovarian physiology was exemplified by the phenotype of a woman with a disrupting mutation of the LH receptor gene. She presented with amenorrhea with normally developed secondary sexual characteristics, increased circulating FSH and LH levels, and low levels of estradiol and progesterone that were unresponsive to HCG treatment. The ovary contained follicles that developed up to antral stage with a well-developed theca layer but no preovulatory follicles or corpora lutea. These observations collectively support the view that LH is essential for ovulation and sufficient estrogen production, whereas follicular development is initially autonomous and at later stages dependent on intact FSH action.

Ovarian Steroidogenesis

The preovulatory follicle secretes estradiol during the first half of the menstrual cycle, whereas the corpus luteum secretes both estradiol and progesterone during the second half of the cycle (Fig. 16-20). The production of these two biologically active steroids is orchestrated in the follicle and corpus luteum in a cell-specific manner under the control of LH and FSH.

The steroid hormone contents of the ovarian vein effluents and peripheral venous blood were compared to distinguish steroids secreted by the ovary from those secreted by the adrenal and from those produced by peripheral conversion of precursors. These studies revealed that the ovaries secrete pregnenolone, progesterone, 17-hydroxyprogesterone, dehydroepiandrosterone (DHEA), androstenedione, testosterone, estrone, and estradiol. Although such measurements provide insights into the steroidogenic pathways under study, they do not identify the specific ovarian cells involved.

Studies using microdissected preovulatory follicles identified estrone and estradiol as the major steroid products (see Fig. 16-20). Progesterone and 17-hydroxyprogesterone, on the other hand, proved to be the major products of the corpus luteum (see Fig. 16-20).

The biologically active ovarian steroids are estradiol and progesterone (Fig. 16-21). The major C₁₈ -steroid product of the ovary, androstenedione, is not biologically active. Androstenedione, however, acts as a dual precursor and contributes to circulating levels of estrone and testosterone through conversion in extraglandular tissues such as adipose tissue and skin (see later). It is likely that aromatization of weak estrone is further converted to the potent estrogen estradiol, and testosterone is converted to the much more potent androgen dihydrotestosterone (DHT) locally in target tissues such as brain, breast, prostate, and genital skin in order to exert potent biologic effects. The presence of multiple proteins with overlapping enzymatic activities (i.e., 17-HSD and 5-reductase) that catalyze these conversions in a large number of human tissues is supportive of this idea.

The general steroidogenic pathway for the production of estrogens and androgens is depicted in Figure 16-21. There are three major categories of ovarian steroids, as follows.

C₁₈ Steroids

The naturally occurring estrogens are C₁₈ -steroids characterized by the presence of an aromatic A ring, a phenolic hydroxy group at C-3, and either a hydroxy group (estradiol) or a ketone group (estrone) at C-17. Aromatase is the key enzyme for estrogen production in the ovary (see Fig. 16-21). The protein P450ør confers the specific activity of the aromatase enzyme complex. P450ør expression in the ovarian granulosa cell is regulated primarily by FSH. The principal and most potent estrogen secreted by the ovary is estradiol. Although estrone is also secreted by the ovary, another important source of estrone is extraglandular conversion of androstenedione in peripheral tissues. Estradiol (16-hydroxyestradiol) is the most abundant estrogen in urine and is produced by the metabolism of estrone and estradiol in extravascular tissues. All C₁₈ -steroids including estrone, estradiol, and estradiol are commonly referred to as estrogens. It should be pointed out, however, that estrone and estradiol are only weakly estrogenic and must be converted
into this cell type through primarily low-density lipoprotein receptors and for secretion of large amounts of progesterone into the circulation. The entry of cholesterol into mitochondria (by StAR) is likely to be the most critical steroidogenic step for progesterone formation in granulosa lutein cells. Androstenedione produced in theca-lutein cells serves as a substrate for estradiol produced in granulosa-lutein cells. Granulosa cells and the transcription factor SF-1 play key roles in important steroidogenic steps in both cell types. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FSH-R, follicle-stimulating hormone receptor; HSD, 3-hydroxysteroid dehydrogenase; LH-R, luteinizing hormone receptor.

to estradiol to show full estrogenic action. There are at least seven enzymes in the 17-HSD family with overlapping activities, which are capable of converting estrone to estradiol in the ovary and extravascular tissues. ['3]

Catechol estrogens are formed by hydroxylation of estrogens at the C-2 or C-4 position. The physiologic role of catechol estrogen, if any, is unclear. Low body weight and hypometabolism are associated with increased formation of catechol estrogens. ['3] Estrone sulfate, formed by peripheral conversion of estradiol and estrone, is the most abundant estrogen in blood but is not physiologically active. ['5] Estradiol sulfate is presumed to serve as a reservoir for estrone formation in a number of tissues, including those that are targets of estrogen. ['6] Estradiol regulates gonadotropin secretion and promotes development of the secondary sexual characteristics of women, uterine growth, thickening of the vaginal mucosa, thinning of the cervical mucus, and linear growth of the dactal region of the breast.

![Figure 16-21](https://example.com/figure1621.png)

**Figure 16-21** Steroidogenic pathway in the ovary. Biologically active steroids progesterone and estradiol are produced primarily in the ovary of a woman of reproductive age. Estradiol production requires the activity of six steroidogenic proteins including StAR and six enzymatic steps. P450c17, product of the CYP17 gene, catalyzes two enzymic reactions. The four rings of the cholesterol molecule and its derivative steroids are identified by the first four letters in the alphabet, and the carbons are numbered in the sequence shown in the insert. 3-HSD-II, 3-hydroxysteroid dehydrogenase [9] 5 isomerase type II; 17-HSD-1, 17-hydroxysteroid dehydrogenase type 1; P450 arom, aromatase; P450c17, 17-hydroxylase/17,20-lyase; StAR, steroidogenic acute regulatory protein.

C_{17}-Steroids

The principal progestogens are C_{19}-steroids and include pregnenolone, progesterone, and 17-hydroxyprogesterone (see Fig. 16-21). Pregnenolone is of primary importance in the ovary because of its key position as precursor of all steroid hormones. Progesterone is the principal secretory product of the corpus luteum and is responsible for the progesterational effects (i.e., cell differentiation and induction of secretory activity in the endometrium of the estrogen-preened uterus). Progesterone is required for implantation of the fertilized ovum and maintenance of pregnancy. It also induces decidualization of the endometrium, inhibits uterine contractions, increases the viscosity of cervical mucus, promotes labor (anterior) development of the breast glands, and increases basal body temperature. On the other hand, 17-hydroxyprogesterone, also secreted by the corpus luteum, has little, if any, biologic activity. ['5]

C_{19}-Steroids

The ovary secretes a variety of C_{19}-steroids, including DHEA, androstenedione, and testosterone (see Fig. 16-21). They are produced by the thecal cells and to a lesser degree by the ovarian stroma. The major C_{19}-sterol is androstenedione, part of which is secreted directly into plasma, with the remainder converted to estrone by the granulosa cells. Androstenedione can be converted to estradiol or testosterone in the ovary and in extravascular tissues. Only testosterone and DHT but not androstenedione are true androgens with the capacity of interacting with the androgen receptor (see later).

Steroids formed by the ovary, as well as other steroid-producing organs, are derived from cholesterol (see Fig. 16-21). There are several sources of cholesterol that can provide the ovary with substrate for steroidogenesis. These include (1) plasma lipoprotein cholesterol, (2) cholesterol synthesized de novo within the ovary, and (3) cholesterol from intracellular stores of cholesterol esters within lipid droplets. In the human ovary, LDL cholesterol is an important source of cholesterol utilized for steroidogenesis. ['1] LH stimulates the activity of adenylyl cyclase, increasing production of cyclic adenosine monophosphate (cAMP), which serves as a second messenger to increase LDL receptor mRNA and the binding and uptake of LDL cholesterol as well as the formation of cholesterol esters. ['4] LDL-derived cholesterol is particularly essential for normal levels of progesterone production in the granulosa lutein cells of the corpus luteum (see Fig. 16-20b). ['5]

The first and rate-limiting step in the synthesis of all ovarian steroid hormones is the movement of cholesterol into the mitochondrion, which is regulated by StAR (see Fig. 16-21). This movement is followed by conversion of cholesterol to pregnenolone, catalyzed by the mitochondrial enzyme complex consisting of P450_{c11}, adrenodoxin, and flavoprotein. ['5] LH induces steroidogenesis by increasing intracellular cAMP, which increases the conversion of cholesterol to pregnenolone in two distinct ways: (1) acute regulation, over minutes, occurs through the phosphorylation of preexisting StAR and rapid synthesis of new StAR protein, and (2) chronic stimulation, within hours to days, occurs through the induction of P450_{c17} expression and consequent increased steroidogenesis (see Fig. 16-20a). Thus, StAR increases the flow of cholesterol to mitochondria, thus regulating substrate availability to whatever amount of P450_{c17} is available on the inner mitochondrial membrane. ['5] In the absence of StAR, only 14% of the maximal StAR-induced level of steroidogenesis persists as StAR-independent steroidogenesis. ['5]

StAR expression in the preovulatory graafian follicle is limited primarily to the thecal cells (see Fig. 16-20a) ['5] The most important product of the thecal cell during the follicular phase is the estrogen precursor androstenedione, whose production is controlled primarily by StAR (see Fig. 16-20b). The biologically active steroid product of the ovary during the follicular phase is estradiol that arises from the granulosa cells located adjacent to theca cells (see Fig. 16-20a). The rate-limiting step for granulosa cell estradiol production is regulated by the FSH-dependent activity of the aromatase enzyme in a cyclic fashion (see Fig. 16-20). During the luteal phase, cells of the corpus luteum, including granulosa lutein cells, also show intense StAR immunoreactivity with a patchy distribution (see Fig. 16-20a). The delivery of cholesterol to the mitochondrial side-chain cleavage enzyme system in the corpus luteum is the rate-limiting step for progesterone biosynthesis and is regulated by StAR (see Fig. 16-20a). Thus, estradiol production seems to be regulated primarily by StAR and P450_{c17} whereas progesterone biosynthesis is under the control of StAR.

The ovarian granulosa, theca, and corpus luteum cells possess StAR plus five distinct proteins with specific enzyme activities for steroid hormone formation. These steroidogenic enzymes are P450_{c17}, 3-HSD-II, P450_{arom}, P450_{c17}, and 17-HSD-1. ['3] ['5] These enzymes are responsible for the conversion of cholesterol to the two major biologically active products estradiol and progesterone. ['1] ['5] Steroidogenesis dependent on LH and FSH in both theca and granulosa cells is mediated by common signaling molecules including cAMP and the transcription factor steroidogenic factor-1 (SF-1) (see Fig. 16-20). ['3] ['5] SF-1 regulates the expression of genes that encode StAR, P450_{c17}, 3-HSD-II, P450_{arom}, and P450_{c17} (see Fig. 16-20). Thus, SF-1 can be regarded as a downstream master switch that orchestrates ovarian steroidogenesis. ['5]

Summary of Updated Two-Cell Theory for Ovarian Steroidogenesis

The classical two-cell theory is supported by molecular findings in the following fashion. Ovarian steroidogenesis in the preovulatory follicle takes place through LH receptors on theca and FSH (possibly plus LH) receptors on granulosa cells (see Fig. 16-20). Cyclic AMP production and increased SF-1 binding to multiple steroidogenic promoters mediate LH action in theca cells. In particular, SF-1 is the primary regulator of production of androstenedione that subsequently diffuses into granulosa cells to serve as the estrogen precursor. In the preovulatory follicle, cholesterol in theca cells arises from circulating lipoproteins and de novo biosynthesis. FSH is responsible for follicular growth and also estrogen formation. FSH induces cAMP formation, increased SF-1 binding activity, and P450_{c17} expression in preovulatory granulosa cells to give rise to estradiol formation primarily through aromatization of androstenedione (see Fig. 16-20).
In the corpus luteum, large deposits of cholesterol (i.e., the yellow color) arise primarily from circulating lipoproteins to support production of extremely high quantities of progesterone. Other key anatomic events in formation of the corpus luteum are the disruption of the basement membrane between the granulosa and theca and strikingly increased vascularization of granulosa lutein cells (see Fig. 16-17) (Figure Not Available). Theca lutein cells possess LH receptors and produce androstenedione. Cyclic AMP, SF-1, and SFAR induced by LH remain as the key regulators for biosynthesis of thecal androstenedione, which serves as the estrogen precursor in neighboring granulosa lutein cells.

The granulosa lutein cell of the corpus luteum is both anatomically and functionally different from its counterpart in the preovulatory follicle. First, these cells are larger and heavily vascularized and contain large quantities of cholesterol. Second, granulosa lutein cells contain high levels of LH receptors in addition to FSH receptors. Third, they produce large quantities of progesterone that is regulated primarily by LH and SFAR. Granulosa lutein cells also aromatize androstenedione of theca origin and eventually give rise to estradiol formation through FSH action and P450 arom. The common known mediators of LH and FSH in granulosa lutein cells are cAMP and increased SF-1 binding activity. Specific functions of these two gonadotropins (i.e., differentiation, growth, and progesterone formation versus estradiol formation) are probably determined by as yet unidentified modifying factors.

---

**Peptide Hormones Produced by Ovary**

The ovary produces a large number of peptides that can act in an intracrine, autocrine, paracrine, or endocrine fashion. These include numerous growth factors (e.g., insulin-like growth factors [IGFs]) and cytokines (e.g., interleukin-1).

The group of peptides including inhibin, activin, and follistatin are produced in ovarian granulosa cells under the control of FSH (see Fig. 16-1). The production of these factors is not limited to the ovary. A number of other tissues, including the adrenal, pituitary, and placenta, synthesize these peptides. It has been well established that inhibin plays a major regulatory role in FSH production in the pituitary. Inhibin is a 32-kd glycoprotein composed of two subunits, (18 kd) and (12 kd), linked by disulfide bonds. Structurally, inhibin is a heterodimer composed of a common subunit but different subunits, denoted α and β. The forms of inhibin, α and β, are termed A and B, respectively. Although inhibin is produced by a number of tissues in the body, the majority is derived from the gonads. In the ovary, the source of inhibin is granulosa cells. The main role of inhibin, for which it was discovered and named, is to suppress FSH production in the pituitary (see Fig. 16-1).

Although both isoforms of inhibin seem to have similar biologic properties, their synthesis is regulated differently during the follicular and luteal phases. Inhibin B is secreted mainly during the early follicular phase, with levels decreasing in midfollicular phase and becoming undetectable after the LH surge. Inhibin A levels are low during the first half of the follicular phase but increase gradually during midfollicular phase with a peak during the luteal phase. All three subunits are detected in small antral follicles by immunohistochemistry and in situ hybridization. The α and β subunits are found in the dominant follicle and in the corpus luteum. All three subunits are expressed in response to gonadotropins or factors that increase intracellular cAMP. The mechanisms underlying the regulation of the different parts of the menstrual cycle by inhibin isoforms need further study for a fuller understanding.

Activin is structurally related to inhibin but may exert opposite actions. Activin contains two subunits that are identical to the subunits of inhibins A and B. Thus, the three activin isoforms are activin A(αA, βA), activin B(αB, βB), and activin AB(αA, βB). In the pituitary, activin stimulates the release of FSH. In the ovarian follicle, activin enhances FSH action.

**Overview of the Hormonal Changes during the Ovarian Cycle**

FSH secretion is suppressed by negative feedback of the ovarian hormones estrogen, inhibin, and progesterone during the early and midluteal phase. Upon the regression of the corpus luteum during the late luteal phase, however, the sharp decline in estrogen, inhibin, and progesterone abolishes this negative feedback of FSH just before and during menses. This initial increase in FSH is essential for follicle recruitment and growth and steroidogenesis (see Fig. 16-22). With continued growth of the follicle, follicular paracrine and autocrine factors produced within the follicle maintain follicular sensitivity to FSH. Continuing and combined action of FSH and activin leads to the appearance of LH receptors on the granulosa cells, a prerequisite for ovulation and luteinization.

Ovulation is triggered by the rapid rise in circulating levels of estradiol. A positive feedback response at the level of the anterior pituitary and possibly at the hypothalamus results in the midcycle surge of LH necessary for expulsion of the egg and formation of the corpus luteum (see Fig. 16-22). A rise in progesterone follows ovulation along with a second rise in estradiol, producing the 14-day-long luteal phase characterized by low FSH and LH levels. The demise of the corpus luteum concomitant with a fall in hormone (progesterone, estradiol, and inhibin A) levels allows FSH to increase again toward the end of the luteal phase, thus initiating a new cycle (see Fig. 16-22). If pregnancy is established by the implantation of a blastocyst, however, the structural integrity and function (progesterone and estradiol production) of the corpus luteum are maintained by HCG that is secreted from the trophoblast. The HCG acts as a surrogate for LH on the corpus luteum.

In addition to FSH and LH, local factors (e.g., activin and inhibin) regulate follicular development and steroidogenesis. In the early follicular phase, activin produced by granulosa in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation while simultaneously suppressing C19 -steroidogenesis in theca cells. In the late follicular phase, increased production of inhibin by the granulosa and decreased activin promote the synthesis of C19- steroids in the theca in response to LH and local growth factors and cytokines to provide larger amounts of the precursor androstenedione for the production of estrone and ultimately estradiol in the granulosa cells (see Fig. 16-20). Both LH-mediated androstenedione production in the theca cells and FSH-mediated estradiol production in granulosa cells are potentiated by IGFs. The major endogenous IGF produced in the human ovarian follicle is IGF-II (versus IGF-I) in both granulosa and theca cells. The actions of both IGF-I and IGF-II are mediated by IGF receptor type 1 in both cells. IGF receptor type 1 is structurally similar to the insulin receptor. Thus, it appears that gonadotropin-related IGF action in the ovary is regulated primarily by IGF-II and IGF receptor type 1.

In summary, ovulation is under the control of substances functioning as classical hormones (FSH, LH, estradiol, and inhibin) transmitting messages between the ovary and the hypothalamic-pituitary axis and paracrine and autocrine factors such as IGF-II, inhibin, and activin, which coordinate sequential activities within the follicle destined to ovulate. The negative feedback relationship between corpus luteum products (estradiol, progesterone, and inhibin) and FSH results in the critical initial rise in FSH immediately before and during menses, and the positive feedback relationship between estradiol and LH is responsible for the ovulatory stimulus (see Fig. 16-22). Within the ovary, IGF-I, inhibin, and activin modify follicular responses necessary for growth and function. These endocrine, paracrine, and autocrine factors undoubtedly represent only a portion of a complete picture. The causes of anovulation are diverse and may be related to defects in cell-surface receptors, intracellular elements of signal transduction, or cell-cell interactions.

**Extravarian Steroidogenesis**

 Estradiol formation takes place in a number of tissues in the woman of reproductive age. These tissues may be placed in three categories: (1) the ovary, (2) peripheral tissues such as subcutaneous fat and skin, and (3) physiologic and pathologic target sites such as the hypothalamus, breast cancer cells, and the cells of endometriosis (Fig. 16-22). The latter two sources of estrogen are particularly critical in anovulatory premenopausal and postmenopausal women. Although small
quantities of estrogen are produced by an individual adipose or skin fibroblast in a continuous fashion, these cell types contribute to circulating estradiol levels because of their relative abundance.

Figure 16-23  Estrogen biosynthesis in women. The biologically active estrogen estradiol \( (E_2) \) is produced in at least three major sites: (1) by direct secretion from the ovary in reproductive-age women; (2) by conversion of circulating androstenedione \( (A) \) of adrenal or ovarian origins, or both, to estrone \( (E_1) \) in peripheral tissues; and (3) by conversion of \( A \) to \( E_1 \) in estrogen target tissues. In the latter two instances, estrogenically weak \( E_1 \) is further converted to \( E_2 \) within the same tissue. The presence of the enzyme aromatase and 17-hydroxysteroid dehydrogenase \( (17\text{-HSD}) \) is critical for \( E_2 \) formation at these sites. \( E_2 \) formation by peripheral and local conversion is particularly important in post-menopausal women and in estrogen-dependent diseases such as breast cancer, endometriosis, and endometrial cancer. (see Fig. 16-23).

This effect is more pronounced in obese women because of increased mass of the adipose tissue and skin.

P450arom in adipose and skin fibroblasts is responsible for peripheral aromatization of androstenedione that arises from both the ovary and adrenal in premenopausal women and primarily from the adrenal in postmenopausal women (see Fig. 16-23). The product of this reaction, estrone, is only weakly estrogenic, however. Estrone is further converted to estrone sulfate, which serves as a reservoir for estrone in blood and other tissues. Estrone (arising from androstenedione and estrone sulfate) is further converted to the biologically active estradiol in target tissues such as the endometrium and breast by a number of enzymatic proteins with overlapping reductive 17-HSD activity (see Fig. 16-23).

It is likely that local P450arom expression in hypothalamus is critical for the regulation of gonadotropin secretion. Finally, estrogen-dependent pathologic tissues such as those in breast cancer and endometriosis contain extremely high levels of P450arom that enhances tissue growth by increasing local estradiol concentrations. Circulating androstenedione is the major substrate for aromatase activity in these physiologic and pathologic target tissues.

Significant quantities of circulating androstenedione can also be converted to testosterone in peripheral tissues (see later). This is probably accomplished by the presence of multiple 17-HSDs with overlapping reductive activities in peripheral tissues. Androgenic action of testosterone is strikingly amplified by its conversion to DHT in peripheral and target tissues (e.g., skin and prostate). At least two distinct proteins encoded by two separate genes, 5-reductase type 1 and type 2, catalyze the conversion of testosterone to DHT in the liver, prostate, and skin. Local production of DHT in genital skin fibroblasts is critical for normal masculinization of external genitalia of male fetuses in utero. DHT formation in the skin is also important in the etiology of hirsutism (see later).
Endometrium

The endometrium is the mucosal lining of the uterine cavity. The decidua is the highly modified and specialized endometrium of pregnancy. From the evolutionary perspective, the human endometrium is highly developed to accommodate the hemochorial endothelial type of placentation, which requires the presence of spiral arteries (Fig. 16-24). Trophoblasts of the blastocyst invade spiral arteries during implantation and placentation in the establishment of utero-placental vessels.

Spiral arteries of the human endometrium also confer another unique process termed menstruation. Menstruation is shedding of endometrial tissue with hemorrhage that is dependent upon sex steroid hormone-directed changes in blood flow in the spiral arteries. The presence of spiral arteries is essential for menstruation because only the human and a few other primates that have endometrial spiral arteries experience menstruation. With nonfertile but ovulatory ovarian cycles, menstruation affects desquamation of the endometrium. New endometrial growth and development must be initiated with each ovarian cycle, so that endometrial maturation corresponds rather precisely with the next opportunity for pregnancy. There seems to be a narrow window of endometrial receptivity to blastocyst implantation that corresponds to the period between days 20 and 24 during a 28-day menstrual cycle.

Functional Anatomy of the Endometrium

The endometrium can be divided morphologically into an upper two-thirds functionalis layer and a lower one-third basalis layer (see Fig. 16-24). The purpose of the functionalis layer is to prepare for the implantation of the blastocyst; therefore, it is the site of proliferation, secretion, and degeneration. The purpose of the basalis layer is to provide the regenerative endometrium following menstrual loss of the functionalis. Major histologic components of the endometrium include (1) stromal cells that constitute the skeleton of the tissue, (2) a single layer of epithelial cells that line the lumens of the endometrial cavity and invaginations of the stroma, (3) blood vessels, and (4) resident immune cells. The epithelial cells that line the rather deep invaginations of the stroma are also referred to as glandular cells. It should be noted, however, that these deep crypts represent simply extensions of the intracavitary lumen and are not true glands. These invaginations lined by epithelial cells extend from the surface of the functionalis layer (i.e., luminal epithelium) deep into the basalis level (the so-called glandular epithelium). Thus, after the functionalis layer is shed at the time of menstruation, the basalis that contains both epithelial and stromal cells can give rise to a new functionalis layer for the upcoming cycle (Fig. 16-25).

The cellular components of the functionalis layer undergo a striking progression during the menstrual cycle, whereas the basalis shows only modest alterations. The sequence of endometrial changes associated with an ovulatory cycle has been carefully studied by Noyes and colleagues in the human and Markee and Bartelmez in the subhuman primate. The histologic changes that occur in the endometrium during the nonfertile but ovulatory menstrual cycle are summarized in Figure 16-26 as described originally by Noyes and co-workers. As described originally by Noyes and colleagues.

Hormone-Induced Morphologic Changes of the Endometrium

The cyclic changes in endometrial histology are faithfully reproduced during each ovulatory ovarian cycle. These sex steroid hormone-induced modifications can be summarized as follows. (1) During the preovulatory, or follicular, phase of the cycle, estradiol is secreted (principally by a single dominant follicle of one ovary) in increasing quantities until just before ovulation. (2) During the postovulatory, or luteal, phase of the cycle, progesterone is secreted by the corpus luteum in increasing amounts (up to 40 to 50 mg/day) until the midluteal phase. (3) Beginning about 7 to 8 days after ovulation, the rates of progesterone (and estrogen) secretion by the corpus luteum begin to decline and then diminish progressively before menstruation (see Fig. 16-22).

In response to these cyclic changes in the rates of ovarian sex steroid hormone secretion, there are five main stages of the corresponding endometrial cycle: (1) menstrual-postmenstrual reapithelialization, (2) endometrial proliferation in response to stimulation by estradiol; (3) abundant epithelial secretion, in response to the combined action of estradiol and progesterone; (4) premenstrual ischemia, the result of endometrial tissue volume involution, which causes stasis of blood in the spiral arteries; and (5) menstruation, which is preceded and accompanied by severe vasconstriction of the spiral arteries and collapse and desquamation of all but the deepest layer of the endometrium. In the final analysis, menstruation is the consequence of the withdrawal of factors that maintain endometrial growth and differentiation. Commonly, the initiation of menstruation is attributed to progesterone withdrawal. This concept was developed because the administration of estrogen to
postmenopausal women and thence treatment or withdrawal with a progestin affect menstruation, even with continued estrogen treatment. Moreover, progesterone facilitates and permits decidualization of the endometrium and the maintenance of pregnancy, whereas progesterone withdrawal favors the initiation of menstruation, lactation, and parturition. There are probably multiple additional coordinated and interactive processes (other than progesterone withdrawal) that are operative and essential for the success of each of these events.

Both the preovulatory (follicular or proliferative) phase and the postovulatory (luteal or secretory) phase of the ovarian-endometrial cycles are customarily divided into early and late stages (see Fig. 16-22). The normal secretory phase of the endometrial (menstrual) cycle can be subdivided rather finely (almost day by day), by histologic criteria, from shortly after ovulation until the onset of menstruation. In fact, Noyes and other investigators have provided an extremely detailed description of the histologic features of the secretory phase endometrium, which permit accurate dating during the luteal phase (see Fig. 16-26). Gynecologists use the histologic dating of the endometrial biopsies obtained during the luteal phase to evaluate ovulation, progesterone production, or the degree of biologic response of the endometrium to progesterone. Normal endometrial development is assumed when the histologic and chronologic endometrial dating agree within 2 days. When they differ by more than 2 days, the endometrium is considered to be out of phase. Out-of-phase endometrial tissue was proposed to be a cause of implantation failure giving rise to infertility. Understanding the limitations of this test is important, if infertility treatments are based on biopsy results, because the sensitivity and the specificity of the dating of endometrial biopsy for the evaluation of infertility are unknown. For

**Effects of Ovarian Steroids on Endometrium**

Estradiol or synthetic estrogens cause a striking thickening of endometrial tissue. Both stromal and epithelial cells of the endometrium proliferate rapidly under the influence of estradiol. Estrogen increases mitotic activity and DNA synthesis in both cell types strikingly (Fig. 16-27). While promoting growth, estrogen also renders endometrial tissue responsive to progesterone by inducing the expression of progesterone receptors (PRs) in this tissue because progesterone action is dependent on previous or concurrent estrogen exposure of the endometrium.

In contrast to the proliferative effects of estrogen, progesterone action primarily gives rise to the differentiation of the endometrium. For example, progesterone can inhibit and even reverse the proliferative action of estrogen on the functionalis layer (Fig. 16-28). Moreover, progesterone action prepares the endometrium for implantation of the embryo through differentiation of both epithelial and stromal cells. Progesterone induces the production and secretion of a glycoprotein-rich substance from the epithelial cells. Progesterone also causes an increase in the stromal cell cytostasis, a process called pseudodecidualization.

**Estrogen Action**

Estrogens, the biologically potent, naturally occurring estrogens, which is secreted by the granulosa cells of the dominant ovarian follicle, acts to promote responses of the endometrium in a manner that is classical for steroid hormone action. Estradiol enters cells from blood by simple diffusion, but in estrogen-responsive cells, binding to the ER sequesters estradiol. ERs are proteins with high affinity for estradiol and other biologically active estrogens, that is, synthetic estrogens. The ER subtypes and are discussed in various chapters of this textbook. Although both ER and PR are present in the endometrium, ER seems to be the primary mediator of the estrogenic action in the endometrium. The estradiol-receptor complex, after transformational changes, is a transcriptional factor that becomes associated with the estrogen response elements of specific genes. This interaction brings about ER-specific initiation of gene transcription, which promotes the synthesis of specific mRNAs and thereafter the synthesis of specific proteins. Among the many proteins synthesized in most estrogen-responsive cells are additional ERs, as well as PRs. Thus, estradiol acts in the endometrium and in other estrogen-responsive tissues to promote the perpetuation of estrogen action and to promote the responsiveness of that tissue to progesterone.

The endometrial epithelial cells are estrogen-responsive but probably do not replicate as a result of the direct action of estradiol on the epithelial cells. Replication of human endometrial epithelial cells in culture is not increased appreciably, if at all, when estrogen is added to the medium. Further, estrogen acts on mouse uterine stromal cells to promote the synthesis of epithelial cell growth factor (see Fig. 16-27). These growth factors operate in a paracrine manner to cause increased DNA synthesis and replication in the adjacent epithelial cells. This type of paracrine arrangement may be the primary mechanism that mediates estrogen action in hormone-responsive tissues.

**Progesterone Action**

Progesterone action is the differentiation of the endometrium. The two PR isoforms, PR-A and PR-B, are both present in the human endometrium. Because PR-B but not PR-A levels in the endometrium are tightly regulated during the human menstrual cycle, PR-B is presumed to play a more important biologic role. Commonly, the cellular content of PRs is dependent on previous estrogen action. The progesterone-PR complex also promotes gene transcription, but the response to progesterone is strikingly different from that evoked by the estradiol-ER complex.

Progesterone action includes a decrease in the synthesis of ER molecules. This is one means by which progesterone (and synthetic progestins) attenuates estrogen action. Progesterone also acts to increase the rate of enzymatic inactivation of estradiol to estrone through an increase in the activity of an oxidative type 17-HSD enzyme. Progesterone-dependent transcription of a specific gene, namely 17-HSD type 2, is responsible for this enzyme activity. Progesterone also acts to increase sulfation of estrogens (estrogen sulfotransferase), another means of estrogen inactivation. Therefore, progesterone acts as an antiestrogen in at least three ways: (1) by reducing the rate of synthesis of ERs, (2) by bringing about a decrease in the tissue levels of estradiol (through conversion to estrone), and (3) by enhancing estrogen inactivation through sulfation. As in the case of estrogen action in the uterus, tissue recombination experiments using uteri of PR knockout and normal mice demonstrated that many effects of progesterone on epithelial cells are also mediated in a paracrine fashion by PRs in stromal cells but not by those in epithelial cells (see Fig. 16-28).

The most striking consequence of progesterone action is the differentiation of the endometrium. The histologic correlates of differentiation, stromal decidualization and epithelial secretion, are correlated with the presence of nuclear PRs and increased levels of circulating progesterone during the luteal phase. Molecular correlates of progesterone action with respect to differentiation include increased production of lactoferrin and glycoprotein in epithelial cells and prolactin and IGF...
Unless the ovum is fertilized within 24 hours of ovulation, it does not survive. Fertilization takes place in the ampullary (one-third distal) portion of the oviduct. Over the next 2 days, the fertilized ovum remains unattached within the tubal lumen, utilizing tubal fluids and residual attached cumulus granulosa cells to sustain nutrition and energy for early cellular cleavage. After this stage, the solid ball of cells (morula), which is the embryo, leaves the oviduct and enters the uterine cavity. Fortunately, by this time endometrial secretions under the influence of luteal progesterone have filled the cavity and bathe the embryo in nutrients. This is the first of many neatly synchronized events that mark the conceptus-uterine relationship. By 6 days after ovulation, the embryo (now a blastocyst) is ready to attach and implant. At this time, it finds an endometrial lining of sufficient depth, vascularity, and nutritional richness to sustain the important events of early placentation to follow. Just below the epithelial lining, a rich capillaryplexus has been formed and is available for creation of the trophoblasticmaternal blood interface. Later, the surrounding superficial portion of the functionalis zone, now occupying more and more of the endometrial cavity, provides a sturdy splint to retain endometrial architecture despite the invasive inroads of the burgeoning trophoblast.

Progesterone is essential for the maintenance of pregnancy. The blastocyst is dependent on progesterone produced by the corpus luteum at this time. The hCG that is secreted by the trophoblast prevents the regression of the corpus luteum by acting as a surrogate LH. This serves to maintain a continued supply of progesterone for the maintenance of pregnancy until the placental tissue itself starts to produce sufficient quantities of progesterone by 6 to 7 weeks after fertilization.

Studies in experimental and domestic animals have demonstrated that there must be synchronous development of the embryo and endometrium for normal implantation and development to occur. In laboratory animals, there is a discrete window for implantation, which in some species lasts only a matter of hours. The receptive phase of the endometrium is the temporal window of endometrial maturation during which the trophoectoderm of the blastocyst can attach to the endometrial epithelial cells and subsequently proceed to invade the endometrial stroma. In the study of human endometrial receptivity, a key question is the determination of the temporal window of implantation. Only factors expressed during this temporal window can be considered either markers or functional mediators of the receptive state.

The window of uterine receptivity can be inferred from what has been learned from transfer of embryos to uteri of women primed with exogenous estrogen and progesterone preparations. There is a distinct window for embryo transfer leading to implantation, which spans endometrial cycle days 16 to 20. Presumably, the actual window of implantation follows this window of transfer because embryos need to develop further from the four-cell to eight-cell stage to the blastocyst stage before initiation of attachment and frank invasion.

The window of implantation in the humans was estimated to be between days 20 and 24 of the cycle using serial measurements of serum hCG as a marker of initial embryonic-maternal interaction. Thus, it appears that the window of implantation in the human is relatively wide (approximately 4 days). These observations agree with the earlier morphologic data from Hertig and colleagues.

Mechanism of Menstruation

In the absence of pregnancy, failure of the appearance of hCG, despite otherwise appropriate tissue reactions, leads to the vasomotor changes associated with estrogen-progesterone withdrawal and menstrual desquamation. A program of endometrial remodeling is initiated; alterations in the extracellular matrix and infiltration of leukocytes lead to hypoxia-reperfusion injury and sloughing of the functionalis, followed by activation of hemostatic and regenerative processes. The main histologic features of the premenstrual phase are degradation of the stromal reticular network, stromal infiltration by polymorphonuclear and mononuclear leukocytes, and secretory exhaustion of the endometrial glands, whose epithelial cells now have basal nuclei. The endometrium shrinks preceding menstruation, in part as a result of diminished secretory activity and the catabolism of extracellular matrix.

The most prominent and final effect of progesterone and estrogen withdrawal is menstruation. The window of uterine receptivity can be inferred from what has been learned from transfer of embryos to uteri of women primed with exogenous estrogen and progesterone preparations. There is a distinct window for embryo transfer leading to implantation, which spans endometrial cycle days 16 to 20. Presumably, the actual window of implantation follows this window of transfer because embryos need to develop further from the four-cell to eight-cell stage to the blastocyst stage before initiation of attachment and frank invasion.

Control of Endometrial Function Employing Synthetic Hormones

The fertility potential of a woman is primarily determined by the biologic quality of her oocytes, reflected in part by the capacity of the fertilized ovum to divide at an optimal rate and contain a normal chromosomal complement. This biologic quality of the oocyte declines sharply after the age of 35. The biologic potential of the endometrium for successful implantation, however, remains intact even at advanced ages. Oocyte donation from a fertile woman and in vitro fertilization of these donor eggs with the recipient's male partner's sperm, followed by embryo transfer into the uterine cavity of the recipient woman who does not have functioning ovaries (e.g., premature ovarian failure), have been used successfully as a therapeutic strategy to treat infertility. This clinical application has provided unique opportunities to examine the hormonal requirements for endometrial maturation. A number of hormone replacement protocols have been proposed, and many pregnancies have resulted from donor oocytes in women with ovarian failure. The success of these procedures has averaged about 50% (pregnancy rate) per embryo transfer.

The degree of endometrial differentiation in response to exogenous hormones has been evaluated by histologic analysis of endometrial biopsy specimens. The epithelial elements exhibit delayed maturation early during progesterone administration on days 20 to 22, but catch up by day 26. Despite this apparent dysynchrony, the pregnancy rate in these patients with donor oocytes is higher than in conventional in vitro fertilization.

The majority of infertility specialists currently use step-up administration of oral micronized estradiol in 2-, 4-, and 6-mg daily doses followed by 4 to 6 mg of estradiol combined with daily intramuscular progesterone (50 mg) to promote the secretory transformation. Serum estradiol levels in these subjects during the replacement "fulfloch" phase reach preovulatory peak levels of 600 to 1000 pg/mL. Intramuscular injection of 50 mg/day of progesterone in oil generates serum levels of progesterone greater than 10 ng/mL. The length of exposure to progesterone, but not absolute plasma progesterone concentrations achieved after adequate priming...
of the endometrium with estrogen, is a key factor for the development of uterine receptivity. Thus, the exogenous administration of only estradiol and progesterone is sufficient to prepare the endometrium for implantation in the absence of ovarian function. This observation further underscores the essential roles of these steroids in uterine physiology.
APPROACH TO THE WOMAN WITH REPRODUCTIVE DYSFUNCTION

Reproductive dysfunction in an adult woman is most often manifest by disruption of cyclic, predictable menses. Efficient diagnosis of the underlying disorder requires a thorough understanding of female reproductive physiology and pathology and an accurate history and physical examination. Without a critical analysis of clinical findings based on thorough knowledge of normal and abnormal reproductive function, the application of predetermined algorithms of laboratory testing causes unnecessary use of hormone measurements or imaging studies and delays diagnosis.

History

An essential tool for the evaluation of a woman with a reproductive disorder is a carefully recorded history. The history should be obtained from the patient with the aim of assessing the biologic effects of each of the various hormones. Recording the details of pubertal development as a starting point for the rest of the particular symptoms provides critical clues to the etiology of certain reproductive disorders. For example, anovulation manifest by irregular uterine bleeding associated with the polycystic ovary syndrome (PCOS) most often begins during the pubertal years. The onset of gradually progressing hirsutism around puberty is suggestive of nonclassical adrenal hyperplasia or PCOS. In these cases, measurement of serum 17-hydroxyprogesterone may help to differentiate nonclassical adrenal hyperplasia from PCOS (see later). The appearance of hirsutism before puberty or several years after normal pubertal development should alert the clinician to the possibility of ovarian or adrenal neoplasms. The sudden (versus gradual) onset of hirsutism at any age or the presence of virilization should prompt the physician to rule out steroid-secreting ovarian or adrenal tumors. Most women with symptomatic endometriosis suffer from severe episodes of painful menses (dysmenorrhea), which start during pubertal years.

Evaluation of female reproductive function starts with a detailed history of the menses. For example, PCOS is extremely unlikely without a long-standing history of irregular periods since the menarche. By the same token, history of a period of cyclic, predictable menses before the onset of menstrual irregularities should draw attention to hypothalamic or other causes of anovulation. The current frequency, regularity, length, and quantity of uterine bleeding should be carefully recorded for several reasons. First, this information reflects tightly regulated interactions of several tissues, including the hypothalamus, pituitary, ovaries, and endometrium. Second, regular, predictable menses imply ovulation. Third, defining the type of menstrual irregularity may help with the diagnosis of the underlying etiology. For example, prolonged amenorrhea in a thin and estrogen-deficient woman suggests anovulation of hypothalamic origin. Infrequent periods of varying duration and amount of blood loss in a well-estrogenized overweight woman, on the other hand, suggest a primary ovarian dysfunction such as PCOS. It should be kept in mind that anovulation in a thin but well-estrogenized woman may also be due to PCOS. Regular but heavy and prolonged menses with intermittent spotting may be due to uterine anatomic disorders such as adenomyosis or leiomyomas. Finally, neoplastic disorders of the endometrium including endometrial polyps, hyperplasia, or malignancies may be manifest by any pattern of irregular bleeding. The combination of vaginal ultrasonography and endometrial biopsy is extremely sensitive for the diagnosis of endometrial neoplasia.

Disruption of cyclic and predictable menses is a common and alarming symptom that initially brings the patient to the clinician. After a careful evaluation of the menstrual symptoms, the clinician should identify other obvious symptoms of endocrine disorder underlying irregular periods. Pregnancy is the most common cause of amenorrhea (and possibly any other menstrual irregularity) in a woman of reproductive age. In a woman presenting with amenorrhea or any other menstrual irregularity, normal pregnancy, ectopic pregnancy or gestational trophoblastic disease must be excluded at the onset. Careful evaluation of any past reproductive history, as well as of the patient’s sexual activity and contraceptive practices, can provide useful indications of the likelihood of pregnancy. Furthermore, the reproductive history may suggest the possibility of Sheehan’s syndrome of postpartum pituitary necrosis if menses did not resume after a delivery complicated by significant hemorrhage. In such instances, evidence of adrenal and thyroid insufficiency should be sought. A classical symptom of Sheehan’s syndrome is the absence of lactation after delivery related to prolactin deficiency.

Amenorrhea is traditionally categorized as either primary (no history of mensturation) or secondary (cessation of menses after a variable time). The causes of primary amenorrhea are diverse and discussed extensively in Chapter 19 and Chapter 21. Although the distinction between primary and secondary amenorrhea is useful for identifying the mechanism of disease and differential diagnosis, the clinician should be aware that some disorders can initially present with either primary or secondary amenorrhea. For example, most women with gonadal dysgenesis have primary amenorrhea, but some patients have residual follicles and ovulate, and in these women with partial gonadal dysgenesis some menstruation and rare pregnancies may occur before the cessation of ovarian function. Patients with PCOS usually have secondary amenorrhea but occasionally have primary amenorrhea.

Secondary amenorrhea is most often due to chronic anovulation, which can be broadly categorized as (1) hypothalamic dysfunction, (2) galactorrhea-associated, (3) ovarian failure, (4) androgen excess, (5) chronic illness, and (6) primary uterine disease (e.g., intrauterine adhesion formation after a postpartum curettage). Establishing any association of secondary amenorrhea with any life events is extremely useful. Strenuous exercise is often associated with amenorrhea. Weight loss often precedes or accompanies secondary amenorrhea and has been suggested as evidence of hypothalamic dysfunction. An unusual dietary history may be suggestive of bulimia or anorexia nervosa. A history of dilatation and curettage, postpartum endometritis, or disseminated tuberculosis with absent to scant menses should suggest the possibility of intrauterine adhesion.

The presence of any signs or symptoms of estrogen deficiency, including painful intercourse, atrophic vagina, emotional lability, and vasomotor instability, should suggest anovulation of a central nature with low concentrations of circulating gonadotropins (hypogonadotropic hypogonadism) or ovarian failure with elevated gonadotropins (hypergonadotropic hypogonadism).

Galactorrhea in the absence of a recent history of pregnancy is suggestive of a host of diagnostic possibilities and is frequently a manifestation of excessive prolactin secretion, although it may be a result of increased sensitivity of breast tissue to the hormones necessary for milk production. This history frequently reveals drug ingestion as the cause. Various drugs (including several psychotropic agents and antihypertensive agents as well as oral contraceptives) have been implicated. Primary hypothyroidism may be associated with precocious puberty with galactorrhea in the child and with amenorrhea, galactorrhea, or both in the adult woman. A history of excessive nipple manipulation or chest wall disease should be elicited and may well be the cause of galactorrhea. Prolactinomas, the prolactin-secreting adenomas of the pituitary, are a common etiology of galactorrhea related to abnormally high serum levels of prolactin.
Physical Examination

The quantity and distribution of excessive hair growth should be considered in light of the familial history. Hypertrichosisexcessive growth of hair on the extremities, the head, and the backmust be distinguished from true hirsutism, which is the development of facial hair, chest hair, and a male escutcheon with or without signs of virilization in response to increased production of or sensitivity to biologically active androgens. Some degree of hypertrichosis is not uncommon in women of Mediterranean descent, whereas the occurrence of any facial hirsutism in the relatively hairless Asian woman may require thorough investigation. Hirsutism is best documented and quantified with the help of photographs. Virilization is characterized as thickening of voice, severe cystic acne, hair loss, increased muscle mass, and clitoromegaly and implies a more severe degree of androgen excess than that found with hirsutism. The syndrome of complete androgen insensitivity is characterized by sparse to absent pubic and axillary hair because of resistance to androgen.

A careful inspection of the breasts is essential for a thorough physical examination. Classification of the stage of breast development according to the method of Marshall and Tanner is a convenient and valuable adjunct. Whether the breasts appear to have decreased in size recently (e.g., severe androgen excess), whether the areolae are well formed and pigmented (as they are in pregnancy), and whether a discharge (e.g., galactorrhea) can be expressed should be assessed.

A woman with PCOS who has never ovulated or taken a progestin-containing medication may have Tanner stage 4 breast development related to adequate estrogen production, whereas the progression to Tanner stage 5 requires exposure to progesterone through either ovulation or ingesting a progestin (e.g., administration of oral contraceptives). See Chapter 22 for a detailed description and hormonal basis of Tanner staging of breast development.

The vulva, vagina, and cervix also represent sensitive indicators of sex steroid action. Because sensitivity of the genital skin and mucosa to androgen decreases with time from the early stages of fetal development to adulthood, the extent of any virilization can be helpful in suggesting the timing of androgen exposure. The most profound androgenic effects, such as posterior labial fusion with or without formation of a penile urethra, are generally observed in patients exposed to androgens during the first trimester (12 weeks) of pregnancy. Such findings have been described in patients with virilizing congenital adrenal hyperplasia, true hermaphroditism, and drug-induced virilization. Significant postnatal clitoromegaly, on the other hand, requires marked hormonal stimulation and, in the absence of significant exogenous steroids, strongly implicates an androgen-secreting tumor. Measurement of the base of the clitoris versus its length is a more accurate method for the determination of androgen-dependent clitoral growth. A clitoral index, defined as the product of the sagittal and transverse diameters at the base, greater than 35 mm falls outside the 95% confidence interval.

The vagina and uterine cervix are the most sensitive indicators of estrogen action. Under the influence of estrogen, the vaginal mucosa progresses during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a dull, gray-pink rugated surface with copious, thick secretions. Well-estrogenized vaginal mucosa with stretchable cervical mucus (spinnbarkeit) may be indicative of the proliferative phase of the menstrual cycle in an ovulatory woman or extraovarian estrogen formation in an anovulatory woman with PCOS. The biologic activity of estrogen can also be quantified by vaginal cytology.

To summarize, irregular uterine bleeding is a common symptom that brings the woman with reproductive dysfunction to the physician’s office. Various disorders of the hypothalamus, pituitary, ovaries, or uterus or other issues that affect reproductive function may be responsible for this alarming symptom. When pregnancy is ruled out, a detailed history and physical examination should be carefully recorded. In particular, the physician should pay attention to the salient features in the history and biologic indicators of hormone action at target tissues during the physical examination. Analysis of these findings most often leads to a tentative diagnosis. This diagnosis should then be confirmed with laboratory testing.
DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

Chronic Anovulation

Chronic anovulation is one of the most common gynecologic problems encountered by the practitioner. These women may present with secondary amenorrhea, infrequent uterine bleeding (oligomenorrhea), or irregular episodes of excessive uterine bleeding. Infertility is an obvious consequence of chronic anovulation.

One group of anovulatory patients are estrogen-deficient. Common findings in this group include hypothalamic anovulation, galactorrhea-hyperprolactinemia (e.g., hypothyroidism, prolactinoma, nonfunctioning pituitary tumor), and premature ovarian failure in a woman of reproductive age. These patients are usually amenorrheic and deficient in estrogen. One serious consequence is bone loss giving rise to osteopenia and osteoporosis. If possible, the underlying cause should be corrected. Hormone replacement should be provided if ovulation cannot be restored.

Women with androgen excess constitute the second major group of anovulatory patients. A serious consequence of anovulation in this group is the greater risk for carcinoma of the endometrium because of unopposed action of estrogen formed continuously in extravarian tissues. The most common disorder of the ovary associated with androgen excess and anovulation is PCOS. There is a new appreciation for the role of insulin resistance in this condition and for the clinical effects of insulin resistance and hyperandrogenism on the risks of developing cardiovascular disease and diabetes mellitus. The clinician must recognize the long-term impact of PCOS and undertake therapeutic management of these anovulatory patients to avoid unwanted consequences. The clinician should also develop a plan with the patient to address long-term complications of unopposed estrogen formation associated with PCOS (e.g., endometrial neoplasia). Oral contraceptives or periodic progesterin supplementation may be provided to prevent endometrial hyperplasia and cancer.

For practical purposes, the following five broad categories include the majority of the etiologic factors giving rise to chronic anovulation in a woman of reproductive age:

1. Hypothalamic anovulation.
2. Hyperprolactinemia.
3. Androgen excess.
4. Premature ovarian failure.
5. Chronic illness (e.g., hepatic or renal failure, acquired immunodeficiency syndrome).

There may be multiple mechanisms responsible for anovulation in chronic illness. Effective treatment of the primary illness may restore normal menses. Alternatively, anovulatory bleeding may be managed by exogenous hormones in these chronically ill patients as outlined further subsequently. The following are detailed descriptions of specific disorders that cause chronic anovulation in a reproductive-age woman.

Hypothalamic Anovulation

Production of LHRH in the neurons of the arcuate nucleus in the hypothalamus and its secretion into the portal vessels in the median eminence in a pulsatile fashion are necessary for the production and secretion of FSH and LH from the pituitary. LHRH neurons depolarize and release LHRH at critical pulse frequencies of 60 to 200 minutes during specific phases of the menstrual cycle to increase or decrease secretion of FSH and LH. Variations in LHRH pulse frequency are achieved, at least partially, by gonadal steroid feedback. Local neuroendulators in the brain, including norepinephrine, dopamine, and -endorphin, mediate the actions of gonadal steroids on the hypothalamus (see Fig. 16-4).

Any disorder of the central nervous system that interferes with this intricate process can thus cause functional hypothalamic anovulation. Some of these disorders may be demonstrated by defined genetic or anatomic evidence such as isolated gonadotropin deficiency (with or without anosmia), infection, suprasellar tumors (pituitary adenomas, craniopharyngioma), and head trauma. These genetic and anatomic disorders affect the function of the hypothalamus, and some of them may be ruled out by history, physical examination, and imaging of the head (Table 16-3).

The most commonly observed form of hypothalamic anovulation, however, is not associated with a demonstrable neuroanatomic finding. This common form is called functional hypothalamic anovulation because it is presumed to involve aberrant but reversible regulation of otherwise normal neuroendocrine pathways. Changes in lifestyle usually result in the return of normal ovulatory cycles. Functional hypothalamic anovulation may be associated with excessive exercise, abrupt weight loss, and emotional distress. It is hypothesized that these stress factors cause anovulation by affecting brain function and the LHRH pulse generator. Other causes of hypothalamic anovulation, however, are relatively rare, and these are covered in detail in other chapters of this textbook (Chapter 8 and Chapter 24).

Functional Hypothalamic Anovulation

Anovulation of hypothalamic origin is characterized by estrogen deficiency and low levels of gonadotropins. No identifiable genetic or anatomic disorders are present in the majority of these patients. The concept of functional hypothalamic anovulation was first postulated 60 years ago as the failure of the hypothalamic-pituitary pathways to release LH from the anterior pituitary. Since then, many clinical studies have confirmed this idea. The data accumulated thus far suggest that the common underlying defect is an alteration in the pulsatile secretion of LHRH. Intriguingly, it has been shown in patients with this disorder that diverse etiologic factors such as malnutrition or caloric restriction, depression or psychogenic stress, excessive energy expenditure related to exercise, or combinations of these have preceded the onset of functional hypothalamic anovulation. Heightened awareness of diet and exercise and unrealistic expectations with respect to the body image of women have most likely contributed to the epidemic of this disorder.

Diagnosis of Functional Hypothalamic Anovulation

Patients with functional hypothalamic anovulation most commonly present with secondary amenorrhea characterized by the absence of menstrual cycles for more than 6 months without evidence of an organic disorder. It should be emphasized once again that the diagnosis of hypothalamic anovulation is one of exclusion. There are many neuroanatomic or genetic disorders that can mimic functional hypothalamic anovulation (see Table 16-3). Thus, a careful and complete diagnostic evaluation is essential to make this diagnosis.

Women with functional hypothalamic anovulation usually present with a history of regular menses for a period of variable length after menarche. Thereafter, this period of normal ovulatory function (by history) is interrupted by anovulation usually manifest by secondary amenorrhea. It should be emphasized that women with functional hypothalamic anovulation may occasionally present with primary amenorrhea.

Women with functional hypothalamic anovulation are typically normal to thin in body weight, driven, and involved in high-stress occupations. The occupation of the patient (e.g., a ballerina or competitive athlete) may be an extremely important clue. A detailed interview may reveal a variety of emotional crises or stressful events (e.g., divorce, death of a friend) preceding the onset of amenorrhea. During the interview, additional environmental and interpersonal factors may become evident, including academic pressure, social maladjustment, and psychosexual problems. When evaluating the patient, one should take note of the current diet regimen, the use of any sedatives or hypnotics, and the rigorousness of the patient's exercise habits. Despite a careful interview, a history of stress, excessive physical exercise, or an eating disorder may not be readily revealed in some women with functional hypothalamic anovulation. These women usually do not complain of hot flashes, which, on the other hand, are commonly observed in ovarian failure.
The physician should exclude a possible hyperprolactinemic etiology (e.g., prolactinoma, hypothyroidism) and evidence of androgen excess (e.g., PCOS) during the physical examination. These women have normal secondary sexual characteristics. The pelvic examination usually shows a thinning vaginal mucosa accompanied by scant to absent cervical mucus with a normal to small uterus, all evidence of estrogen deficiency. Signs

of a well-estrogenized vagina and cervix observed during the physical examination make the diagnosis of hypothalamic anovulation unlikely.

Laboratory tests are obtained to exclude other causes of anovulation and secondary amenorrhea. LH and FSH levels should be obtained. Gonadotropin levels are usually lower than the normal values ordinarily found in the early follicular phase. TSH and prolactin levels are obtained to rule out hypothyroidism and hyperprolactinemia. The progestin challenge test (medroxyprogesterone acetate at 10 mg/day for 10 days) shows either a small spotting episode or absence of withdrawal uterine bleeding in most patients. This confirms that there is a scant or absent estrogenic effect on the endometrium because circulating estradiol levels are typically in the low or early follicular phase range. Measurement of the serum estradiol level is not necessary. Because a suprasellar or large pituitary tumor is in the differential diagnosis, a magnetic resonance imaging (MRI) scan of the head is necessary to rule this out. Imaging of the head is especially important if amenorrhea develops suddenly or is associated with a neurologic sign, both of which make the presence of a tumor more likely.

**Pathophysiology of Functional Hypothalamic Anovulation**

A key observation in functional hypothalamic anovulation is the absence of increased gonadotropin secretion despite the lack of inhibitory factors of ovarian origin, such as estradiol

and inhibit. The secretory pattern of LH is abnormal. The causative factor in women with this type of anovulation is a slowdown in the frequency of pulsatile LHRH secretion. Frequent peripheral blood samples were obtained from these patients to quantify the episodic secretion of LH, which provided an indirect assessment of endogenous LHRH secretion. There is considerable variability in the amplitude and frequency of the pulsatile LH secretion in functional hypothalamic anovulation. When the LH secretory patterns are compared with that of the follicular phase of the menstrual cycle, a characteristic abnormality in the LH pulse frequency and amplitude and on occasion a regression to a pronounced variability similar to what is seen in the prepubertal pattern are present. In severe cases, the frequency and amplitude of LH pulses are markedly reduced. These LH patterns also suggest that LHRH pulsatile secretion is not altered to the same degree in each individual. During the recovery phase of hypothalamic anovulation, a reversal of the LHRH-LH secretory pattern is often present, characterized by a sleep-associated increase in LH amplitude. The response of the pituitary gland to LHRH with respect to production and release of gonadotropins is not impaired in functional hypothalamic anovulation. Intravenous pulsatile LHRH administration can regulate levels of LH and FSH.

Norepinephrine, dopamine, and serotonin produced in the brain have been shown to modulate LHRH or LH release in animal studies. Patients receiving medication that alters these neurotransmitters (e.g., sedatives, antidepressants, stimulants, and antipsychotics) have presented with abnormalities in their menstrual cycles. Thus, it can be noted as circumstantial evidence that disruptions of neural pathways can alter LHRH release in the human. From these observations, it appears that activation of the noradrenergic neurons principally stimulates release of LHRH, whereas dopaminergic and serotoninergic neurons can stimulate
or inhibit LH-RH-LH secretion. A number of neuropharmacologic agents have been used as probes to determine whether LH-RH-LH secretion can be normalized. For example, metoclopramide blocks the action of dopamine. A metoclopramide injection results in a prompt increase in LH secretion in patients with functional hypothalamic anovulation. These studies suggest enhanced dopaminergic activity in functional hypothalamic anovulation. It should be emphasized, however, that chronic administration of dopamine antagonists (e.g., haloperidol, metoclopramide) may also cause anovulation.

Another group of substances that have inhibitory influences on LH-RH secretion are endogenous opioid peptides. Blockage of endogenous opiate receptors by the administration of naloxone, an opiate antagonist, to women with this disorder caused an increase in the frequency and amplitude of pulsatile LH release. Gonadotropin secretion resumes if the activity of the opiate receptor is blocked by long-term naloxone use in these anovulatory patients, and ovulatory function may even be regained in some cases. These studies suggest that there is an overall increase in endogenous opiate activity, which can reduce pulsatile LH secretion in functional hypothalamic anovulation.

Reproductive function may be disrupted by chronic exposure to stress. In fact, activation of the pituitary-adrenocortical system is a common response in patients with chronic stress. In functional hypothalamic anovulation, stressors such as exercise or emotional stress can chronically activate the hypothalamic-pituitary-adrenal axis. Daytime cortisol levels are markedly elevated, and the pituitary response to corticotropin-releasing hormone (CRH) is blunted. The stress response is associated with increased secretion of CRH, adrenocorticotropic hormone (ACTH), cortisol, prolactin, oxytocin, vasopressin, epinephrine, and norepinephrine.

The association between emotional or physical stress and disruption of the reproductive function of the hypothalamus is complex and involves several mechanisms. In the animal model, CRH seems to be an important factor in the inhibition of LH-RH pulsatility. This inhibitory effect can be prevented by coadministration of a CRH antagonist or reversed by the opiate antagonist naloxone, which suggests that the action of CRH is mediated, in part, by activation of the opioidergic system. Moreover, ACTH administration blocks the pituitary response to LH-RH at the pituitary level. In addition, another stress hormone, oxytocin, can inhibit hypothalamic LH-RH secretion. In summary, overproduction of CRH and other stress-related hormones in the brain and activation of the pituitary-adrenocortical system by chronic stress seem to play causative roles in the inhibition of gonadotropin secretion in functional hypothalamic anovulation.

Hypothalamic Anovulation and Exercise

Regular vigorous exercise can lead to menstrual disturbances, a delay in menarche, luteal phase dysfunction, and secondary amenorrhea. Thirty percent of adolescent ballet dancers have problems with the progression of puberty. The mean age of menarche is delayed until 15. In fact, advancement of pubertal stages seems to coincide with times of prolonged rest or following recovery from an injury. The intensity, length, and type of the sport determine the severity of the disease. Activities associated with an increased frequency of reproductive dysfunction are those that favor a lower body weight and include middle-distance and long-distance running, competitive swimming, gymnastics, and ballet dancing.

Competitive athletes show endocrine abnormalities in the central nervous system consistent with those in other forms of functional hypothalamic anovulation. These include elevations on central CRH and endorphin levels.

The management of exercise-related anovulation is dependent on the patient’s choices and expectations. Side effects such as osteoporosis and delay of puberty must be discussed at length with the patient. Decrease in exercise level and behavioral modification may be sufficient for the return of ovulatory function. Hormone replacement should be provided if sufficient results are not achieved. A low-dose oral contraceptive is a suitable option for women of reproductive age.

Hypothalamic Anovulation Associated with Eating Disorders

Two common eating disorders associated with hypothalamic dysfunction are anorexia and bulimia. In anorexia nervosa, there is an extreme loss of weight (weight decrease of greater than 25% of original body weight) and a distorted body image accompanied by a striking fear of obesity. Bulimia is a related disorder characterized by alternating episodes of binge eating followed by periods of food restriction, self-induced vomiting, or excessive use of laxatives or diuretics. About 90% to 95% of these patients are female. Most patients with female eating disorders anorexia and bulimia are from middle-class or upper-middle-class families. The incidence of classical anorexia nervosa is about 1 per 100,000 in the general population. Among high school and college female students, bulimia, however, is fairly common (2%). The incidence of anorexia nervosa peaks twice during the teen years at ages 13 and 17. Bulimia usually begins at a later age, between 17 and 25 years. Anorexia nerva has an extremely high mortality of 9% and is a true medical emergency. Death may be secondary to cardiac arrhythmia, which may be precipitated by diminished heart muscle mass and associated electrolyte abnormalities. These patients are also at increased risk for suicide.

Gonadotropin secretion in anorexic women exhibits a prepubertal pattern that is similar to other forms of hypothalamic anovulation. Transitional patterns of LH secretion are seen when there are moderate degrees of weight recovery and there is a normal or supranormal response to LH-RH. Anovulation can persist in up to 50% of anorexic patients even after achieving normal weight. Both anorexic and bulimic patients exhibit hyperactivation of the hypothalamic-pituitary system. Although the diurnal variation is maintained, there is a persistent hypersecretion of cortisol throughout the day. Cushionoid features, however, are not present, in part because of mild hypercortisolism and also a reduction of peripheral glucocorticoid receptors. Levels of both CRH and endorphin are increased in the central nervous system.

In anorexia nervosa, basal metabolism is decreased because peripheral conversion of thyroxine (T4) to biologically potent triiodothyronine (T3) is decreased. Instead, T3 is converted to reverse T3, an inactive isomer. This alteration is also observed in severely ill patients and during starvation. Anorexics also have partial diabetes insipidus and are unable to concentrate urine appropriately because of the impaired secretion of vasopressin.

Both anorexia nervosa and bulimia are extremely difficult to treat. The most accepted approaches include individual psychotherapy, group therapy, and behavior modification. Patients with eating disorders should have psychiatric consultation and follow-up. This helps with both the diagnosis and treatment. In patients who weigh less than 90% of their ideal body weight, chronic hospitalization is recommended. The treatment of anorexia nervosa includes nutritional therapy; other consequences are estrogen deficiency and generalized effects of malnutrition. Hormone replacement in the form of an oral contraceptive should be provided until ovulatory function is achieved.

Treatment and Management of Functional Hypothalamic Anovulation

Treatment of chronic anovulation resulting from central nervous system hypothalamic disorders should be directed at reversal of the primary cause (e.g., stress management, reduction of exercise, or correction of weight loss). The successful treatment of this disease state is underscored because these women are prone to the development of osteoporosis. For a considerable number of patients, spontaneous recovery of menstrual function takes place after a modification of lifestyle, psychological guidance, or accommodation to environmental stress. Therefore, the initial treatment should be directed to a change in lifestyle and tailored to the individual patient. For individuals who remain amenorrheic, periodic assessment of reproductive status (every 4 to 6 months) is prudent. If anovulation persists for more than 6 months or if reversal of the primary cause is not practical (e.g., professional athletes, ballerinas), a major concern is the long-term effect of hypogonadism, especially on bone metabolism. In addition to estrogen deficiency, IGF-I deficiency, hypercortisolism, or nutritional factors may all contribute to bone loss in this disorder. Unfortunately, epidemiologic data on the risk of fractures and the benefits of hormone replacement are scant.

On the basis of studies of reproductive-age women who have been ovariectomized or who have undergone treatment with LH-RH agonist for endometriosis, bone density would be expected to decrease significantly even within the first 6 months of amenorrhea. Because these patients are often reluctant to take medications, serial bone density studies of the lumbar spine and femur may be necessary to convince them of the necessity to begin estrogen replacement therapy. If the patient is not at risk for thromboembolism and does not smoke cigarettes, a low-dose combination oral contraceptive is a reasonable replacement option. Alternatively, a combination of conjugated estrogens (0.625 mg) and medroxyprogesterone acetate (2.5 mg) daily may be administered to provide estrogenic support.
The progestin (medroxyprogesterone acetate) is added solely to prevent endometrial hyperplasia.

If the patient desires ovulation in order to achieve pregnancy, the most physiologic approach is ovulation induction with pulsatile LHRH. This is currently the best physiologic means of induction because the cause of the anovulatory state is the decrease in endogenous LHRH secretion. Pulsatile intravenous LHRH, 5 µg every 90 minutes, was shown to be effective. Monitoring of serum estradiol levels or follicular development can be minimized because the ovarian follicular response and gonadotropin output mimic the natural menstrual cycle. In these patients, either continuation of pulsatile LHRH or human chorionic gonadotropin, 1500 units intramuscularly every 3 days for a total of four doses, can support the corpus luteum function. The intravenous LHRH treatment results in ovulation rates of approximately 90%, pregnancy rates up to 30%, and hyperstimulation rates of less than 1% per treatment cycle. Because the intravenous LHRH pump is not a practical choice for many women, an alternative strategy is the use of subcutaneous recombinant FSH for the development of one to three follicles and the induction of ovulation with intramuscular hCG followed by luteal support using either intramuscular hCG or progesterone in oil.

**Hyperprolactinemia**

**Prolactin and Reproductive Function**

**Structure and Function of Prolactin**

Prolactin is secreted from the anterior pituitary and is essential for lactation. It is a 198-amino-acid polypeptide with a molecular mass of 22 kd. Its structure is remarkably similar to that of growth hormone. The secondary structure is folded into a globular shape, and three disulfide bonds connect the folds. The amino acid sequences among prolactin, growth hormone, and human placental lactogen show an impressive degree of homology. Prolactin is produced in the lactotroph of the anterior pituitary. In the human pituitary, lactotrophs constitute 10% to 30% of the total pituitary cell mass and are located primarily in the posterior and lateral aspects of the adenohypophysis.

**Regulation of Prolactin Secretion**

A process that includes activation of a number of signaling pathways and gene transcription regulates prolactin synthesis and release. Prolactin is synthesized and packaged into secretory granules and is stored in the cytoplasm pending its release. Exposure to secretagogues, lactotrophs release prolactin from a readily releasable pool, and newly synthesized prolactin replenishes the releasable pool as well as a storage pool. Dopamine, thyrotropin-releasing hormone (TRH), and estradiol were shown to regulate transcription of the prolactin gene.

Dopamine is a well-characterized inhibitor of prolactin secretion. Dopamine release is achieved through the portal vessels of the tuberoinfundibular dopaminergic system. Cell bodies of these neurons are located in the arcuate nucleus, and the axons extend to the median eminence. The biosynthesis and release of dopamine occur within the axonal terminals, which are adjacent to the portal capillaries. Thus, dopamine reaches the lactotroph by way of the portal circulation. Dopamine binds to its receptors on the lactotroph with resultant inhibition of prolactin secretion. Dopamine concentrations are higher in the central portal vessels than in the lateral vessels. The availability of lower amounts of circulating dopamine in the lateral aspects of the pituitary may account for the common presence of prolactinomas in the peripheral portions of the anterior pituitary.

In contrast to dopamine, TRH stimulates the release of pituitary prolactin. TRH stimulates prolactin gene transcription within minutes because specific TRH receptors are present on the lactotroph. The result is an increase in mRNA accumulation in the cytoplasm and acute release of translated prolactin protein. Although the prolactin- and TSH-releasing actions of TRH are distinct, circulating levels of TSH and TSH influence prolactin release in response to TRH stimulation. Subnormal serum levels of TSH and T3, as in the case of primary hypothyroidism, increase TRH-induced prolactin release, whereas higher than normal serum levels of T4 and T3 inhibit prolactin mRNA accumulation and release of protein. Unlike TSH, estradiol amplifies the stimulatory effects of TRH on prolactin release. Thus, a number of factors, including thyroid hormones, estradiol, and antithyroid medications, can modify the effects of TRH on prolactin release.

Estrogen stimulates the secretion of prolactin from the anterior pituitary in a dose- and time-dependent fashion. Administration of synthetic or natural estrogen increases blood prolactin levels in both premenopausal and postmenopausal women. Estrogen increases prolactin synthesis and release by direct stimulation of prolactin gene transcription, lactotroph proliferation, increased TRH receptors, and a decrease in dopaminergic activity. The stimulatory effect of estrogen on prolactin secretion in vivo is usually subtle, as illustrated by mild increases in prolactin levels in women taking oral contraceptives.

**Prolactin Action**

The prolactin receptor belongs to the cytokine receptor superfamily that also includes the growth hormone receptor. Human prolactin, on the other hand, does not bind to the human growth hormone receptor. There are long and short isoforms of the prolactin receptor. Both isoforms can bind prolactin with high affinity and can stimulate prolactin-responsive cells to grow. The functions of prolactin and growth hormone receptors are mediated, at least in part, by two families of signaling molecules: Janus kinases (JAKs) and signal transducers and activators of transcription (STATs).

The prolactin receptor is widely distributed; in some instances in the same tissue in which the ligand prolactin is also expressed. The receptor has been found in the hypothalamus, pituitary gland (both normal and neoplastic), gastrointestinal tract, prostate, bone, decidua, fetal membranes, and Leydig cells as well as in normal and neoplastic breast. The expression of prolactin and its receptors in diverse tissues (pituitary gland, gastrointestinal tract, prostate, decidua, and the breast) is suggestive of the presence of autocrine and paracrine interactions in these tissues. Although a classical endocrine negative feedback cycle between prolactin and pituitary gonadotropin and its target tissues has not been described, these potential local mechanisms within target tissues may play important roles in the regulation of prolactin biosynthesis and action.

**Hyperprolactinemia**

Galactorrhea associated with hyperprolactinemia is one of the most common entities associated with chronic anovulation or secondary amenorrhea, or both. The impaired inhibition of prolactin secretion because of decreased dopamine production.

- ACTH, adrenocorticotropic hormone; CNS, central nervous system; GH, growth hormone.

Hyperprolactinemia results in functional and secondary hyperprolactinemia, such as that caused by psychotropic medications. Another common cause of hyperprolactinemia is hypothyroidism associated with overproduction of TRH, which is a known inducer of prolactin secretion. The most common neuroanatomically demonstrable cause of hyperprolactinemia is a prolactin-secreting adenoma or prolactinoma. The processes that lead to the elevation of prolactin are numerous and can be found in Table 16-4.

Hyperprolactinemia Induced by Medications

A large number of medications impair dopaminergic inhibition of prolactin and give rise to hyperprolactinemia. The drugs that block synthesis, metabolism, reuptake, or receptor binding of dopamine reduce dopamine availability and result in the hypersecretion of prolactin (see Table 16-4). Conversely, drugs that enhance dopamine biosynthesis or dopamine agonists suppress the release of prolactin. Galactorrhea, therefore, is a relatively common complication in patients treated with phenothiazines, metoclopramide, reserpine, methyldopa, or similar agents.

Menstrual irregularities or amenorrhea often develops in these patients, reflecting the importance of neurotransmitters and hyperprolactinemia in the regulation of LHRH secretion and impairment of ovarian function.

Hyperprolactinemia and Primary Hypothyroidism

Hyperprolactinemia and anovulation may be associated with primary hypothyroidism. Enlargement of the pituitary gland is frequently seen in long-standing primary hypothyroidism. A number of mechanisms may be involved. First, the clearance of prolactin tends to be decreased in hypothyroidism. Second, patients with severe hypothyroidism may have elevated total and free estradiol levels, giving rise to increased prolactin production stimulated by excess free estrogen. The third, and possibly the most significant, mechanism involves the inhibitory effects of T3 on TRH production and on TRH receptor expression. A decrease in T3 feedback in hypothyroidism may induce an increase in hypothalamic TRH production and in the number of TRH receptors in the lactotroph. Increased TRH action on the lactotroph, in turn, may stimulate prolactin secretion.

Pituitary Prolactinoma

Prolactinomas are the most common hormone-producing pituitary tumors in women. Signs and symptoms include galactorrhea, anovulatory bleeding, amenorrhea, headache, and bitemporal hemianopsia. Prolactinomas are commonly classified as microadenomas for tumors less than 1 cm in diameter and macroadenomas for tumors larger than 1 cm. Macroprolactinomas are more likely to cause headaches and visual symptoms than microprolactinomas. Macroprolactinomas usually give rise to higher serum prolactin levels than microprolactinomas, although circulating prolactin levels associated with microprolactinomas and macroprolactinomas overlap extensively. Prolactin-secreting adenomas are almost always benign. Prolactin measurements and radiologic imaging lead to the diagnosis of these tumors. MRI is a suitable
choice for imaging because it does not involve ionizing radiation and sensitivity is high. The lateral aspects of the pituitary represent the most common locations for prolactinomas. Currently, the most common form of treatment is a dopamine agonist. Among these agents, bromocriptine has been the most commonly used drug. Tumor shrinkage is achieved in most cases. Prolactin levels return to normal; this usually results in the disappearance of headaches and galactorrhea, and the resumption of menses follows. Treatment must usually be continued indefinitely to maintain the euneprolactinemic state. Treatment should be administered to amenorrhoic women even if pregnancy is not the goal because osteopenia often occurs within 6 months of the amenorrhea because of the associated hypoestrogenemia. The increase in parathyroid hormone-related protein (PTHrP) levels in hyperprolactinemic women may also contribute to bone loss.

Side effects of bromocriptine are not uncommon and include syncope, nausea, and vomiting. A long-acting, parenteral form of bromocriptine decreases the incidence of side effects but is not yet approved for use in the United States. Selective D2-type dopamine receptor agonists have become available. These include cabergolide and quinagolide. Both of these drugs have been shown useful in the treatment of bromocriptine-resistant tumors, in which there is decreased expression of the two D2 dopamine receptor isoforms. Cabergoline has a long half-life, requiring only twice-weekly dosing, and is approved for use in the United States; quinagolide requires daily administration and is not yet approved for use in the United States. The long half-life and decreased side effects of cabergoline have led to its increased use.

Treatment in the past was commonly transphenoidal resection of these prolactin-secreting adenomas. There is, however, frequently a recurrence of hyperprolactinemia within 5 to 7 years after the surgery. Thus, dopamine antagonists are the first line of therapy for both microadenomas and macroadenomas.

Continuation of bromocriptine therapy during pregnancy appears to be safe. If bromocriptine is stopped during pregnancy, however, clinically significant enlargement of prolactinomas is relatively uncommon. Approximately 6% of microadenomas and 30% of macroadenomas continue to grow during pregnancy. Eventually, the tumor may reach a size sufficient to cause headache and visual symptoms related to chiasmal compression. When visual symptoms become evident during pregnancy, resuming a dopamine agonist usually reduces the tumor mass and thus the visual symptoms. Transphenoidal resection during pregnancy is rarely required when medical treatment is not sufficient to control visual disturbances and tumor growth. Placental apoplexy is an uncommon but serious complication of prolactinomas during pregnancy.

During pregnancy, serum prolactin levels cannot be used reliably to monitor the size of pituitary adenomas because the decidua (differentiated endometrial tissue under the unique hormonal influence of pregnancy) and normal prolactin-producing pituicytes are additional potential sources of serum prolactin. Therefore, central nervous system symptoms, such as subjective visual symptoms, and objective visual field examinations are used monthly to observe pregnant patients.

**Hyperprolactinemia and Androgen Excess**

Androgen excess and hirsutism were found in a significant number of patients with classical galactorrhea-anovulation syndromes in original reports. This finding was verified by subsequent publications, which demonstrated that almost 40% of patients with pituitary adenomas and hyperprolactinemia had abnormal secretion and metabolism of androgen. Hyperprolactinemia and ultrasound evidence of polycystic ovaries frequently overlap. Hirsutism was observed in 59% of hyperprolactinemic patients with polycystic-appearing ovaries and in 41% of hyperprolactinemic patients with normal-appearing ovaries on ultrasoundography.

Levels of testosterone and androgen precursors, namely dehydroepiandrosterone sulfate (DHEAS) and DHEA, are elevated, whereas testosterone-binding globulin (TeBG, see later) is reduced. Reversal of these changes occurs after lowering the prolactin levels using oral bromocriptine. Furthermore, the levels of elevated androgen precursors are suppressed by dexamethasone, suggesting that hyperprolactinemia may exert a stimulatory action on adrenal C17-steroid secretion.

**Hyperprolactinemia and Bone Loss**

Hyperprolactinemia is commonly associated with reduced bone mineral density. Although hypoestrogenism can cause a decrease in bone mineral content, some eustrogenic patients have also been found to have reduced bone density. A direct action of prolactin on calcium mobilization may be a possible underlying mechanism. Prolactin has been shown to stimulate calcium mobilization from the bone independent of vitamin D and parathyroid hormone in the rat. In addition, prolactin receptors are present in bone cells, thus, prolactin may directly act on the bone. Alternatively, prolactin-dependent increases in PTHrP levels in women with hyperprolactinemia may contribute to the osteoporotic effects of excessive prolactin. Regardless of the mechanism, hyperprolactinemic patients are at risk for development of osteoporosis, and assessment of estrogen and bone mineral status is indicated. Prompt correction of hyperprolactinemia is the approach of choice. If hyperprolactinemia cannot be corrected, hormone replacement in the form of oral contraceptives is indicated.

**Hyperprolactinemia and Hypothalamic Anovulation**

Hyperprolactinemia is usually associated with anovulation, as exemplified by postpartum lactational amenorrhea and the galactorrhea-amenorrhea syndrome. Increased levels of prolactin inhibit the hypothalamic-pituitary-ovarian axis. Both opioid peptides and hypothalamic dopamine regulate the pulsatile secretion of LHRH. Hyperprolactinemia inhibits LHRH activity by interacting with the hypothalamic dopaminergic and opioidergic systems through a short-loop feedback mechanism or by a direct effect on LHRH neurons, in which prolactin receptors are expressed. Both possibilities are consistent with the observation that suppression of prolactin by the dopamine receptor antagonist bromocriptine restores ovulatory function.

**Chronic Anovulation and Androgen Excess**

**Approach to the Patient with Androgen Excess**

Two natural androgens are testosterone, which is transported to target tissue by the circulation, and DHT, which is produced primarily by target tissues. Increased levels of these androgens can lead to hirsutism, which is excessive androgenic hair growth, or to virilization, a more severe form of androgen excess. Hirsutism is defined as the presence of terminal (coarse) hair in locations at which hair is not commonly found in women. It includes facial hair on the cheek, above the upper lip, and on the chin (Figs. 16-30 and B). The presence of midline chest hair is also significant (Fig. 16-30 C). In addition, a male escutcheon, hair on the inner aspects of the thighs, and midline lower back hair entering the intergluteal area are hair growth patterns compatible with androgen excess. A moderate amount of hair on the forearms and lower legs by itself may not be abnormal, although it may be viewed by the patient as undesirable and may be mistaken for hirsutism. Numerous scoring systems are available for quantifying hirsutism. One of the most detailed scales was proposed by Ferriman, Galloway, and Lorenz. A practical and clinically useful means of quantifying hirsutism is recording the hair growth in detail using simple drawings and photographs. In particular, photographs are invaluable for documenting hirsutism accurately.

In contrast to hirsutism, virilization is a more severe form of androgen excess and implies significantly higher rates of testosterone production. Its manifestations include temporal balding, deepening of voice, decreased breast size, increased muscle mass, loss of female body contours, and clitoral enlargement (Fig. 16-31). Even if testosterone levels are moderately increased (>1.5 ng/mL), temporal balding and clitoromegaly may be observed over a long period of time (>1 year) in the presence of persistent androgen excess. A marked increase in androgen secretion, as may occur from production by neoplasms, however, leads to a more full-blown picture of virilization over a short duration of time (less than a few months).

Measurements of an enlarged clitoris may be used for the quantification of virilization. A clitoral length more than 10 mm is considered abnormal. A clitoral length is quite variable, however. An increase in clitoral diameter is a much more sensitive indicator of androgen action. Normal values for clitoral diameter are less than 7 mm at the base of the glans. The most accurate definition of clitoromegaly involves the use of the clitoral index (the product of the width and length of the glans clitoris). A clitoral index greater than 35 mm² is abnormal and correlates statistically with androgen excess.
For practical purposes, measuring the levels of all of these C₁₇-steroids is not clinically necessary in the majority of patients presenting with androgen excess. The purpose of measuring serum testosterone is to establish circulating androgen action (see Fig. 16-32). Although the achievement of this diagnostic yield of this measurement is clearly superior to that of total serum testosterone, the correlation between total and nonTeBG-bound testosterone is excellent and can frequently be predicted. TeBG is one of the primary regulators that determines the amounts of circulating bound and bioavailable testosterone available to act on target tissues. Conditions that decrease TeBG binding (e.g., androgen excess, obesity, acromegaly, hypothyroidism, and liver disease) also increase bioavailable testosterone, thus augmenting the effect of testosterone. TeBG also regulates the circulating amounts of bioavailable estradiol by binding a significant fraction of circulating estradiol. Hence, conditions that decrease TeBG binding (e.g., hirsutism, virilization) and estrogen-dependent disorders (e.g., malignancies of breast and endometrium) also give rise to increased bioavailable (nonTeBG-bound) estradiol.

TeBG is the portion not bound to TeBG but rather loosely associated with albumin, and the fraction not bound by either TeBG or albumin, that is, free or dialyzable testosterone. Biologically active testosterone includes both the free and albumin-bound fractions. Thus, the blood concentration of testosterone available to diffuse into target tissues is referred to as bioavailable or nonTeBG-bound testosterone. The remainder is tightly bound to the protein TeBG.

TeBG synthesis in women. There are two biologically active androgens, testosterone (T) and dihydrotestosterone (DHT). Depending on the menstrual cycle phase or postmenopausal status, 20% to 30% of T is secreted by the ovary. The rest of T production (blood) is accounted for by the conversion of circulating androstenedione (A) to T in various peripheral tissues. Both the adrenal and ovary contribute to circulating A directly or indirectly depending on the cycle phase, reproductive-age versus postmenopausal status, and chronicologic age. Moreover, T may also be formed locally in androgen target tissues. Finally, T is converted to the potent androgen DHT within the target tissues and cells. For example, local conversion of T to DHT in sex skin fibroblasts and hair follicles amplifies androgenic action for clitoral enlargement and hirsutism. DHEA, dehydroepiandrosterone; HDSD, hydroxysteroid dehydrogenase.

Two natural C₁₇-steroids are capable of acting as androgens on target organs: testosterone and DHT. In this chapter, the use of the term androgen refers to either of these steroids. Testosterone in reproductive-age women is produced by two major mechanisms: (1) direct secretion by the ovary, accounting for roughly one third of testosterone production, and (2) conversion of the precursor androstenedione to testosterone in the peripheral (extragonadal) tissues, accounting for two thirds of testosterone production (Fig. 16-32). The peripheral tissues include the skin and adipose tissue. Androstenedione, the direct precursor of testosterone, is produced in both the ovary and the adrenal. The C₁₇-steroids DHEAS and DHEA of adrenal origin and DHEA of ovarian origin indirectly contribute to testosterone formation by first being converted to androstenedione that is subsequently converted to testosterone (see Fig. 16-32).

Whereas testosterone is an androgen, DHEAS and DHEA is a biologically inert steroid. Up to 20 mg of DHEAS is produced daily versus only 3 mg of androstenedione and 8 mg of DHEA per day. These C₁₇-steroids of adrenal origin (DHEAS, DHEA) exert their effects after conversion to the potent androgen testosterone (see Fig. 16-32). Only androstenedione can be converted directly to testosterone. The conversion rate of circulating androstenedione to testosterone in extragonadal tissues is about 5% in both men and women.

TeBG measurement is not clinically necessary in the majority of patients presenting with androgen excess. The purpose of measuring serum testosterone is to establish circulating androgen action (see Fig. 16-32). Although the achievement of this diagnostic yield of this measurement is clearly superior to that of total serum testosterone, the correlation between total and nonTeBG-bound testosterone is excellent and can frequently be predicted. The purpose of measuring serum testosterone is to establish circulating androgen excess, to estimate the source of androgen production, and to detect extremely high values that might originate from an androgen-secreting neoplasm.

The normal serum levels of androgens and their precursors in women vary from laboratory to laboratory. Some approximate levels are as follows: testosterone, less than 0.6 ng/mL; free testosterone, less than 8 pg/mL; nonTeBG-bound testosterone (free + albumin-bound), less than 0.1 ng/mL; androstenedione, less than 3 ng/mL; DHEA, less than 9 ng/mL; DHEAS, less than 2.5 µg/mL; and DHT, less than 0.3 ng/mL. Androstenedione, DHEA, testosterone (total and free), and DHT fluctuate during the ovulatory cycle, and highest levels are found during the luteal phase because of increased secretion of these steroids or their precursors from the corpus luteum. Thus, steroid measurements should be obtained routinely during the early follicular phase, preferably at cycle day 3 (±1 day), so that these levels can be compared and interpreted more easily.

For practical purposes, measuring the levels of all of these C₁₇-steroids is not clinically necessary in the majority of patients presenting with androgen excess. The...
most useful initial test is a serum total testosterone level. An abnormal level in the presence of hirsutism or virilization may be associated with PCOS, hyperthecosis, nonclassical adrenal hyperplasia, or an androgen-secreting neoplasm. The majority of androgen-secreting tumors are of ovarian origin. The likelihood of a neoplasm correlates roughly with increasing testosterone levels. The following tests may be added on the basis of the clinical presentation: serum 17-hydroxyprogesterone (nonclassical adrenal hyperplasia), serum prolactin and TSH (mild androgen excess associated with hyperprolactinemia), serum FSH and LH (elevated LH:FSH ratio in PCOS), serum DHEAS (adrenal tumors), and imaging of ovaries and adrenals (PCOS, tumors).

### Causes of Androgen Excess

A variety of disorders give rise to androgen excess. These include unusual causes such as iatrogenic or drug-induced androgen excess, congenital genital ambiguity (e.g., excessive in utero androgen formation in female pseudohermaphroditism), and conditions unique to pregnancy (luteoma of pregnancy and hyperreactio luteinalis). These uncommon causes and relatively more prevalent disorders associated with androgen excess are listed in Table 16-5. The term extra-ovarian steroid formation is used synonymously for extraglandular, extragonadal, or peripheral steroid formation in this text.

In most hyperandrogenic disorders, androgen originates from more than one source (see Fig. 16-32). For example, testosterone secretion is somewhat increased from the ovary in PCOS, but the bulk of testosterone comes from extraovarian conversion of significantly elevated circulating androstenedione of ovarian origin to testosterone. To add a further twist, patients with PCOS also show increased adrenal output of DHEAS, which (after peripheral conversion to DHEA that is further converted to androstenedione) contributes indirectly to extraovarian testosterone formation (see Fig. 16-32).

When androgen excess is associated with primary amenorrhea, abnormal in utero sexual differentiation should be strongly suspected. These disorders are covered in detail in Chapter 22. Furthermore, before embarking on a major workup for hirsutism or virilization, the physician is well advised to rule out exogenous androgen use. It is best to ask the patient to list all prescriptions and over-the-counter medications that she takes on her own, including injections. This is usually more rewarding than simply asking the patient whether she takes any androgens. Medications that can cause hirsutism or virilization are related to testosterone. These include anabolic steroids and similar compounds.

The most common identifiable cause of androgen excess is PCOS. PCOS is discussed under a separate heading in this chapter. In this section, we first define some of the other disorders associated with hirsutism or virilization. This is followed by a simplified treatment strategy, which may be applied to the majority of hirsute patients within the categories PCOS, nonclassical adrenal hyperplasia, and idiopathic hirsutism.

#### Idiopathic Hirsutism

Excessive hair growth in the absence of demonstrable androgen excess in ovulatory women is also referred to as idiopathic or constitutional and occurs more frequently in certain ethnic populations, particularly in women of Mediterranean ancestry. It is defined as hirsutism in conjunction with regular menstrual cycles and normal levels of serum testosterone. Idiopathic hirsutism is not associated with any sign of virilization. Its cause is not understood completely. It has been proposed that women with idiopathic hirsutism have significantly increased cutaneous 5-reductase activity. At this time, the presence or absence of such an association is not clear. Likewise, it is still unclear which of the 5-reductase isoenzymes (type 1 or 2), if any, is predominant in the development of idiopathic hirsutism.

Idiopathic hirsutism is diagnosed in women who have (1) hirsutism, (2) normal ovulatory function, and (3) normal total or free testosterone levels. Overall, more than 80% of women with cyclic predictable menses are ovulatory. Ovulatory function may be verified by a luteal phase day 7 progesterone level, which should be at least 5 ng/mL. Luteal phase day 7 corresponds to cycle day 17 for 24-day intervals, cycle day 21 for 28-day intervals, and cycle day 28 for 35-day intervals. The presence of oligo-ovulation or anovulation in hirsute women after the exclusion of related disorders (e.g., hyperprolactinemia, hyperprolactinemia, or nonclassical adrenal hyperplasia) is consistent with the diagnosis of PCOS. Thyroid dysfunction and hyperprolactinemia should be excluded by the measurements of TSH and prolactin. The follicular phase basal 17-hydroxyprogesterone level should be measured to exclude 21-hydroxylasedeficient, nonclassical adrenal hyperplasia. The use of exogenous androgens should also be excluded. In summary, the diagnosis of idiopathic hirsutism is one of exclusion, in which ovulatory dysfunction, elevated circulating testosterone, and other causes of androgen excess are ruled out.

#### PCOS, Polycystic Ovary Syndrome

The majority of androgen-secreting tumors arise from the ovary. These ovarian tumors secrete large quantities of testosterone or its precursor androstenedione. They include Sertoli-Leydig cell tumors, hilus cell tumors, and, infrequently, granulosa-theca tumors. Steroidogenically inert ovarian neoplasms such as epithelial cystadenomas or cystadenocarcinomas may produce factors that stimulate steroidogenesis in adjacent non-neoplastic ovarian stroma and induce production of sufficient amounts of androgen precursors such as androstenedione. Approximately 5% of androstenedione is converted to testosterone in extraglandular tissues to give rise ultimately to androgen excess (see Fig. 16-32). Sertoli-Leydig cell tumors, which account for less than 1% of all solid ovarian tumors, tend to occur during the second to fourth decades of life, whereas hilus cell tumors occur more frequently in postmenopausal women. By the time the signs and symptoms of androgen excess cause the patient to seek medical assistance, Sertoli-Leydig cell tumors are usually so large that they are readily palpable on pelvic examination, whereas hilus cell tumors are still small. In women with either type of tumor, serum testosterone is markedly elevated. Granulosa-theca tumors primarily produce estradiol but may occasionally produce testosterone.

| PCOS | Hyperthecosis (a severe PCOS variant) |
| Ovarian tumor (e.g., Sertoli-Leydig cell tumor) |
| Adrenal | Nonclassical adrenal hyperplasia |
| Cushing's syndrome |

Laboratory Testing to Aid the Differential Diagnosis of Androgen Excess

Non-Neoplastic Adrenal Disorders and Androgen Excess

A number of adrenal disorders, such as classical congenital adrenal hyperplasia, Cushing's syndrome, and glucocorticoid resistance, give rise to androgen excess related to overproduction of testosterone precursors from the adrenal. These disorders are discussed in other chapters. Here, we discuss nonclassical adrenal hyperplasia.

The debate regarding the diagnosis and prevalence of nonclassical adrenal hyperplasia still continues, although the disorder clearly exists. Other terms that have been used to describe this syndrome include late-onset, adult-onset, attenuated, incomplete, and cryptic adrenal hyperplasia. This form of adrenal hyperplasia is caused by a partial deficiency in 21-hydroxylase activity. Although deficiencies in 11-hydroxylase and 3-HSD may result in the disorder, defects in 21-hydroxylase account for more than 90% of cases.

The clinical presentation is almost identical to that of patients with PCOS. The prevalence of this disorder varies according to ethnic background, and the prevalence reported by different investigators has varied widely. The characteristic presentation consists of anovulatory uterine bleeding and progressive hirsutism of the proliferative phase in affected or disease-free ovulatory women.

The prevalence of this disorder varies according to ethnic background, and the prevalence reported by different investigators has varied widely. The characteristic presentation consists of anovulatory uterine bleeding and progressive hirsutism of the proliferative phase in affected or disease-free ovulatory women.

The diagnosis of nonclassical adrenal hyperplasia can be made if the basal 17-hydroxyprogesterone level is higher than 8 ng/mL. No further testing is required in these cases. Values between 2 and 8 ng/mL are considered increased but not diagnostic of nonclassical adrenal hyperplasia. For example, disease-free women or patients with PCOS may also have basal 17-hydroxyprogesterone levels higher than 8 ng/mL. Therefore, use of an LHRH agonist cannot be relied upon to distinguish a neoplasm from another functional state.

Under these circumstances, the scan can be deferred until further investigation has been carried out. Levels of a variety of adrenal steroids including corticosteroids may be elevated in various combinations in the presence of an adrenal tumor. Thus, it is not possible to describe a particular pattern of hormones that defines an adrenal tumor. In general, high levels of serum DHEAS (>8 µg/mL) are suggestive of an adrenal tumor. Testosterone-secreting adrenal tumors are extremely rare. Virilizing ovarian tumors, on the other hand, are encountered much more frequently than those of an adrenal origin. If the presentation is compatible with an androgen-secreting tumor and the ovaries are normal by transvaginal ultrasonography, the adrenals should be evaluated next by imaging.

Testosterone levels three times the upper normal range (or > 2 ng/mL) and DHEAS levels higher than 8 µg/mL have been used as guidelines to investigate further whether neoplasms of the ovary or adrenal are the sources of androgen excess. It should be emphasized that these numbers are provided only as guidelines and not as rules. The following exceptions to these guidelines must be pointed out. First, because tumors secrete androgens episodically, more than one value may be required to detect a significantly elevated level. Second, other precursor steroids are often elevated as well (particularly androstenedione), and their measurement should be considered. Finally, the tumors may give rise to milder elevations of DHEAS and testosterone levels. In particular, even mild elevations in a postmenopausal woman are highly suspicious of an androgen-secreting tumor. By the same token, severely elevated serum testosterone levels (three times the upper normal range or > 2 ng/mL) may be observed in women with severe ovarian hyperthecosis (a severe variant of PCOS) in the absence of a tumor.

Virilization of recent onset and short duration should warrant further investigation, even if testosterone and DHEAS are mildly elevated. With improvements in scanning techniques and ultrasonography for the ovary; abdominal ultrasonography; computed tomography, and MRI for the adrenal the diagnosis of a small (ovarian or adrenal) tumor may be made. However, if no neoplasm can be localized, imaging of the ovary or adrenal after intravenous administration of radiolabeled analogs of hCG (e.g., hCG-B, hCG-A, hCG-D), which detects active steroid-producing tumors, has proved useful. These diagnostic studies should be pursued aggressively before the surgical exploration of a suspected tumor.

Screening may first be carried out by obtaining an 8:00 AM serum 17-hydroxyprogesterone level in an anovulatory patient on any day. Although the majority of women with nonclassical adrenal hyperplasia are anovulatory, some women with this disorder present with regular periods and hirsutism of pubertal onset or with only unexplained infertility. If nonclassical adrenal hyperplasia is suspected in an ovulatory patient on the basis of clinical presentation, an 8:00 AM serum 17-hydroxyprogesterone level should be obtained during the follicular phase because 17-hydroxyprogesterone levels are higher in the luteal phase versus the proliferative phase in affected- or disease-free-ovulatory women. A level less than 2 ng/mL effectively rules out this diagnosis.

The diagnosis of nonclassical adrenal hyperplasia can be made if the basal 17-hydroxyprogesterone level is higher than 8 ng/mL. No further testing is required in these cases. Values between 2 and 8 ng/mL are considered increased but not diagnostic of nonclassical adrenal hyperplasia. For example, disease-free women or patients with PCOS may also have basal 17-hydroxyprogesterone levels in this indeterminate range. The only way to distinguish nonclassical adrenal hyperplasia from PCOS under these circumstances is with an ACTH stimulation test. A rise of 17-hydroxyprogesterone to at least 10 ng/mL 60 minutes after intravenous injection of ACTH has been considered diagnostic of nonclassical adrenal hyperplasia. It should be noted, however, that a higher basal 17-hydroxyprogesterone level within the 2 to 8 ng/mL range is associated with a higher likelihood of nonclassical adrenal hyperplasia. For example, an 8:00 AM 17-hydroxyprogesterone level higher than 4 ng/mL had a sensitivity of 90% for the diagnosis of nonclassical adrenal hyperplasia.

In a patient with androgen excess who belongs to an ethnic group in which there is high prevalence, a baseline 17-hydroxyprogesterone level should be measured at 8:00 AM. In addition, the following patients should have a screening baseline 17-hydroxyprogesterone level obtained: patients with premature pubarche, those with androgen excess of early pubertal onset, women with progressive hirsutism or virilization, and patients with strong family histories of severe androgen excess.
importance to guide laboratory testing. The most important features include the onset and severity of the signs and the rapidly with which they progress. Rapidly progressing severe androgen excess implies an androgen-secreting tumor until proved otherwise. The possibility of a tumor is further underscored in a postmenopausal woman or in a reproductive-age woman with a recent history of cyclic, predictable periods. Ovarian hyperthecosis, a severe variant of PCOS, also gives rise to severe androgen excess that may progress rapidly, especially at the time of expected puberty. Androgen excess emerging at the time of puberty may be indicative of PCOS or nonclassical adrenal hyperplasia.

The most useful initial test to evaluate androgen excess is serum total testosterone (Table 16-6). Testosterone levels in most normal ovulatory women are below 0.6 ng/mL, although the value may vary from laboratory to laboratory. Women with idiopathic hirsutism have cyclic menses and normal testosterone levels. No further testing for androgen excess is required in this group.

If the testosterone level is elevated in an anovulatory woman, serum TSH and prolactin should be obtained next to rule out anovulation associated with hyperprolactinemia. Ultrasonography of the ovaries is also helpful at this time to assess the presence or absence of an ovarian tumor or polycystic ovaries. If the ethnic background of the patient (Ashkenazi Jews, Hispanics, and those of central European ancestry), onset of hirsutism (puberty), or family history is suggestive of nonclassical adrenal hyperplasia, a baseline serum 17-hydroxyprogesterone level should be obtained at 8:00 AM. Rare etiologies of androgen excess include an adrenal tumor, Cushning's syndrome, and glucocorticoid resistance. A serum DHEAS level and adrenal imaging are required to assess the presence or absence of an adrenal tumor. A computed tomographic scan, MRI scan, or abdominal ultrasonography may be used to assess the adrenals, depending on the expertise of the local radiology laboratory. A screening test for Cushings's syndrome and glucocorticoid resistance may be performed to explore rare adrenal causes of androgen excess. See Chapter 14.

Most women with chronic anovulation and mild to moderate hirsutism of pubertal onset fall into the category of PCOS. These women have high normal or elevated testosterone levels and no other laboratory abnormalities. When other diagnoses are ruled out either by laboratory testing or on clinical grounds, a diagnosis of PCOS can be made.

Treatment of Hirsutism

Therapy for androgen excess should be directed toward its specific cause and at suppression of abnormal androgen secretion. Specific treatments for hirsutism and virilization would be indicated for the following conditions: ovarian and adrenal tumors, hyperthecosis, Cushings's syndrome, and adrenal hyperplasia. Neoplasms warrant surgical intervention and are not discussed in greater detail. Suppression with an LHRH analogue may be tried initially for ovarian hyperthecosis. Unfortunately, bilateral oophorectomy is inevitable to control androgen excess arising from hyperthecosis in the majority of patients (see later). Patients with adrenal disease are treated specifically. For Cushings's syndrome, treatment is according to the source of hypercortisolism. For nonclassical adrenal hyperplasia, glucocorticoid replacement should be implemented as for adrenal insufficiency. When treating androgen excess associated with nonclassical adrenal hyperplasia, an androgen antagonist (e.g., spironolactone) in combination with an oral contraceptive or a glucocorticoid may be used. The doses of glucocorticoids needed to suppress the adrenal, however, can often cause symptoms and signs of glucocorticoid excess during long-term treatment. Thus, a combination oral contraceptive plus spironolactone should be favored to treat androgen excess if the patient responds to this treatment with decreased hirsutism. Greater details of glucocorticoid therapy may be found in Chapter 14 and in Chapter 22.

The general treatment of androgen excess is directed toward the prevention of abnormal hair growth and virilization. For practical purposes, the same approach is used for androgen excess associated with idiopathic hirsutism, PCOS, and nonclassical adrenal hyperplasia. The existing hair follicles and manifestations of virilization (e.g., thickening of voice, clitoromegaly, temporal balding) remain even after the elimination of excessive androgen production. Therefore, terminal hair should be removed by mechanical methods (e.g., electrolysis) at least 3 months after androgen suppression is achieved. Patients with clitoromegaly may be referred to a urologist for clitoral reduction surgery after the source of virilization is effectively eliminated. The following medications are available for the treatment of androgen excess and hirsutism.

Oral contraceptives reduce circulating testosterone and androgen precursors by suppression of LH and stimulation of TeBG levels and, thereby, reduce hirsutism in hyperandrogenic patients. Oral contraceptives decrease circulating androgen in patients with PCOS and synergize with the effects of antiandrogens. It is possible that oral contraceptives may further improve the results of antiandrogen therapy in idiopathic hirsutism. It is advisable to use an oral contraceptive containing either 30 or 35 µg of ethinyl estradiol to achieve effective suppression of LH.

Spironolactone

The most common androgen blocker used for the treatment of hirsutism in the United States is spironolactone, an aldosterone antagonist structurally related to progestins. Spironolactone is effective for abnormal hair growth associated with PCOS or idiopathic hirsutism.

Because spironolactone acts through mechanisms different from that of oral contraceptives, the overall effectiveness is improved by combining these two medications, even in patients with idiopathic hirsutism. Apart from the inhibition of steroidogenesis and acting as an androgen antagonist, spironolactone has a significant effect in inhibiting 5-reductase activity. Basic and several clinical studies clearly point to the efficacy of spironolactone for hyperandrogenism and suggest that the

principal effect is related to its peripheral blocking ability. [338]

Doses of spironolactone have varied in clinical studies from 50 to 400 mg daily. Although doses of 100 mg/day are generally effective for the treatment of hirsutism, higher doses (200 to 300 mg/day) may be preferable in extremely hirsute or markedly obese women. [337] [358] Thus, it is recommended to start with 100 mg/day and gradually increase the dose by 25 mg/day increments every 3 months up to 200 mg/day on the basis of the response. This approach may be helpful to minimize side effects such as gastritis, dry skin, and anovulation.

In patients with normal renal function, hyperkalemia is almost never seen. Hypotension is rare except in older women. Monitoring, however, is imperative for electrolytes and blood pressure within the first 2 weeks at each dose level. Adjustments in dose should be made only after 3 to 6 months, as with other androgens, to account for the slow changes in the hair cycle. Patients usually note an initial transient diuretic effect. Some women with normal cycles complain of menstrual irregularity with spironolactone. The latter complaint is remedied by either a downward dose adjustment or the addition of an oral contraceptive. The mechanism for abnormal bleeding is unclear. In women with oligomenorrhea, such as those with PCOS, resumption of normal menses may occur. In part, this may be due to an alteration in levels of circulating androgens, although LH levels have only occasionally been noted to decrease. [338] Another important consideration is the potential in utero feminizing effect of this antiandrogen on the genitalia of a 46,XY fetus. Thus, effective contraception should always be provided in women taking spironolactone.

Cyproterone Acetate

Cyproterone acetate is a 17-hydroxyprogesterone acetate derivative with strong progestagenic properties. Cyproterone acetate acts as an antiandrogen by competing with DHT and testosterone for binding to the androgen receptor. There is also some evidence that cyproterone acetate and ethinyl estradiol in combination can inhibit 5-reductase activity in skin. [361] Cyproterone acetate is currently not available in the United States but has been used in other countries. The drug is mostly administered in doses of 50 to 100 mg from days 5 through 15 of the treatment cycle. Because of its slow metabolism, it is administered early in the treatment cycle, whereas ethinyl estradiol, when added, is usually used at 50-µg doses between days 5 and 26. This regimen is needed for menstrual control and is usually referred to as the reverse sequential regimen. Cyproterone acetate in doses of 50 to 100 mg/day, combined with ethinyl estradiol at 30 to 35 µg/day, is as effective as the combination of spironolactone, 100 mg/day, and an oral contraceptive in the treatment of hirsutism. [364] In smaller doses (2 mg), cyproterone acetate has been administered as an oral contraceptive in daily combination with 50 or 35 µg of ethinyl estradiol. This regimen is primarily suited for individuals with a milder form of hyperandrogenism. [365]

Finasteride

Finasteride inhibits 5-reductase activity and has been used primarily for the treatment of prostatic hyperplasia. [366] It can also be used in the treatment of hirsutism. [367] [368] At a dose of 5 mg/day, a significant improvement of hirsutism is observed after 6 months of therapy, without significant side effects. In hirsute women, the decline in circulating DHT levels is small and cannot be used to monitor therapy. Although this treatment regimen increases testosterone levels, testosterone dihydrogenone (TeBG) levels remain unaffected. [359]

Finasteride primarily inhibits 5-reductase type 2. As hirsutism results from a combination of effects of type 1 and type 2, this agent is only partially effective. Although prolonged experience with finasteride is lacking, one of the potential advantages of this agent appears to be its benign side-effect profile. One study showed efficacy with 1 year of hirsutism treatment. [369] It was also reported that finasteride is less effective than spironolactone with respect to the reduction of hirsutism. [370] Nevertheless, finasteride represents a useful option for treating women with hirsutism at a dose of 5 mg/day for prolonged periods because of its benign side-effect profile and good tolerance by patients.

Flutamide

Flutamide is a potent antiandrogen used in the treatment of prostate cancer. [357] It has been shown to be effective in the treatment of hirsutism. [358] [359] [360] [361] Nevertheless, occasional severe hepatotoxicity makes this drug unsuitable for the indication of hirsutism. [362] [363]

Summary

The preceding medications may be effective when administered as individual treatments. Patients with the most common form of hirsutism (i.e., PCOS) are often initially treated with a combination of two agents, one that suppresses the ovary (e.g., oral contraceptive) and another agent that suppresses the extraglandular (peripheral) action of androgens (e.g., spironolactone). Thus, an oral contraceptive containing 30 to 35 µg of ethinyl estradiol combined with spironolactone, 100 mg/day, is the initial treatment of choice. Even in women with idiopathic hirsutism, the addition of an oral contraceptive to the antiandrogen spironolactone can improve efficacy and prevent abnormal bleeding. For women with only minor complaints of hirsutism, the use of an oral contraceptive alone may be an appropriate first approach.

Because the growth phase of body hairs lasts 3 to 6 months, one should not expect a response before 6 months from the onset of the treatment. Objective means should be used to assess changes in hair growth. Scoring systems and evaluation of anagen hair shafts are difficult; taking photographs is the simplest and most objective tool. Patients are often unaware that change is indeed taking place unless there is some objective measurement. Pictures of face and selected midline body areas before and during therapy are especially useful for the encouragement of the patient and compliance with the treatment. Suppression of androgen production and action only inhibits new hair growth. Thus, existing coarse hair should be removed mechanically. Plucking, waxing, and shaving are ineffective for hair removal and cause irritation, folliculitis, and ingrown hairs. Electrolysis is still the method of choice. Laser epilation is relatively new and needs further evaluation. [364]

The majority of patients with PCOS and idiopathic hirsutism respond to this treatment within 1 year. Patients should be encouraged to continue treatment for at least 2 years. After this, depending on the wishes and clinical responses of patients, therapy can be stopped and the patient reevaluated. Many patients require continuous treatment for the suppression of hirsutism.

The Polycystic Ovary Syndrome

PCOS is the most common form of chronic anovulation associated with androgen excess, perhaps occurring in 5% to 10% of reproductive-age women. [363] The diagnosis of PCOS is made by excluding other hyperandrogenic disorders (e.g., non-classical adrenal hyperplasia, androgen-secreting tumors, and hyperprolactinemia) in women with chronic anovulation and androgen excess. [365]

During the reproductive years, PCOS is associated with important reproductive morbidity including infertility, irregular uterine bleeding, and increased pregnancy loss. [364] The endometrium of the patient with PCOS must be evaluated by biopsy because long-term unopposed estrogen stimulation leaves these patients at increased risk for endometrial cancer. [366] PCOS is also associated with increased metabolic and cardiovascular risk factors. [367] These risks are linked to insulin resistance and compounded by the common occurrence of obesity, although insulin resistance is also present in nonobese women with PCOS. [368]

PCOS is now viewed as a heterogeneous disorder of multifactorial etiology. PCOS risk is significantly increased with a positive family history of chronic anovulation and androgen excess, and this complex disorder may be inherited in a polygenic fashion. [369] [370] [371] [372] [373] [374] [375]

Historical Perspective

In their pioneering studies, Stein and Leventhal described an association between the presence of bilateral polycystic ovaries and signs of amenorrhea,
Prolactin and TSH should be obtained routinely to rule out mild androgen excess and anovulation that may be associated with hyperprolactinemia. If basal LH levels are elevated, it is important to consider the possibility of androgen excess. As emphasized earlier, elevated total testosterone is the most direct evidence for androgen excess. Varying levels of testosterone are present in women with PCOS.

Glucocorticoid resistance is characterized by preserved diurnal rhythm despite significantly elevated cortisol, ACTH, and adrenal Cₐₙ-s-steroid levels. This morphologic change is called stromal hyperthecosis and appears to be directly correlated with circulating insulin levels. Glucocorticoid resistance and the polycystic ovary syndrome: mechanism and implications for pathogenesis. Endocr Rev 1997; 18:774800. Copyright © 1997 by The Endocrine Society.

One of the most significant discoveries regarding the pathophysiology of PCOS was the demonstration of a unique form of insulin resistance and associated hyperinsulinemia. For the first time, Burghen and co-workers reported this finding in 1980. The presence of insulin resistance in PCOS has since been confirmed by a number of groups worldwide. Diagnosis of Polycystic Ovary Syndrome and Laboratory Testing

One of the most prominent features of PCOS is the history of ovulatory dysfunction (amenorrhea, oligomenorrhea, or other forms of irregular uterine bleeding) of pubertal onset. Thus, a clear history of cyclic predictable menses of menarchal onset makes the diagnosis of PCOS unlikely. Acquired insulin resistance associated with significant weight gain or an unknown cause, however, may occasionally induce the clinical picture of PCOS in a woman with a history of previously normal ovulatory function. Hirsutism may develop prepubertally or during adolescence, or it may be absent until the third decade of life. Seborrhea, acne, and alopecia are other common clinical signs of androgen excess. In extreme cases of ovarian hyperthecosis (a severe variant of PCOS), clitoromegaly may be observed. Nonetheless, rapid progression of androgenic symptoms and virilization are rare in ordinary PCOS. Some women may never have signs of androgen excess because of genetic differences in target tissue sensitivity to androgens. Infertility related to the anovulation may be the only presenting symptom.

During the physical examination, it is essential to search for and document signs of androgen excess (hirsutism or virilization or both), insulin resistance (acanthosis nigricans), and the presence of unopposed estrogen action (well-rugated vagina and stretchable clear cervical mucus) to support the diagnosis of PCOS. It should be noted that none of these signs are specific for PCOS and may be associated with any of the conditions listed under the differential diagnosis of PCOS.

The currently recommended diagnostic criteria for PCOS are androgen excess and ovulatory dysfunction with the exclusion of other causes of androgen excess such as nonclassical adrenal hyperplasia (21-hydroxylase deficiency), hyperprolactinemia (with or without hypothyroidism), or androgen-secreting neoplasms (Table 16-8). The exclusion of hyperprolactinemia, hyperthyroidism, nonclassical adrenal hyperplasia, and tumors requires a careful history and physical examination as well as laboratory testing as detailed previously (see Table 16-6). Cushing's syndrome and glucocorticoid resistance may give rise to androgen excess and anovulation after a period of normal ovulatory function in teens. An 8:00 AM cortisol level after dexamethasone (1 mg) administration at midnight is a useful screening test for both conditions. Cushing's syndrome may be recognized by its typical signs, whereas 8:00 AM and 4:00 PM cortisol levels are essential to suspect the diagnosis of glucocorticoid resistance. Glucocorticoid resistance is characterized by preserved diurnal rhythm despite significantly elevated cortisol, ACTH, and adrenal C₁₇α-steroid levels and absence of cushingoid symptoms and signs.

As emphasized earlier, elevated total testosterone is the most direct evidence for androgen excess. Varying levels of testosterone are present in women with PCOS. Rarely, serum testosterone levels higher than 2 ng/mL may be encountered in association with the most severe form of PCOS, ovarian hyperthecosis. Overall, it is much more common to observe high normal levels or borderline elevations of testosterone in women with PCOS.

Prolactin and TSH should be obtained routinely to rule out mild androgen excess and anovulation that may be associated with hyperprolactinemia. If basal LH levels

(Demonstration of polycystic ovaries on ultrasonography is a common feature that is not essential for diagnosis)
are used as a marker for PCOS, a significant number of patients slip through the cracks because they do not all manifest elevated LH levels or increased LH:FSH ratios. This issue prompted a National Institute of Child Health and Human Development-sponsored consensus conference on diagnostic criteria for PCOS in 1990 and the recommendation that LH and the LH:FSH ratio are not required for the diagnosis of PCOS. The heterogeneity of LH values in PCOS may be caused by the pulsatile nature of LH secretion and negative effects of obesity on LH levels. Thus, an elevated LH:FSH ratio is supportive of the diagnosis of PCOS and may be useful in differentiating mild cases of nonobese PCOS without prominent androgen excess from hypothalamic anovulation. Failure to exhibit an elevated LH level, however, is of no diagnostic value.

By definition, nonclassical adrenal hyperplasia is not manifest as genital virilization of external genitalia. Hyperandrogenic symptoms most commonly appear peripubertally or postpubertally. A 17-hydroxyprogesterone level at 8:00 AM is essential to rule out 21-hydroxylase-deficient nonclassical adrenal hyperplasia. The majority of symptomatic patients with nonclassical adrenal hyperplasia are anovulatory and can be tested on any day at 8:00 AM. In an occasional ovulatory woman with androgen excess and suspected nonclassical adrenal hyperplasia, the 17-hydroxyprogesterone level should be obtained during the follicular phase to maximize specificity. A basal 17-hydroxyprogesterone level less than 2 ng/mL effectively rules out nonclassical adrenal hyperplasia. Patients with (proliferative phase 8:00 AM) 17-hydroxyprogesterone levels higher than 2 ng/mL should undergo an ACTH stimulation test. A 17-hydroxyprogesterone level higher than 10 ng/mL at 60 minutes after intravenous injection of ACTH is diagnostic of nonclassical adrenal hyperplasia. Please refer to Chapter 11 and Chapter 19 for details of the ACTH stimulation test. A screening test for Cushing's syndrome or glucocorticoid resistance should be performed as clinically indicated (see Chapter 14 and Chapter 22).

Serum DHEAS levels may be increased (up to 8 µg/mL) in about 50% of anovulatory women with PCOS. DHEAS originates almost exclusively from the adrenal. The etiology of adrenal hyperactivity in PCOS is not known. Obtaining a DHEAS level routinely in a patient with PCOS is not recommended because it does not change the diagnosis or management. On the other hand, if an adrenal tumor is suspected, a DHEAS level should be obtained. DHEAS levels above 8 µg/mL may be associated with steroidogenically active adrenal tumors, and imaging is then indicated.

The use of ultrasonography in the diagnosis of PCOS must be tempered by an awareness of the broad spectrum of women with ultrasonographic findings characteristic of polycystic ovaries. The typical polycystic-appearing ovary emerges in a nonspecific fashion when a state of anovulation persists for any length of time (Fig. 16-35)(Figure Not Available). Whether diagnosis is by ultrasonography or by the traditional clinical and biochemical criteria, a cross-section of all anovulatory women at any point in time reveals that approximately 75% have polycystic-appearing ovaries as determined by ultrasonography. As there are numerous causes of anovulation, there are also numerous reasons for polycystic ovaries. A similar clinical picture and ovarian condition can reflect any of the dysfunctional states discussed previously. In other words, the polycystic-appearing ovary is the result of a functional derangement but not a specific central or local defect.

The application of rigid endocrine or clinical criteria for the diagnosis of PCOS results in a focused portion of the broad clinical spectrum of PCOS. This particularly applies to diagnosing PCOS with the use of ultrasonography. Criteria include an increase in the number of follicles and their frequent necklace-like arrangement, accompanied by an increase in ovarian volume related to stromal increase (see Fig. 16-35)(Figure Not Available). From 8% to 25% of normal women demonstrate ultrasonographic findings typical of polycystic ovaries. Even 14% of women taking oral contraceptives have been found to have this ultrasonographic picture. Thus, ultrasonography is not a tool of choice and its use as a diagnostic aid is not of value. Magnetic resonance studies further confirm the unreliability of the imaging finding (i.e., the polycystic ovary) that was once presumed to be diagnostic of this condition.

Biochemical evidence of insulin resistance or glucose intolerance is also not necessary for the diagnosis of PCOS. Glucose intolerance should nonetheless be investigated. Therefore, plasma glucose levels should be measured after a 75-g glucose load as a screen for glucose intolerance.

Women with PCOS commonly present with irregular uterine bleeding in the form of infrequent periods (oligomenorrhea) or amenorrhea. It is not necessary to document anovulation by ultrasonography, progesterone levels, or otherwise, especially if menstrual cycles are irregular with periods of amenorrhea. To confirm the diagnosis of chronic anovulation and unopposed estrogen exposure, most clinicians perform a progesterin challenge test after a negative urine pregnancy test. Because endometrium is exposed to estradiol chronically in PCOS, these women respond to a challenge with a progestin (e.g., medroxyprogesterone acetate 10 mg/day orally for 10 days) by uterine bleeding within a few days after the last pill of progestin. The reasons for lack of uterine bleeding after a progestin challenge include pregnancy, insufficient progesterone exposure of the endometrium, or anatomic defect. If uterine bleeding does not follow progestin challenge, pregnancy should be ruled out again along with other causes of chronic anovulation as described in this chapter. An anatomic defect such as intrauterine adhesions may be ruled out with a hysterosalpingogram or hysteroscopy.

Finally, during the initial work-up, it is advisable to obtain an endometrial biopsy specimen using a plastic miniscissure cannula (e.g., Pipelle) in the physician's office. If chronic anovulation persists, endometrial biopsies should be repeated periodically. Response to oral contraceptives or periodic progestin treatment with predictable withdrawal bleeding episodes is reassuring, and these patients with predictable bleeding patterns do not need endometrial sampling during these treatments. In untreated patients, the risk of endometrial hyperplasia and malignancy is significantly increased even in young women with PCOS because of unopposed estrogen exposure.

Gonadotropin Production in Polycystic Ovary Syndrome

Women with PCOS have higher mean concentrations of LH but low or low-normal levels of FSH compared with levels found in normal women in the early follicular phase. The elevated LH levels are partly due to increased sensitivity of the pituitary to LHRH stimulation manifest by increases in LH pulse frequency and, in particular, LH pulse amplitude. Intestinally, an increased level of LH bioactivity accompanies high levels of LH in women with PCOS.

The elevated LH levels in PCOS are presumed to be primarily due to accelerated LH:RH-LH pulsatility. Central opioid tone appears to be suppressed because the pattern of LH secretion does not change in response to naloxone. Indeed, the enhanced pulsatile secretion of LH has been attributed to a reduction in hypothalamic opioid inhibition caused by the chronic absence of progesterone. An increase in amplitude and frequency of LH secretion also correlates with the steady-state levels of circulating estrogen.

In obese women with PCOS, LH levels are not increased. The increase in LH pulse frequency is characteristic of the anovulatory state regardless of the body fat content. LH pulse amplitude, however, is comparatively normal in overweight women with PCOS, whereas it is...
increased in nonobese women with PCOS. The overall LH reduction in obese women with PCOS may also be due to factors other than changes in LH pulse amplitude. It should be noted again that a low LH value does not rule out the diagnosis of PCOS, whereas a high LH/FSH ratio is supportive of this diagnosis in an anovulatory woman.

Steroid Production in Polycystic Ovary Syndrome

Ovulatory cycles are characterized by cyclic fluctuating hormone levels that regulate ovulation and menses. Anovulation in women with PCOS, on the other hand, is associated with steady-state levels of gonadotropins and ovarian steroids. In patients with persistent anovulation, the average daily production of estrogen and androgens is both increased and dependent on LH stimulation. This is reflected in higher circulating levels of testosterone, androstenedione, DHEA, DHEAS, 17-hydroxyprogesterone, and estrone. Testosterone, androstenedione, and DHEA are secreted directly by the ovary, whereas DHEAS, elevated in about 50% of anovulatory women with PCOS, is almost exclusively an adrenal contribution. Circulating levels of androstenedione, secreted by polycystic ovaries, are particularly high.

Estrogen arises primarily from peripheral aromatization of androstenedione and, in part, from ovarian secretion. Estrone itself is not a potent estrogen but can be viewed as a precursor that must be converted to estradiol to exert full estrogenic action. The presence of a number of 17-HSD isoenzymes with overlapping activities that catalyze the conversion of estrone to estradiol in peripheral (extraovarian) tissues is, in part, responsible for maintaining estradiol production in women with PCOS. Increased androstenedione leads to a detectable increase in circulating levels of estradiol in women with PCOS compared with estradiol levels measured during the first few days of an ovulatory cycle. This occurs through aromatase and 17-HSD activities in extraovarian tissues such as skin and subcutaneous adipose tissue. Also, local conversion of estrone to estradiol is an important physiologic process for certain estrogen target tissues such as disease-free breast and genital skin. Finally, local conversion can also promote the growth of pathologic estrogen-dependent tissues such as breast cancer and endometriosis.

Overall, androstenedione of ovarian origin is the most strikingly elevated steroid in PCOS. Androstenedione is not biologically active but serves as a dual precursor for both androgens (testosterone that is further converted to the biologically far stronger androsterone DHT) and estrogen (estrogen that is further converted to biologically active estradiol in target tissues). Estradiol is an extremely potent steroid. Biologically effective circulating levels of estradiol are measured using units of pg/mL or pmol/L, whereas biologically effective levels of testosterone are measured in units of ng/mL or nmol/L, and circulate at 10 to 100 times the physiologic levels of estradiol. Thus, even small rates of conversion of androstenedione to estrone may have a significant biologic impact, whereas markedly elevated production of androstenedione is required to produce significant amounts of testosterone and manifestations of androgen excess. Because such elevated production of androstenedione does occur in PCOS, extraovarian production of testosterone is biologically significant in this disease. In contrast, in postmenopausal women, who have much lower levels of androstenedione, extraovarian production of testosterone is less important. On the other hand, relatively small quantities of estrone (and estradiol) produced primarily by peripheral aromatization of androstenedione have a biologic impact in men and postmenopausal women.

Production of Testosterone-Binding Globulin in Polycystic Ovary Syndrome

TeBG binds both testosterone and estradiol and thus decreases the biologic activities of these critical steroids. In PCOS, there is an increase in the net production of androgen and estrogen. Increased estrogenic and androgenic effects in PCOS, however, are also due to a decrease in TeBG concentration giving rise to increased free or biologically active quantities of both estradiol and testosterone. The levels of TeBG are controlled by a balance of hormonal influences on its synthesis in the liver. Testosterone and insulin inhibit, whereas estrogen and FSH stimulate, TeBG formation. In anovulatory women with PCOS, circulating levels of TeBG are reduced approximately 50%, this may be a hepatic response to increased circulating levels of testosterone and insulin. Circulating free estradiol and testosterone levels are increased because of the significant decrease in TeBG in patients with PCOS.

Thus, three mechanisms contribute to the presence of increased quantities of biologically available estradiol in PCOS: (1) increased production of estradiol from estrone in peripheral (extraovarian) tissues giving rise to increased levels of circulating estradiol; (2) increased biologically available circulating estradiol because of decreased TeBG, and (3) local conversion of estrone to estradiol at target tissues. The last local mechanism is likely to be physiologically significant in estrogen targets such as the breast that proliferates in response to estrogen and in the central nervous system, which produces LHRH and gonadotropins under feedback regulation by estrogen.

In addition to giving rise to increased biologically available estradiol, decreased serum TeBG causes elevations in biologically available free testosterone levels. In turn, testosterone decreases serum TeBG levels, giving rise to a vicious feedback circle favoring low TeBG and high bioavailable testosterone levels.

Follicular Fate in Polycystic Ovary Syndrome

Under the influence of relatively low but constant levels of FSH, follicular growth is continuously stimulated, but not to the point of full maturation and ovulation. Despite the fact that full growth potential is not realized, the follicular life span may extend several months in the form of multiple follicular cysts. Most of these follicles in polycystic ovaries are 2 to 10 mm in diameter, whereas some can be as large as 15 mm. Hyperplastic theca cells, often luteinized in response to the high LH levels, surround these follicles. The accumulation of follicles arrested at various stages of development allows increased and relatively constant production of steroids in response to steady-state levels of gonadotropins.

These follicles are also subject to atresia and are replaced by new follicles of similar limited growth potential. A steady state of stromal cell turnover contributes to the stromal compartment of the ovary, and it is sustained by tissue derived from follicular atresia. A degenerating granulosa compartment, leaving the theca cells to contribute to the stromal compartment of the ovary, accompanies atresia. This functioning stromal tissue secretes significant amounts of androstenedione under the influence of increased LH. Androstenedione is not a biologically active steroid but acts as a double precursor converted to both estradiol and testosterone in extraovarian tissues. In turn, elevated testosterone suppresses TeBG synthesis, resulting in elevated free testosterone and free estradiol levels. The elevation in free testosterone further decreases TeBG. From the point of view of steroidogenesis and steroid action, the PCOS is the result of a complex vicious circle that includes a number of positive and negative feedback mechanisms.
These findings suggest an in vivo resistance to FSH action in PCOS, possibly related to the pathologic absence of an interaction between FSH- and IGF-related signaling pathways. Induction of ovulation in PCOS is achieved, therefore, by increasing FSH levels to overcome the block at the granulosa cell level. Two currently popular treatments, oral clomiphene citrate and injectable recombinant FSH, aim to provide increased levels of endogenous or exogenous FSH to overcome this in vivo defect. Granulosa cells develop and grow in response to FSH and produce estradiol; this increase in estradiol production precedes the resumption of ovulation. In fact, the polycystic ovary often overreacts to pharmacologic levels of FSH by the recruitment of a large number of developing follicles at once, occasionally giving rise to the ovarian hyperstimulation syndrome.

Ovarian Hyperthecosis

Ovarian hyperthecosis is a severe variant of PCOS. The term refers to significantly increased stromal tissue with luteinized theca-like cells scattered throughout large sheets of fibroblast-like cells. Both clinical and histologic findings represent an exaggerated version of PCOS. This diagnosis can be made on clinical grounds; an ovarian biopsy is not necessary except to rule out an ovarian tumor. Increased androgen production leads to the clinical picture of more intense androgenization. The higher testosterone levels may also lower LH levels by blocking estrogen action at the hypothalamic-pituitary level.

Hyperthecosis seems to be an exaggerated version of the same process that gives rise to chronic ovulation in PCOS. A correlation exists between the severity of insulin resistance and the degree of insulin resistance. And in turn, because insulin and IGF-I stimulate proliferation of thecal interstitial cells, hyperinsulinemia may be an important pathophysiologic factor in the etiology of hyperthecosis.

It is not uncommon to encounter markedly high levels of testosterone, even above 2 ng/mL, in ovarian hyperthecosis. Virilization is common. These patients usually do not ovulate in response to clomiphene or recombinant FSH. It is usually difficult to suppress testosterone production even using an LHRH agonist. Bilateral oophorectomy should be used as the last resort but, unfortunately, may be necessary to control testosterone production in a significant portion of these patients.

Increased waist-to-hip ratio compounded by significantly increased body mass index is called android obesity because this type of adipose tissue distribution is

Role of Obesity in Insulin Resistance and Anovulation

Increased body mass index is associated with increased estradiol and decreased sex hormone-binding globulin levels. In turn, the circulating estradiol level increases and androgen production is influenced by a genetic predisposition. In fact, women with hyperandrogenism, anovulation, and polycystic ovaries have a higher incidence of females with hyperinsulinemia and male relatives with baldness. Finally, familial aggregation of increased serum testosterone levels in PCOS suggests that androgen excess per se is a genetic trait. Genetic linkage studies are under way to identify individual gene defects that may be responsible for PCOS.

Insulin Resistance and Polycystic Ovary Syndrome

Insulin resistance is a major factor in the pathogenesis of noninsulin-dependent diabetes mellitus (NIDDM). The term insulin resistance can be defined as impaired whole-body insulin-mediated glucose disposal, as determined using techniques such as the hyperinsulinemic clamp technique. Insulin resistance is defined clinically as the inability of a known quantity of exogenous or endogenous insulin to increase glucose uptake and utilization in an individual as much as it does in the normal control. Insulin resistance is frequently observed in hyperandrogenic and obese women with PCOS. More severe degrees of insulin resistance or impaired glucose tolerance, however, are more common in obese women with PCOS.

The association between a disorder of carbohydrate metabolism and androgen excess was first described in 1921 by Archard and Thiers and was called the "diabetes of bearded women." Since then, the association between PCOS and insulin resistance or impaired glucose tolerance has been well recognized. This clinical association of insulin resistance and anovulatory hyperandrogenism is commonly found throughout the world and among different ethnic groups. In addition, the strong link between hyperinsulinemia and hyperandrogenism suggests that the stimulatory effect of insulin on ovarian androgen production is influenced by a genetic predisposition. In fact, women with hyperandrogenism, anovulation, and polycystic ovaries have a higher incidence of females with hyperinsulinemia and male relatives with baldness. Finally, familial aggregation of increased serum testosterone levels in PCOS suggests that androgen excess per se is a genetic trait. Genetic linkage studies are under way to identify individual gene defects that may be responsible for PCOS.

Insulin resistance is characterized by an impaired glucose response to a specific amount of insulin. In many of these patients, normal glucose levels are maintained at the expense of increased circulating insulin to overcome the underlying defect. More severe forms of insulin resistance in PCOS range from impaired glucose tolerance to frank NIDDM. Resistance to insulin-stimulated glucose uptake is a relatively common phenomenon in the general population, sometimes referred to as syndrome X. The fundamental abnormality leading to the manifestations that make up syndrome X is resistance to insulin-mediated glucose uptake in muscle and increased lipolysis giving rise to elevated circulating free fatty acid levels. These individuals also have dyslipidemia, hypertension, and increased risk of developing cardiovascular disease. Not surprisingly, the incidences of dyslipidemia and cardiovascular risk are also increased significantly in women with PCOS.

The incidence of hypertension increases significantly after the menopause in women with a history of PCOS. Thus, there is probably a significant clinical and pathologic overlap between syndrome X and PCOS. The extent of this overlap is not known at this time.

The clinical presentation of patients with insulin resistance depends on the ability of the pancreas to compensate for the target tissue resistance to insulin. During the first stages of the development of this condition, compensation is effective, and the only metabolic abnormality is hyperinsulinemia. In many patients, the beta cells of the pancreas eventually fail to meet the challenge, and declining insulin levels lead to impaired glucose tolerance and eventually frank diabetes mellitus. In fact, beta cell dysfunction is demonstrable in women with PCOS before the onset of glucose intolerance.

Studies of well-characterized causes of hyperinsulinemia and androgen excess have illuminated various mechanisms of insulin resistance. Factors such as a decrease in insulin binding related to autoantibodies to insulin receptors, postreceptor defects, and a decrease in insulin receptor sites in target tissues are all involved in insulin resistance. These rare syndromes, however, are found in an extremely small portion of women with anovulation, androgen excess, and insulin resistance, leaving the majority of PCOS patients without any demonstrable abnormalities in the number or quality of receptors or antibody formation. The exact nature of insulin resistance in the great majority of women with PCOS is not well understood.

In order to understand the molecular defect underlying insulin resistance in PCOS, Dunai and co-workers studied the differences between skin fibroblasts from women with and without PCOS with respect to insulin-dependent signal transduction. The fibroblasts of women with PCOS showed no change in insulin binding or receptor affinity. In half of the women with PCOS, however, a postreceptor defect was observed. This defect is characterized by increased basal insulin receptor serine phosphorylation and a decrease in insulin-dependent tyrosine phosphorylation of the insulin receptor. These abnormal patterns of phosphorylation of specific residues of the insulin receptor might represent a molecular mechanism responsible for the insulin resistance, anovulation, and androgen excess of PCOS. The cause of this abnormal phosphorylation pattern and consequences for insulin action are important topics for future study.

Rule of Obesity in Insulin Resistance and Anovulation

Increased waist-to-hip ratio compounded by significantly increased body mass index is called android obesity because this type of adipose tissue distribution is observed more commonly in men. Overweight women with anovulatory androgen excess commonly have this particular body fat distribution. Android obesity is the result of fat deposited in the abdominal
wall and visceral mesenteric locations. This fat is more sensitive to catecholamines, less sensitive to insulin, and more active metabolically. Android obesity is associated with insulin resistance, glucose intolerance, diabetes mellitus, and an increase in androgen production rate resulting in decreased levels of TeBG and increased levels of free testosterone and estradiol. 414 430 432 433 Not surprisingly, android obesity is associated significantly with cardiovascular risk factors, including hypertension and dyslipidemia. It is also important to emphasize that android obesity has been linked to a notable increase in the risk of breast cancer, with a poor prognosis. 432 433 No direct association, however, has been reported between PCOS and breast cancer risk. 433

Although the combination of insulin resistance and androgen excess is often observed in obese women overall, women with android-type obesity appear to be at a significantly higher risk for insulin resistance and androgen excess. However, insulin resistance and androgen excess are not confined to obese anovulatory women but also occur in nonobese anovulatory women. 414 430 432 433 Although obesity by itself causes insulin resistance, the combination of insulin resistance and androgen excess is a specific feature of PCOS. Not surprisingly, the combination of obesity and PCOS is associated with more severe degrees of insulin resistance than those found in nonobese women with PCOS. 432 433 434 Android-type obesity, in contrast to general obesity, is a much more specific risk factor for PCOS.

Diagnosis of Insulin Resistance

In everyday clinical practice, the biochemical diagnosis of insulin resistance in an individual patient has not been standardized and is extremely complex. First, a quarter of the normal population has fasting and glucose-stimulated insulin levels that overlap those of insulin-resistant individuals 434 435 because of great variability of insulin sensitivity in normal subjects. Second, clinically available measures of insulin action, such as fasting or glucose-stimulated insulin levels, do not correlate well with more detailed measurements of insulin sensitivity in research settings.

In view of these constraints, it is reasonable to consider all women with PCOS at risk for insulin resistance and the associated abnormalities of the insulin resistance syndrome (syndrome X) dyslipidemia, hypertension, and cardiovascular disease. A lipid profile should be obtained in all cases of PCOS. Especially obese women with PCOS should have fasting glucose levels and glucose levels 2 hours after a 75-g glucose load as a screen for glucose intolerance. The clinician should encourage the patient to take every possible measure (e.g., weight reduction and exercise) to reduce insulin resistance.

Use of Antidiabetic Drugs to Treat Anovulation and Androgen Excess

A logical approach to the management of PCOS includes the use of medications that improve insulin sensitivity in target tissues, thus achieving reductions in insulin secretion and stability of glucose tolerance. Oral agents employed in the treatment of diabetes mellitus, such as metformin and troglitazone, have been used to induce ovulation and decrease circulating androgen in anovulatory women with PCOS. The biguanide metformin improves insulin sensitivity, but the primary effect is a significant reduction in glucose tolerance, thus decreasing hepatic glucose production.

Metformin at a dose of 500 mg three times a day reduced hyperinsulinemia, basal and stimulated LH levels, and free testosterone concentrations in overweight women with PCOS. 414 430 436 A significant number of these anovulatory women ovulated and achieved pregnancy. 432 433 The addition of metformin to clomiphene citrate resulted in a remarkable improvement in the ovulation rate in obese women with PCOS. 432 433 The improvements in ovulation and androgen levels in this study might in part result from the weight loss that often accompanies the use of metformin. 432 433 Investigators of subsequent published studies, however, concluded that in both lean and obese anovulatory women, metformin treatment reduced hyperinsulinemia and androgen excess independent of changes in body weight. 434 435 437 Metformin thus has the added benefit of having a promising medication for the reduction of cardiovascular risk and induction of ovulation in women with PCOS. The benign side-effect profile of this medication also makes it an attractive choice.

The thiazolidinediones are pharmacologic ligands for the nuclear receptor peroxisome proliferator-activated receptor (PPAR). A member of this family, troglitazone, at a dose of 400 mg/day, markedly improves insulin action and insulin secretion through improved peripheral glucose utilization and beta cell function without weight changes. Troglitazone decreased insulin, LH, and testosterone levels and increased circulating TeBG. 432 434 435 Resumption of ovulation in obese women has been reported with the use of troglitazone. 434 435 However, troglitazone, the first thiazolidinedione approved by the Food and Drug Administration in the United States, proved to be hepatotoxic and was withdrawn from the market after the report of several dozens of deaths and cases of severe hepatic failure requiring liver transplantation. The safety and therapeutic potential of new thiazolidinediones currently are being tested in PCOS. 432

Management of Long-Term Deleterious Effects of Polycystic Ovary Syndrome

The long-term consequences of PCOS include irregular uterine bleeding, anovulatory infertility, androgen excess (hirsutism or virilization or both), chronically elevated free estrogen associated with an increased risk of endometrial cancer, and insulin resistance associated with an increased risk of cardiovascular disease and diabetes mellitus. Therefore, treatment must encompass the following: (1) in achieving a healthy lifestyle and normal body weight, protection of the endometrium from unopposed estrogen effects, and a reduction in testosterone levels.

If the patient desires pregnancy, she is a candidate for the medical induction of ovulation. When pregnancy is achieved, patients with polycystic ovaries appear to have an increased risk of spontaneous miscarriage. However, patients with PCOS who have not ovulated spontaneously have a normal spontaneous pregnancy rate. This increased risk may be related to elevated levels of LH that may produce an adverse environment for the oocyte and the endometrium. Therefore, LH levels should be suppressed with oral contraceptives before inducing ovulation. This suppression can be achieved in most patients with PCOS by the use of an oral contraceptive for 4 to 6 weeks before ovulation induction with clomiphene citrate or recombinant FSH.

If the patient does not wish to become pregnant, therapy is directed toward the interruption of unopposed effect of estrogen on the endometrium. Nonfluctuating levels of unopposed estradiol in the absence of progesterone cause irregular uterine bleeding, amenorrhea, and infertility and increase the risk of endometrial cancer. Anovulatory women with PCOS may have endometrial cancer even in their early 20s. 432 434 435 Therefore, endometrial biopsy should be performed periodically in untreated women with PCOS regardless of age. The uterine bleeding pattern should not influence the decision to perform an endometrial biopsy. The presence of amenorrhea does not rule out endometrial hyperplasia. The critical factor that determines the risk of endometrial neoplasia is the duration of anovulation and exposure to unopposed estradiol. Long-term treatment with a progestin or oral contraceptive significantly decreases the risk of endometrial cancer.

One of the simplest and most effective ways to administer a progestin in the long term is to use an oral contraceptive. Also, oral contraceptives provide two more benefits: reduction of androgen excess and contraception. Oral contraceptive pills reduce circulating androgen levels through suppression of circulating LH and stimulation of TeBG levels and have been shown to reduce hirsutism in hyperandrogenic patients. 435

A concern regarding possible insulin-desensitizing effects of oral contraceptives has been raised. 435 Older oral contraceptives cause increased insulin resistance because of the high estrogen component. 435 Long-term follow-up studies, however, have failed to detect any increase in the incidence of diabetes mellitus in past or current users of high-dose pills. 435 436 In fact, more recent studies demonstrated that new oral contraceptives induced neither change or a significant decrease in insulin resistance in women with PCOS. The oral contraceptives that did not induce insulin resistance in women with PCOS contained an ethinyl estradiol dose of 30 µg or less and a desogestrel, norgestimate, or gestodene as the progestin component. 435 436 Furthermore, past users of oral contraceptives have no increased cardiovascular risk. 435 Low-dose oral contraceptives have also been administered to women with gestational diabetes or insulin-dependent diabetes mellitus without an adverse impact. 435 436 437 438 Low-dose oral contraceptives have not increased the risk of retinopathy or nephropathy in diabetic patients, nor has there been any deterioration of lipid or biochemical markers. 435 436 437 438 It should be emphasized again that the major contributing factor to hyperinsulinemia and insulin resistance in PCOS is obesity. 435 438 In summary, oral contraceptive treatment for anovulatory and hyperinsulinemic women with androgen excess does not increase cardiovascular risk.

For the patient who does not complain of hirsutism but is anovulatory and has irregular bleeding, treatment with a single progestin may be attempted as an alternative to oral contraceptives. Progestin therapy is directed toward interruption of the chronic exposure of endometrium to unopposed effects of estrogen.
Medroxyprogesterone acetate, 10 mg daily for the first 10 days of every month, can be administered to ensure withdrawal bleeding and prevent endometrial hyperplasia. This treatment does not decrease androgen excess, nor does it provide contraception. Because new oral contraceptives (with an ethinyl estradiol content of 30 µg or less and a new progestin) suppress androgen excess of ovarian origin, provide contraception, protect the endometrium, and do not increase insulin resistance, a new low-dose oral contraceptive is the treatment of choice for nonsmokers with PCOS. An oral contraceptive together with the antiandrogen spironolactone, 100 mg/day, is the recommended starting treatment for a hirsute woman with PCOS. The dose of spironolactone can be increased in increments to suppress hair growth as previously described in this section.

Treatment with an oral contraceptive (plus or minus spironolactone) may not be effective in androgen suppression in severe cases of PCOS. In these patients resistant to oral contraceptives, suppression of the ovary with an LHRH agonist may be required. Because glucocorticoids increase insulin resistance, they should be used with caution in patients with hyper-insulinemia. Spironolactone does not affect insulin sensitivity in anovulatory women and can be used safely without causing adverse effects on carbohydrate or lipid metabolism. Therefore, long-term follow-up studies have shown a significantly increased risk for the development of frank diabetes mellitus in anovulatory patients with PCOS. It is therefore important to monitor glucose tolerance with periodic glucose levels after fasting and after a 75-g glucose load.

Because insulin resistance contributes to the abnormal lipid profile and increased cardiovascular risk in women with PCOS, weight loss is a high priority for patients who are overweight. Both insulin resistance and androgen excess can be reduced with a weight reduction of at least 5%. Significant weight loss also resulted in ovulation and pregnancy in a number of patients with PCOS. Therefore, long-term nutritional counseling and an emphasis on lifestyle changes are essential components of the long-term management of PCOS.

The place of insulin sensitizers, such as metformin and thiazolidinediones, in the treatment of PCOS remains to be determined by data from future clinical trials. When one takes into account the design of how this treatment should work, the potential for its preventive benefits is impressive. Preliminary findings suggest that thiazolidinediones are a potent group of medications that restore ovulation by reducing insulin resistance and androgen excess. Unfortunately, troglitazone, the first compound approved by the Food and Drug Administration in the United States, proved to be hepatotoxic and was withdrawn from the market after the report of a small but significant number of liver failures and deaths. The most important factor determining the extent of use of new thiazolidinediones in PCOS will be their side-effect profiles (e.g., liver toxicity and teratogenesis). By contrast, the majority of publications on metformin show no serious side effects or teratogenicity. Metformin does seem to improve metabolic abnormalities and restore ovulation. Further studies are in progress to determine the roles of these antidiabetics as therapeutic agents in PCOS.

In long-term follow-up of women with PCOS, android obesity and hyperinsulinemia persisted during the postmenopausal years. Thus, postmenopausal women who have previously been anovulatory, hyperandrogenic, and hyperinsulinemic are at risk for cardiovascular disease and diabetes mellitus. Aggressive preventive health care interventions that lower cardiovascular risk and other unfavorable consequences of PCOS are appropriate.

Genetic counseling is of paramount importance for the families of patients with PCOS. A growing body of evidence suggests that up to half of first-degree relatives and sisters may be affected by PCOS or at least by androgen excess in the presence of regular menses. These individuals may be at higher than average risk for cardiovascular disease and may benefit from preventive measures that reduce this risk.

Ovulation Induction by an Aromatase Inhibitor

Clomiphene Citrate.

To induce ovulation in PCOS, FSH levels are increased through the use of, for example, clomiphene citrate or by injection of recombinant FSH. Presumably, pharmacologic levels of FSH overcome the ovarian defect responsible for anovulation in PCOS.

Clomiphene citrate is a nonsteroidal ovulation-inducing ER ligand with mixed agonistic-antagonistic properties. Acting as an antiestrogen, clomiphene citrate is thought to displace endogenous estrogen from hypothalamic ERs, thereby removing the negative feedback effect exerted by endogenous estrogens. The resultant increase in pulsatile LHRH release is thought to normalize the release of pituitary FSH and LH, followed by follicular recruitment and selection, assertion of dominance, and, ultimately, ovulation.

Clomiphene citrate treatment can be started at any time in an amenorrheic and anovulatory patient provided that a pregnancy test is performed beforehand. Alternatively, urine

bleeding may be induced after a 21-day treatment with an oral contraceptive or 10-day treatment with medroxyprogesterone acetate (10 mg/day). Clomiphene citrate at 50 mg/day is started orally on day 3, 4, or 5 of the cycle and continued for 5 days. Over the past 20 some years, we have used a practical approach termed triple-7 in order to monitor indicators of ovulation after the administration of clomiphene citrate. The protocol is depicted in Figure 16-38. This approach is timed favorably to detect the preovulatory surge of serum estradiol 7 days after the last clomiphene citrate dose (arrow pointing up) and a serum progesterone level 14 days after the last clomiphene citrate dose (arrow pointing down) in order to document ovulation. A repeated office visit is scheduled 7 days after the progesterone determination, that is, 21 days after the last clomiphene citrate dose (see Fig. 16-38). The patient should be encouraged to have intercourse every other day during the 10-day period following the last clomiphene citrate dose. Alternatively, measurement of urinary LH to detect an LH surge can be used to time intercourse.

If ovulation does not occur after the first course of therapy with clomiphene citrate at 50 mg/day, a second course of 100 mg daily for 5 days may be started. Lack of response at doses of 150 to 200 mg daily for 5 days should be an indication for a change of treatment. Most patients desired to conceive do so with the starting dose of clomiphene citrate (50 mg/day for 5 days). Most clomiphene citrate initiated conceptions are likely to occur within the first six ovulatory cycles. The incidence rate for multiple gestation in clomiphene citrate induced pregnancies is 7.9%, of which 6.9% are twins.

Letrozole.

The aromatase inhibitor letrozole has been used as an experimental medication to induce ovulation. The mechanism of action appears to be similar to that of clomiphene citrate. Oral administration of letrozole (2.5 mg/day on days 3 to 7 after uterine bleeding) is effective for ovulation induction in anovulatory infertility.

Ovulation induction by an aromatase inhibitor is presumed to be mediated by estrogen deficiency induced at the level of the hypothalamus. Letrozole appears to avoid the unfavorable effects on the endometrium frequently seen with the use of antiestrogens (e.g., clomiphene citrate) for ovulation induction. Clinical data regarding this experimental treatment are extremely scarce at the moment.

For women who do not ovulate in response to clomiphene citrate, recombinant FSH is administered subcutaneously at a starting dose of two ampules (equivalent to 150 IU of FSH), starting on day 3 of spontaneous or progesterin-induced uterine bleeding and increasing by 75 IU at 3- to 7-day intervals until serum estradiol concentrations begin to increase. The dose is then maintained until follicular rupture, which is induced by intramuscular administration of hCG (10,000 IU). Follicular growth is monitored by transvaginal ultrasonography and blood estradiol levels, which serve as biochemical markers for the granulosa cell mass in the growing

Figure 16-38 Hormonal monitoring in clomiphene citrate initiated ovulation: use of the triple-7 regimen. Please see text. (From Adashi EY. Clomiphene citrate-initiated ovulation: a clinical update. Semin Reprod Endocrinol 1996; 4:255-271.)
Three important complications of gonadotropin therapy in PCOS are significantly increased rates of multiple pregnancies, severe ovarian hyperstimulation syndrome, and spontaneous miscarriage. Conventional-dose gonadotropin therapy causes two important complications: (1) an alarming number of multiple pregnancies (range, 14% to 50% of treatment cycles) and (2) a significantly increased risk of severe ovarian hyperstimulation syndrome (range, 1.3% to 9.4% of treatment cycles).

Conventional-dose FSH regimens for induction of ovulation for women with PCOS have succeeded in reducing the rate of multiple pregnancies to as low as 6% in some series. The low-dose regimen also practically eliminated the complication of severe ovarian hyperstimulation syndrome. This has been achieved by reaching, but not exceeding, the threshold level of FSH, starting with a daily dose of 75 IU for 14 days and using small incremental dose increases when necessary. This regimen induces the development of a single follicle in 70% of cycles. Conception rates are comparable to those achieved with conventional therapy. The miscarriage rate remains somewhat higher than that after spontaneous conception (20% to 25%). The treatment time for the low-dose regimen is significantly longer than that required for conventional gonadotropin treatment. New data obtained using recombinant FSH for a low-dose regimen, rather than urinary gonadotropins, suggest that treatment time may be shortened.

Premature Ovarian Failure

Premature ovarian failure, which is defined as early depletion of ovarian follicles before the age of 40, is a state of hypergonadotropic hypogonadism. These patients present with amenorrhea or oligomenorrhea. They go through a normal puberty and a variable period of cyclic menses followed by oligomenorrhea and amenorrhea. Therefore, premature ovarian failure should always be included in the differential diagnosis of chronic anovulation. History and physical examination may reveal menstrual irregularity or secondary amenorrhea accompanied by symptoms and signs of estrogen deficiency, such as hot flashes and urogenital atrophy. Elevated FSH levels (above the 95% confidence limits of the midcycle gonadotropin peak of the normal menstrual cycle, i.e., > 40 IU/L) on at least two occasions confirm the diagnosis.

On average, the menopause occurs at the age of 50 years, with 1% of women continuing to menstruate beyond the age of 60 years and another 1% whose menopause occurs before 40 years. Thus, premature menopause or ovarian failure has been arbitrarily defined as the cessation of menses before 40 years of age. In most cases, the etiology of premature ovarian failure is not clear. The patient may be counseled that the disorder is probably a genetic one causing ovarian follicles to disappear at a rate faster than normal. Specific sex chromosome anomalies may be identified in a subset of patients presenting with premature ovarian failure. Among these, 45,X and 47,XXY are the most common, followed by mosaicism involving various combinations.

The underlying ovarian defect may be manifest at varying ages, in the number of follicles present in the ovaries. The different symptoms may be regarded as phases in the process of perinatalgonadal change regardless of the actual age of the patient. If loss of follicles occurs rapidly before puberty, primary amenorrhea and lack of secondary sexual development ensue. The degree to which the adult phenotype develops and when the secondary amenorrhea actually occurs depend on whether follicle loss took place during or after puberty. In cases of primary amenorrhea associated with sexual infantilism, the ovarian remnants exist as streaks, and transvaginal ultrasonography usually cannot detect any ovaries.

Premature ovarian failure can be due to an autoimmune process, as this condition is frequently detected in association with autoimmune polyendocrine syndromes. Other causes of premature ovarian failure can be related to the sudden destruction of the follicles through factors such as chemotherapy, radiation, or infections such as mumps or gonorrhea. The effect of radiation is dependent upon age and the x-ray dose. Steroid levels begin to fall and gonadotropins rise within 2 weeks after radiation of the ovaries. Young women exposed to radiation are less likely to have permanent ovarian failure because of the higher number of oocytes present at younger ages. When the radiation field excludes the pelvis or the ovaries are transposed out of the pelvis by laparoscopic surgery before radiation, there is no risk of premature ovarian failure. Most chemotherapeutic agents used for the eradication of malignancies are toxic to the ovaries and cause ovarian failure. Resumption of menses and pregnancy have been reported after radiotherapy or chemotherapy. By the same token, premature ovarian failure may occur years after chemotherapy or radiotherapy.

Finally, single gene defects may give rise to ovarian failure. These include mutations of FSH and LH receptors and galactosia. Mutations of galactose-1-phosphate uridyltransferase, for example, can lead to ovarian failure because of the accumulation of galactose-1-phosphate at toxic levels.

Diagnosis and Management of Premature Ovarian Failure

Premature ovarian failure should be suspected in a woman who is younger than 40 years who presents with amenorrhea, oligomenorrhea, or another form of menstrual irregularity. Menopausal serum FSH levels (40 IU/L) on at least two occasions are sufficient for the diagnosis of premature ovarian failure. Thus, these young women can be diagnosed with ovarian failure and infertility if gonadotropin levels are repeatedly elevated. There are, however, a number of case reports of pregnancies in affected women occurring during hormone replacement therapy. A randomized trial of hormone replacement in this setting showed that folliculogenesis occurred often but was less frequently followed by ovulation and even less frequently by pregnancy (up to 14%); estrogen therapy did not improve the rate of folliculogenesis, ovulation, or pregnancy. Therefore, the clinician should inform patients diagnosed with premature ovarian failure that there is a small but significant likelihood of spontaneous pregnancy in the future. Women desirous of achieving pregnancy are still best served by assisted reproductive technology employing donor oocytes because the probability of spontaneous pregnancy is low. Use of donor oocytes followed by in vitro fertilization with the partner's sperm and intratubal embryo transfer after synchronization of the recipient patient's endometrium with the donor's cycle using exogenous estrogen and progesterone are offered to the patient who wishes to carry a pregnancy in her uterus. This approach offers an excellent chance of pregnancy (>50% per donor oocyte in vitro fertilization cycle).

Patients with premature ovarian failure are at increased risk for having an abnormal complement of chromosomes. The risk of having an abnormal karyotype increases with decreasing age of onset of the ovarian failure. A chromosomal analysis is recommended for some of these patients because of increased risk of a gonadal tumor associated with the presence of a Y chromosome. The arbitrarily chosen age group for chromosomal analysis includes women 30 years of age or younger because it is extraordinarily rare to encounter a gonadal tumor in patients with premature ovarian failure after the age of 30.

The presence of mosaicism including a Y chromosome has been associated with a high incidence of gonadal tumors. These malignant tumors arise from germ cells and include gonadoblastomas, dysgerminomas, yolk sac tumors, and choriocarcinoma. In particular, the presence of secondary virilization in these patients with karyotypic abnormalities and premature ovarian failure significantly increases the risk of a dysontogenetic gonadal tumor. The precise risk of a tumor in various subsets of these patients is not well known because a significant number of women carrying a Y chromosome do not have symptoms of virilization. The frequency of Y-chromosome material determined by polymerase chain reaction is high in Turner's syndrome (12.2%), but the occurrence of a gonadal tumor among these Y-positive patients needs to be as low as 7% to 10%.

| TABLE 16-9 – Laboratory Evaluation of Premature Ovarian Failure |
|------------------|------------------|------------------|------------------|------------------|
| Karyotype (< 30 yr of age or sexual infantilism) | Cortisol after ACTH stimulation (adrenal insufficiency) | TSH (hypothyroidism) | Glucose (fasting and 2 hr after 75-g glucose load, diabetes mellitus) |
| FSH (to establish the diagnosis of premature ovarian failure) | | | |

637
Calcium and phosphorus (hypoparathyroidism)
Sedimentation rate, complete blood count with differential, antinuclear antibody, rheumatoid factor (autoimmune disease)
Pregnenolone (to evaluate 17-hydroxylase deficiency in sexually infantile women)
Galactose-1-phosphate (galactosemia)

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone.

Premature ovarian failure may also occur as an isolated autoimmune disorder or in association with hypothyroidism, diabetes mellitus, hypoadrenalism, hypoparathyroidism, or systemic lupus erythematosus. Therefore, the tests listed in Table 16-9 should be performed every few years because premature ovarian failure can be part of an autoimmune polyendocrine syndrome. Thyroid and adrenal insufficiency and diabetes mellitus are the endocrine disorders most frequently associated with premature ovarian failure. It should be noted, however, that overall it is fairly rare to encounter any endocrine disorder associated with premature ovarian failure.

Treatment of premature ovarian failure should be directed toward its specific cause, if this is possible. In most cases, however, it is not possible to identify a specific etiology if there are no karyotypic anomalies. If the patient desires pregnancy, she should be offered ovum donation and in vitro fertilization using her partner's sperm (see Fig. 16-29). If pregnancy is not desired, she should be treated with an oral contraceptive or with estrogen and progestin replacement. Estrogen therapy promotes and maintains secondary sexual characteristics and prevents premature osteoporosis.
Differential Diagnosis and Management of Anovulatory Uterine Bleeding

Acyclic production of estrogen during anovulatory cycles gives rise to irregular shedding of the endometrium. These bleeding manifestations of anovulatory cycles in the absence of uterine pathology or systemic illness are commonly referred to as dysfunctional uterine bleeding. Anovulatory uterine bleeding is the most common cause of chronic menstrual irregularities and is a diagnosis of exclusion. Pregnancy, uterine leiomyomas, endometrial polyps, and adenomyosis should be ruled out as anatomic causes of irregular uterine bleeding. Malignancies of the vagina, cervix, endometrium, myometrium, fallopian tubes, and ovaries should also be ruled out before a diagnosis of anovulatory uterine bleeding is made. Finally, coagulation abnormalities should be excluded.

Anovulatory uterine bleeding can be managed without surgical intervention by either restoring ovulation or mimicking the ovulatory hormonal profile by providing exogenous steroids. The rationale for using exogenous steroids is based on the knowledge of predictable responses of the endometrium to estrogen and progesterone. Physiologic responses of the endometrium to natural ovarian steroids have been uncovered by observing the gross and microscopic changes in the endometrium during thousands of normal ovulatory cycles in humans and other primates. The pharmacologic application of exogenous estrogens and progestins in women with anovulatory bleeding aims to correct the production of local tissue factors, which mediate physiologic steroid action, and thus reverse the excessive and prolonged flow typical of anovulatory cycles.

Clinical management of irregular uterine bleeding with exogenous hormones is a time-honored method and is also of diagnostic value. Failure to control vaginal bleeding with hormonal therapy, despite appropriate application and utilization, makes the diagnosis of anovulatory uterine bleeding considerably less likely. In this case, attention is directed to an anatomic pathologic entity within the reproductive axis as the cause of abnormal bleeding.

Heavy but regular menstrual bleeding (hypermenorrhea) can be encountered in ovulatory women. It may be due to anatomic causes such as a leiomyoma impinging on the endometrial cavity or the diffuse and pathologic presence of benign endometrial glands in the myometrium (adenomyosis). In the absence of a specific pathologic cause, however, it is presumed that hypermenorrhea reflects subtle disturbances in the endometrial tissue mechanism. In essentially all cases, evaluation and treatment are identical to the approach detailed in this section.

Characteristics of Normal Menstrual Periods

Normal menstruation takes place about 14 days after each ovulation episode as a consequence of postovulatory estrogen-progesterone withdrawal. The quantity and duration of bleeding are quite reproducible. This predictability leads many women to expect a certain characteristic flow pattern. Any slight deviations, such as plus or minus 1 day in duration or minor deviation from expected tampon utilization, are causes for major concern in the patient. Most women of reproductive age can predict the timing of their flows so accurately that even some instances of minor variability may require reassurance by the clinician. Although variability of menstrual cycles is a common feature during teenage years and the perimenopausal transition, the characteristics of menstrual bleeding do not undergo appreciable change between ages 20 and 40.

For ovulatory women, the changes in the length of menstrual cycles over the period of reproductive age are predictable. Between menarche and age 20, the cycle length for most ovulatory women is relatively longer. Between 20 and 40, there is increased regularity as cycles shorten. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles occurs before age 20 and after age 40. In this age group, the average length of a cycle is between 25 and 28 days. Among ovulatory women, the frequency of a cycle less than 21 days long or a cycle greater than 35 days is extremely rare (less than 2%). Overall, most women have cycles that last from 24 to 35 days. Between ages 40 and 50, menstrual cycle length increases and anovulation becomes more prevalent. The average postovulatory bleeding lasts from 4 to 6 days. The normal volume of menstrual blood loss is 30 mL. More than 80 mL is considered abnormal. Most of the blood loss occurs during the first 3 days of a period, so excessive flow may exist without prolongation of flow.

During an ovulatory cycle, the duration from the ovulation to menses is relatively constant and averages 14 days. Greater variability in the length of proliferative phase, however, produces a distribution in the duration of a menstrual cycle. Menstrual bleeding more often than every 24 days or less often than every 35 days requires evaluation. Flow that lasts 7 or more days also requires evaluation. A flow that totals more than 80 mL per month usually leads to anemia and should be treated. In clinical practice, however, it is quite difficult to quantify menstrual flow because evaluation and treatment are based solely on the patient's perceptions regarding the duration, amount, and timing of her menstrual bleeding. Despite this difficulty in quantifying menstrual blood loss, the clinician should evaluate the cause of excessive uterine bleeding. Anemia should be ruled out by a complete blood count. A low hemoglobin value accompanied by microcytic and hypochromic red blood cells suggests excessive blood loss during menses. These patients should be provided with iron supplementation. The likely presence of coagulation defects, uterine leiomyomas, or adenomyosis underlying prolonged menses should also be evaluated in anemic patients through a meticulous history and physical examination followed by relevant laboratory tests.

Termination of Menstruation

Oligomenorrhea is defined as intervals between episodes of uterine bleeding greater than 35 days, and the term polymenorrhea is used to describe intervals less than 24 days. Hypomenorrhea refers to regular intervals (24 to 35 days) but excessive flow or duration of bleeding, or both. Hypomenorrhea refers to diminution of the flow or shortening of the duration of regular menses, or both.

Uterine Bleeding in Response to Steroid Hormones

Exogenous Estrogens

Uterine bleeding follows acute cessation of estrogen support to the endometrium. Thus, this type of uterine bleeding can occur after bilateral oophorectomy, radiation of the ovaries, or cessation of exogenous estrogen therapy. Similarly, the bleeding that occurs between cycles can be delayed by concomitant estrogen therapy. Flow occurs on discontinuation of exogenous estrogen. Thus, estrogen withdrawal by itself (in the absence of progesterone) almost invariably causes uterine bleeding.

Exogenous Progestins

Chronic exposure to varying quantities of estrogen stimulates the growth of endometrium continuously in the absence of progesterone, as in the case of excessive

639

Figure 16-39. Variation of the duration of the menstrual cycle in women with regular cycles. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In Williams Obstetrics, 19th ed. Stamford, Conn, Appleton & Lange, 1993, pp 81109.)

639

In clinical practice, however, it is quite difficult to quantify menstrual flow because evaluation and treatment are based solely on the patient's perceptions regarding the duration, amount, and timing of her menstrual bleeding. Despite this difficulty in quantifying menstrual blood loss, the clinician should evaluate the cause of excessive uterine bleeding. Anemia should be ruled out by a complete blood count. A low hemoglobin value accompanied by microcytic and hypochromic red blood cells suggests excessive blood loss during menses. These patients should be provided with iron supplementation. The likely presence of coagulation defects, uterine leiomyomas, or adenomyosis underlying prolonged menses should also be evaluated in anemic patients through a meticulous history and physical examination followed by relevant laboratory tests.

Terminology Describing Abnormal Uterine Bleeding

Oligomenorrhea is defined as intervals between episodes of uterine bleeding greater than 35 days, and the term polymenorrhea is used to describe intervals less than 24 days. Hypomenorrhea refers to regular intervals (24 to 35 days) but excessive flow or duration of bleeding, or both. Hypomenorrhea refers to diminution of the flow or shortening of the duration of regular menses, or both.
extragonadal estrogen production in PCOS. After a certain point, the amount of estrogen produced in extraovarian tissue remains insufficient to maintain structural support for the endometrium. This gives rise to unpredictable episodes of shedding of the surface endometrium. Relatively low doses of estrogen yield intermittent spotting that may be prolonged but is generally light in quantity of flow. On the other hand, high levels of estrogen and sustained availability lead to prolonged periods of amenorrhea followed by acute, often profuse episodes of bleeding with excessive loss of blood.

**Progesterone Withdrawal Bleeding.**

The typical progesterone withdrawal bleeding occurs after ovulation in the absence of pregnancy. Removal of the corpus luteum is another example that leads to endometrial desquamation. Pharmacologically, a similar event can be achieved by administration and discontinuation of progesterone or a synthetic progestin. Progesterone withdrawal bleeding occurs only if the endometrium is initially primed by endogenous or exogenous estrogen. If estrogen therapy is continued as progesterone is withdrawn, the progesterone withdrawal bleeding still occurs. Only if estrogen levels are increased markedly is progesterone withdrawal bleeding delayed. Thus, progesterone withdrawal bleeding is quite predictable in the presence of previous or concomitant estrogen exposure.

**Progestin Breakthrough Bleeding.**

This is a pharmacologic phenomenon that occurs in the presence of an unfavorably high ratio of progestin to estrogen. In the absence of sufficient estrogen, continuous progestin therapy leads to intermittent bleeding of variable duration, similar to the low-dose estrogen breakthrough bleeding noted previously. This type of bleeding is associated with the combination oral contraceptives that contain low-dose estrogen and the long-acting progestin-only contraceptive methods such as Norplant and Depo-Provera. Progestin breakthrough bleeding is highly unpredictable and characterized by extensive variability between women.

**Causes of Irregular Uterine Bleeding**

Pregnancy and its complications represent one of the most common causes of irregular uterine bleeding (Table 16-10). Pregnancy should be ruled out by a urine test in any woman of reproductive age presenting with irregular bleeding (Table 16-11).

As pointed out earlier, anovulatory uterine bleeding arising from responses of the endometrium to inappropriate production of ovarian steroids has also been called dysfunctional uterine bleeding because treatments that restore ovulatory function potentially reverse the irregular bleeding pattern. Common examples of anovulatory bleeding include those associated with exercise-related anovulation, hyperprolactinemia, hypothroidism, or PCOS. In these cases, either restoring ovulatory menses by correction of the underlying disorder or use of exogenous hormones can achieve predictable uterine bleeding. On the other hand, various pathologic entities of the genital tract (ovaries, uterus, vagina, or vulva) or a coagulation abnormality may also cause deviation from normal menses (see Table 16-10).

Anovulatory uterine bleeding is a diagnosis of exclusion for the following reasons. Vulvar, vaginal, or uterine malignancies can give rise to irregular bleeding. Moreover, an estrogen- or androgen-secreting ovarian tumor may cause abnormal uterine bleeding (see Table 16-10). Pregnancy and pregnancy-related problems such as ectopic pregnancy or spontaneous miscarriage are extremely common causes of abnormal uterine bleeding. In fact, the most common cause of disruption of a normal menstrual pattern is pregnancy or a complication of pregnancy. Another

AIDS, acquired immunodeficiency syndrome; LHRH, luteinizing hormone-releasing hormone; PCOS, polycystic ovary syndrome.

Commonly Used Tests

Urine hCG test
Serum hCG level (incomplete miscarriage, ectopic pregnancy)
Transvaginal pelvic ultrasonography (intrauterine or ectopic pregnancy, uterine leiomyoma, endometrial polyp or neoplasia, ovarian tumor)
Serum FSH, LH (anovulation; ovarian failure)
Serum prolactin, TSH (anovulation; hyperprolactinemia)
Complete blood count, PT, PTT (coagulation defect)
Liver and renal functions, HIV (anovulation; chronic disease)
Endometrial biopsy (endometrial disease; polyp, neoplasia, endometritis)

Less Commonly Used Tests

Evaluation for PCOS, ovarian or adrenal tumor, nonclassical adrenal hyperplasia, Cushing's syndrome and glucocorticoid resistance (androgen excess)
Head CT or MRI scan (hypothalamic anovulation, hyperprolactinemia)
Pelvic MRI scan (adenomyosis, uterine leiomyoma)
Hysterosonography with intrauterine saline installation (endometrial polyp, uterine leiomyoma)
Hysteroscopy (endometrial polyp, uterine leiomyoma)
Dilatation and curettage (endometrial disease not diagnosed by ultrasonography or biopsy)

CT, computed tomography; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; HIV, human immunodeficiency virus; LH, luteinizing hormone; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TSH, thyroid-stimulating hormone.

common cause of irregular uterine bleeding is observed in oral contraceptive users in the form of progestin breakthrough bleeding. Progestin breakthrough bleeding during postmenopausal hormone replacement is also common (see later). Patients may be using other hormonal medications unknowingly with an impact on the endometrium. For example, the use of ginseng, an herbal root, has been associated with estrogenic activity and abnormal bleeding. Although uterine bleeding is a common benign side effect of various long-term hormonal treatments, the clinician should always be convinced that no other pathology is present. Anatomically demonstrable pathologies of the menstrual outflow tract include endometrial hyperplasia and cancer, endometrial polyps, leiomyomata uteri, adenomyosis, and endometritis. Irregular, serious bleeding may also be associated with chronic illness, such as renal failure, liver failure, and acquired immunodeficiency syndrome. Finally, careful examination is worthwhile to discover genital injury or a foreign object. At puberty, the most common cause of irregular uterine bleeding is anovulation. Approximately 20% of these adolescents with excessive irregular uterine bleeding, however, have a coagulation defect. Among all women of reproductive age with hypermenorrhea, the prevalence of a coagulation disorder was reported to be 17%. Von Willebrand's disease was the most common defect, and factor XI deficiency was the second common diagnosis. Bleeding secondary to a coagulation defect is usually a heavy flow with regular, cyclic menses (hypermenorrhea), and the same pattern can be seen in patients being treated with anticoagulants. Bleeding disorders are usually associated with hypermenorrhea since menarche and a history of bleeding with surgery or trauma. Hypermenorrhea may be the only sign of an inherited bleeding disorder.

Early pregnancy or its complications should always be ruled out first by a sensitive urine hCG measurement in any reproductive-age women presenting with irregular bleeding. Threatened or incomplete miscarriage and ectopic pregnancy are extremely common causes of irregular uterine bleeding. Other tests should be ordered if necessary on the basis of the initial clinical evaluation. These include tests to evaluate anovulatory disorders of various etiologies in patients with a history of prolonged heavy menses (hypermenorrhea) of pubertal origin, coagulation studies (e.g., prothrombin time, partial thromboplastin time, and bleeding time) and a complete blood count should be obtained.
Pelvic ultrasonography through a vaginal probe is an extremely useful test for the evaluation of normal or abnormal pregnancy, uterine leiomyomas, endometrial neoplasia, and ovarian tumors (see Table 16-11). Other imaging studies may be used judiciously to rule out pathologies of the hypothalamic, pituitary, or adrenal (see earlier). Of note is the use of pelvic MRI to rule out adenomyosis, a uterine disorder characterized by the abnormal presence of diffuse endometrial tissue in the myometrial layer (see Table 16-11). Advanced adenomyosis is associated with diffuse enlargement of the uterus, hypermenorrhea, and anemia.

Endometrial histology should be determined by an endometrial biopsy performed in the physician’s office in patients at risk for the development of endometrial hyperplasia or cancer (e.g., PCOS, liver failure, obesity, diabetes mellitus, hormone replacement). A benign endometrial polyp or a uterine leiomyoma protruding into the uterine cavity can be diagnosed by hysterosonography using intrauterine saline installation or hysteroscopy. Hysterosonography and hysteroscopy are not appropriate tests to evaluate endometrial hyperplasia or cancer because these procedures may cause dissemination of malignant cells. If malignancy is suspected, it should be ruled out by an office endometrial biopsy (see Table 16-11). Occasionally, an office endometrial biopsy cannot be performed or is not diagnostic of endometrial neoplasia. In these rare instances, endometrial curettage under anesthesia is performed for a reliable tissue diagnosis.

We should underscore again that a careful history and physical examination eliminate the need for most of these diagnostic tests. A useful question to ask oneself before ordering a certain diagnostic study is whether that particular test will alter the ultimate clinical management.

Management of Anovulatory Uterine Bleeding

The terms dysfunctional uterine bleeding and anovulatory bleeding are used interchangeably and denote inappropriate stimulation of the endometrium during dysfunctional states of the reproductive system. If ovulatory function can be restored, anovulatory bleeding usually gives way to cyclic predictable periods. Because restoring ovulatory function may not be possible or practical in a large number of these women, exogenous estrogen and progestin are administered for a number of purposes. The indications for hormonal treatment of uterine bleeding include the need to stop acute uterine bleeding, to maintain predictable bleeding episodes, or to prevent endometrial hyperplasia. A number of hormonal treatments are used to stop anovulatory uterine bleeding and to induce predictable bleeding episodes. We should reemphasize that anovulatory uterine bleeding is a diagnosis of exclusion. Various anatomically demonstrable pathologies of the genital tract as listed in Table 16-10 should be ruled out before administration of the following regimens.

Oral Contraceptives

Use of combination oral contraceptives in an acute or chronic fashion is the most common treatment for irregular uterine bleeding. The estrogen component of the combination pill stabilizes the endometrial tissue and stops shedding within hours and decreases ovarian secretion of sex steroids by suppression of gonadotropins within several days. The progestin component of the pill directly affects endometrial tissue to decrease shedding over days and potentiates ovarian suppression induced by estrogen. The progestin (in the presence of estrogen) induces differentiation of the endometrial tissue into a stable form termed pseudodecidual. Typically, a monophasic oral contraceptive preparation that contains 30 or 35 μg of ethinyl estradiol is preferred. Triphasic oral contraceptives or those with less than 30 μg of ethinyl estradiol are not suitable for the treatment of excessive anovulatory uterine bleeding. A combination oral contraceptive in high doses (two or three pills a day) can be used for short intervals (weeks) to treat an acute episode of excessive uterine bleeding. A usual dose (one pill per day) may be administered for years to manage chronic anovulatory bleeding associated with PCOS or hyperprolactinemia.

Oral Contraceptives and Acute Excessive Uterine Bleeding Associated with Amenorrhea

Unopposed estrogen exposure in women with anovulatory uterine bleeding is commonly associated with chronic endometrial buildup and heavy bleeding episodes. Therapy is administered as one pill twice a day for 1 week. In obese women, the oral contraceptive may be given three times a day. This therapy is maintained despite cessation of flow within 2 days. If flow does not abate, other diagnostic possibilities (polyps, incomplete abortion, and neoplasia) should be reevaluated. In case of anovulatory bleeding, the flow does diminish rapidly within 2 days after the beginning of high-dose (one pill two or three times a day) oral contraceptive treatment. Specific causes of anovulation and possible coagulation disorders are evaluated during the following few days. At this time, the physician also considers whether blood replacement or initiation of iron therapy is necessary. The hypothalamic-ovarian-progestin combination has produced the structural rigidity intrinsic to the compact pseudodecidual reaction for the moment. Continued random breakdown of formerly fragile tissue is avoided and blood loss stopped. A large quantity of tissue, however, remains to react to estrogen-progestin withdrawal. The patient must be warned to anticipate a heavy flow with severely cramping flow a few days after stopping this therapy. The patient should also be warned of possible nausea that may be caused by high-dose oral contraceptive treatment.

At the end of a week of high-dose oral contraceptive treatment, the pill is stopped temporarily. A heavy flow usually starts within a few days. On the third day of this withdrawal bleeding, a regular dose of combination oral contraceptive medication (one pill a day) is started. This is repeated for several 3-week treatments interrupted by 1-week withdrawal intervals. A decrease in volume with each successive cycle is expected. Oral contraceptives reduce menstrual flow by more than half in most women. Early application of the estrogen-progestin combination limits growth and allows orderly regression of excessive endometrial height to normal levels. Because oral contraceptives do not treat the underlying cause of anovulation but provide symptomatic relief by directly affecting the endometrium, cessation of oral contraceptives results in the return of erratic uterine bleeding. Regardless of the requirement for contraception, oral contraceptives represent the best choice for hormonal management of heavy anovulatory bleeding and should be offered as long-term management.

Oral Contraceptives and Chronic Irregular Uterine Bleeding

PCOS is a common form of anovulation associated with chronic steady-state levels of unopposed estrogen that may give rise to endometrial hyperplasia and cancer (see earlier). Hypothalamic anovulation and hyperprolactinemia, on the other hand, are associated with low estrogen levels, insufficient to prevent bone loss. A combination oral contraceptive is a suitable long-term treatment for both forms of chronic anovulation.

Oral contraceptives represent the most suitable long-term symptomatic management option for any kind of anovulatory uterine bleeding, including oligomenorrhea. Before the administration of an oral contraceptive, pregnancy should be ruled out. For this purpose, one pill per day is ordinarily administered for 3-week periods interrupted by 1-week hormone-free intervals. Withdrawal bleeding is expected during the hormone-free interval. The progestin component serves to prevent endometrial proliferation associated with withdrawal of estrogen. In patients with PCOS (see earlier). In cases of anovulation associated with hypothalamic amenorrhea (e.g., hypothalamic anovulation, hyperprolactinemia), on the other hand, the estrogen component of the pill provides sufficient replacement to prevent bone loss. The risk of thromboembolism, stroke, or myocardial infarction associated with long-term administration is extremely low in current nonsmokers and in the absence of a history of thromboembolism. Provided that an oral contraceptive controls the abnormal uterine bleeding effectively, a chronically anovulatory woman can continue this regimen until the menopause.

Synthetic Progestins

Synthetic progestins enhance endometrial differentiation and antagonize proliferative effects of estrogen on the endometrium (see Fig. 16-28). The effects of progestins or natural progesterone include limitation of estrogen-induced endometrial growth and prevention of endometrial hyperplasia. The absence of naturally synthesized prostegnerone in anovulatory states is the rationale for administering a progestin.

The most common indication for long-term cyclic progestin administration is to prevent endometrial malignancy in a patient with PCOS and unopposed chronic estrogen exposure of the endometrium. A combination oral contraceptive is the treatment of choice in these cases. If the patient cannot use an oral contraceptive for some reason (e.g., history of thromboembolism), a progestin can be administered in a cyclic fashion to prevent endometrial hyperplasia. Before the administration of a progestin (or oral contraceptive), pregnancy should be ruled out. In the treatment of oligomenorrhea associated with PCOS, orderly limited withdrawal bleeding can be accomplished by administration of a progestin such as medroxyprogesterone acetate, 10 mg/day for at least 10 days every 2 months. Alternatively, norethindrone...
Acetate at 5 mg/day or megestrol acetate at 20 mg/day may be administered for 10 days every 2 months. Absence of withdrawal bleeding requires further work-up.

In the treatment of excessive uterine bleeding (hypermenorrhea or polymenorrhea), these progestins at higher daily doses (medroxyprogesterone acetate 20 mg/day, norethindrone acetate 10 mg/day, or megestrol acetate 40 mg/day) are prescribed for 2 weeks to induce predecidual stromal changes in the endometrium. A heavy progestin withdrawal flow usually follows within 3 days after the last dose. Thereafter, repeated progestin treatment (medroxyprogesterone acetate 10 mg/day, norethindrone acetate 5 mg/day, or megestrol acetate 20 mg/day) is offered cyclically for at least the first 10 days of every other month to ensure therapeutic effect. Failure of progestin to correct irregular bleeding requires diagnostic reevaluation such as endometrial biopsy. On the other hand, predictable withdrawal bleeding within several days after each cycle of progestin administration suggests the absence of endometrial malignancy.

**High-Dose Estrogen for Acute Excessive Uterine Bleeding**

As already outlined, an oral contraceptive given two or three times a day is the treatment of choice to stop heavy anovulatory bleeding. A high-dose oral contraceptive regimen should be offered to women with heavy uterine bleeding plus or minus asymptomatic anemia after an anatomically demonstrable pathology of the genital tract has been ruled out (see Table 16-10). On the other hand, a patient with acute and severe anovulatory bleeding accompanied by symptomatic anemia represents a medical emergency. These patients should be hospitalized immediately and offered a blood transfusion. When genital tract pathology has been ruled by history, physical examination, and pelvic ultrasonography, intravenously administered high-dose estrogen is the treatment of choice to stop life-threatening bleeding. A well-established regimen is 25 mg of conjugated estrogen administered intravenously every 4 hours until bleeding markedly slows down or for at least 24 hours. Estrogen most likely acts on the capillaries to induce clotting. Before intravenous estrogen treatment is discontinued, an oral contraceptive pill is started three times a day. Oral contraceptive treatment is continued as described previously.

Because high-dose estrogen is a risk factor for thromboembolism, taking two or three oral contraceptives per day for a week or large doses of intravenous conjugated estrogens for 24 hours should also be regarded as significant risks. There are no data available, however, to evaluate any risk associated with this type of acute use of hormonal therapy for such short intervals. The physician and patient should make a decision regarding high-dose hormone therapy after considering its risks and benefits. Alternative treatment options may be offered to patients with significant risk factors. In women with a past episode of idiopathic venous thromboembolism or a strong family history, exposure to high doses of estrogen should be avoided. High-dose hormone treatment should also be avoided in women with severe chronic illness such as liver failure or renal failure. One alternative for these patients is dilatation and curettage, followed by an oral contraceptive at one pill per day until the uterine bleeding is under control.

**Luteinizing Hormone Releasing Hormone Analogues for Excessive Anovulatory Uterine Bleeding**

LHRH analogues (see Table 16-1) may be given to women with excessive anovulatory bleeding or hypermenorrhea related to severe chronic illness such as liver failure or coagulation disorders. It should be pointed out that monthly depot injections of LHRH agonists are not effective for acute excessive uterine bleeding and may increase uterine bleeding for the first 2 weeks. LHRH antagonists, on the other hand, down-regulate FSH and LH without a delay and achieve amenorrhea more rapidly. Depot formulations of LHRH antagonists, however, are not available at present. Long-term side effects of LHRH analogues including osteoporosis make this an undesirable choice for long-term therapy. If long-term treatment with LHRH analogues is chosen, a combination of 0.625 mg of conjugated estrogens and 2.5 mg of medroxyprogesterone acetate daily should be added back when excessive anovulatory bleeding is controlled. This add-back regimen is usually sufficient to prevent osteoporosis and does not ordinarily worsen the uterine bleeding.
Hormone-Dependent Benign Gynecologic Disorders

Endometriosis

Endometriosis is defined as the presence of endometrium-like tissue outside the uterine cavity, most often on the peritoneal surfaces of the pelvis and the ovaries. It is one of the most common causes of infertility and chronic pelvic pain and affects 1 in 10 women in the reproductive age group. 

Reliable diagnosis of endometriosis can be made only by direct visualization of these peritoneal lesions by laparoscopy or laparotomy. As in other common chronic diseases such as diabetes mellitus and asthma, endometriosis is inherited in a polygenic manner. Relatives of women with this disease have a sevenfold increase in the incidence of endometriosis compared with relatives of control subjects. Sampson proposed the most widely accepted mechanism for the development of endometriosis on pelvic peritoneal surfaces as the implantation of endometrial tissue on the peritoneum through retrograde menstruation. Because retrograde menstruation occurs in more than 90% of all women, endometriosis may be caused by genetic defects that favor survival and establishment of endometrial tissue in menstrual debris on the peritoneum. 

Endometriosis and normal endometrial tissues respond to estrogen and progesterone with similar histologic changes. Estrogen favors the growth of endometriosis, whereas progesterone may limit this mitogenic action of estrogen. Some endometriotic implants undergo atrophy in response to prolonged oral contraceptive therapy just as the normal endometrium does, the so-called pregnancy state. Yet, endometriotic tissue does not respond to progestins or native progesterone as predictably as normal endometrium does. Endometriotic tissue in ectopic locations such as the peritoneum or ovary is strikingly different from the eutopic endometrium within the uterus with respect to production of cytokines and prostaglandins, steroid biosynthesis and metabolism, steroid receptor content, and clinical response to progestins.

Although current hormonal therapy for infertility associated with endometriosis is not of proven value, it is somewhat successful for pelvic pain associated with endometriosis. The duration of relief provided by medical (hormonal) treatment, however, is relatively short. Various agents used are comparable in terms of efficacy. Most current medical treatments were designed to decrease estrogen secretion by the ovaries (e.g., LHRH agonists, oral contraceptives, danazol and progestins) or to antagonize the effects of estrogen on endometrial implants (e.g., oral contraceptives, danazol and progestins). A possible alternative mechanism of action of the androgenic steroid danazol or a progestin is a direct antiproliferative effect on endometriotic tissue.

Many patients and physicians do not favor danazol because of its anabolic and androgenic side effects of weight gain and muscle cramps and occasional irreversible virilization (e.g., clitoromegaly and voice changes). In fact, up to 50% of patients with endometriosis fail to complete 6 months of treatment with danazol. The rest of the hormonal agents, contraceptives, progestins, and LHRH agonists show comparable efficacy for the control of endometriosis-associated pain. A 6-month course using any one of these agents results in a significant reduction of pain in more than 50% of patients. Induction of pain relief with a continuously administered oral contraceptive or progestin takes longer than with an LHRH agonist. There is, however, a high incidence of persistence of the disease after all of these medical therapies. Six months after completion of a 6-month course of treatment with a progestin, oral contraceptive, or LHRH agonist, moderate to severe pain symptoms recurred in 50% of initial responders. The recurrence rate of pain in the rest of the patients was approximately 5% to 20% per year during a 5-year follow-up. A 6-month course of LHRH agonist treatment is currently the most popular regimen. The most serious side effect of the LHRH agonist treatment for endometriosis is bone loss related to estrogen deficiency, and oral estrogen-progesterin preparations or bisphosphonates are usually added back to minimize bone loss.

We are still far from the cure of endometriosis, and current treatments are not satisfactory for effective control of pain. The radical treatment is the removal of both ovaries, and even this was not found to be effective in a number of cases of postmenopausal endometriosis. New strategies are needed to offer women with endometriosis a reasonable chance to live without suffering from chronic pelvic pain for decades. There are two important caveats, which are not addressed by the LHRH agonist treatment. First, large quantities of estrogen can be produced locally within the endometriotic cells. This represents an intracellular mechanism of estrogen action, in contrast to ovarian secretion, which is an endocrine means of supplying this steroid to target tissues. Second, estradiol produced in peripheral tissue sites (e.g., adipose tissue and skin fibroblasts) may give rise to pathologically significant circulating levels of estradiol in a subset of women. LHRH agonists do not inhibit peripheral estrogen formation or local estrogen production within the estrogen-responsive lesion. As a further twist, endometriosis is resistant to selective effects of progesterone and currently used progestins. Thus, aromatase inhibitors and selective progesterone response modulators are candidate therapeutic agents for endometriosis. Preliminary evidence suggests that unusually aggressive endometriotic lesions resistant to other therapy can be treated successfully with aromatase inhibitors.

Uterine Leiomyomas

Uterine leiomyomas originate from the myometrium and are the most common solid tumor of the pelvis. Leiomyomas are responsible for over 200,000 hysterectomies per year in the United States. They are almost invariably benign and represent clonal expansion of individual myometrial cells. Leiomyomas can cause a variety of symptoms including irregular and excessive uterine bleeding, pressure sensation in the lower abdomen, pain during intercourse, pelvic pain, recurrent pregnancy loss, infertility, and compression of adjacent pelvic organs, or they may be totally asymptomatic. The prevalence rate of uterine leiomyomas is estimated to be 25% to 30%. Uterine leiomyomas are more common in black women and have a polygenic inheritance pattern. Diagnosis can be made by abdominal and transvaginal ultrasonography. Transvaginal ultrasonography is a sensitive method for determining the size, number, and location of uterine leiomyomas.

Uterine leiomyomas appear during the reproductive years and regress after menopause, indicating their ovarian steroid-dependent growth potential. The role of steroids or other growth factors in the initiation and growth of these tumors, however, is not well understood. The neoplastic transformation of myometrium to leiomyoma probably involves somatic mutations of normal myometrium and the complex interactions of sex steroids and growth factors. Traditionally, estrogen has been considered the major promoter of myoma growth. More recent biochemical, histologic, and clinical evidence suggests an important role for progesterone in the growth of uterine leiomyomas. Biochemical and clinical studies suggest that progesterone and progestins, acting through the PR, might enhance proliferative activity in leiomyomas.

The therapeutic choices depend on the goals of therapy, with hysterectomy most often used for definitive treatment and myomectomy when preservation of childbearing is desired. Intradecidual and submucous leiomyomas can be removed by hysteroscopic resection. Laparoscopic myomectomy is now technically possible but apparently involves an increased risk of uterine rupture during pregnancy. The overall recurrence rate after myomectomy varies widely (10% to 50%). Although LHRH agonist-induced hypogonadism can reduce the overall volume of the uterus containing leiomyomas and tumor vascularity, the severe side effects and prompt recurrences make LHRH agonists useful only for short-term goals such as reducing anemia related to uterine bleeding or decreased tumor vascularity before hysteroscopic resection.
MANAGEMENT OF THE MENOPAUSE

Consequences of the Menopause

The Climacteric

The menopause is the permanent cessation of menses as a result of the irreversible loss of a number of ovarian functions, including ovulation and estrogen production. The climacteric is a critical period of life during which striking endocrinologic, somatic, and psychologic alterations occur in the transition to the menopause. The climacteric is also referred to as the perimenopause. The climacteric encompasses the change from ovulatory cycles to cessation of menses and is marked by irregularity of menstrual bleeding.

The most sensitive clinical indication of the climacteric is the progressively increasing occurrence of menstrual irregularities. The menstrual cycle for most ovulatory women lasts from 24 to 35 days, whereas approximately 20% of all reproductive-age women experience irregular cycles. When women are in their 40s, anovulation becomes more prevalent; prior to anovulation, the menstrual cycle length increases, beginning several years before menopause. The median age for the onset of the climacteric transition is 47.5 years. Regardless of the age of its onset, the menopause (cessation of menses) is consistently preceded by a period of prolonged cycle intervals. Elevated circulating FSH marks this menstrual cycle change before menopause and is accompanied by decreased inhibin levels, normal levels of LH, and slightly elevated levels of estradiol. These changes in serum hormone levels reflect a decreasing ovarian follicular reserve and can be detected more reliably on day 2 or 3 of the menstrual cycle.

During the climacteric, serum estradiol levels do not begin to decline until less than a year before menopause. The average circulating estradiol levels in perimenopausal women are estimated to be somewhat higher than those in younger women because of an increased follicular response to elevated FSH. The decline in inhibin production by the follicle, allowing a rise in FSH, in the later reproductive years reflects diminishing follicular reserve and competence. Ovarian follicular output of inhibin begins to decrease after 30 years of age, and this decline becomes much more pronounced after age 40. These hormonal changes are parallel to a significant decrease in fecundity, which starts at around 35 years.

The climacteric is a transitional period during which postmenopausal levels of FSH can be observed despite continued menses, whereas LH levels still remain in the normal range. The perimenopausal woman is not beyond the realm of an unexpected pregnancy because there is occasional ovulation and functional corpus luteum formation. Thus, until complete cessation of menses is observed or FSH levels higher than 40 IU/L are measured on two separate occasions, some form of contraception should be recommended to prevent unwanted pregnancies.

The climacteric represents an optimal period to evaluate the general health of the mature woman and introduce the measures to prepare her for striking physiologic changes that come with the menopause. The patient and her clinician should attempt to achieve several important aims during the climacteric. The long-term goal is to maintain an optimal quality of physical and social life. Another immediate objective is the detection of any major chronic disorders that occur with aging. Finally, the clinician should counsel the perimenopausal woman about the symptoms and long-term consequences of menopause. The benefits and risks of lifelong hormone replacement should be discussed at great length at this time.

The Menopause

The median age of the menopause is approximately 51. The age of menopause is probably determined in part by genetic factors because mothers and daughters tend to experience menopause at the same age. A number of environmental factors may modify the age of menopause. For example, current smoking is associated with an earlier menopause, whereas alcohol consumption delays menopause. Oral contraceptive use does not affect the age of menopause.

The symptoms frequently seen and related to decreased estrogen production in menopause include irregular frequency of menses followed by amenorrhea, vasomotor instability manifest as hot flashes and sweats, urogenital atrophy giving rise to pain during intercourse and a variety of urinary symptoms, and consequences of osteoporosis and cardiovascular disease. The combination and the extent of these symptoms differ widely for each patient. Some patients experience multiple severe symptoms that may be disabling, whereas others have no symptoms or mild discomfort associated with the climacteric.

Biosynthesis of Estrogen and Other Steroids in the Postmenopausal Woman

No follicular units can be detected histologically in the ovaries after the menopause. In reproductive-age women, the granulosa cell of the ovulatory follicle is the major source of inhibin and estradiol. In the absence of these factors that inhibit gonadotropin secretion, both FSH and LH levels increase sharply after menopause. These levels peak a few years after menopause and decrease gradually and slightly thereafter. The postmenopausal serum level of either gonadotropin may be more than 100 IU/L. FSH levels are usually higher than LH levels because LH is cleared from the blood strikingly more quickly and possibly because the low levels of inhibin in the menopausal serum selectively lead to increased FSH secretion. Nevertheless, increased LH is a major factor that maintains significant quantities of androstenedione and testosterone secretion from the ovary, although the total production rates of both steroids decline after menopause.

The primary steroid products of the postmenopausal ovary are androstenedione and testosterone. The average premenopausal rate of production of androstenedione of 3 mg/day is decreased by half to approximately 1.5 mg/day. This decrease is primarily due to a substantial reduction in the ovarian contribution to the circulating androstenedione pool. Adrenal secretion accounts for most of the androstenedione production in the postmenopausal woman, with only a small amount secreted from the ovary. Both DHEA and DHEAS originate almost exclusively from the adrenal and decline steadily with advancing age independent of the menopause. The serum levels of both DHEA and DHEAS after menopause are about one fourth of those in young adult women.

Testosterone production is decreased by approximately one third after menopause. Total testosterone production can be approximated by the sum of ovarian secretion and peripheral formation from androstenedione (see Fig. 16-32). In the premenopausal woman, significant amounts of testosterone are produced by reduction of androstenedione in extracellular tissues. Because ovarian androstenedione secretion is substantially decreased after the menopause, the decrease in postmenopausal testosterone production is accounted for, in large measure, by a decrease in the relative contribution of extracellular sources. With the disappearance of follicles and decreased estrogen, the elevated gonadotropins drive the remaining stromal tissue in the ovary to maintain testosterone secretion at levels observed during the
premenopausal years. Thus, the contribution of the postmenopausal ovary to the total testosterone production is increased in the presence of seemingly unaltered ovarian secretion.  

The most dramatic endocrine alteration of the climacteric involves the decline in the circulating level and production rate of estradiol. The average menopausal level of circulating estradiol is less than 20 pg/mL. Both estradiol and estrone levels in postmenopausal women are usually slightly less than those in adult men. Circulating estradiol in postmenopausal women (and men) is derived from the peripheral conversion of androstenedione to estrone, which is, in turn, converted peripherally to estradiol (see Fig. 16-23).  

The mean circulating level of estrone in postmenopausal women (37 pg/mL) is higher than that of estradiol. The average postmenopausal production rate of estrone is approximately 42 pg per 24 hours. After menopause, almost all estrone and estradiol are derived from the peripheral aromatization of androstenedione. Thus, there is a drastic change in the androgen-to-estrogen ratio because of the sharp decrease in estradiol levels and slightly reduced testosterone. The frequent onset of a mild hirsutism after menopause reflects this striking shift in the hormone ratio. During the postmenopausal years, DHEAS and DHEA levels continue to decline steadily with advancing age, whereas serum androstenedione, testosterone, estrone, and estradiol levels do not change significantly.

The aromatization of androstenedione to estrone in extracervical tissues correlates positively with weight and advancing age (see Fig. 16-23 and Fig. 16-37). Body weight correlates positively with the circulating levels of estrone and estradiol. Because aromatase enzyme activity is present in significant quantities in adipose tissue, the aromatization of androstenedione to estrone in overweight individuals may reflect the increased aromatization of tissue containing the enzyme. In addition, there is a twofold to fourfold increase in the specific activity of aromatase per cell with advancing age. An increased overall number of adipose fibroblasts with aromatase activity and a decrease in the levels of TeBG cause an increased free estradiol level and contribute to the increased risk of endometrial cancer in obese women. The production rate and circulating levels of estradiol after menopause are clearly insufficient to provide support for urogenital tissues and bone. Thus, osteoporosis and urogenital atrophy are some of the most dramatic and unwanted consequences of estradiol deficiency during the menopause.

The consistent association between the onset of flashes and acute estrogen withdrawal is also supported by the effectiveness of estrogen therapy and the absence of hot flashes in postmenopausal women who are receiving estrogens. Under these circumstances of acute estrogen withdrawal, the lower frequency and intensity of hot flashes may vary from extremely rare to recurring every few minutes. At night, flashes are more frequent and severe enough to awaken a woman from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment. 

The hot flash results from a sudden reduction of estrogen levels rather than from hypoestrogenism itself. Therefore, regardless of the cause of menopause, natural, surgical, or estrogen withdrawal caused by a long-acting LHRH agonist, hot flashes are associated with an acute and significant drop in estrogen level. 

The consistent association between the onset of flashes and acute estrogen withdrawal is also supported by the effectiveness of estrogen therapy and the absence of hot flashes in postmenopausal women who are receiving estrogens. Under these circumstances of acute estrogen withdrawal, the lower frequency and intensity of hot flashes may vary from extremely rare to recurring every few minutes. At night, flashes are more frequent and severe enough to awaken a woman from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment. 

These flashes often occur in the menopause due to increased production of estrogens. The production rate and circulating levels of estradiol after menopause are clearly insufficient to provide support for urogenital tissues and bone. The clinical relevance of these findings was exemplified by the successful use of aromatase inhibitors as both first-line and second-line endocrine treatments for postmenopausal breast cancer.

Menopause and Uterine Bleeding

Perimenopausal or postmenopausal bleeding can be due to hormone administration or excessive extravascular estrogen formation. Irregular uterine bleeding is commonly observed during the perimenopausal transition as anovulatory cycles alternate with ovulatory cycles. Uterine bleeding after the menopause is less common if the patient is not receiving hormone replacement treatment (HRT). Obese patients are more likely to experience postmenopausal bleeding because of increased peripheral aromatization of androstenedione. Patients receiving continuous estrogen replacement therapy may experience unpredictable bleeding (see later). The major objective in these circumstances is to rule out endometrial malignancy. This can be best achieved by tissue diagnosis through an office endometrial biopsy using a plastic cannula. Transvaginal ultrasonographic measurement of endometrial thickness may be used in postmenopausal women to avoid unnecessary biopsies. A biopsy is required if an endometrial thickness greater than or equal to 5 mm is observed.

Before employing ultrasonography and endometrial biopsy to explore the etiology of bleeding that is assumed to arise from the intrauterine cavity, the clinician should rule out diseases of the vulva, vagina, and cervix as other potential causes of vaginal bleeding. Careful inspection of these organs and a normal cervical Pap smear within the past year are sufficient to rule out the vulva, vagina, and cervix as potential sources of bleeding. Postmenopausal uterine bleeding is the most common initial event for the patient and her physician to the possibility of endometrial cancer. On the other hand, the causes of postmenopausal uterine bleeding are benign most of the time. Endometrial malignancy is encountered in patients with bleeding in only about 1% to 2% of postmenopausal endometrial biopsies. Approximately three quarters of these biopsies reveal either no pathology or an atrophic endometrium. Other histologic findings include hyperplasia (15%) and endometrial polyps (3%). Persistent unexplained uterine bleeding requires repeated evaluation, biopsy, hysteroscopy, or dilatation and curettage.

Unpredictable irregular uterine bleeding is observed in approximately 20% of postmenopausal women receiving a long-term (>1 year) continuous estrogen-progesterone combination. This should also be evaluated appropriately with ultrasonography or biopsy, or both (see later).

Hot Flash

The most frequent and striking symptom in the climacteric is the hot flash. The hot flash typically occurs at the time of transition from perimenopause to postmenopause, is the climacteric. The flash is also a major symptom of the postmenopause and can last up to 5 years after menopause. More than four fifths of postmenopausal women experience hot flashes within 3 months after the cessation of ovarian function, whether natural or surgical in origin. Of these women, more than three fourths have them for more than 1 year and approximately half for up to 5 years. Hot flashes lessen in frequency and intensity with advancing age, unlike other sequelae of the menopause, which progress with time.

A hot flash is a subjective sensation of intense warmth of the upper body, which typically lasts for 4 minutes but may range in duration from 30 seconds to 5 minutes. It may follow a prodrome of palpitations or headache and is frequently accompanied by weakness, faintness, or vertigo. This episode usually ends in profuse sweating and a cold sensation. The frequency may vary from extremely rare to recurring every few minutes. At night, flashes are more frequent and severe enough to awaken a woman from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment.

The hot flash results from a sudden reduction of estrogen levels rather than from hypoestrogenism itself. Therefore, regardless of the cause of menopause, natural, surgical, or estrogen withdrawal caused by a long-acting LHRH agonist, hot flashes are associated with an acute and significant drop in estrogen level. 

The consistent association between the onset of flashes and acute estrogen withdrawal is also supported by the effectiveness of estrogen therapy and the absence of hot flashes in postmenopausal women who are receiving estrogens. Under these circumstances of acute estrogen withdrawal, the lower frequency and intensity of hot flashes may vary from extremely rare to recurring every few minutes. At night, flashes are more frequent and severe enough to awaken a woman from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment. 

Urogenital Atrophy

The urogenital sinuses give rise to the development of the lower vagina, vulva, and urethra during embryonic development, and these tissues are estrogen-dependent. The urogenital atrophy at menopause causes the vaginal walls to become pale because of diminished vascular supply and to thin down to only three to four cell layers. The vaginal epithelial cells in postmenopausal women contain less glycogen, which prior to menopause was metabolized by lactobacilli to create an acidic pH, thereby protecting the vagina from bacterial overgrowth. Loss of this protective mechanism leaves the thin, friable tissue vulnerable to infection and ulceration. The vagina also loses its rugae and becomes shorter and inelastic. Postmenopausal women may complain of symptoms secondary to vaginal dryness, such as pain during intercourse, vaginal discharge, burning, itching, or bleeding. Genitourinary atrophy leads to a variety of symptoms that affect the ease and quality of living.

Urethritis with dysuria, stress urinary incontinence, and urinary frequency are further results of mucosal thinning of the urethra and bladder. Intravaginal estrogen use of aromatase inhibitors as both first-line and second-line endocrine treatments for postmenopausal breast cancer.
treatment can effectively alleviate recurrent urinary tract infections and vaginal symptoms in the postmenopausal patient. Oral estrogen replacement also rapidly reverses vaginal atrophy and urethral symptoms caused by estrogen deficiency.

Cognitive Function and Estrogen

Although Alzheimer's disease affects both men and women, studies in many different populations show that 1.5 to 3 times as many women as men suffer from this disease. For women with this disease, one needs to consider behavioral and cognitive problems, therapeutic issues, and other gender-related risks. One obvious consideration is a possible link between estrogen deficiency and the increased incidence of Alzheimer's disease in postmenopausal women. A number of studies have suggested that the association is stronger among women without Alzheimer's disease. Treatment of women free of Alzheimer's disease with hormone replacement for signs and symptoms of menopause led to improvements in verbal memory, vigilance, reasoning, and motor speed but no enhancement of other cognitive functions. A meta-analysis of observational studies suggested that HRT was associated with a decreased incidence of dementia. However, possible biases and lack of control for potential confounders limit interpretation of these studies. Two small but randomized studies reveal the estrogen and short-term hormone therapy in women with Alzheimer's disease produced conflicting data. Thus, future large randomized trials should target the potential benefits of HRT in improving cognition in women with menopausal symptoms as well as in the prevention and treatment of Alzheimer's disease. The ongoing large trial called the Women's Health Initiative may provide some answers in several years.

Cardiovascular Disease

It has long been suggested that estrogen protects against atherosclerosis because the incidence of cardiovascular disease is lower in women than in men in all age groups. The gender gap is widest during the premenopausal years. For example, myocardial infarction is six times less common in premenopausal women than in men of the same age. This discrepancy has been attributed, in part, to the effects of estrogen. During reproductive life, women have lower LDL cholesterol than men, although these levels gradually increase with advancing age and rise rapidly after menopause. In contrast, despite consistently higher high-density lipoprotein (HDL) cholesterol levels in women than men throughout adulthood, this discrepancy persists after the menopause. HDL cholesterol becomes higher in premenopausal women but does not change greatly at menopause. The increases in LDL and total cholesterol levels at menopause are partially reversible with estrogen treatment. Therefore, the increased myocardial infarction rate after menopause may be a function of rising LDL cholesterol levels that seem to be related to decreased estrogen levels. Although HDL cholesterol levels do not decrease significantly in postmenopausal women, replacement with oral estrogen increases HDL cholesterol levels significantly; this may contribute to the cardioprotective effect of HRT.

A strong correlation of a cause-and-effect relationship has been established between cholesterol levels and coronary heart disease in postmenopausal women. Because menopausal postmenopausal women with elevated total cholesterol levels have a significantly increased risk of coronary heart disease compared with women with low levels. This risk is more pronounced in the first two decades after the menopause. The association becomes less pronounced with advancing age. In both men and women, an HDL cholesterol level is the most specific determinant of coronary heart disease. High levels of HDL cholesterol are protective, whereas a low level is a strong predictor of increased cardiovascular risk. Therefore, monitoring HDL cholesterol as well as total and LDL cholesterol levels is important in determining cardiovascular risk in postmenopausal women.

Replacement with estrogen decreases LDL and increases HDL cholesterol levels in postmenopausal women. Although estrogen also increases triglyceride levels, the impact of this effect on the cardiovascular system is unknown. If a progestin is added, the beneficial effects of estrogen may diminish. Overall, postmenopausal estrogen replacement with or without added progestin produces a favorable lipid profile. These favorable biochemical effects may provide some protection against cardiovascular disease. Many trials including a large, randomized study demonstrated a favorable impact on cardiovascular risk factors in women taking estrogen as well as a combination of estrogen and progestin. Moreover, the great majority of studies investigating coronary or cerebrovascular disease as an outcome concluded that postmenopausal use of estrogens protected against cardiovascular disease; although these studies have been observational rather than randomized and blinded trials. Thus, the opinion of the medical community in general was that exogenous estrogen given in postmenopausal replacement doses decreased cardiovascular risk for all women.

A later randomized study of estrogen-progestin users with preexisting coronary disease (Heart and Estrogen/progestin Replacement Study, or HERS) showed an early increase in mortality. Consequently, in 1999 the American College of Cardiology and American Heart Association revised their guidelines for providing HRT to patients with a history of acute cardiovascular infarction. The authors of HERS concluded that, over an average follow-up of 4 years, treatment with oral conjugated equine estrogen plus medroxyprogesterone acetate did not reduce the overall rate of coronary heart disease events in postmenopausal women with established coronary disease. However, it was associated with a small but statistically significant increase in the risks of deep vein thrombosis and pulmonary embolism. No significant effect of HRT on the risk of stroke was detected in these postmenopausal women with coronary disease. HRT in HERS also resulted in a marginally significant increase in the risk of symptomatic gallbladder disease and biliary tract surgery. It was recommended that hormone replacement therapy should not be initiated solely for prevention of cardiovascular disease in postmenopausal women with preexisting coronary heart disease but can be continued in patients with cardiovascular disease already receiving HRT for other reasons.

Another randomized trial showed that estradiol does not reduce mortality or the recurrence of stroke in postmenopausal women with preexisting cerebrovascular disease. Thus, HRT should not be prescribed for the secondary prevention of cerebrovascular disease.

Recent findings from the Women's Health Initiative reinforce and expand the concerns raised by these randomized trials. In the Women's Health Initiative, more than 16,000 women with intact uteri were randomized to receive either placebo or conjugated estrogens 0.625 mg and medroxyprogesterone 2.5 mg daily. The study was designed to investigate cardiovascular disease. However, possible biases and lack of control for potential confounders limit interpretation of these studies. Recent findings from the Women's Health Initiative reinforce and expand the concerns raised by these randomized trials. In the Women's Health Initiative, more than 16,000 women with intact uteri were randomized to receive either placebo or conjugated estrogens 0.625 mg and medroxyprogesterone 2.5 mg daily. The study was designed to investigate cardiovascular disease. However, possible biases and lack of control for potential confounders limit interpretation of these studies. For example, the estrogen plus progestin arm of the study was associated with an increased risk of coronary heart disease events, while the estrogen-only arm was associated with a decreased risk. These findings have been interpreted as evidence against the use of estrogen therapy in postmenopausal women, especially those with a history of cardiovascular disease.

Cardiovascular disease.

Postmenopausal Osteoporosis

Osteopenia and osteoporosis are extremely common in elderly postmenopausal women. Osteopenia indicates low bone mass measured by densitometry, whereas the term osteoporosis implies severely decreased bone mass associated with a significantly increased risk for fractures. The most frequent sites of fracture are the vertebrae, hip, and wrist. Despite the high prevalence of osteoporosis, the condition is often unrecognized. In postmenopausal women, it is currently an epidemic proportion in the United States, affecting over 20 million people. The majority of osteopathic patients are postmenopausal women.

Osteoporosis in postmenopausal women is a function of both advancing age and estrogen deficiency. Seventy-five percent or more of the bone loss in women during the first 15 years after menopause is attributed to estrogen deficiency rather than to aging itself. For the first 20 years after the cessation of ovarian estrogen secretion, postmenopausal osteoporosis accounts for a 50% reduction in trabecular bone and 30% loss of cortical bone. Vertebral bone is especially vulnerable because the trabecular bone of the vertebral bodies is metabolically very active and decreases dramatically in response to estrogen deficiency. Vertebral bone mass is already significantly decreased in perimenopausal and early postmenopausal women who have rising FSH and decreasing estrogen levels, whereas bone loss from the radius is not detected until at least a year after the menopause.

The risk of fracture depends on two factors: the peak bone mass achieved at maturity (at approximately age 30) and the subsequent rate of bone loss. An accelerated rate of bone loss after menopause strongly predicts an increased risk of fracture. The combination of low postmenopausal bone mass and accelerated loss of bone after menopause is additive, and these individuals are at the highest risk of fracture. An increased rate of average bone loss during menopause is an indicator of lower endogenous estrogen levels because postmenopausal bone loss is considerably slower in women with increased adipose tissue mass and thus elevated...
It has been shown conclusively by numerous studies that hormone replacement started at the climacteric prevents postmenopausal bone loss. Hormone replacement started at any age in a postmenopausal woman has potential beneficial effects by at least preventing additional bone loss. It should be noted, however, that the incidence of fractures or rate of height loss was not reduced during a 4-year follow-up in women starting HRT at a mean age of 66.7 (± 6.7) years. More recently, in the part of the Women's Health Initiative discussed above, a decreased number of hip and vertebral fractures were noted in the group of postmenopausal women receiving estrogen/progestin; this important evidence was the first from randomized trials suggesting that estrogen prevents fractures.
Postmenopausal Hormone Replacement

The most common current practice is to treat all women disturbed by the symptoms of hormone deprivation (hot flashes and urogenital atrophy) with estrogen and to use long-term hormonal prophylaxis against osteoporosis and cardiovascular disease on the basis of an informed decision by the patient. Patients who have undergone a hysterectomy can be given estrogen therapy alone. A progestin is added to estrogen in the postmenopausal woman with a uterus in order to prevent endometrial hyperplasia or cancer. The recent findings from the Women's Health Initiative trial are too new to allow prediction of how the negative findings from this trial will affect practice. Modest increases in breast cancer, coronary heart disease, and stroke were balanced by modest decreases in fractures and colon cancer. How individual patients and physicians will balance the immediate and common benefits in the treatment of hot flashes and urogenital atrophy against the predominantly negative long-term consequences that affect a modest fraction of patients (at least over 5 years) remains to be determined. It should be noted that the part of the Women's Health Initiative involving the use of estrogen without progestin to treat women after hysterectomy has not been halted; those results will become available in 2005. The decision for using long-term hormone replacement should be made by the patient based on accurate information. The primary role of the physician is to provide scientific information to a patient, using understandable language. This is not an easy task, given the complexity of the existing data and occasionally opposite opinions.

Estrogens and progestins used for postmenopausal hormone replacement are among the most commonly prescribed medications in the United States. Currently, 46% of women who have experienced a natural menopause and 71% of women who have had bilateral oophorectomy report having used postmenopausal HRT. The average duration of use in the United States as of 1992 was 6.6 years, but only 20% of users had maintained treatment for at least 5 years. Emphasizing the education of the patient and primary care physician on the basis of appropriate interpretation of epidemiologic studies and clinical trials will ensure appropriate use of long-term postmenopausal HRT.

Target Groups for Hormone Replacement

In women with gonadal dysgenesis and surgical menopause, the duration of estrogen deprivation is prolonged. Estrogen replacement is recommended for these patients for the reduction of hot flashes and for long-term prophylaxis against cardiovascular disease, osteoporosis, and target organ atrophy. A low-dose contraceptive may be offered to nonsmoking women until the age of 45. After this age, doses of estrogen equivalent to 0.625 mg of conjugated estrogens may be more appropriate because of a sharp age-related increase in risk for thromboembolic events. The physician should recommend a continuous estrogen-progestin combination to those with a uterus and an estrogen-only regimen to women without a uterus.

During the climacteric, hot flashes can be suppressed with an estrogen-progestin combination. Because bone loss related to estrogen deprivation also begins during this period, starting hormone replacement therapy during the climacteric is of paramount importance for minimizing osteoporosis. In climacteric women, unexplained uterine bleeding should be evaluated with an endometrial biopsy before the start of hormone replacement.

The lifelong use of hormone therapy after menopause is dependent on the informed decision of the woman based on balanced and evidence-based advice provided by her physician. The benefits of hormone replacement with respect to bone metabolism, cognitive function, urogenital health, and sexual function are substantial and for many women outweigh the increased breast cancer and cardiovascular disease risk.

Estrogen Preparations and Beneficial Dose of Estrogen

The amount of estrogen that is optimally effective in maintaining the spine and femoral neck bone mass is equivalent to 0.625 mg/day of conjugated estrogens. The effective doses of oral estrogen that reduce the incidence of fracture are 0.625 mg/day of conjugated estrogens and 1.25 mg/day of estrone sulfate. Also, transdermal estradiol at a rate of 0.05 mg/贴 is also presumed to lower fracture risk based on equivalent doses of various preparations that provide similar average circulating estradiol levels. Oral intake of 0.625 mg of conjugated estrogen, 1.25 mg of estrone sulfate, or 1 mg of micronized estradiol results in similar average serum levels of estrogens: estradiol, 30 to 40 pg/mL, and estrone, 150 to 250 pg/mL. Transdermal administration of estradiol with patches releasing 0.05 mg/day gave rise to similar average serum estradiol (30 to 40 pg/mL) but much lower estrone (40 pg/mL).

Short-term cardiovascular or hemodynamic effects of estrogen vary according to blood estrogen levels. Improvements in left ventricular contraction and function are associated with levels achieved by 0.625 mg of oral conjugated estrogens. Extremely high estradiol levels achieved with large doses of estrogen, on the other hand, decrease left ventricular function and aortic blood flow. The beneficial effect of postmenopausal estrogen in preventing the hyperinsulinemia associated with aging is present with a dose of 0.625 mg of conjugated estrogens but lost with a dose of 1.25 mg.

The effect of estrogen on arterial thrombosis is also dose-related. For example, oral contraceptives with high doses of estrogen significantly increase the risks of myocardial infarction and stroke, especially in smokers. Numerous studies suggest that doses of conjugated estrogens greater than 0.625 mg are, in fact, not as beneficial in terms of cardiovascular disease and mortality. However, the number of patients receiving these high doses was not large enough to achieve statistical significance. Thus, it is imperative to achieve and maintain the lowest beneficial levels of circulating estradiol and avoid higher levels associated with unfavorable hemodynamic effects or thrombosis.

Estrogen-Progestin Regimens

The addition of a progestin, either cyclically or continuously, to concomitant estrogen replacement reduces the risk of estrogen-induced endometrial hyperplasia or carcinoma but poses additional problems. These problems include regular withdrawal bleeding in up to 90% of women treated with cyclic therapy and irregular spotting in 20% of women treated with continuous estrogen plus progestin. Furthermore, progestins appear to reduce the beneficial effects of estrogen on HDL and LDL cholesterol and possibly cardiovascular risk.

A time-honored sequential regimen involves oral administration of 0.625 mg of conjugated estrogens or the equivalent dose of a variety of available products from day 1 to 25 of each month. A daily dose of 10 mg of medroxyprogesterone acetate is added from day 12 to 25 or from day 16 to 25. Withdrawal bleeding is expected on or after day 26 of each month. Another common cyclic regimen involves continuous oral administration of 0.625 mg of conjugated estrogens or the equivalent daily dose. A daily dose of 5 to 10 mg of medroxyprogesterone acetate is added for the first 10 to 14 days of each month. One-year randomized trial data indicate that the 5-mg dose protects the endometrium as well as the 10-mg dose. Progestin withdrawal bleeding occurs in 90% of women with a sequential or cyclic regimen. These regimens can also cause adverse symptoms related to the relatively high daily doses of progestin, such as breast tenderness, bloating, fluid retention, and depression. Thus, the

[Larsen: Williams Textbook of Endocrinology, 10th ed., Copyright © 2003 Elsevier]
The lowest possible dose of a progestin is recommended.

The continuous combined method of treatment, on the other hand, has the potential benefit of reduced bleeding and amenorrhea but is occasionally complicated by breakthrough bleeding (see Fig. 16-41). In this regimen, a combination of 0.625 mg of conjugated estrogens and 2.5 mg of medroxyprogesterone acetate is given orally every day. The continuous combination regimen is simple, convenient, and associated with a higher incidence of amenorrhea in 80% of patients after at least 6 months of use. The rest of the patients continue to experience some degree of unpredictable spotting. Thus, overall compliance is much better in users of the continuous combination regimen. Moreover, the lower daily dose of medroxyprogesterone acetate is associated with a lower incidence of breast tenderness with this regimen. Other estrogen-progestin combinations are also available for similar continuous use.

Most postmenopausal women stop HRT within several years after the initiation of therapy because hot flashes decrease significantly or disappear at this time. Upon the cessation of HRT that had lasted several years, hot flashes usually do not return or are less severe than during the climacteric. Consequently, long-term compliance with HRT remains poor. The fear of malignancy and irregular uterine bleeding are two major factors that stop women from continuing HRT indefinitely. The current data on breast cancer are indicative of a slightly increased breast cancer risk for estrogen-only and estrogen plus progestin regimens. The addition of a progestin to the estrogen-only regimen, on the other hand, has effectively prevented endometrial cancer. Irregular uterine bleeding is another major reason for discontinuation of HRT. The incidence of persistent uterine bleeding with the traditional sequential regimen can be as high as 90%, which deters women from taking lifelong men. By switching to the continuous combination regimen, this bleeding can be reduced to a 20% incidence of spotting with long-term (>1 year) use. Thus, more clinicians start women with the continuous combination treatment with the hope of improving compliance for long-term use (see Fig. 16-41).

Selective estrogen receptor modulators are compounds that act like estrogen in some target tissues but antagonize estrogenic effects in others. One of the first selective estrogen receptor modulators was tamoxifen, for which estrogen-like agonist activity on bone was observed to occur simultaneously with estrogen antagonist activity on the breast. An unwanted effect of tamoxifen is its estrogen-like action on the endometrium. Second-generation compounds have since been developed, notably raloxifene, which has estrogen-like actions on bone, lipids, and the coagulation system; estrogen antagonist effects on the breast; and no detectable action in the endometrium.

In randomized placebo-controlled studies involving postmenopausal women or patients with osteoporosis, raloxifene at 60 to 150 mg/day was effective in increasing bone mineral density over 12 to 36 months. Raloxifene also decreased the risk of vertebral fractures. Raloxifene is similar to placebo in its endometrial effects and similar to estrogen in causing a twofold to threefold increase in the risk of venous thromboembolism. Raloxifene lowers total and LDL cholesterol. HDL cholesterol and triglycerides are virtually unaffected. Patients receiving either a cyclic or daily combination hormone replacement regimen who have an endometrial thickness less than 5 mm can be managed conservatively. The propensity of raloxifene to cause hot flashes precludes its use in women with vasomotor symptoms. On the other hand, the lack of stimulatory effects on the endometrium and the reduction in the incidence of invasive breast cancer indicate that raloxifene is an alternative to tamoxifen for the management of postmenopausal osteoporosis, especially for patients reluctant to use estrogen. It should be emphasized that, at this time, postmenopausal hormone replacement with estrogen remains the "gold standard" for health benefits with respect to bone, cardiovascular system, urogenital organs, and possibly the central nervous system.

Approximately 90% of women receiving estrogen plus cyclic administration of a progestin have monthly progestin withdrawal bleeding in a predictable fashion, whereas continuous combined estrogen-progestin therapy causes breakthrough bleeding in approximately 40% of women during the first 6 months. (The rest of the women with a continuous combination regimen are amenorrheic.) The pattern of vaginal bleeding in the continuous regimen is unpredictable and causes anxiety in most patients. Fortunately, the incidence of breakthrough bleeding with the continuous combined regimen decreases to 20% after 1 year of treatment.

Breakthrough bleeding with the combined continuous regimen remains the most important reason for discontinuance of this therapy. Most patients find it unacceptable and prefer to switch to a cyclic progestin regimen or discontinue hormone replacement altogether. There is no effective pharmacologic method to manage the breakthrough bleeding associated with continuous combined estrogen-progestin regimens. One can only reassure the patient that the bleeding is likely to subside within a year from the start of HRT. If breakthrough bleeding continues beyond a year, the regimen should be changed to daily estrogen plus cyclic progestin monthly for 10 days.

HRT can be started in the amenorrheic postmenopausal patient at any time. Perimenopausal women with oligomenorrhea, hot flashes, or other associated symptoms should also be given HRT. In the oligomenorrheic patient, a hormone replacement regimen can be initiated on day 3 of one of the infrequent menses. If the candidate for hormone replacement does not have irregular uterine bleeding, it is not essential to perform endometrial biopsies routinely before beginning treatment. Studies indicate that asymptomatic postmenopausal women rarely have endometrial abnormalities. Pretreatment biopsies using a thin plastic biopsy cannula in the office may be limited to patients at higher risk for endometrial hyperplasia (e.g., unpredictable uterine bleeding, history of PCOS or chronic anovulation, obesity, liver disease, and diabetes mellitus).

Giving a woman a combined estrogen-progestin regimen does not preclude the development of endometrial cancer. It is, therefore, necessary to rule out endometrial malignancy in women receiving HRT who are experiencing irregular uterine bleeding. The important task is to differentiate breakthrough bleeding from bleeding induced by hyperplasia or cancer. Because breakthrough bleeding is extremely common, a large number of biopsies would have to be performed to detect a rare case of endometrial abnormality during HRT. In order to decrease the number of endometrial biopsies, a screening method using transvaginal ultrasonography has been introduced. The thickness of the postmenopausal endometrium as measured by transvaginal ultrasonography in postmenopausal women correlates with the presence or absence of pathology. Patients receiving either a cyclic or daily combination hormone replacement regimen who have an endometrial thickness less than 5 mm can be managed conservatively. An endometrial thickness equal to or greater than 5 mm requires biopsy. Following this algorithm, it is estimated that 50% to 75% of bleeding patients receiving HRT and evaluated by ultrasonography require biopsy.

Hypertension

This rare side effect is observed in patients with severe familial hypertriglyceridemia. An oral estrogen regimen can hasten severe hypertriglyceridemia or pancreatitis in women with severely elevated triglyceride levels. Therefore, estrogen replacement is a relative contraindication in women with substantially increased triglyceride levels.

Gallbladder Disease

There is a minimally increased risk of gallbladder disease with estrogen use during the menopause. There is a marginally significant increase in the risk of cholecystectomy in past and current users of HRT. Preexisting gallbladder disease is a relative contraindication for estrogen replacement.

Breast Cancer

It has been debated whether continuous combination hormone replacement using conjugated estrogens (0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) increases the risk of venous thromboembolism. A recent randomized clinical trial has shown that this regimen of HRT significantly increases the risks of deep venous thrombosis and pulmonary embolism, although these increases were modest. Even if the relative risk is significantly increased, the actual risk remains extremely low because of the low frequency of this event in the general population.
Breast tissue is a major target for estrogen, and most breast tumors are estrogen-responsive. A number of case-control and cohort studies concluded that 5 or more years of current use of postmenopausal HRT is associated with a slight increase in the risk of breast cancer, a risk that is less than that associated with postmenopausal obesity or daily alcohol consumption.\footnote{648} \footnote{649} Many observational studies, however, have failed to develop evidence that long-term postmenopausal HRT increases the risk of breast cancer.\footnote{648} \footnote{649} Moreover, none of the epidemiologic studies found an increased risk of breast cancer associated with less than 5 years of use or past use of postmenopausal HRT.\footnote{649} The addition of a progestin to the treatment regimen slightly increased the risk observed in estrogen-only users.\footnote{649} In this context, the recent findings from the Women's Health Initiative support and extend the previous work, in that the combined use of estrogen and progestin led to a statistically significant increase in invasive breast cancer over the 5.2 years of the study.\footnote{593A} Because breast cancer was uncommon in this group of postmenopausal women, this increase represented an absolute increase of 8 cases per 10,000 women receiving hormone replacement.

Epidemiologic data indicate that a positive family history of breast cancer should not be a contraindication to postmenopausal estrogen use. Moreover, postmenopausal women in whom the cancer develops during HRT have a reduced risk of dying from breast cancer.\footnote{649} This reduced risk may be due to an increased rate of early detection and development of less aggressive tumors in association with HRT. In conclusion, there may be a minimally increased real risk of developing breast cancer in long-term HRT users. This risk, however, is extremely small compared with the clear-cut benefits of estrogen such as osteoporosis prevention and urogenital tissue support.

Hormone Replacement Therapy after a Diagnosis of Breast Cancer.

HRT is typically withheld from women with breast cancer because of concerns that estrogen may stimulate recurrence. Surprisingly, a number of relatively small studies showed either unaltered or lower risks of recurrence and mortality in women who used HRT after a diagnosis of breast cancer compared with nonusers.\footnote{650} \footnote{651} HRT in most of these small studies was started after at least a 5-year disease-free interval.\footnote{650} \footnote{651} On the basis of these insufficient but encouraging data, a decision to provide HRT is dependent on the choice of the individual patient. In these patients, tamoxifen or raloxifene represents a viable alternative to estrogen replacement for long-term prophylaxis against osteoporosis.

Chapter 17 - Fertility Control: Current Approaches and Global Aspects

Michael Kafriessen
Eli Adashi

GLOBAL ASPECTS OF FERTILITY CONTROL

Regulation of human fertility encompasses social, legal, and health care measures, including the employment of medical technologies and procedures that result in limiting the number of offspring. This can be achieved by spacing the birth of individual children in the sense of family planning or by terminating procreation when the desired family size has been achieved. The aim of fertility control is to achieve a family or population size that is compatible with a reasonable quality of life and is culturally and economically supported.

Growth of the Human Population

History and Current Status

The explosion of the world population is a relatively recent phenomenon (Fig. 17-1). By AD 1, 200 million people lived on this planet. By 1650, more than 1600 years later, this number had increased to 500 million. Thereafter, the population-doubling time became progressively shorter. By 1850, the human population numbered 1 billion, and within 80 years, in 1930, the population reached 2 billion. In 2000 the world population crossed the 6 billion milestone, and the growth continues.

Consequences of Overpopulation: From Malthus to Ehrlich

During the industrial revolution, Thomas Malthus, an English political economist, noticed the soaring population of the British Isles, a geographic area with limited arable land, and concluded that the human population would outrun the available food supplies. Between 1778 and 1816, Malthus published a series of essays in which he predicted that a collision of population growth and lack of world food supplies would result in worldwide disasters such as famines, epidemics, and wars. Malthus believed that strict limits on reproduction were essential to the betterment of humankind.

In 1968, at a time when humankind experienced the most prominent population increase (see Fig. 17-1), Paul Ehrlich, a biologist at Stanford University, brought the issue of overpopulation to the public consciousness in his disquisition *The Population Bomb*. Ehrlich pointed out the negative effects of population growth on the environment, nonrenewable natural resources, and general economic progress.

Coping with the Population Growth

Human ingenuity has largely disproved the predictions of both Malthus and Ehrlich. The extraordinary demographic history of the 20th century that occurred without global malthusian disasters can be explained mainly by two phenomena: innovations in agriculture and advances in medicine.

Agriculture: From the Neolithic to the Green Revolution

Historically, the phases in which the growth of the world population took an upward trend have coincided with improvement in agricultural techniques. In the Neolithic era, humans started to grow food supplies and this transition from hunting and gathering resulted in the first substantial population growth. However, further agricultural progress was slow, and so was the population growth.

Not until the 18th and 19th centuries were more advanced agricultural methods applied. The industrialization of agriculture dates only from the beginning of the 20th century, when the farm tractor, introduced in Iowa in 1901, led to mechanization of the farmer’s work. Further improvements, known collectively as the green revolution, followed. They included the use of chemical fertilizers, herbicides, and insecticides; the development of hybrid grains; and, more recently, the genetic manipulation of rice and grains. Farmers in the United States planted hybrid seeds and increased yields of grains by one third in only one decade, between 1930 and 1940.

During the first 35 years of the green revolution, global grain production doubled.

Famine, which historically has been a worldwide and perennial problem, became much less of a threat in the 20th century. Although the last 100 years have seen devastating famines in numerous areas of the world and millions of undernourished people have died, the demographic impact of these famines was relatively local and short-term. Famines are endemic on the Indian subcontinent, for example, but its population increased from 300,000 in the year 1900 to 1.3 billion in 2001. Despite predictions that the world population would outstrip food production, food production has risen a full 16% above population growth.

Today, there are fewer hungry people than ever before in history. In 1996, the number of hungry people of the world was 17%, whereas in 1970, 25 years earlier, 35% of the world's people fit in the “hungry” classification.

The increased productivity of industrialized agriculture has demographic consequences. Currently, 2% of the world's farmers, most of them in developed and rapidly developing countries, produce one fourth of the world's food. The reduced need for workers has liberated the industrial farmer from the pressure to have a large family. By contrast, traditional farmers, mostly in the underdeveloped countries, still feel the need to secure the necessary agricultural workforce through having more children.

The success of industrial farming, however, came at a price. The expansion of arable land disturbed the balance of the ecosystem. For example, deforestation and reduction of natural pastures led to droughts and floods in certain areas. During the next 50 years, the growing global population will require further advances in agricultural production to ensure a sufficient, secure, and equitable food supply. To control population growth...
reversethe environmental impacts of agricultural expansion, intensive scientific efforts must be implemented along with regulatory, technologic, and policy changes.10

Medicine: From Art to Science

During the 20th century, major advances in the practice of medicine and the application of preventive medicine increased worldwide population survival rates. A number of factors contributed to enhanced survival: an increase in the number of infants born alive, a decrease in infant and child mortality, and the containment of the spread of major epidemics. In the developed countries, the perinatal mortality rate fell from 225 per 1000 live births to under 20 per 1000. In the less developed countries, the perinatal mortality rate also decreased, but the disparity between underdeveloped and some industrialized nations was staggering. In 1988, the perinatal mortality was 5 per 1000 for Japan but it was 118 per 1000 for Bangladesh.11

Globally, life expectancy increased from approximately 30 years at the beginning of the 20th century to 47 years in the middle of the century and 65 years by the end of the century. It is projected that by the year 2050, life expectancy will be 76 years. The current 180,000 living centenariansmost of them in Europe, Japan, China, and the United Statesbest attest to the improved health conditions of humankind.

The kinds of epidemics that decimated populations in the past have become less of a peril. Historians estimate that in the 1350s, in medieval England, the epidemic of plague known as the "black death" reduced the total English population by 20% and decreased life expectancy to under 18 years.12 The acquired immunodeficiency syndrome (AIDS), a modern-day parallel to a medieval plague, has taken its toll mainly in Africa, where 28 million of the 36 million AIDS-affected people live. Nevertheless, even in the sub-Saharan nations, where the incidence of AIDS is as high as 30% and life expectancy has been reduced to 37.2 years, the population continues to expand, although at a slower rate than before the outbreak of the epidemic. However, in some countries of sub-Saharan Africa, notably in South Africa and Zimbabwe, a negative growth rate is expected.13

In summary, malthusian predictions of global catastrophes caused by overpopulation did not materialize. However, the balance of a steadily growing population and potential technologic limitations on resources remains precarious.
Population Projections

Current projections for the growth of the world population by the middle of the 21st century vary from 7.9 billion to 10.9 billion. [See Fig. 17-1]. With respect to individual continents, Asia will remain the most populous. The most significant growth is expected to occur in Africa, with the population rising from the current 900 million to 2 billion. Notable population growth is also projected for countries in both North America and Latin America. The United States will probably be the only industrialized nation with a population increase. The population of Europe is expected to decrease [Fig. 17-2]. However, there is a broader question related to the world population growth, namely what is the optimal number of people the world can support? In 1994, a serious attempt to answer this question was made at the International Conference on Population and Development, now known as the Cairo Conference. The conference forecasted a world population of 10 billion in 2050 and recommended holding the population at that level.
The Future of the World Population

Medical progress has affected human demographics by another innovation: the development of effective means of preventing pregnancy. Introduced in the 1960s when the population was increasing, modern contraception was immediately recognized as a potential instrument for large-scale family planning. Indeed, available demographic data show that since the 1980s, population growth rates, along with fertility rates, have been falling (Fig. 17-3: see Fig. 17-1). This signifies a tapering off of the most rapid phase of world population growth. However, the data also show that the momentum of growth will persist into the middle of this century, when the world population is projected to be 10 billion.

The goal of holding the world population at 10 billion can be accomplished if the fertility rate is limited to an average of 2.1 children per woman, the essential replacement rate; this can be achieved by effective fertility control.
Historically, most societies rewarded families for having children by reducing their tax burden and giving awards to mothers of numerous children. In the second half of the last century, however, certain societies, pressured by overpopulation, installed strong disincentives for families that had more than a prescribed number of children. In China, for example, a family that has more than the allowable one child is castigated. In Singapore, a highly developed but crowded country, the acceptable number of children for a family used to be determined, among other things, by the parents' educational level. In other cultural environments, the government resorted to positive incentives by providing gifts to individuals who underwent voluntary sterilization. Coercive methods of family planning have been criticized and are globally unacceptable.

Modern family planning must respect the freedom of reproductive choices, free access to family planning facilities, and availability of up-to-date methods of fertility control. Individual families as well as entire nations must be educated to comprehend that effective family planning makes good social and economic sense. Currently available data show that the decrease of birth rates is inversely proportional to the percentage of the population practicing contraception. The data also show that nations enjoying the highest living standards or those striving to overcome economic hurdles have the lowest birth rates. Examples of the latter are the countries of the former Eastern European bloc.

Effective fertility control can be achieved only when the society supports it. Initially, after their introduction in the 1960s, modern methods of human fertility control were accessible only to the affluent. Today, in the milieu of globalization, contraception has become a matter of governmental policy in many nations. It is also of primary concern to global organizations such as the World Health Organization (WHO) and the United Nations Educational, Scientific, and Cultural Organization as well as private institutions such as the Population Council and the Alan Guttmacher Institute of Family Planning.
The Role of the Physician and Other Health Care Givers in Fertility Control

Health care givers in nearly all specialties have become increasingly involved in issues of fertility control. Practitioners ranging from pediatricians who care for teenage girls to internists who care for premenopausal women are frequently asked to provide contraceptive advice.

The role of medical specialists in reproductive health care is also undergoing a transition. Two major challenges have arisen. The first is a result of the existing and widening cultural diversification in developed countries, where physicians frequently face problems that not only challenge their medical skills but also test their ability to deal with the family planning needs of communities with diverse ethnic, cultural, and religious backgrounds. The second challenge has to be met by all those working in reproductive health care and family planning: the increasing emphasis on state-of-the-art medical practice. There is a global need for the rapid incorporation of appropriate technologies into daily clinical practice, substantially increasing the quality of rational medical care, worldwide.

The individual methods and technologies of fertility control are discussed in the following sections of this chapter.
**Methods of Fertility Control: Efficacy, Continuation of Use, Changing Trends**

When making a recommendation to a candidate for contraception, three aspects of each method have to be examined: efficacy, tolerability, and whether the method is suitable for temporary or permanent cessation of procreation. Table 17-1 lists the principal methods of fertility control currently available and indicates their contraceptive efficacy as well as the average time patients adhere to an individual method.

The estimates of contraceptive failure during "perfect" use are derived from studies conducted for research and registration purposes; they include volunteers or self-selected groups who are highly motivated to adhere to the study protocol. Therefore, the results are more favorable than those obtained during "typical" use, that is, use in the general population. Data on the efficacy for typical use are generated by the National Surveys of Family Growth, among others.

**Efficacy and Continuation**

If the outcome was left to chance—that is, no method of fertility control was practiced—5 of 100 women of reproductive age would become pregnant within a year. Surgical sterilization, for both men and women, remains one of the most effective methods of contraception, although it is not failure proof. The small proportion of early failures may be associated with suboptimal surgical techniques, such as mistaken anatomical structures for the fallopian tube or vas deferens; insufficient electrocoagulation when this method is used in women; or unprotected early intercourse after vasectomy while live spermatozoa are still present in the part of the vas deferens that is distal to the interruption. Late failures, between the third and tenth years after surgery, also occur and are discussed in the section on sterilization. The major advantage of surgical sterilization is that it is permanent and can be a welcome solution to parents with large families. Chemical sterilization of women aims at producing tubal occlusion by injection of a substance (e.g., quinacrine) into the junction between the tube and the uterus. Data from a large study conducted in Vietnam show that this method is inferior to surgical sterilization.

Among the hormonal contraceptive methods, long-acting approaches such as implants, injectables, and copper- or hormone-containing intrauterine devices (IUDs) achieve a higher level of efficacy than oral contraceptives (OCs) that require a daily conscientious action by the user. According to revised data of 1995, the failure rates of OC formulations are higher than previously thought. Emergency postcoital contraception, when properly used, is also effective; however, it is recommended only as an emergency provision.

Hormonal methods of fertility control also encompass non-surgical termination of pregnancy by pharmacologic means ("contragestion"). Mifepristone and prostaglandins administered not later than the seventh week of pregnancy achieve complete abortion in a high proportion of cases. The procedure is less effective when employed after the seventh week of pregnancy.

The efficacy of IUDs has been improved by incorporating either progesterone or a synthetic progestogen, levonorgestrel. The copper IUD has staged an impressive revival, principally outside the United States. Its efficacy and safety have been improved and are now comparable to those of hormonal contraception. Copper- and progesterin-bearing IUDs are likely to continue to grow in popularity.

Other methods of fertility control are less effective. For the barrier methods, there is a large discrepancy between the efficacy of ideal use and that of typical use. With the cervical cap and the vaginal sponge, failure rates are high even with perfect use. The same applies to the "natural" methods of fertility control. They rely, one way or another, on prediction or detection of ovulation and require continuous watchfulness and motivation of both partners. Therefore, their efficacy does not compare favorably with that of the hormonal or intrauterine

Lactational amenorrhea provides an effective but temporary method of contraception

ND, no data.

*Data from references [17][18][19].

New estimates of contraceptive failure according to correction for abortion underreporting, from 1995 National Survey of Family Growth. [20]

Data on quinacrine sterilization from reference [21].

§Periodic abstinence methods. Calendar: The woman records the length of 6 to 12 cycles and determines the beginning of the fertile period by subtracting 18 days from the shortest cycle. The end of the fertile period is estimated by subtracting 11 days from the longest cycle. Ovulation method: Women are taught to recognize the characteristic of the cervical mucus during the fertile period. Sexual abstinence begins on the day when the mucus becomes clear, slippery, and stretchy (usually a few days before ovulation). At the peak of the fertile period, the mucus stretches between the finger and thumb to the maximum (spinnbarkeit). Intercourse is resumed on the third or fourth day after the peak mucus. Symptothermal method: Cervical mucus (ovulation) method supplemented by calendar in the preovulatory phase and basal body temperature in the postovulatory phase. Postovulatory method: Ovulation is estimated by the basal body temperature or cervical mucus methods; unprotected intercourse is allowed 3 to 4 days thereafter. Note: Sophisticated electronic devices are currently available to estimate ovulation more precisely, some of them measuring the estrogen and luteinizing hormone concentrations in urine.

Lactational amenorrhea affords protection against pregnancy; however, breakthrough ovulations do occur, particularly when breast-feeding is not exclusive and is interrupted by other types of baby nourishment.

Women frequently discontinue the use of contraception. Overall, 31% of women discontinue use of reversible contraceptives for a method-related reason within 6 months of use; 44% do so within 12 months. However, 68% of women overall resume use of a method within 1 month and 76% do so within 3 months. High rates of method-related discontinuations reflect dissatisfaction with available methods or management, or both. [22]

Trends in Fertility Control in the United States

In the third quarter of the last century, the use of fertility control methods in the United States underwent a major change (Table 17-2) [23][24][25].

Among women, hormonal contraception has remained the most popular method. Two events positively influenced the employment of hormonal methods: the advent of hormonal implants and the approval of medroxyprogesterone acetate (MPA) depot injections for contraception.

As physicians became versatile in laparoscopic surgeries, the
frequency of female sterilization jumped from 12% in 1973 to 23% in 1982; 1995 brought a further increase to nearly 30%. The proportion of male sterilization remained stable at 11%.

The condom now ranks as the third method of choice. Between 1982 and 1995, the frequency of its use rose from 12% to 27%, most markedly among unmarried women in the age group 15 to 29 years. Fear of human immunodeficiency virus (HIV) and other sexually transmitted diseases (STDs) impelled this shift.

Possibly the most dramatic change in the use of contraceptive methods was the virtual abandonment of IUDs in the United States. This was triggered by the Dalkon Shield episode ending in 1973—the occurrence of excess pelvic infection in women using the device. Another negative factor was the recall of the "copper 7" IUD from the market in 1986 because of putative infertility of women who had discontinued its use. A newly designed copper IUD has surfaced, although U.S. physicians are still more hesitant to prescribe it than their colleagues outside the United States. Uptake of the hormone-bearing IUD is similarly slow.

Contraceptive foams alone are used rarely; currently, manufacturers and physicians recommend that they be used simultaneously with barrier methods.

Surgical female sterilization is the most frequently used method of effective fertility control in the developing countries (Table 17-3). The biggest difference between the United States and developing countries is the high use of IUDs; use by approximately 30% of women in developing countries makes IUD insertion the second most frequent method of contraception. Hormonal contraception ranks third, possibly because of its high cost and problems with access. In Sri Lanka, for instance, some women buy only five pills at a time because their financial situation does not allow them to acquire a full month’s supply.

### Contraceptive Failures

Given the length of time that most women practice a reversible method of fertility control, experiencing at least one contraceptive failure is likely. By sheer statistical probability, failure can happen even if the most effective methods are used perfectly. Between the ages of 16 to 30, a hormonal contraception user has a more than 50% chance of becoming pregnant. During a lifetime of use of reversible methods, the typical woman experiences 1.8 contraceptive failures. This applies particularly when the health status of a woman prohibits the use of a highly effective method, such as the pill, and the couple has to resort to methods that have fewer adverse effects but may also be less effective.

A National Survey of Family Growth analyzed the outcome of unplanned pregnancies in the United States that occurred despite contraception between 1994 and 1995. The analysis took into account the total number of births and therapeutic abortions in the year 1994. Miscarriages were excluded from analysis because it was difficult to calculate the proportion of women who did not plan the pregnancy. For purposes of the analysis, the authors assumed that all therapeutic abortions resulted from unintended pregnancies.

In 1994, there were 5.38 million pregnancies in the United States; of those, 2.73 million (51%) were intended and resulted in births of live children. A full 2.65 million (49%) pregnancies were unintended, of those, 1.22 million or 46% resulted in births and 1.43 million or 54% ended as therapeutic abortions. Alternatively, of the total 3.95 million births (100%), the majority of 2.75 million or 70% were intended and 1.22 million or 30% were unintended.

The survey further revealed that 48% of women from 15 to

From Henshaw SK, Kost K. Abortion patients in 19941995: characteristics and contraceptive use. Fam Plann Perspect 1998; 28:140147, 158.

44 years of age had had one or more unintended pregnancies, either an unplanned birth or an abortion, or both. The percentage increased with age to a high of 60% among women in the age group 35 to 39 years.

The information on the use of contraceptive methods at the time when an unplanned pregnancy was conceived and later resulted in therapeutic abortion is based on a representative subset of 9885 patients who had abortions. Of these, 42.5% did not use any contraception at the time of conception and 57.5% practiced some method of fertility control. The male condom was most frequently associated with contraceptive failure. More than half of the women who resorted to abortion reported the use of condoms.

Among women who experienced contraceptive failure, 76% of those younger than 18 years preferred the condom. However, only 46% of women older than 30 years used this method. Pill use peaked at 25% among women aged 20 to 29 and decreased to 16% after the age of 30. On the other hand, the use of methods classified as other rose from 1% in the age group younger than 18 years to 24% in the age group 30 years or older.

The Need for Future Improvements

The high discontinuation rate, the number of unintended pregnancies, and the number of abortions testify to the fact that present reproductive health care is still deficient in providing adequate fertility control options to all women. The health care system alone cannot be blamed for the large number of unplanned pregnancies. Patients frequently choose methods of low efficacy, the primary example being the use of the male condom. When effective methods are recommended, they are frequently applied incorrectly or their use is interrupted, even if it is resumed later on.

These problems can be partially remedied by appropriate information about the available contraceptive choices and by intensive counseling adjusted to the level of the individual patient. Informing the general public about new findings and advances in reproductive health care has been largely facilitated by access to electronic sources of information; the medical profession should take full advantage of this progress.

The proportion of women who did not use any contraception at the time of an unplanned conception is disturbing. This problem could be partially addressed by the development of a highly effective postcoital method. An alternative solution would be implementation of an effective system that would make the presently available postcoital contraceptives promptly accessible. Finally, there must be renewed interest in improving present methods and designing new effective and safe approaches to fertility control.
Hormonal Contraception

The knowledge that estrogens and progestagens can inhibit ovulation has been the foundation of the modern hormonal methods of contraception. In 1940, for the first time, Sturgis and Albright achieved inhibition of ovulation in women by estrogens in order to relieve dysmenorrhea.

The foundation of modern contraception was laid in Manhattan in 1950 at a lengthy conference. Among the participants were Gregory Pincus, director of the Worcester Foundation, and a small group of fertility control advocates including Margaret Sanger, the founder of the Planned Parenthood movement. The conference ended by granting Pincus seed money of $2100 to initiate his research on hormonal contraception. In 1953, working with a Boston gynecologist, John Rock, Pincus started to test oral progesterone for ovulation inhibition. In 1956, Pincus’ group of scientists and physicians published results of the first successful contraceptive clinical trial, which took place in Puerto Rico using a synthetic progestagen, norethynodrel, provided by the G.D. Searle company. Norethynodrel, however, was not the first orally active progestagen. This priority belongs to norethindrone, synthesized in 1951, which became the lead compound in the development of clinically important oral progestagens.

Starting in the 1930s, chemists searched for orally active steroids. In 1938, a group at the Schering Corporation in Berlin, Germany, developed the first orally active steroidal estrogen by attaching the ethinyl group (-CCH) to the 17th carbon of the estradiol molecule (Fig. 17-6). Ethinylestradiol still constitutes the estrogenic component of nearly all combined OCs. The development of orally active progestagens was triggered by the discovery that when the C-19 methyl group of testosterone is split off, the resulting molecule loses androgenicity and acquires progestagenic properties. In 1951, Carl Djerassi, leading a team of chemists in Mexico City, reasoned that attaching the ethinyl group (-CCH) to the 17th carbon of the nortestosterone molecule would greatly enhance its progestagenic activity and make the compound orally active (Fig. 17-7 and Fig. 17-8). Djerassi and colleagues produced 17-ethinyl-19-nortestosterone. The compound, known by its generic names norethindrone and in Europe norethisterone (commonly abbreviated NET), had 10 times the activity of natural progesterone when orally administered. To this day, norethindrone has remained the progestagenic component of many combined OCs (Table 17-6). In a parallel development, manipulation of the progesterone molecule produced a group of orally highly active progestagens, such as medroxyprogesterone acetate (MPA) (Provera) (see Fig. 17-16 later).

Originally, hormonal contraception included only the pill, that is, an orally active combination of an estrogen and a progestagen. The pill offered several advantages over other available contraceptive methods. For the first time, its high efficacy brought confidence in a contraceptive method and freedom from the fear of pregnancy. It produced only temporary and reversible infertility; therefore, it was ideal for family planning. Because the method was not linked to coitus, the spontaneity of the sexual act could be preserved. The pill has become popular among women in both developed and developing countries, and today 10 million women in the United States and 60 million women worldwide adhere to this method.

However, use of the pill requires a conscious daily action on the part of the user, and it has been postulated that missing pills could be the reason for the discrepancy between pregnancy rates during perfect and typical use (see Table 17-1). To close this gap, long-term methods of hormonal contraception have been invented that require only one or a limited number of actions on the part of the user. Hormonal implants, depot injections, and hormonal IUDs are examples of such long-term methods with high efficacy during typical use.

Unintended pregnancies can result from failure of contraceptives or from exposure to an unplanned sexual contact. Such events necessitate short-term preventive steps. Two important developments took place in this direction: emergency post-coital contraception and the use of anti progestagenic steroids for contraception.

The hormonal contraceptives available today can be categorized by the way they are administered and by the duration of their action (see Table 17-5).
Oral Contraception

Steroidal Components

In the following paragraphs we describe the pharmacologic and biologic properties of the two hormonal components of OCs, the estrogens and the progestagens.

Contraceptive Estrogens

Structure and Function

In the combined estrogen-progestagen OCs, one type of estrogen prevails, 17-ethinylestradiol. A limited number of OC preparations contain a derivative of ethinylestradiol, mestranol.

The ethinyl group protects ethinylestradiol and mestranol (MEE) from oxidation and conversion into less active estrogens such as estriol. Mestranol is a prodrug that does not bind to estrogen receptors and has to be converted into ethinylestradiol in order to become biologically active. MEE has been replaced by ethinylestradiol in virtually all OCs worldwide.

Pharmacokinetics and Metabolism

After ingestion, ethinylestradiol is rapidly absorbed from the gastrointestinal tract. The time to the maximum ethinylestradiol concentration in plasma ($T_{\text{max}}$) is 1 to 2 hours and the elimination half-life is wide, ranging from about 9 to 27 hours. In the intestine and in the liver, ethinylestradiol is readily conjugated with sulfuric and glucuronic acids and undergoes enterohepatic circulation. Intestinal bacteria possessing the appropriate enzymes can hydrolyze ethinylestradiol sulfates, and some of the deconjugated estrogen is reabsorbed. One could speculate that the use of oral antibiotics that affect intestinal flora may influence blood levels of ethinylestradiol; so far, clinical proof of this assumption is lacking. The pharmacokinetics and metabolism of mestranol are similar to those of ethinylestradiol except that $T_{\text{max}}$ is longer than might have been expected because mestranol has to be converted to ethinylestradiol.\[37\]

Individual subjects vary considerably in the amount of absorbed ethinylestradiol and the circulating concentrations of ethinylestradiol as well as in the elimination time. Intrasubject variations can also be prominent. These variations may explain why adverse effects and contraceptive failures occur in only certain individuals and why the same woman can experience side effects during some treatment cycles but remains symptom-free during others. The basis of the intersubject and intrasubject variations has not been explained satisfactorily.

As we are witnessing another wave of reduction of the ethinylestradiol content in the combination pills to 20 µg, bioavailability becomes an issue. As these and ever lower doses of ethinylestradiol become more common, we must be certain to provide OCs in formulations that deliver the digested amounts of steroids at appropriate concentrations for the individual user.

Contraceptive Progestagens

In contrast to estrogen synthesis, the synthesis of progestagens has been prolific. The reasons for this dichotomy are several. Because ethinylestradiol exhibited potent oral activity and was not protected by patents, there was little incentive to search for other OC estrogens. New progestagens were synthesized in order to secure proprietary rights for the developers of OCs. Also, synthesis of new compounds was prompted by the desire to produce a highly effective progestagen that would minimize the dose of the progestagen in the OC combination and thus reduce the incidence of progestagen-related adverse events. Currently, about a dozen progestagens are being used clinically in established contraceptive preparations and several compounds are in various stages of preclinical and clinical testing.

According to the classical definition, progestagens transform the estrogen-primed endometrium into a secretory one and support the development and maintenance of pregnancy. The advent of molecular biology has defined progestagens as compounds that bind to and activate progesterone receptors within the target cells.

However, binding to progesterone receptors does not preclude the progestagen molecule binding with other receptors or expressing effects other than progestagenic effects, or both. For example, norethindrone, under certain circumstances, can stimulate the proliferation of the atrophic endometrium.\[38\]\[39\] Besides being a potent progestagen, cyproterone

### Table 17-5 — Hormonal Contraceptives in Clinical Use

| Oral contraception (see details in Table 17-6) |
| Cyclic estrogen-progestagen combinations |
| Continuous progestagen-only oral contraception |
| Long-acting preparations |
| Injectable preparations |
| Progestagen-only preparations |
| Depo-medroxyprogesterone acetate, 150 mg, q3mo, IM |
| Norethindrone enanthate, 200 mg, q2mo, IM (not used in the United States) |
| Medroxyprogesterone combination injectables |
Norplant: 6 capsules with total amount of 216 mg of levonorgestrel
Norplant II (Jadelle): 2 rods with total amount of 150 mg of levonorgestrel

Hormonal intrauterine systems

Progestasert: T-shaped; vertical arm releases progesterone, 65 µg/d
Mirena (levonorgestrel-20): T-shaped; vertical arm releases levonorgestrel, 15 µg/d
Vaginal rings releasing contraceptive hormones
NuvaRing approved in 2001
Transdermal patch releasing contraceptive hormones
Ortho EVRA: 20 cm² patch, delivers 150 µg noretisteron, 20 µg/d ethinylestradiol

Emergency methods of fertility control

Postcoital hormonal contraception
a. 1 mg norgestrel and 100 µg ethinylestradiol within 72 h of unprotected intercourse, repeated after 12 h
b. 0.75 mg levonorgestrel within 72 h of unprotected intercourse, repeated after 12 h

Contraception

Mifepristone, 200-600 mg, orally, followed by 400-800 µg misopristol orally

---

Figure 17-9
Classification of contraceptive steroids. Hybrid progestagens are in gray boxes. In parentheses are the active progestagenic metabolites of norgestimate and desogestrel.

Figure 17-8
Classification of contraceptive progestagens. Hybrid progestagens are in gray boxes. In parentheses are the active progestagenic metabolites of norgestimate and desogestrel.

Classification of Contraceptive Progestagens

Contraceptive progestagens have been classified in various ways, for example, according to the amount of ethinylestradiol with which they are combined, the type of progestagen they contain, and the time when they became available for clinical use.

According to the chemical structure of the steroids, the classification of contraceptive progestagens presented recognizes three basic groups, 

1. pregnanes,
2. estranes, and
3. gonanes.

These chemical reactions led to the synthesis of norethindrone, the first orally highly active progestagen, which enabled the development of oral contraception. All estranes are 19-norsteroids.

Gonanes

The gonane structure lacks both the C-18 and the C-19 angular methyl radicals. However, all gonane progestagens bear an ethyl group between rings C and D at C-13 (Fig. 17-12 and Fig. 17-13; see Fig. 17-8). This chemical modification makes them more active progestational agents than estranes.

---

Norplant and levonorgestrel are derivatives of 13-ethylgonane. Because they were developed in the 1960s, they are categorized as early gonanes. Only the
dl-Norgestrel and levonorgestrel were synthesized in order to acquire a more potent progestagen than norethindrone, but they also increased the compound's androgenic properties with undesired clinical and metabolic effects. Thus, the next task of the steroid chemist was to produce highly active progestagens without the androgenic effects. The synthesis of the later gonanes met this challenge.

Later Gonanes.

Three progestagens belong to this family, norgestimate, desogestrel, and gestodene (see Fig. 17-13).

**Norgestimate.**

The key difference between norgestimate and other progestagens is the oxime group (-C=N-OH) in position 3 of the molecule instead of the keto group (C=O). Norgestimate is solely the biologically active levor form. Because the C-3 keto group is typical of androgenic compounds, its replacement by the oxime may contribute to the reduced androgenicity of norgestimate as compared with levonorgestrel.

**Desogestrel.**

This advanced gonane is interesting in that its progestagenic activity has been increased by substitution on C-11. Manipulations at C-11 give the steroid molecule the ability to bind to the progesterone, glucocorticoid, and mineralocorticoid receptors. The intensity of the binding depends on the structure of the substituting groups.

**Gestodene.**

Gestodene differs from norgestrel in a single feature, namely the double bond between C-15 and C-16. This seemingly simple change has a profound effect on the configuration of the molecule, principally on the spatial arrangement of the D ring and C-17. One can speculate that these changes affect the conformation of the molecule in a way that affects its binding to hormone receptors. In vitro studies have shown that gestodene binds to the heme of the P450 enzymes that inactivate estrogens, with consequent increased concentrations of these hormones. The clinical relevance of this finding is unknown.

**Some Aspects of the Clinical Pharmacology of Contraceptive Progestagens.**

The orally active contraceptive progestagens are rapidly absorbed from the digestive tract and are transported to the liver through the portal circulation. Thereafter, they enter the general circulation, where they form a hormonal pool. In the general circulation, progestagens are present either in the free form or bound to albumins or to the sex hormone-binding globulin (SHBG), or both. Only the free form reaches receptors in the respective target tissues and becomes biologically active. Progestagens can easily be released from the steroid-albumin complex; the bond with SHBG is firmer.

During first-pass liver metabolism, progestagens can be structurally modified with consequent changes of their biologic activity. Glucuronidation and sulfuration of progestagens facilitate their excretion by the kidneys. A variable fraction of progestagens is excreted in the feces. During first-pass liver metabolism, progestagens act on hepatocytes in ways that can alter their metabolism (see later).

The pharmacologic properties of progestagens determine their clinical use. Progestagens of the pregnane series can bind strongly to progestagenic as well as to androgenic receptors and can act as antiestrogens. Oral MPA is used for treatment of various gynecologic disorders, for example, for the management of dysfunctional uterine bleeding, and in the menopause. The compound has been developed as the first injectable long-term contraceptive. In the past, medroxyprogesterone and other pregnane derivatives were proscribed for contraceptive use in the United States because preclinical toxicology had shown an accelerated development of benign and malignant breast nodules in beagle dogs as breed that suffers spontaneously from a high incidence of breast tumors, including carcinoma. Extensive clinical trials conducted by the WHO have lifted the cloud of potential carcinogenicity hanging over MPA, and it is used as an injectable contraceptive globally.

The accelerated growth of breast nodules in beagle dogs was not observed in toxicologic studies with progestagens of the estrane and gonane series. The reasons for this difference in animal carcinogenic potential of pregnanes versus estranes and gonanes have not been adequately elucidated. It is noteworthy that long-term toxicologic studies in monkeys have not shown the formation of any type of breast nodules. In monkeys, spontaneous breast carcinoma is unknown, and the induction
of hormone-associated breast pathology would have been particularly important.

Of the other pregnanes, acetates of chlormadinone, cyproterone, and megestrol are used in OCs in some countries outside the United States. They are also used for management of breast, endometrial, and prostatic carcinomas. Because they are also highly effective antiandrogens, they have been part of the management of benign prostatic hypertrophy, prostatic carcinoma, precocious puberty, and certain hyperandrogenic symptoms in women.

In the estrane series, the four derivatives of norethindrone are rapidly converted to norethindrone. Within 30 minutes after ingestion of any of the derivatives, only norethindrone can be detected in the general circulation.

The earliest OCs contained norethindrone and norethynodrel, originally combined with up to 150 µg of ethinylestradiol. Today, OCs containing more than 50 µg of ethinylestradiol are considered "high-dose" estrogen preparations and have been removed from the OC market in the United States. "Mid-dose"

The early gonanes, norgestrel and levonorgestrel, display certain unique features. The time required for the circulating levels of levonorgestrel to decline by 50% is about 15 hours, and for norethindrone it is about 7 hours. The difference in the elimination time is one of the reasons that contraceptive doses of levonorgestrel can be lower than those of norethindrone. Norgestrel and levonorgestrel are strong progestagens with antiestrogenic properties; however, they also show some androgenicity. Levonorgestrel also decreases the plasma concentration of SHBG by 50% and, in combined OCs, suppresses the estrogen-induced formation of SHBG. Consequently, less SHBG is available for binding testosterone. A combined OC composed of 150 µg of levonorgestrel and 30 µg of ethinylestradiol increases the levels of SHBG slightly by about 20% from baseline. In contrast, women using norgestimate or desogestrel-ethinylestradiol OCs have a three-fold increase in circulating levels of SHBG, which results in a 50% decrease of free testosterone.

Compounds of the late gonane series, norgestimate and desogestrel, are metabolized extensively. After ingestion, norgestimate is rapidly converted into noregestromin and desogestrel is converted into etonogestrel. These metabolites account for the biologic activity of the parent compounds. Noregestromin has been synthesized as a specific hormone for the contraceptive patch, and etonogestrel is used in silastic implants for contraception.

Gestodene is the only compound of the gonane series that is not rapidly metabolized. It is a highly potent progestagen; however, at the time of this writing the compound has not been approved for clinical use in the United States.

**Hybrid Progestagens**

**19-Norpregnanes**

The 19-norpregnanes are a cross between the pregnanes and estranes. These compounds are derived from 17-hydroxyprogesterone acetate but lack the C-19 methyl radical and in that respect are related to estranes. *Noregestrol*, an important member of this series, is currently being investigated as a contraceptive implant.

*Nestorone* is another 19-norpregnane of the 17-acetoxyprogesterone series, which has a methylene group on C-16. In receptor assays, nestorone had progestational effects equal to or better than those of levonorgestrel without estrogenic, androgenic, and anabolic activities. However, nestorone binds to glucocorticoid receptors. Nestorone has low oral but high parenteral progestational activity. Therefore, the Population Council is studying nestorone as a contraceptive implant in subdermal implants, vaginal rings, and transdermal formulations. The compound may be suitable for use in nursing mothers because of its low oral bioavailability.

**Other Hybrid Progestagens**

Dienogest is a new addition to the estranes. In this compound, the cyanomethyl group (CN) has replaced the C-17 ethinyl group (CH₂). Dienogest is 100% orally available. Some evidence suggests that the compound lacks androgenic activity and produces less glucocorticoid antagonism than mefiopristone.

The compound suppresses endometrial growth and is being tested in the management of endometriosis. The antiestrogenic activity of Dienogest is relatively low, mandating the use of 2 mg in combination with 30 µg of ethinylestradiol in a 21-day cyclic regimen.

**Drospirenone**

An addition to contraceptive progestagens has been *drospirenone*. It is a progestagen derived from spironolactone, a potent steroid with antimineralocorticoid activity, which also has progestagenic properties. Drospirenone is relatively weak progestagen; a daily dose for a contraceptive regimen is 3 mg combined with 30 µg of ethinylestradiol. The compound has antiandrogenic and antiimineralocorticoid properties and causes potassium retention. Therefore, it should not be taken by patients with kidney, liver, or adrenal gland disease or with other drugs that increase potassium concentrations in the circulation. Such drugs include nonsteroidal anti-inflammatory drugs, potassium-sparing diuretics (spironolactone and others), potassium supplementation, angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, and heparin.

**Progestagenic Potency, Androgenicity, and Comparative Metabolic Effects of Oral Contraception**

**Multiple Steroid Actions**

Significant determinants of the biologic activity of a steroid include its bioavailability to the target tissues and its affinity for relevant receptors. The multifaceted nature of the steroid molecule is illustrated by its capacity to bind to several different receptors and activate them to various degrees. The final biologic activity depends on the proportion of activated receptors. Progestagenic, estrogenic, androgenic, and glucocorticoid actions. Therefore, the most appropriate progestagens are found in the progestogen androgen receptors. Moreover, some progestagens bind to glucocorticoid receptors.

**Progestagenic and Androgenic Activity**

It is difficult to establish the relative progestagenic and androgenic potency of progestagens because systematic testing of all progestagens by one method has not been performed. Different progestagens have been tested by different methods. The relative binding affinities of progesterone and gonanes for rabbit uterine
progestagen receptors are shown in Figure 17-16. The binding affinity of norgestimate and its 17-deacetylated metabolite (norelgestromin) was similar to that of progesterone; levonorgestrel was at about five times and gestodene and 3-ketodesogestrel were about nine times more active than progesterone.

The relative binding activities of progestogene and gonane progestagens for rat prostatic androgen receptors are depicted in Figure 17-16. Norgestimate and norelgestromin, which have the same progestagenic activity as progesterone, display low androgenic activity. Levonorgestrel, a 5 times more potent progestagen than progesterone, has 44 times higher androgenic activity than progesterone. Although 3-ketodesogestrel and gestodene are more active progestagens than levonorgestrel, they have less androgenic activity than levonorgestrel. In this assay, the androgenic activity of dihydrotestosterone is 200-fold greater than that of progesterone (not shown in Fig. 17-16). The androgenic activity of levonorgestrel is one fourth the activity of dihydrotestosterone.

Biologic tests of androgenicity were conducted on castrated rats, the end point being the weight increase of the prostatic gland. In this assay, the androgenic potency of testosterone equals 100%, that of levonorgestrel is 15% and that of norethindrone is only 1.6%. Medroxyprogesterone and chlormadinone acetate displayed no androgenic action in this test.

NonReceptor-Mediated Action

In skin and some other tissues, testosterone is a prohormone and becomes biologically active only after conversion into dihydrotestosterone by 5-reductase. In vitro experiments have demonstrated that norgestimate and desogestrel inhibit the action of 5-reductase. This may partially explain the beneficial effects of these progestagens in the management of androgenic skin lesions such as acne.

Lipid Metabolism

Important differences exist among progestagens in their effect on lipid metabolism, particularly on the cardioprotective lipoproteins. Estrogens increase total cholesterol, but they also increase the high-density lipoprotein (HDL) fraction and decrease the low-density lipoprotein (LDL) fraction of cholesterol. Progestagens exert an antagonistic effect on these positive actions of estrogens by various mechanisms, including an increase in the activity of hepatic lipase, which degrades HDL. There are quantitative differences among individual progestagens, however, and the net metabolic effect depends on an intricate interplay between the two components of the combined contraceptives, the type and dose of the progestagen, and the treatment regimen, whether it is monophasic or triphasic. In general, the higher the androgenic properties of a progestagen, the more pronounced are the negative effects on cardioprotective lipoproteins.

Because norethindrone and estrane progestagens are derived from testosterone, and testosterone is part of the chemical name of the compounds, it is sometimes assumed that norethindrone and its analogues have androgenic properties. In doses and combinations used in current clinical practice, norethindrone and its analogues do not exhibit substantial clinical or metabolic androgenic effects. A monophasic combination OC (0.5 μg of norethindrone plus 35 μg of ethinylestradiol per day) has been associated with a 10% increase in HDL and a 10% decrease of LDL.

With respect to gonanes, levonorgestrel increases LDL only slightly but reduces HDL significantly. Norgestimate, a later gonane, significantly elevates HDL with a nonsignificant effect on LDL. (Fig. 17-17)

Protein Binding

Natural and synthetic sex steroid hormones enter the target cells by passive diffusion. The capacity of sex steroids to reach receptors in these target cells is modulated by SHBG and other proteins, such as albumins. Natural sex steroids and some synthetic progestagens bind to SHBG with higher affinity and specificity than they bind to albumin. As long as a sex steroid is bound to SHBG, it cannot affect its biologic action, which is accomplished by the free or non-SHBG-bound fraction of the steroid. The binding of sex steroids to albumin is less tight, and albumin-bound steroids are more readily available to target cells, ensuring a rapid pharmacologic response.

Estrogens stimulate hepatocytes to produce SHBG, and androgens and some progestagens interfere with this action. Depending on their composition, OCs are associated with increased formation of SHBG and reduced levels of free.

Insulin and Carbohydrate Metabolism

The original high-dose OCs were associated with insulin resistance and glucose intolerance. Glucose tolerance tests showed a significant increase of blood glucose and insulin after 1 year of OC use. It was initially thought that these changes in glucose tolerance were related to the estrogenic component of the pill. However, after tests of estrogens alone, even in high doses, demonstrated no such negative effects, it was found that high doses of many progestagens can impair carbohydrate metabolism. With the advent of low-dose OCs, the effect of contraceptive hormones on carbohydrate metabolism has been minimized.

Mechanism of Contraceptive Action

Originally, it was assumed that the contraceptive action of combined steroid hormones primarily involved inhibition of the pituitary gonadotropins with consequent blocking of ovulation. This is certainly the case with the combined estrogen-progestagen OC. However, blood levels of progesterone and pituitary gonadotropins indicated that during progestagen-only contraception, ovulatory function has been preserved during many cycles. Therefore, other mechanisms of contraceptive action were explored. Among these were changes in the consistency and increases in the thickness of the cervical mucus that impair the ability of the sperm to penetrate it. Low doses

Figure 17-15 Relative binding affinities of contraceptive progestagens for progesterone receptors. The assay measures displacement of H-labeled R5020 from progestagen receptors isolated from the rabbit uterus. The binding affinity of contraceptive progestagens for progesterone receptors is shown in Figure 17-15. The androgenic activity of levonorgestrel is about one fourth the activity of dihydrotestosterone. (Data from Phillips A, Demarest K, Hahn DW, et al. Progestational and androgenic receptor binding affinities and in vivo activities of norgestimate and other progestins. Contraception 1990; 41:399.)

Figure 17-16 Relative binding affinity of contraceptive progestagens for androgen receptors. The assay measures displacement of H-labeled dihydrotestosterone from rat prostatic androgen receptors. (Data from Phillips A, Demarest K, Hahn DW, et al. Progestational and androgenic receptor binding affinities and in vivo activities of norgestimate and other progestins. Contraception 1990; 41:399.)
of progestagens also alter the function of the endometrium, leading to an intruterine milieu hostile to pregnancy.\textsuperscript{119}

**Oral Contraceptive Treatment Regimens**

**Combined Oral Contraception: Cyclic Estrogen-Progestagen Combinations**

In this method both hormonal components are given in a cyclic fashion, usually from the 5th through the 25th day of the menstrual cycle. With most of the currently used preparations, a 7-day placebo period follows the 21-day hormonal treatment so that women do not need to keep track of when to start a new cycle of contraceptive pills. There is growing interest in developing combined oral contraception (COC) for continuous use to avoid monthly withdrawal bleeding.

Since the inception of COC, the developmental trend aimed at reduction of the amounts of hormonal components in the combination to a level that would make the pill safer and still provide high contraceptive protection and cycle control.

The current COC preparations can be classified according to the amount of ethinylestradiol in the daily dose: (1) 20 µg of estrogen, the lowest dose used in the United States; (2) more than 20 µg to less than 50 µg, the dose most frequently recommended today; and (3) 50 µg, a dose that is rarely recommended. Preparations with an estrogen content greater than 50 µg/day have been removed from the market in the United States. A further distinction is made according to whether the dosage regimen is monophasic, biphasic, or triphasic.

The monophasic dosage regimens consist of contraceptive steroids given in a fixed estrogen-progestagen combination from the 1st through the 21st day of treatment.

With the biphasic preparations, the daily dose of ethinylestradiol is usually constant throughout the entire 21 days of use but the initially low progestagen dose increases at the middle of the cycle, from day 11 on. A special case of biphasic dosage is a preparation (Mircette) employing a constant dose of 20 µg of ethinylestradiol combined with 150 µg of desogestrel given from day 1 through 21. This is followed by 2 days of placebo and then 5 days of ethinylestradiol at 10 µg/day.

In the triphasic treatment regimens, the daily doses of one or both steroid components are modified three times during the treatment period. The individual dosage regimens for OC are listed in Table 17-6.

The development of the biphasic and triphasic treatment regimens was motivated by the desire to mimic the hormonal events of the normal menstrual cycle and to decrease the total load of contraceptive steroids per month. These dosage modifications have contributed to the variety of OC choices. Rigorous comparative studies have not been conducted to show whether the phasic regimens offers any clinically meaningful advantages over the monophasic schedules. However, similar performance at lower hormonal doses has theoretical appeal.

**The Sequential Method**

In this method, estrogens were given in a fixed dose throughout the 21-day treatment period; however, progestagens were given only during the last 5 to 9 days. The use of this regimen was discontinued in the United States in the 1970s because of concerns that repeated exposure of the endometrium to unopposed estrogens may induce atypical hyperplasia. The method is mentioned here because it is described in earlier literature.

**Continuous Progestagen-Only Oral Contraception**

The continuous progestagen-only method, known as the minipill, was developed to eliminate the estrogens entirely from OC preparations. The preparations currently available in the United States contain norethindrone, 350 µg/day; norgestrel, 75 µg/day; and levonorgestrel, 30 µg/day. Outside the United States, preparations with other progestagens are available: lynestrenol, 500 µg/day; ethynodiol diacetate, 500 µg/day; and desogestrel, 75 µg/day. The pregnancy rate for a typical user is higher than with the estrogen-progestagen OC, and the cycle control is less satisfactory.

The method is well suited for breast-feeding mothers. The amounts of progestagen that are excreted into the milk of breast-feeding mothers are negligibly low and do not affect the quantity and the composition of the milk. The combination of the ovulation-suppressive effect of prolactin and the contraceptive effects of the progestagen-only pill offers excellent protection from pregnancy. Another group of women who could benefit from this method are women around the age of 40 with naturally decreased fecundity. Good candidates for progestagen-only contraception are women who do not tolerate estrogens and who reject the use of an IUD.

Some preparations using the continuous progestagen-only method (minipill) have been associated with ectopic pregnancy. For this reason, when pregnancy occurs, all efforts must be made to rule out ectopic pregnancy. The physician must be attentive to complaints of pelvic pain by users of the progestin-only method; sometimes the diagnosis of ectopic pregnancy is delayed because symptoms of ectopic pregnancy such as irregular uterine bleeding, prolonged cycles, and amenorrhea resemble typical side effects.

The decreased efficacy of the minipill compared with combined OCs is probably due to its mechanism of action. The minipill does not consistently inhibit ovulation (about 40% of cycles are ovulatory); thus, other mechanisms become operative. Prevention of fertilization is largely due to changes in viscosity of the cervical mucus in addition to other changes that are inhospitable to impregnation of the ovum.

**Benefits of Oral Contraception**

Physicians, patients, and the general public have been made well aware of adverse effects of hormonal contraception. Data obtained over the last two decades brought evidence that the

</table>
The decreased risk is related to the length of use of OCs. A decrease is evident after only 1 year of use; women who have been practicing hormonal contraception for 4 years or more have risk reduced by more than 50%. It is important to note that hormonal contraception offers long-term protection and that the residual protective effects persist for 20 years or longer. It is also important that the protective effect has been associated with the use of all OCs for which data have been gathered.

Data on progestagen-only contraception and preparations with 20 µg of ethinylestradiol are not yet available, but it is likely that they would offer the same protection as the other preparations.

The mechanism of the protective effect on the endometrium most likely involves the direct antiestrogenic effects of the progestagen component of the OCs. Estrogens stimulate synthesis of both estrogen and progestagen receptors, and progestagens inhibit this synthesis. Part of the antiestrogenic effect of progestagens may also involve the stimulation of estradiol 17-hydrolases in the endometrial cell and accelerated conversion of estradiol to estrone, a less potent estrogen than estradiol. Consequently, the proliferation of the endometrial epithelium, both endometrial glands and stroma, proceeds at a reduced rate with less mitotic activity.

With an estimated 26,700 new cases per year, ovarian carcinoma occurs less frequently than endometrial carcinoma; however, it is more deadly. With 14,800 deaths per year, ovarian cancer is the fourth leading cause of death from cancer, after lung, breast, and colon and rectal carcinomas. The 5-year survival rate is less than 45% after the diagnosis has been established. The protective effect of hormonal contraception is evident with only 3 to 6 months of use. It becomes highly significant after 7 years of use (relative risk 0.2 to 0.4), and the residual protective effect extends at least 10 to 15 years after termination of use.

Hormonal contraception reduces the risk of functional ovarian cysts by 60%. This can be important because functional ovarian cysts are the fourth leading reason for hospitalization of women in the United States, with 160,000 admissions per year. We can speculate that the decreased relative risk of both ovarian carcinoma and functional ovarian cysts is probably due to inhibition of monthly proliferation of the graafian follicles.

Each year, more than 1 million women in the United States experience an episode of pelvic inflammatory disease (PID). Epidemiologic data suggest that women taking OCs have a reduced risk of being hospitalized for PID, but further work is needed to assess the effects of OCs on the incidence of PID.

With respect to ectopic pregnancy, studies from the early...
1990s showed that the incidence rate of ectopic pregnancy per 1000 woman-years is 3.0 for women who do not practice contraception at all. The incidence rate is reduced to 0.005 in women using combination OCs. In women using a Cu-T IUD or the levonorgestrel-containing implant Norplant and in women who have undergone tubal sterilization, the incidence rate is still low (0.2 to 0.3). 684 685

Uterine Leiomyomas

High doses of norethindrone only, or norethindrone given simultaneously with gonadotropin-releasing hormone (GnRH) agonists, can achieve reduction of the size of leiomyomas. Because leiomyoma is the most frequently encountered tumor of the female genital tract, there has been great interest in determining whether OCs protect against the occurrence of this tumor. The question has been addressed by several studies that provided opposing results, and the problem remains unresolved. At least, there does not appear to be an increased risk. 686 687

Endometriosis

OCs have been recommended for mild forms of endometriosis. However, well-designed studies proving a substantive effect are lacking. OCs may protect against the occurrence of endometriosis, 688 and some clinicians use OCs as a follow-up for the prevention of recurrence of endometriosis after a completed course of GnRH agonists.

Other Reproductive Noncontraceptive Benefits

Table 17-7 also shows the beneficial effect of OCs on conditions that are not always serious but negatively affect the quality of life. Such conditions include dysmenorrhea, mittelschmerz, menorrhagia and irregular menses, premenstrual syndrome, and iron deficiency anemia. The beneficial effects are achieved by suppression of ovulation and by influencing the endometrium.

Nonreproductive Benefits of Oral Contraception

Management of Hyperandrogenism

OCs have been used in the management of hyperandrogenic conditions such as acne, seborrhea, and hirsutism. Triphasic norgestimate-ethinylestradiol regimens and other OC combinations of ethinylestradiol with norethindrone acetate, levonorgestrel, or desogestrel have been shown in randomized, blinded, placebo-controlled trials to be effective in the treatment of acne. The efficacy of other OCs has also been supported by studies conducted under less rigorous protocols. 689 690 For example, a single-blind randomized study demonstrated alleviation of acne by treatment with a progestagen, chloromadinone acetate, combined with ethinylestradiol. 691

Several modes of action have been considered to explain the efficacy of OCs in hyperandrogenism. OCs can suppress production of ovarian androgens by inhibiting pituitary gonadotropins. An increase of circulating levels of SHBG is associated with a decrease of bioavailable testosterone, and inhibition of 5-reductase in the skin tissues can also contribute to this antiandrogenic effect.

Medical treatment of hirsutism with OCs is more difficult. In addition to a number of supportive case series reports, two well-controlled clinical trials using OCs with or without GnRH agonists have been reported. 692 693 The first one employed a randomized, double-blind, placebo-controlled study design. Neither the OC Norinyl 1/35 (1 mg of norethindrone plus 35 µg of ethinylestradiol) nor placebo had a beneficial effect on hirsutism. In the second study, which was investigator-blind but not placebo-controlled, the contraceptive Demulen (1 mg of ethynodiol diacetate plus 35 µg of ethinylestradiol) had no effect on hirsutism. However, OC complements GnRH agonist analogues in the management of hirsutism. In these two studies, only the combination of OC and a GnRH agonist had a clinically and statistically significant beneficial effect on hirsutism.

Bone Mineral Density

Well-designed studies demonstrate that the use of OCs increases bone mineral density so that users enter menopause with higher bone mass than nonusers, by 12% on the average. This beneficial effect depends on the duration of OC use; the greatest protection is afforded to women who use OCs for 10 years or more. The ultimate question, whether previous OC users suffer fewer bone fractures during menopause than nonusers, has been addressed by a large case-control study. The results have shown a 25% reduction in hip fractures in previous users of OCs. 694 695

Rheumatoid Arthritis

The relationship between OC use and rheumatoid arthritis has been of interest in countries where this disease affects larger segments of the population. A case-control study from Holland reported 60% protection in ever-users of OCs. 696 Other studies and meta-analyses of various clinical trials have not provided an unequivocal conclusion. 697

Colorectal Cancer

Several studies employing epidemiologic methodology have provided evidence that OCs afford about 50% protection from colorectal cancer and that this effect is directly proportional to the duration of OC use. The subject remains controversial because other clinical observations failed to confirm the protective effect. The mechanism by which OCs would exert a protective effect against colorectal cancer is not clear. 698 699

Adverse Events Associated with the Use of Oral Contraception

The frequency of adverse events associated with oral contraception has decreased continuously since hormonal contraception was first introduced for general clinical use. There are several reasons for this favorable development. The amount of estrogens in the pill has been gradually reduced since estrogens were identified as the culprit in the most severe adverse events, principally cardiovascular and cerebrovascular complications. This reduction was paralleled by decreases in the daily doses of the progestagenic component of OC. In addition, candidates for OCs are being selected more carefully as risk factors for potential complications have been identified, notably smoking among women older than 35. Researchers realized that more frequent follow-up of new OC users could detect early signs and symptoms of complications. For example, measurements of blood pressure before therapy and during the first 3 months of OC use identify individuals predisposed to hypertension. Finally, physicians defined appropriate contraceptive options for patients with medical problems.

Most Commonly Reported Adverse Events

The use of hormonal contraception is associated with a number of less serious adverse events that are nonetheless important because they constitute reasons for discontinuation.

Breakthrough Bleeding.

This event can be expected in 10% to 30% of women during the first 3 months of use of hormonal contraception; thereafter, it is much less frequent. Depending on its intensity and duration, it can be handled by reassuring the patient or by short-term administration of a supplementary estrogen such as micronized estradiol.
Amnenorrhea.

Amnenorrhea, that is, lack of bleeding during the active pill-free period, is always a cause for anxiety because of the possibility of pregnancy. Pregnancy should be ruled out by a sensitive urine or blood pregnancy test. If pregnancy is ruled out and the patient is comfortable with amenorrhea, she may resume the same OC. Alternatively, she may be switched to another OC, usually with more estrogen dominance. Sometimes supplementation by estrogens is recommended. Repeated episodes of amenorrhea can be bothersome and irritating, and it is sometimes best to recommend another method of contraception. A positive pregnancy test should alert the physician to the unlikely but critical possibility of an ectopic pregnancy.

Other Adverse Effects.

One study compared two groups of patients, randomly assigned to receive either a tricyclic combination of ethinylestradiol and norgestimate (Ortho Tri-Cyclen) or a placebo. Symptoms that are usually attributed to the use of OCs, such as common headaches, nausea, breast tension and tenderness, weight gain, and mood change, were assessed before and during treatment. The difference in the incidence of side effects between the two groups was not statistically significant. Only the higher incidence of breast tenderness and mood change in the OC group approached significance (P = .07).

Women who discontinue OC use conceive later than women practicing nonhormonal methods of contraception. "Postpill amenorrhea" develops in 1% of users.

Caution.

Despite the reassuring reports with respect to adverse events, the prescribing physician must be aware that certain conditions warrant caution or constitute a frank contraindication to hormonal contraception. These conditions are discussed in the sections "Contraindications" and "Contraception for Women with Health Problems."

Cardiovascular and Cerebrovascular Adverse Events

From the inception of their clinical use in the 1960s, OCs have been associated with cardiovascular and cerebrovascular complications, namely idiopathic venous thromboembolism (VTE), stroke, and myocardial infarction (MI). These adverse events merit reevaluation in the light of epidemiologic studies that were prompted by the introduction of low-dose OCs into clinical practice.

Venous Thromboembolism

The Role of Estrogens.

Since the first reports of VTE in OC users, clinicians suspected that the noxious agent is the estrogenic component of the combination pill. A dose-response relationship between the estrogen dose and VTE was demonstrated in an epidemiologic study of 234,218 women between 1980 and 1986, when both high-dose and low-dose estrogen pills were being prescribed. The highest incidence of VTE, 10 per 10,000 woman-years, occurred among women who used OCs with an ethinylestradiol content of more than 50 µg/day. With preparations containing the medium dose of ethinylestradiol, 50 µg/day, the incidence of VTE decreased to 7 per 10,000 woman-years; with pills having an ethinylestradiol content less than 50 µg/day, the rate of VTE decreased to 4.2 events per 10,000 woman-years. The difference between the

incidence of VTE at 50 µg/day ethinylestradiol and the incidence at less than 50 µg/day ethinylestradiol was statistically significant.

A subsequent study analyzed idiopathic VTE in a cohort of 74,086 women during the 5-year period from 1993 to 1997. In this epidemiologic study, the relative risk of VTE was defined for pregnancy, various forms of oral contraception including combination OC and the progestagen-only method, therapeutic use of progestagens, and hormonal replacement therapy. The results are summarized in Table 17-8, to which we have added an analysis of the relative risk of VTE associated with emergency contraception. The highest risk of VTE is associated with pregnancy13 times higher than in nonpregnant women. Emergency contraception is not associated with a substantive risk. There is a slight but nonsignificant association between progestagen-only contraception and VTE, the relative risk being 2.4 with a 95% confidence interval (CI) of 0.8 to 6.5. A similar association has been reported for women using hormonal replacement therapy, the relative risk being 2.3 (CI 0.4 to 15.0). With the therapeutic use of progestagens for menstrual disorders, the relative risk for development of VTE rose to 5.3 (CI 1.6 to 18.7). The daily doses in progestagen-only contraception are normally less than 0.5 mg, whereas the therapeutic doses range from 5.0 to 30.0 mg/day.

An ongoing controversy involves reports that the risk of VTE associated with combination OCs containing desogestrel and gestodene is more than twice that for OCs with norgestrel and norethindrone (3.4 versus 8.0). This finding merits a discussion of the role of progestagens in the genesis of VTE.

The Role of Progestagens.

In 1995, several independent clinical epidemiologic studies presented evidence that OCs containing desogestrel and gestodene are associated with double the risk of nonfatal VTE compared with earlier OCs containing norethindrone or levonorgestrel. The results were surprising because thrombotic phenomena have not been conventionally associated with the progestagenic component of OCs. The data were immediately questioned, and the relationship of the various progestagens to VTE became controversial. However, a study analyzing OC use for the 7-year period between 1993 and 1999 confirmed that the risk for development of

VTE of women using OCs containing desogestrel and gestodene is twice that of women using OCs with levonorgestrel. The controversy concerning the third-generation pills containing gestodene and desogestrel continued into 2001, when a meta-analysis established a 1.7-fold risk for third-generation versus second-generation pills.

Norgestimate has not been included in these analyses. An analysis based on postmarketing surveillance of adverse events associated with the use of COCs
Venous Thromboembolism and Coagulation Factors.

Studies of the effects of hormonal contraceptive agents on blood coagulation factors reveal that OCs increase the synthesis of globulins in the liver, including many clotting factors. Consequently, circulating concentrations of many clotting factors are affected but not to a clinically significant level. Most frequently affected are fibrinogen and factors dependent on vitamin K (prothrombin and factors VII, IX, and X) and factor XII. At the same time, a decrease in the levels of antithrombin III, an anticoagulant factor, was noted. Despite the fact that these changes had occurred in virtually all OC users tested, VTE remains a rare event.

In discussing these findings, several issues have to be taken into account. Even under physiologic conditions, concentrations of the clotting factors are excessive in the circulation of healthy women, in some cases reaching 200% of the "normal" values. For hemostasis, however, only a fraction of this activity is needed. The coagulation factors are proenzymes that are present in the circulation in their inactive form. Damage to the blood vessel must occur to activate the coagulation cascade. With respect to antithrombin III, the OC-induced decrease is about 10%, far short of the profound reduction needed to form a clot.

Changes in blood coagulation depend on the dose of estrogen. The decrease of the ethinylestradiol content to below 50 µg/day, common in current OC preparations, has considerably limited the changes in blood coagulation factors that were observed in OCs with a higher ethinylestradiol content.

Venous Thromboembolism and Leiden Factor V.

During the normal coagulation process, protein C and its cofactor S prevent hypercoagulation by inhibiting the activity of coagulation factors V and VII. The Leiden mutation, a genetic mutation of factor V consisting of an alteration of a single amino acid, makes factor V resistant to the action of protein C. The Leiden mutation of factor V occurs in 5% of the U.S. white population and is less frequent in black and Hispanic women. Its presence predisposes the carrier to VTE. (Table 17-9).

In women of reproductive age, the rate of VTE increases to 5.7 VTE events per 10,000 woman-years, and in OC users the increase amounts to 28.5 events per 10,000 woman-years. The identification of the Leiden factor V mutation is the first instance in which increased VTE events in OC users could be linked to a concrete defect in a coagulation cascade. However, screening for the Leiden mutation would be impractical because examination of 1 million potential OC users would detect only 50 women at risk. In addition, 62,000 women would have false-positive results.

Physicians generally consider a personal history of venous thrombosis an absolute contraindication to the use of OCs. Screening

| TABLE 17-9 – Oral Contraception and Factor V Leiden: Risk of Idiopathic Venous Thromboembolism |
| Population | Relative Risk | Incidence per 10,000 Woman-Years |
| Controls | 1 | 0.8 |
| Oral contraception only | 3.8 | 3.0 |
| Factor V Leiden mutation | 7.9 | 5.7 |
| Factor V Leiden mutationoral contraceptive users | 34.7 | 28.5 |

for factor V Leiden may be justified in women with a strong family history of venous thrombosis. The presence of superficial varicose veins that are not a consequence of previous venous thrombosis is not a contraindication to the use of oral contraception.

In conclusion, although significant strides have been made in accumulating knowledge about VTE and OCs, the phenomenon remains as enigmatic as before. Reducing the dose of ethinylestradiol in the combination pill to less than 50 µg/day, along with other preventive measures, has substantially lowered the risk of VTE although it has not been eliminated entirely. There are no substantive data supporting increased safety for products containing 20 µg versus 30 to 35 µg despite the logical appeal. In-depth molecular biologic research is needed to understand VTE and pave the road to its rational prevention.

Stroke and Oral Contraception.

Stroke has been recognized as one of the serious complications of OC use, although its incidence has been rare. In 1976, Vessey and Doll reported 41 to 45 strokes per 100,000 woman-years in OC users, a fourfold to fivefold increase over the rate of stroke in nonusers. Later studies had more reassuring outcomes. In 1996, a large epidemiologic study demonstrated that women using OCs with a low estrogen content (<50 µg of ethinylestradiol) are not at increased risk for stroke.

The published findings were based on investigations of a large California health organization, Kaiser Permanente, and included an analysis of 1.1 million women, 14 to 40 years of age, who were observed during the 5 years 1991 to 1994 for a total of 3.6 million woman-years. During this time period, 408 women suffered a proven stroke. This confirms the fact that stroke occurs rarely in young women, with an incidence rate of only 11.3 cases per 100,000 woman-years. With respect to OCs, 1.93 (0.874.29) strokes per 100,000 woman-years in OC users, a fourfold to fivefold increase over the rate of stroke in nonusers. Later studies had more reassuring outcomes. In conclusion, although significant strides have been made in accumulating knowledge about VTE and OCs, the phenomenon remains as enigmatic as before.

The association of stroke, OCs, and smoking is not as strong as that for MI, although an increased risk of stroke for smokers using OCs was demonstrated in significantly higher, 6.88 (95% CI 5.05 to 9.36). Nonsmokers showed a strong dose response, from 2.47 (95% CI 1.12 to 5.45) in smokers of 1 to 5 cigarettes per day to 74.6 (95% CI 33.0 to 169.0) in smokers of 40 cigarettes per day.

Between 1997 and 1999, three important studies addressed this issue. A multicenter study organized by the WHO found a 5-fold increased risk of MI in current users of OC in Europe but only a 2.6-fold increase in women who had their blood pressure checked before prescription of an OC. When a subset of patients from England was analyzed, the odds ratio was 2.10 (CI 0.63 to 7.07); in other countries the odds ratio was much higher, possibly indicating different practices in selecting patients for OC. Another international study pointed out that any risk of MI is confined to women with known cardiovascular risk factors.

The third study was a case-control study conducted in 1993 to 1995. A group of 448 women of childbearing age, all of whom had suffered an incident of MI, was matched with 1728 control subjects without a history of MI. It is important to note that during the time period of the analysis, OCs with an ethinylestradiol content of less than 50 µg, combined with norgestrel or levonorgestrel as well as with norgestimate, desogestrel, and gestodene, were already in clinical use. This study had sufficient power to examine the effects of OCs with different progestagens on the incidence of MI.

The study has shown that the risk of MI in OC users is not increased and that there is no difference between OCs with an ethinylestradiol content less than 50 µg combined with norgestrel or levonorgestrel or with norgestimate, desogestrel, and gestodene. Progestagen-only contraception was found to have no effect on the genesis of MI. The study confirmed the high risk of MI associated with hypertension, diabetes, hyperlipidemia, angina, diabetes mellitus, and smoking. Of these, the highest risk factor was smoking. On the other hand, modest alcohol intake (once a week) and physical exercise for 1 hour or more per week were found to be beneficial. These study conclusions were strengthened by the observation that of women younger than 45 years who suffered MI, 87% were not taking OCs but most of them had one or more known cardiovascular risk factors.

Oral Contraception and Smoking

Perhaps in no other condition have the adverse effects of smoking been so well defined as in oral contraception. Cardiovascular and cerebrovascular complications of OC use have been recognized since the early surveillance studies that also pointed out the negative effects of smoking. Whereas the probability of developing these complications has been minimized for nonsmokers by reducing the amount of estrogens, smoking OC users are still exposed to a considerable risk of MI and stroke.

A long-term follow-up of women by the Royal College of General Practitioners contributed considerably to our understanding of the relation between OC, smoking, and MI. In 1998, data for 10,073 women were evaluated to determine whether changes in smoking habits have an effect on the risk estimates for MI. When the information on smoking supplied by the women at their entrance into the study was taken into consideration, the relative risk of MI was 3.6 (95% CI 2.2 to 5.9). However, during the study, 53% of women who had ever smoked regularly stopped smoking and only 4.5% of nonsmokers started smoking. Therefore, the authors performed another analysis in which they took into consideration the smoking status of the women at the occurrence of MI. As expected, women who continued smoking throughout the study were at a much higher risk for MI than those who did not smoke at the occurrence of the event. The relative risk for smokers was 5.1 (95% CI 3.0 to 8.7).

The increased risk of smokers for MI has also been underscored in the Myocardial Infarction Causality case-control study conducted between 1993 and 1995 in the United Kingdom. Odds ratios for risk of MI in smokers versus nonsmokers showed a strong dose response, from 2.47 (95% CI 1.12 to 5.45) in smokers of 1 to 5 cigarettes per day to 74.6 (95% CI 33.0 to 169.0) in smokers of 40 cigarettes per day. The relative risk of MI for all users of combination OCs was at 1.40 (95% CI 0.78 to 2.52), but the relative risk for women who ever smoked was significantly higher, 6.88 (95% CI 5.05 to 9.36).

The association of stroke, OCs, and smoking is not as strong as that for MI, although an increased risk of stroke for smokers using OCs was demonstrated in...
The landmark epidemiologic study by Petitti and colleagues in 1996 showed that for young women smokers in the United States using OCs with less than 50 µg of ethinylestradiol, the risk of hemorrhagic stroke is three times higher than for nonsmokers. In this study, smoking did not increase the risk of ischemic stroke.

Two WHO collaborative studies in 1996 evaluated the effect of smoking in a case-control design. With respect to hemorrhagic stroke in women of all ages, the odds ratios for current OC users who were also current cigarette smokers were greater than 3. For female smokers younger than 35 years of age, the odds ratios were 2.6 in Europe and developing countries; for female smokers older than 35 years the odds ratios were 3.9 for Europe and 5.4 for developing countries. With respect to ischemic stroke, the WHO collaborative study showed that the OC-associated odds ratios were higher among current smokers in Europe (7.2 smokers versus 2.1 nonsmokers) as well as in developing countries (4.8 smokers versus 2.6 nonsmokers), suggesting a synergistic effect of both factors.

Currently, mechanisms by which smoking exerts its negative effects are being investigated. Attention is focused on nicotine’s interference with endothelial cells, principally with their ability to secrete vasodilating substances and to regenerate.

The data presented indicate that OCs can be safely prescribed to women of all ages as long as they do not smoke and have no other risk factor. OCs can be prescribed to smokers younger than 35 years, but after this age limit OCs must be avoided unless the women stop smoking. For patients of any age, smoking cessation may be the single most effective preventive action any health care provider can recommend. Women seeking contraceptive advice must be thoroughly questioned about their smoking history, and the dangers of smoking must be clearly delineated.

Breast Cancer

Breast cancer is a frightening malignancy. In the United States, 182,000 new cases are detected annually. It is the most common carcinoma in women, and with 46,000 deaths a year it is the second most lethal cancer in women. Because of fear of breast cancer, many women do not start OCs or may discontinue their use. Fortunately, a recent study has convincingly demonstrated that present or past use of oral contraceptives is not associated with an increased risk of breast cancer.

This clinical trial was a population-based case-control study conducted under an extremely rigorous protocol. The *cases*4575 women newly diagnosed with breast cancer during July 1994 through April 1996, were matched and compared to 4682 control women without breast carcinoma. The probands were 3564 years of age, a period of life during which breast cancer strikes most frequently. The study enrolled both Caucasian as well as African Americans and was conducted in five regions of the United States. Among current OC users the relative risk of breast cancer was 1.0 (95% confidence interval 0.8 to 1.3); for former users the risk was 0.9 (95% confidence interval 0.8 to 1.0). The study has also failed to detect any significant association between the risk of breast cancer and the amount of estrogen in the combination, duration of OC use, the initiation of use during adolescence, the race of the probands, or family history of breast cancer.

An earlier study from 1996 was a meta-analysis of 54 small studies conducted over a period of 25 years. However, the study had the disadvantages of a meta-analysis, for example, non-uniform study designs and protocols, different quality of study conduct and analyses, and follow-up. The study showed only a slightly increased risk of breast cancer among current OC users and a gradual decline of the risk during the postpill period, until the risk completely disappeared 10 years after stopping the pill. Why breast cancer in OC users is less advanced than in nonusers has not been explained.

Whether women with a family history of breast cancer are at a higher risk for the disease while using OCs was analyzed in more detail in another case-control study. Study participants included 394 sisters and daughters and 3002 granddaughters and nieces of 436 families of breast cancer probands. OC use was associated with an increased risk of breast cancer among daughters and sisters (relative risk 3.3, CI 1.6 to 6.7) but not among granddaughters and nieces. Other studies have been consistent with regard to family history as an OC risk factor. The study underscores the importance of obtaining a thorough family history not only before prescribing OCs but for women in general.

Cervical Carcinoma and Oral Contraception

In the United States, 12,800 cases of invasive cervical cancer are diagnosed annually and 4800 women die from this disease. Cervical cancer used to be the most frequently diagnosed malignancy in women in the United States. Over the last 30 to 40 years, its incidence has been declining, most likely as a result of early treatment of precursor lesions. Today, it has assumed the fifth place among the most frequently encountered cancers in women. Nevertheless, concerns about its association with the use of OCs remain.

Squamous Cell Cervical Carcinoma

Epidemiologic studies of the relation between oral contraception and squamous cell carcinoma of the uterine cervix originate from the late 1980s and early 1990s. No association between cervical carcinoma and OCs was found during the first 5 years of use, but the incidence of cervical carcinoma doubled at and after 10 years of use. Squamous cell carcinoma arises from the columnar epithelium of the endocervical canal and constitutes 10% to 15% of all cervical cancers. It has been linked to the use of OCs for several reasons. A doubling of its incidence along with a decrease in the frequency of squamous cell cervical cancer was noted in the 1970s and 1980s. This time period coincides with the rise of OC use. Notably, the malignancy affected women between the ages of 20 and 35 years from higher socioeconomic backgrounds, a group that was inclined to practice hormonal contraception.

Episodic studies of OCs and endocervical carcinoma showed that OC use was associated with a risk of adenocarcinoma of the cervix twice that in never-users and that the risk increased with the duration of use, being highest after 12 years of use.

As with its squamous cell counterpart, the incidence of endocervical cancer depends on the sexual habits of affected women, such as age at first sexual intercourse, number of sexual partners, and the use of barrier methods of contraception including spermicides. However, the most confounding factor is exposure to the human papillomavirus (HPV) epidemic that occurred at the time when the incidence of adenocarcinoma of the cervix began to rise. It is not clear whether OC use and the coinciding change in sexual behavior, including displacement of barrier methods, may have provided conditions suitable for the virus to flourish.

A study from the National Cancer Institute in 1999 has shown that both types of cervical cancers are associated with OC use. However, the positive association was weak for squamous cell carcinoma but strong for adenocarcinoma. After accounting for HPV infection, sexual history, and cytologic screening, the association between OCs and squamous cell in situ carcinoma, squamous cell invasive carcinoma, and invasive adenocarcinoma disappeared. A positive association remained between current use of OCs and adenocarcinoma in situ. These results are reassuring, but they underscore the necessity of properly collecting endocervical cells and
taking cervical samples for cytologic screening. Women at risk for STD should rely on an effective method of contraception to reduce the likelihood of unintended pregnancy. They should combine that use with a condom or diaphragm to reduce the risk of infection.

Liver Tumors

Contraceptive steroids have been associated with an increased incidence of benign liver adenomas. However, the association has been questionable at best. Because of the rarity of liver adenomas, their incidence is difficult to establish, even in the general population. Earlier estimates for OC users varied from one adenoma in 300,000 to one in 1 million women.

An increased risk of liver cancer among users of OC has not been proved. The incidence of this malignancy and the rate of death have remained relatively stable in the United States over the decades when generations of women have used OCs. Nevertheless, the provider should be alert to the possibility of liver cancer in this population.

Mortality Associated with Oral Contraceptive Use

The most comprehensive analysis of mortality and OCs has been performed by the Royal College of General Practitioners in Britain. A total of 46,000 women, half of them OC users, were observed for 25 years from 1968 to 1993. Over the entire period, 1599 deaths were reported. Oral contraception did not increase or decrease total mortality. The relative risk of death from all causes combined did not differ significantly between ever-users and never-users. The relative risk of death from ovarian and colorectal cancer was significantly lower in ever-users, and the risk of dying from circulatory disease was higher in the OC group. During the use of OC and up to 10 years after discontinuation, the risk of cervical carcinoma was higher in the OC group (see also discussion of oral contraception and neoplasia). It should be noted that the study was done during a time when most of the OCs contained 50 µg or more of ethinylestradiol. Nevertheless, the overall data are reassuring.

Contraindications

With the current types of low-dose OCs, there are few contraindications to their use. Those that exist include presence of or a history of thromboembolic disease, thrombophlebitis, coronary occlusion, atherosclerosis and stroke, uncontrolled hypertension, most cases of systemic lupus erythematosus, and diabetic retinopathy or nephropathy, although uncomplicated diabetes mellitus is not an absolute contraindication to the use of OCs. For patients with known or suspected breast carcinoma, the use of OCs is contraindicated. Therefore, the prescribing physician must pay close attention to a personal and family history of breast carcinoma and examine potential OC users for breast nodules and breast carcinoma.

Any type of amenorrhea or abnormal uterine bleeding, or both, should be understood before prescribing OCs. Proper examinations and tests should rule out pregnancy as well as premalignant and malignant changes of the uterus or vagina. Amenorrhea may be the first sign of prolactinomas, and their presence must be ruled out if the patient’s amenorrhea cannot be plausibly explained. Smokers older than 35 years should not use OCs. Women with migrainoid headaches, severe depression, diabetes mellitus, and a history of gallbladder disease should be carefully observed while taking OCs. The presence of leiomyomas is not a contraindication, but it warrants monitoring.

With respect to the liver, hormonal contraception is contraindicated for women with active liver disease (i.e., currently abnormal liver function tests, infiltration, severe cirrhosis). Patients with acute viral hepatitis should not use OCs; however, after liver function tests have been normal for at least 3 months, combined OCs can be started or resumed. Further, the use of OCs is contraindicated in women with a history of cholestatic jaundice during prior pregnancy or OC use, the presence of or a history of a liver adenoma or malignant liver tumors, and the presence of hepatic porphyrias. In compensated liver cirrhosis and in less serious liver diseases, low-dose OCs can be used provided the patient is monitored by regular examinations including liver function tests. The section “Contraception for Women with Health Problems” includes additional information on indications and contraindications for the use of contraceptive methods.

Drug Interactions

Certain drugs can accelerate the biotransformation of contraceptive hormones, particularly of estrogens to metabolites that are less active. This was first reported for rifampin, which is used in the treatment of tuberculosis. Other drugs such as phenobarbtlone, promethazine, chlorpromazine, and phenytoinmost of them used in psychotherapy were also implicated. The basis of this drug interaction is probably induction of liver microsomal enzymes. It is not clear whether the accelerated metabolism of OCs by these compounds would be sufficient to cause reduced ovarian suppression or uterine breakthrough bleeding, or both. As with all effective methods of contraception, the product label provides up-to-date guidance as the field evolves.
LONG-ACTING PREPARATIONS

Hormonal Subdermal Implants

Contraception by means of hormonal implants was developed for women who seek a reliable and reversible long-term method of fertility control that requires less than daily compliance on their part. Hormonal implants are suitable for women who do not wish to take a pill daily or to return regularly for depot injections and who desire or need protection from pregnancy for 1 to 5 years.

Types of Implants and Hormones Used

Table 17-12 summarizes hormonal implants that are currently available for general clinical use as well as preparations that are still in research. There are essentially three types of hormonal implants.

The first type consists of rod-like silicone capsules that are filled with the active steroid in microcrystalline form. The capsule determines the rate of drug release from the system. Norplant is an example of this type of implant.

Levonorgestrel was chosen as the progestagen for Norplant, the first contraceptive hormonal implant introduced into general clinical practice. Levonorgestrel is a highly active progestagen, which means that the necessary amount can be loaded into capsules of relatively small volume. The original version required six capsules to be implanted to achieve a contraceptive concentration of the hormone in the circulation. The number was later reduced to two implants. Norplant affords protection from pregnancy for 5 years. The number of implants in Norplant has been a source of numerous problems (see later); therefore, simplified methods have been pursued.

The second form of implants consists of rods with a matrix that carries the active hormone. The matrix is covered with a thin membrane that controls the release of the drug from the matrix into the surrounding tissues and ultimately into the circulation. The system is encased in silicone tubing. One version consists of two rods in which levonorgestrel is embedded.

*Plans to make the system clinically available have been deferred by the company holding the progestagen patent. Registered in Brazil for treatment of endometriosis.

in a silastic matrix covered by a membrane and encased in silastic tubing. Implanon is a single-rod system that employs etonogestrel (3-ketodesogestrel), the biologically active metabolite of desogestrel. It is designed to provide protection for 3 years. Uniplant is a single-rod system that contains nomegestrol acetate, a hybrid progestagen of the 19-norpregnane series (see “Classification of Contraceptive Progestagens”). It is effective for 1 year; however, the corporation holding the patent for the compound has deferred introduction of this system into clinical practice. Clinical research studies are also being conducted with Elcometrin, a system that releases nestorone and is effective for 2 years with a 6-month safety margin. In research. In the third system, the matrix is made of a biodegradable material that is firm enough to be implanted. The drug is released from the matrix, which is slowly degraded until it is completely used. Two prototypes of these systems have been in clinical research: (1) a caprolactone rod-shaped matrix containing levonorgestrel that provides protection for 1 year and (2) norethindrone or norgestimate embedded in pellets that are injected subcutaneously.

Mechanism of Action

Levonorgestrel exerts multiple contraceptive actions. When in sufficient concentrations, levonorgestrel suppresses ovulation; up to 90% of cycles are anovulatory during the first 2 years after insertion. The number of ovulations increases with time so that during the fifth year of use 50% of women ovulate, particularly those with a larger body mass. When ovulation occurs, secondary contraceptive mechanisms remain operative. The ovulatory cycles are frequently associated with an insufficient luteal phase, but the main contraceptive effect involves changes in the viscosity and consistency of the cervical mucus that make it difficult for the sperm to penetrate. Levonorgestrel also has a profound effect on the uterine mucosa that is out of phase, and researchers speculate that it becomes hostile to fertilization. Segal and colleagues have proved that fertilization with subsequent interruption of early pregnancy (menstrual abortion) does not occur during the use of Norplant.
Efficacy and Properties of Individual Steroids

The contraceptive efficacy of Norplant is high. Extensive data show pregnancy rates of less than 0.5 per 100 woman-years even after 5 years of use. Bleeding irregularities may be a problem, particularly during the first year of use. The contraceptive efficacy of Implanon, the system using etonogestrel, is also impressively high; no pregnancies were reported during more than 53,000 cycles of use. This high efficacy is probably related to ovulation suppression throughout the projected time of effective use; only during the last 6 months of use has an occasional ovulation been observed. The system is designed for 3 years of protection.

So far, data on the nestorone implant have shown high contraceptive efficacy, with only one pregnancy during 4000 cycles of use. Nestorone is a unique steroid that is not orally active because of rapid disintegration in the alimentary tract. Therefore, the implant is especially well suited for breast-feeding mothers.

Return to Fertility

After removal of the implant, ovulatory cycles occur promptly with rapid return of fertility. This is the main difference between the implant and MPA depot injections (Depo-Provera), in which residual deposits release the compound for a prolonged period after treatment has been discontinued, thus delaying pregnancy.

Adverse Events and Continuation Rates

During the first year after implantation, the major complaint has been irregular uterine bleeding, which caused some patients to discontinue the method. During later months of use, amenorrhea becomes more prominent. Despite these complications, the continuation rate after the first year has been close to 80% and after 5 years it has been 35% to 70%.

Because in some cases Norplant capsules were difficult to insert and even more difficult to remove, formation of scar tissue could not be avoided. The ensuing medical-legal problems and diminished demand led to voluntary withdrawal of the preparation from some markets, notably in Great Britain.

In conclusion, the advantages and disadvantages of hormonal implants are summarized in Table 17-13.
Injectable Progestagen-Only Preparations

The progestagens most widely used in long-acting injectable preparations are MPA, under the name Depo-Provera, and norethindrone enanthate, which is not available in the United States.

**Depot Medroxyprogesterone Acetate**

Depot MPA is an aqueous suspension on microcrystals of the hormone. A dose of 150 mg is injected every 3 months intramuscularly, preferably deep into the gluteal or deltoidal muscle. There is at least a 2-week safety margin after the prescribed 90 days when a new injection should be administered. A 300-mg dose is given every 6 months. The efficacy of depot MPA is high; the pregnancy rate is 0.5 per 100 woman-years for 12 months of use. This result presumes that women are able to obtain their injection at appropriate intervals.

**Norethindrone Enanthate**

Norethindrone enanthate is given intramuscularly in a dose of 200 mg. The first two injections should be given at 60-day intervals (±5 days), followed by injections every 12 weeks or 84 ± 7 days. The contraceptive efficacy of norethindrone enanthate is high, usually less than 1 pregnancy per 100 woman-years.

Long-acting injectable preparations are usually administered within the first 5 days of the menstrual cycle; when given later, a backup method usually a barrier contraceptives should be used for the first 14 days after dosing.

The main disadvantages of progestagen-only contraception are bleeding irregularities including metrorrhagia and amenorrhea. Another disadvantage is the delayed return to fertility; women do not become pregnant until about 6 months after they have discontinued treatment. Appropriate pretherapy counseling reduces requests for discontinuation. Depot MPA has been associated with decreased circulating levels of estradiol and a small and reversible decrease of bone mineral density. This finding is still debated, particularly with regard to use of depot MPA as a contraceptive method for teenage women.
Monthly Injectable Combination Contraception

To circumvent the disadvantages of progestagen-only contraception, monthly combination injectable contraception has been developed. Injection of 25 mg of MPA combined with 5 mg of estradiol cypionate (a long-acting derivative of estradiol) is performed within the first 5 days of the menstrual cycle and repeated every 28 ± 5 days. This method presents several improvements over the progestagen-only injectables for women who may use estrogen. Improvements include regular cyclic bleeding and, after discontinuation of this method, prompt resumption of fertility as with combination OC. Unlike use of OC, monthly injectable combination contraception does not require daily actions on the part of the users; however, the user must return to the health care practitioner every month to receive the injection. This presents a certain disadvantage compared with an injection of depot MPA or norethindrone enanthate every 3 months. However, the combination injections provide a high degree of protection; the reported pregnancy rate is 0.1 per 100 woman-years for women who return for injection at appropriate intervals.
Contraceptive Vaginal Rings

Contraceptive vaginal rings use another route of administration of contraceptive steroids. Vaginal mucosa has been found to absorb steroid hormones in amounts that are sufficient for contraception. In the United States, Mishell’s group has devoted considerable effort to the development of hormone-releasing vaginal rings since the late 1960s.

The current vaginal contraceptive rings are of the core design, in which the steroid is formulated into silicone rods that are placed within polysiloxane tubing. The release rate is directly proportional to the surface of the silicone core and inversely proportional to the thickness of the polysiloxane tubing.

The vaginal ring system was studied for progestagen-only contraception using two strategies: intermittent application, with monthly removal and reinsertion of the device, or continuous use for 3 months, after which the ring is exchanged. Nearly all available progestagens have been tested in the vaginal rings.

Other clinical studies were conducted with vaginal rings containing an estrogen-progestagen combination. In 2001, the Food and Drug Administration (FDA) approved the use of a vaginal ring releasing etonogestrel and ethinylestradiol over 21 days (NuvaRing, Organon, West Orange, New Jersey).
Transdermal Contraceptive Patch

Skin has been recognized as an excellent tissue for delivery of drugs. Hormonal patches for menopausal women were developed many years ago and have been well accepted.

The development of the contraceptive hormonal patch was motivated, in part, by the need to increase the compliance of patients who do not wish to take the pill daily. At present, only one contraceptive patch is available: Ortho EVRA. The patch is about 4 cm in diameter (20 cm$^2$), and it is designed to deliver 150 µg of norelgestromin and 20 µg of ethinylestradiol daily for 7 days. Effectiveness and compliance have been comparable to those of a triphasic OC regimen in clinical studies. Like monophasic OCs, the patch may one day be explored as a continuous versus cyclic method.
EMERGENCY METHODS OF FERTILITY CONTROL

Hormonal Method

Despite the wide availability of birth control methods, many women become pregnant unintentionally. In the United States, this number reaches an annual total of close to 3.5 million pregnancies; of these, over 1 million end in abortion. The following situations may lead to unintended pregnancies:

1. Unprotected intercourse.
2. Intercourse during failure or inadequate use of a barrier contraceptive method, such as a slipped or broken condom; incorrectly inserted, dislodged, or expelled diaphragm, cervical cap, or IUD; incorrectly placed female condom.
3. Intercourse after having missed progestagen-only contraceptive pills at any time of the cycle or after having missed combined contraceptive pills, in particular at the beginning or at the end of the pack, so that the pill-free interval is more than 7 days.
4. Unprotected intercourse or improper contraception shortly after a vasectomy when viable sperm are still in the vas deferens distal to the ligation (see "Vasectomy").

The need for emergency contraception, popularly known as the "morning-after pill," had already been perceived in the development of hormonal contraceptive methods. Morris and van Wagenen[145] coined the term "interception" and conducted early studies with diethylstilbestrol. Although diethylstilbestrol successfully prevented unintended pregnancy, it was quickly abandoned because of unacceptable adverse effects such as nausea, vomiting, and metrorrhagia.

More successful was the Yuzpe method, named after the Canadian gynecologist who invented it. The method consists of taking two tablets, each containing 0.5 mg of norgestrel combined with 50 µg of ethinylestradiol. This dose of 1 mg norgestrel and 100 µg ethinylestradiol must be repeated after 12 hours. Under ideal circumstances, the first dose should be taken within 72 hours of unprotected intercourse.[146]

In order to eliminate the estrogen-related adverse events of the combination pills, emergency contraception with a progestagen only has been developed. The treatment regimen consists of taking two doses of 0.75 mg of levonorgestrel 12 hours apart. As with the Yuzpe method, the dosing must start within 72 hours after the unprotected intercourse. The protective effect of the regimen gradually decreases when the pills are started later than 72 hours after unprotected intercourse. [147]

Successful clinical studies have been conducted with mifepristone in twice-daily doses of 5.0 and 25 mg. Compared with the methods described previously, mifepristone (see "Contragestion")

at the lower dose is associated with somewhat decreased side effects, principally vomiting, and the higher dose is associated with postponement of menses (Table 17-14)[148]

The mechanism of action has not been completely elucidated. The hormonal intervention may affect the timing of ovulation mostly postponement and produce an out-of-phase endometrium. The administered hormones may interfere with fertilization by affecting the ovum or the transport of sperm, or both.

The emergency contraception just described provides about 98% protection from an exposure to pregnancy risk when taken as prescribed. One of the major disadvantages of emergency contraception is not the method itself but its availability. Two states, Washington and California, have initiated a pilot program in which selected pharmacies following a strict protocol can distribute the morning-after pill directly to women who ask for it. Similar programs are being prepared in Oregon and Alaska.

When resorting to emergency contraception, patients are advised to take certain precautions that are specific for this kind of contraception. Along with combined estrogen-progestagen emergency pills, the patients may be given an antiemetic drug to minimize the adverse gastrointestinal events. After taking emergency hormones, ovulation and the following menstruation may be delayed. Patients should be advised to schedule an examination if menstrual bleeding does not occur within 3 weeks after the treatment. Patients should also be instructed to start to use a regular method of contraception. The use of emergency contraception as a primary method must be discouraged because of its side effects, including cycle and ovulation irregularities, and its relative unreliability with cumulative failure rates if used as the routine method.
Intrauterine Device as an Emergency Contraceptive

An IUD inserted 5 to 7 days after unprotected intercourse can provide an effective means of emergency fertility control. The method is contraindicated if an STD is present or suspected. Consequently, it is not suitable after rape, after coerced intercourse, or for women with multiple partners. In addition, the presence or a history of PID and suspected ectopic pregnancy are important contraindications to the method. The mechanism of IUD emergency contraception has not been defined. Also, unlike hormonal methods that are FDA approved, the IUD approach is not currently an approved method for emergency contraception.
Contragestion

The attempts to terminate early pregnancy by pharmacologic means have culminated in the development of a hormonal method for which the name contragestion has been suggested. The key hormone is mifepristone, a synthetic derivative of norethindrone, characterized by a complex structure (dimethylaminophenyl group) attached to C-11 (Fig. 17-19). It is recognized that manipulation of the C-11 position of the steroid molecule leads to compounds with glucocorticoid activity as well as to compounds with an increased capacity to bind to progesterone receptors. Desogestrel, a C-11 substituted steroid, is a potent progestagen. The modification on C-11 of mifepristone gives the molecule a unique ability to compete for specific binding sites on progesterone receptors. In fact, mifepristone has twice as much affinity for progesterone receptors as progesterone itself but without exercising any progestagenic activity. Thus, mifepristone is a true progestrogen antagonist. Mifepristone also binds to glucocorticoid receptors. However, in order to exercise any antiglucocorticoid activity, the amounts must be larger than those needed for its antiprogestagenic action.

It has been assumed that brief interruption of progesterone action leads to irreversible damage to the decidualized endometrium and interferes with nidation and the development of the early conceptus. Progesterone has a quieting effect on myometrial contractility. By antagonizing progesterone, mifepristone releases the myometrium from the suppressive action of progesterone, and myometrial activity intensifies. However, complete expulsion of the conceptus follows in only 40% of cases. Prostaglandins are potent stimulators of myometrial contractions, but when administered by themselves, they were able to terminate pregnancy in only 20% of the cases. With the availability of orally active prostaglandins, it was logical to combine the effect of an antiprogestagen with a prostaglandin. With administration before the 49th day of pregnancy, the success rate of complete abortion has been 92% to 98%.

Most experience with contragestion has been in England, France, and China. The treatment regimens consist of a single dose of mifepristone, 200 to 600 mg orally. Thirty-six to 48 hours thereafter, the women return to the clinic to receive an oral dose of 400 to 800 µg of misoprostol, a synthetic analogue of the natural prostaglandin E₃.

Prostaglandin vaginal suppositories can also be used. Prostaglandins of the prostaglandin E₂ series exert a dilatory effect on the uterine cervix, and it is possible that placing the prostaglandin suppository close to the cervix facilitates this effect. A large, well-designed study has proved that vaginal misoprostol is highly effective in achieving complete abortion; however, the study did not compare vaginal and oral dosing directly.210

Because approximately 50% of women expel the conceptus within 4 hours and an additional 11% do so during the fifth hour after the administration of misoprostol, women should be under observation at the clinic for up to 5 hours. If they do not expel the conceptus and there are no medical reasons for further observation or intervention, the woman is allowed to complete the abortion at home. She is scheduled for a follow-up examination within the next 14 days and instructed to notify the clinic if she experiences excessive uterine bleeding or other medical complication or if no bleeding occurs. Within 24 hours after receiving misoprostol, 75% of women expel the conceptus completely.

In the United States, a large study was conducted under the auspices of the Population Council.34 A total of 2015 women, 49 to 63 days pregnant, were enrolled. Of these, 92% achieved complete termination of pregnancy when the hormones were given on or before the 49th day of pregnancy. With more advanced gestation, the success rate decreased substantially. Complete abortion occurred in 83% of women pregnant 50 to 56 days and in 77% of women pregnant 57 to 63 days. Overall, for 85% of the 2015 patients, the treatment resulted in complete abortion. This percentage would probably be close to the success rate of the method in “real-life” situations, when the selection of suitable patients is less strict than under tightly controlled research conditions.

After dosing, the patients bleed for a median of 13 to 15 days. Although uterine bleeding is expected after pregnancy interruption, this bleeding was the main source of complaints and complications. Some of the complications required surgical intervention, intravenous administration of fluids, and, infrequently, blood transfusions. Other reported adverse events included uterine cramping, abdominal pain, nausea and vomiting, diarrhea, dizziness, and headaches. In some patients, endometritis was reported.

Mifepristone has been approved for general clinical use in the United States and is available under the name Mifeprex. Women seeking abortion should be counseled about the details of all options. Surgical intervention remains most common in the United States.
INTRAUTERINE DEVICES

Currently, there are three types of IUDs: nonmedicated, copper, and hormone-releasing intrauterine systems. Only the latter two are available in the United States.

The first modern IUD was designed by E. Gräfenberg, a German physician, in the 1920s. It was a pliable ring of coiled silver wire, 18 mm in diameter, inserted into the uterus after cervical dilation. This basic design has been modified over the years in various parts of the world, and stainless steel has replaced silver. With the advent of plastic materials with memory, new forms and shapes of IUDs were invented in order to increase efficacy, make the insertion easier, and facilitate the IUD's removal when needed.

Today, the WHO does not recommend the use of inert IUDs because copper IUDs and the hormone-releasing intrauterine systems are more effective and safer.

In the United States, IUDs have declined in popularity because of problems with the Dalkon Shield. This IUD was designed to cover a large area of the uterine cavity because it was speculated that the contraceptive efficacy of IUDs was directly related to the area of contact with the endometrium. However, the use of this device became associated with an increased risk of PID, and the Dalkon Shield was withdrawn from the market in 1974. It is believed that the reason for the increased incidence of PID was the multiframe tailstring, which facilitated proliferation of bacteria between the meshes of the string and ascension of infection into the uterine cavity. Current IUDs are equipped with a monofilament tailstring, and no substantive increased risk of PID has been associated with this appendage.

The first copper-bearing IUD was devised by the Chilean scientist Jaime Zipper, who studied the antifertility properties of copper. The first marketed copper IUD was the copper 7 IUD, based on Zipper's studies. It was distributed by the G.D. Searle company until 1986, when it was withdrawn from the market because of putative infertility of women who discontinued its use.

The modern copper IUDs are represented by Paragard T380. The IUD has a T-shaped polyethylene body with a copper wire wound around the vertical arm of the T; each of the transverse arms carries a copper sleeve. The exposed areas of copper are 380 mm², hence the name. This IUD is designed for 10-year protection against pregnancy. However, it is likely that the duration of efficacy is years longer. The pregnancy rate under controlled conditions is 0.7% and 0.3% for the first and the second year, respectively.

In Europe, a frameless copper IUD is being developed. The protective duration is 5 years. This IUD consists of a string with six copper beads covering a surface area of 330 mm². The string is anchored in the fundal myometrium. This kind of IUD is recommended for women who experience difficulties, principally uterine cramping, with other IUDs. However, users of this frameless IUD must be alert to the possibility of "silent" expulsion.

The first hormone-releasing intrauterine system was the Progestasert (1971). It is a T-shaped device with a drug reservoir in the vertical arm of the T containing progesterone in silicone oil. A vinyl membrane controls the rate of releaseapproximately 65 µg of progesterone per day. The pregnancy rate for Progestasert is about 2 per 100 woman-years. In addition, it must be replaced annually.

Another hormone-releasing IUD uses levonorgestrel (LNG). The LNG-20 or Mirena is also a T-shaped device with a sleeve on the vertical arm, which is a reservoir for a total of 52 mg of levonorgestrel. The hormone is released into the uterine cavity at a daily rate of 15 µg (calculated from in vitro release). The reported pregnancy rate for perfect use is 0.2% for the first year. It is intended for 5-year use.

Management Issues with Intrauterine Devices

Pregnancy and Continuation Rates

The modern copper and hormone-releasing IUDs are among the most effective means of reversible contraception. With long-term use the yearly pregnancy rate is less than 0.5%, and the cumulative pregnancy rate of 2.2% over a 12-year period rivals the 10-year pregnancy rate of tubal ligation (1.9%). The continuation rate of IUDs is the highest among all reversible methods of fertility control80% after the first year of use. The 5-year continuation rate is 40% among women using the copper IUD and 33% among women fitted with the levonorgestrel-releasing device. Medical therapy for Wilson's disease has been increasingly successful with the result that many affected women enter the reproductive age and need contraceptive counseling. Concerns have been expressed that copper ions released from the copper IUD may reach the general circulation and precipitate symptoms of the disease. In healthy women wearing copper IUDs,

![Figure 17-20 Types of intrauterine devices (IUDs). The copper T380 and the levonorgestrel-releasing IUD are clinically used in the United States. The frameless copper IUD is available in Europe.](image)

circulating concentrations of copper and ceruloplasmin have not been elevated even after 12 to 24 months of use. The amount of copper released from the IUD has been calculated as 14 to 29 µg/day, which constitutes only about 1% to 2% of the dietary intake of copper. In Wilson's disease, serum ceruloplasmin levels are decreased and free serum copper concentrations are increased, although total copper levels can be within normal limits or low. It seems unlikely that wearing a copper IUD could affect circulating copper levels in Wilson's disease. This condition is rare, 1 in 200,000; thus, it has been difficult to generate data on contraceptive practices of the affected women. However, because Wilson's disease is a serious condition and numerous contraceptive options exist, the lack of substantive safety data relegates copper-bearing IUDs to a bottom-tier choice for women with this condition.

Uterine Perforation

The rate of uterine perforations is low, 0.6 per 1000 insertions. With the progestagen-containing IUD, it is 1.1 per 1000 insertions.

Expulsion

The spontaneous expulsion rate for modern IUDs, including the copper T380 and levonorgestrel-releasing systems, is 5%.
to 6% during the first year and 1% to 2% per year during the subsequent years of use. Primiparas, secundiparas, and women 15 to 24 years of age have a higher rate of expulsions than women who are older or have had more than two pregnancies, or both. 159

**Changes in Uterine Bleeding**

The copper T380 is removed for uterine bleeding and cramping in 12% of users during the first year and 2% to 4% during subsequent years. The levonorgestrel-releasing system usually decreases uterine bleeding, and this phenomenon can be utilized therapeutically in patients with menorrhagia or adenomyosis and can prevent proliferative endometrial changes in patients undergoing long-term tamoxifen treatment. 156 On the other hand, patients using the levonorgestrel-releasing system complain of a higher incidence of amenorrhea, and removal of the device for this side effect is the main reason for the lower continuation rate compared with the copper T380 IUD. In both cases, proper counseling enhances continuation.

**Pelvic Inflammatory Disease**

The risk of IUD users for PID is inversely related to the time since insertion. A large WHO study concluded that the risk of PID is increased during the first 20 days after IUD insertion; beyond this time period, PID is an infrequent event. 166 167 This finding may be related to bacteriologic evidence showing bacterial contamination of the uterus at insertion of the IUD. Women scheduled for hysterectomy had an IUD inserted 24 hours before the surgery. Upon culture of the uterine contents, bacterial contamination was frequently found. It is even more significant that 30 days after IUD insertion, the uterine contents were sterile. 159

The development of PID also depends on the lifestyle of the women receiving the IUD. Women who are at minimal or no risk of exposure to sexually transmitted infections are less likely to experience PID than those who are. This is true with or without an IUD. As with other effective methods, an IUD user who is at risk for STDs should use a barrier method as well. In order to prevent PID, the use of prophylactic antibiotics is sometimes recommended. However, large clinical trials have shown that with copper IUDs the rate of salpingitis is 1 per 1000, regardless of whether prophylactic antibiotics were given. In general, in the United States, prophylaxis is not routinely recommended. 159

A direct comparison of levonorgestrel-releasing systems and copper IUDs demonstrated a low PID rate over a 7-year period with both IUDs and no significant difference between the two types. 169 A large multicenter European study showed that after 36 months, the cumulative discontinuation rates for PID were 0.8% and 2.0% for the levonorgestrel and copper IUDs, respectively (P < .02); after 60 months, the corresponding rates were 0.8% and 2.2%. 170

Tubal infertility is closely related to the problem of PID. Conflicting results have been reported; however, a thorough review of the question concluded that fair evidence indicates no important effect of IUD use on infertility. 159
Pregnancy and Intrauterine Devices

Intrauterine Pregnancy

Pregnancy with an IUD in situ frequently leads to spontaneous abortion and, rarely, sepsis. Physicians recommend removal of the IUD when pregnancy has been diagnosed. There is no evidence that the risk of malformations is increased in infants born to women with an IUD in situ.

Ectopic Pregnancy

Studies with the modern copper and levonorgestrel-releasing IUDs have demonstrated a low incidence of ectopic pregnancy. For users fitted with IUDs releasing copper from a 200-mm² surface, the estimated rate of ectopic pregnancy was four tenths that of nonusers of contraception; the rate of ectopic pregnancy with devices releasing copper from a 350-mm² surface was one tenth of that of nonusers of contraception. With the hormonal IUD releasing 20 µg of levonorgestrel daily, the ectopic pregnancy rate was also one tenth of the rate for nonusers. These studies dispel the worries of physicians and women about ectopic pregnancy with respect to the modern copper and levonorgestrel IUDs. It can be concluded that the modern IUDs reduce the risk of both uterine and ectopic pregnancy.
Selection of Candidates and Contraindications for Intrauterine Devices

Selection

As with any contraceptive method, contraceptive protection, acceptable adverse events, and continuation of use of IUDs depend on the proper selection of candidates. PID is best prevented by selecting candidates at low risk for PID and excluding the presence of PID during the preinsertion examination. Clinically manifest vaginal and cervical infection should be identified and treated, and bacteriologic examination of the cervix should be carried out when possible. The appropriate IUD candidate is a parous woman at low risk for sexually transmitted infection. IUDs are well suited for women who cannot use or do not desire hormonal contraception. It is a particularly important option for women considering surgical sterilization. A decade of easily reversible contraception may suit many women. Because the association between IUDs and PID is limited to the 3 weeks after insertion, it is prudent to observe the patient for symptoms of PID.

Contraindications

Insertion of an IUD is contraindicated when a pregnancy is suspected or confirmed and during an acute episode of PID. Caution should be exercised for women with a history of PID, undiagnosed uterine bleeding, enlarged or distorted uterus, confirmed or suspected uterine or cervical malignancy, untreated acute cervicitis or vaginitis, multiple sexual partners, and the presence of genital actinomycosis. Patients (and providers) sometimes have a sketchy memory; therefore, the presence of a previously inserted IUD must be excluded.
Noncontraceptive Benefits and Advantages and Shortcomings of Intrauterine Devices

The possible role of IUDs in carcinogenesis has been addressed in several population-based studies. Two well-conducted case-control studies have provided reassurance that IUDs do not increase the risk of endometrial cancer and suggested a possible protective effect, even in women older than 55 years, an age group with an increased risk of endometrial cancer. Two other case-control studies have shown a straightforward protective effect. The relative risk of developing an endometrial carcinoma was 0.51 and 0.61 in these two respective studies, with a 95% CI of 0.3 to 0.8. IUD use has no effect on the development of cervical carcinoma or breast tumors. An extended nonmedical benefit of IUDs is their low life-use cost. When used in the long term, they are the least expensive contraceptive agents.

Table 17-15 summarizes advantages and disadvantages of IUDs and shows that benefits outweigh shortcomings of intrauterine contraception.
Mechanism of Action

At least two studies have demonstrated that IUDs exert their contraceptive action before fertilization occurs.

An especially intriguing finding came from studies with volunteers wearing copper IUDs. Over several cycles, blood samples were examined for human chorionic gonadotropin (hCG) by extremely sensitive methods from day 10 of the cycle until the onset of menses. Concentrations of hCG were not elevated in any subject with an IUD. In the control group of women who wished to become pregnant, two showed an increase of hCG during the critical period of the luteal phase and this "chemical" pregnancy was later confirmed by obstetric examination. Further, failed attempts to retrieve fertilized ova support prevention of fertilization as the mechanism of action.

Several modes of contraceptive action of IUDs have been suggested. After insertion, IUDs incite a foreign body reaction in the uterine cavity, which includes rapid invasion of leukocytes and increased production of prostaglandins. The changed environment in the uterine cavity impairs the viability of the sperm and inhibits its motility. This reaction is particularly well expressed with the copper IUDs. The levonorgestrel IUDs inhibit endometrial growth and induce changes in the cervical mucus that make sperm penetration difficult. However, the contraceptive action of IUDs has not been clarified.
BARRIER METHODS

The Male Condom

The male condom is important not only as a contraceptive device but also as one that reduces the risk of both HIV and HPV infection, the latter being associated with condylomata acuminata and cervical cancer. Modern condoms were originally made of rubber, but since a liquid latex process was introduced in the 1930s, the bulk of the world's condom supply has been made of latex. The production process was gradually mechanized, which lowered the cost substantially. The condom is one of the least expensive contraceptive methods and is the best protection against the spread of sexually transmitted infection.

Condoms can also be made of polyurethane and silicone rubber as well as of lamb intestines. The "natural skin" condoms do not protect against the viral STDs.

The production standard requires that the thickness of a condom does not exceed 0.03 to 0.08 mm, and there are strict quality control safeguards against leakage and breakage. For example, FDA regulations require that randomly selected condoms from the production run be filled with 300 mL of water and inspected for leaks. In Britain, the condom is required to hold 3 L of water without breaking.

Latex can be weakened by oil-based lubricants and by various vaginal ointments or creams. Instructions for the use of vaginal antifungal preparations contain a warning that women should not rely on condoms for protection against pregnancy and STDs while using such preparations. Condoms made of polyurethane are not harmed by oil-based lubricants, but their breakage rate is significantly higher than that of latex condoms.

| TABLE 17-15 -- Advantages and Shortcomings of Intrauterine Devices |
|---------------------------------|------------------|
| **Advantages**                  | **Disadvantages** |
| Easiness of application, low costs | Transient increased risk of pelvic inflammatory disease |
| High protection against pregnancy | Expulsion |
| Highest continuation rate of all reversible methods | Uterine perforation |
| Immediately reversible | |
| Suitable for breast-feeding mothers | Candidates must be carefully examined for factors predisposing to the development of pelvic inflammatory disease |
| Protection against endometrial cancer | |
| No increased risk of cervical and breast cancer | Close follow-up during the first 34 wk after insertion is needed |
| Levonorgestrel-releasing IUDs control excessive uterine bleeding | Amenorrhea associated with levonorgestrel-releasing IUD causes discontinuation of use |

The surface of some types of condoms can be coated with an appropriate lubricant or spermicide, or both, to improve acceptability and efficacy.
The Female Condom

The female condom is much less frequently used than the male condom. The female condom is a polyurethane sheath 15 cm in length and 7 cm in diameter. A flexible ring is attached to its open end, and a loose removable ring inside the condom facilitates the insertion of the device into the vagina. The advantages of the female condom over the male condom are that the method is controlled by the woman and it is independent of the immediate sexual act. The female condom can be placed into the vagina several hours before intercourse takes place. \[179\]
The Diaphragm

Diaphragms are made of latex in the form of a thin dome mounted on a ring containing a flat or spiral spring. The sizes vary in diameter from 45 to 105 mm in steps of 2.5 to 5.0 mm. In determining the correct size of diaphragm, the distance between the posterior aspect of the symphysis pubis and the posterior fornix of the vagina is assessed. A correctly fitted diaphragm occupies this space with the dome covering the cervix. The diaphragm should always be applied with a spermicidal cream or jelly and should be left in place for a minimum of 6 hours after intercourse. After removal, the diaphragm should be washed and dried but no talcum powder should be applied.

Used consistently, the diaphragm has a low failure rate: 2% to 3%. This low failure rate is rarely achieved; in fact, rates of 20 to 30 pregnancies per 100 woman-years have been reported. The high failure rate results from poor motivation, inconsistency of use, poor fit of the diaphragm because the anatomy of the genitalia has changed (e.g., after delivery), incorrect insertion, slippage during intercourse, defects in the latex, and reluctance of users to apply the spermicide because it is "messy." A diaphragm should not be prescribed if there is an evident uterine prolapse, poor vaginal tonus, or a marked cystocele. After delivery, fitting of a diaphragm should be delayed at least a few weeks to allow rebuilding of muscular tone.

Clinicians speculate that diaphragms may reduce the risk of cervical gonorrhea, PID, and possibly cervical and endocervical malignancies. However, data on these subjects are not as supportive as those for the male condom. On the other hand, an increased incidence of urinary tract infection has been observed among diaphragm users. A few cases of toxic shock syndrome have been reported in cases in which the diaphragm was left in situ for 24 hours or longer.

In conclusion, a diaphragm with a spermicide is an inexpensive way to prevent pregnancy, and it is an excellent choice for women who do not wish to use one of the more effective methods, have infrequent intercourse, and are compliant. Such women are more inclined to use the method consistently, and consistency of use is the key to barrier success.
The Cervical Cap

In the United States, one type of cervical cap has been approved for general use. The Prentif cap is made of soft rubber, and a firm round rim is affixed to the open end. When successfully inserted, the rim fits around the cervix close to the vaginal fornices.

The efficacy is about the same as that of a diaphragm at best and can be ensured by filling the cup with a spermicide. For nulliparous women, the failure rate is 20% for typical use and 9% for perfect use. For parous women, the failure rate is higher, 40% for typical use and 26% for perfect use. The cap can stay in place for 48 hours irrespective of the frequency of intercourse during that time. The earliest time for removal of the cervical cap is 8 hours after intercourse. The major problems with the cap are difficulties with insertion and with proper fitting and the possibility of displacement. Also, some women find it difficult to remove.

[181]
NATURAL FAMILY PLANNING

Natural family planning restricts intercourse to the "safe period," that is, the period of "physiologic sterility" in each menstrual cycle. Assuming that ova are available for fertilization for only 24 hours and that spermatozoa remain highly viable for 48 hours, theoretically, there would be only 3 days in each cycle during which conception is possible. To identify the days of possible conception and decide which days are safe is difficult given the less than perfect regularity of the menstrual cycle. The calendar method is based on the expectation that ovulation takes place 12 to 16 days prior to the next menstruation. In this "rhythm" method, the woman records the length of 6 or preferably 12 cycles and determines the beginning of the fertile period by subtracting 18 days from the shortest period. Then she estimates the end of the fertile period by subtracting 11 days from the longest cycle.

Women practicing the cervical mucus method are instructed to observe the changes of the cervical mucus throughout the cycle and recognize the characteristics of the mucus during the fertile period. The symptothermal method combines the cervical mucus method with measurements of basal body temperature. With this method, abstinence begins on the day when mucus becomes clear, slippery, and stretchy (spinnbarkeit); this usually happens a few days before ovulation. Intercourse is resumed on the third or fourth day after the basal body temperature shifts to the luteal phase pattern.

There are various modifications of these three methods, and instruments have been designed to facilitate monitoring the safe period. The failure rate, when the methods are correctly practiced, can be as low as 2% to 3%. However, typical failure rates can be 20% or more.

The high typical failure rate for natural family planning results from several factors. The method depends on keeping meticulous records of menstrual cycles for 6 to 12 months in order to determine the safe period. This may be difficult for the busy modern woman. A less controllable reason is the unpredictable duration of the follicular phase of the menstrual cycle and consequently of the entire cycle. If the differences between the cycle lengths exceed 10 days, natural birth control should not be practiced.

In addition, in some individuals, emotional or physical stress can postpone the time of ovulation, creating the possibility that intercourse, based on previous calculations, may take place during the "unsafe" period. Although the efficacy of the rhythm method can be improved by daily measurements of basal body temperature, this too can be complicated because not all basal body temperature curves can pinpoint the occurrence of ovulation. Self-examination of cervical mucus can be somewhat awkward and the results even more difficult to interpret.

All in all, natural family planning requires alertness on the part of the woman and a high level of motivation, cooperation, and discipline in both partners. It also requires a clear understanding that pregnancy is a distinct possibility.
STERILIZATION

Female Sterilization

Female sterilization involves occluding or dividing the fallopian tubes. The approach of choice is laparoscopy as an outpatient procedure. Minilaparotomy or a full laparotomy is usually performed when complications are anticipated with laparoscopy, for example, when a patient has extensive adhesions after previous surgeries, after PID, and post partum.

The procedure is usually done using general anesthesia. Local anesthesia with sedation is also common. After proper insertion of the laparoscope into the abdominal cavity under visual control, the fallopian tube is grasped by an instrument approximately 1 to 2 cm from the isthmus, and electrocoagulation is performed to the extent of 2 to 3 cm. The tubes can also be occluded by insertion of clips or a silastic ring. A loop of the fallopian tube is pushed through a dilated ring, which is then allowed to contract, thus providing tight occlusion of the tube.

When sterilization is done through minilaparotomy or laparotomy, most surgeons prefer the simple Pomeroy procedure or partial tubectomy. A loop of the tube is formed by grasping the tube with a forceps and ligating the loop about 1 to 2 cm below the apex of the loop. The segment of the tube that forms the loop is then dissected, and the open ends of tube may be electrocoagulated. A vaginal approach to tubal ligation has also been developed.

Efficacy

All methods of tubal sterilization are highly effective in reducing the risk of pregnancy. The pregnancy rate after tubal sterilization is 0.1% during the first year after the procedure, although the rates vary by procedure. The long-term pregnancy rates are higher. In the United States, a Collaborative Review of Sterilization Group observed 10,685 women for 8 to 14 years after tubal sterilization and identified 143 failures, with pregnancies occurring later than 2 years after the procedure. The cumulative 10-year probability of pregnancy was 18.5 per 1000 procedures irrespective of which method was used. The most effective methods were partial postpartum salpingectomy and laparoscopic unipolar coagulation, with 7.5 pregnancies per 1000 procedures. The clip was associated with 36.5 pregnancies per 1000 procedures. An overall cumulative probability of ectopic pregnancies was calculated as 7.5 per 1000 procedures.

Women sterilized at young age had the highest risk of pregnancy, most likely because they were being exposed to the possibility of recanalization or fistulization of the tubes for a longer period of time.

Complications

The most serious complications are those associated with bowel or blood vessel damage. The post-tubal sterilization syndrome includes a number of symptoms that women frequently ascribe to the procedure, such as premenstrual tension, dysmenorrhea, and emotional and psychosexual problems. The attributable reality of this syndrome is controversial. The length of the menstrual cycle is not influenced by tubal sterilization.

Manifestations of regret are more common in younger women. A functional reanastomosis may be difficult to achieve; however, success rates up to 70% have been reported. As discussed previously, the long-duration IUD and other methods should be discussed as alternatives to surgical sterilization.

Chemical Sterilization

Cyanoacrylates and quinacrine, a resin-like substance, have been evaluated as tubal occlusive materials. Neither has yet succeeded. For example, quinacrine causes local inflammation, fibrosis, and occlusion of the intramural segment of the tube. The method had been used on a large scale in India, where it was banned because of the associated high rate of pregnancies and complications. Data from Vietnam indicate a pregnancy rate of 13% for women younger than 35 years of age and 7% for women older than 35 years, higher occurrence of ectopic pregnancy, and PID.
Male Surgical Sterilization

Vasectomy

This procedure is done mostly using local anesthesia. The vas is palpated through the skin of the upper scrotum and exposed through a small incision. The vas is ligated at two sites, and the part between the two ligations is then surgically severed or excised. The vas may also be occluded by diathermy or by a clip.

Efficacy

It is important to convey to the patient that vasectomy is not immediately effective. It may take several weeks before all the sperm that remains in the distal part of the vas is ejaculated. An alternative method of contraception must be used until azoospermia is achieved, usually after 12 weeks or 20 ejaculations. In about 2% of cases, vasectomy is not successful and must be redone if sperm is present in the seminal fluid for several months. Rarely, spontaneous late reanastomosis can occur up to 10 years after vasectomy. Pregnancy that occurs such a long time after the procedure is a sensitive issue because questions of paternity may arise, and it must be handled judiciously.

Complications

Complications of vasectomy are rare and consist mostly of local infection and hematoma. Antisperm antibodies develop in about 50% of men, but there is no evidence that this is associated with any pathologic condition. [185]
SURGICAL ABORTION

Surgical abortion should not be a primary method of fertility control, although in some countries it is practiced as such. It is estimated that, worldwide, 50 million abortions are performed annually, 20 million of these illegally.

In the United States, after legalization of therapeutic interruption of pregnancy, the number of abortions rose from 16.3 per 1000 women in 1973 to 29.3 per 1000 in 1980. Thereafter, the rate of therapeutic abortions declined steadily to 22.2 per 1000 women in 1987. In that year, 1.33 million abortions were performed. Statistics also indicated that the majority (52%) of those undergoing abortion were younger than 25 years and 29% were teenagers.

In the United States, therapeutic abortions are performed by suction curettage under local or light general anesthesia. The mortality associated with therapeutic abortion is exceedingly low at 1 in 530,000 if performed within the first 8 weeks of pregnancy. This rate increases to 1 per 17,000 at 16 to 20 weeks and 1 per 6000 at 21 weeks of gestation. The overall mortality rate associated with abortion is 0.8 per 100,000 legal abortions. The maternal mortality rate at childbirth is 10 per 100,000 births, and that associated with ectopic pregnancy is 50 per 100,000 cases. The risk of nonfatal complications is less than 1%. These complications include pelvic infection, hemorrhage requiring a blood transfusion, and unintended major surgery.

The majority of abortions, 57%, are performed during gestations of less than 6 to 8 weeks duration. Thirty percent of women have abortions between weeks 9 and 12, and 12% have abortions later than 15 weeks. Approximately 50% of women having an abortion later than 15 weeks indicate that the delay was caused by problems of finding abortion facilities and having the procedure done. Teenagers are more inclined to delay abortion than older women.
DISCUSSING CONTRACEPTIVE CHOICES WITH THE PATIENT

Before recommending a specific method of contraception, the health status of the woman and her personal circumstances must be thoroughly evaluated. Crucial in the contraceptive decision-making process is whether the woman wishes to preserve her fertility or has attained her reproductive goals and is ready for permanent cessation of childbearing. The contraceptive choice is further influenced by the age of the patient, her smoking habits, her weight, and the presence or a history of health problems such as cardiovascular and cerebrovascular diseases and diabetes mellitus.

The initial visit and the yearly follow-up examinations are an opportunity to conduct a complete physical examination, take Pap smears, check for the presence of vaginal and sexually transmitted infections, and perform breast examinations. Mammography may be recommended, depending on the findings, the age of the woman, and her family history of breast disease. It is also prudent to check the lipid profile and blood sugar. The physician should discourage smoking, particularly if the contraceptive choice is hormonal.

Sexually active women frequently need protection not only against pregnancy but also against STDs, particularly in regions with a high prevalence of HIV and AIDS, chlamydia, gonorrhea, and syphilis infections. Dual protection, such as oral contraception along with the use of a condom, may be recommended, depending on the individual circumstances of the woman. Hormonal contraception for teenagers may be started after menarche. At the other end of the spectrum, women who have completed their families may choose an IUD or surgical sterilization. The important watchword is individualization of choice among all appropriate methods.

Lactation provides protection against pregnancy only if the woman is exclusively breast-feeding, but even such women can experience breakthrough ovulations, particularly after the 10th postpartum week. As long as a woman is breast-feeding, combination hormonal contraceptives should be avoided because they suppress production of breast milk. If breast-feeding is interrupted by bottle feeding, the risk of breakthrough ovulations increases significantly. For lactating women, progestagen-only contraception is an excellent choice irrespective of whether they breast-feed exclusively or supplement breast-feeding by bottle feeding. Low-dose progestagen-only contraception does not affect the composition and quantity of breast milk and can be started immediately after delivery.

In nonlactating women, uterine bleeding followed by ovulation usually occurs after the sixth week of the puerperium but can happen earlier. Therefore, nonlactating women should not delay contraception for more than 2 to 3 weeks. Combination OCs have not been recommended before the third week after delivery because of concern that they could compound the naturally increased risk of postpartum thromboembolism. In nonlactating women, a progestagen-only OC or an effective nonhormonal contraceptive method, such as an IUD, can be started immediately post partum.

After an uncomplicated spontaneous or induced abortion, women can start OCs on the same day. Provided there are no contraindications, an IUD can be inserted at the conclusion of the procedure.

Women who have achieved their desired family size should be offered surgical sterilization or an appropriate reversible method, such as a copper IUD.

It is good clinical practice to schedule women for a follow-up examination within 3 months after starting contraception. At that time, the physician determines whether the patient practices contraception correctly and inquires about possible adverse effects, such as chest pain, shortness of breath, edema, headaches, blurred vision, and depression. If the findings are satisfactory, the patient typically moves to an annual visit schedule.

An important part of recommending a contraceptive method is counseling about expected adverse events and pointing out those that are transient and benign versus those that require medical attention. Factual and balanced information about adverse events frequently averts discontinuation of the contraceptive method by the patient but can also facilitate therapeutic intervention if required.
CONTRACEPTION FOR WOMEN WITH HEALTH PROBLEMS

Recommending an adequate contraceptive method to women with health problems is always a challenge. In women with compromised health, both pregnancy and contraception could bring about a deterioration of the underlying disease. The risks of contraception versus the risks of pregnancy must be carefully weighed. Extensive and sensitive counseling by health personnel is especially important for women with medical problems because erroneous information can further imperil their health. Support of the partner can also be a positive influence on the success of a contraceptive method.

Both physician and patient must collaborate fully in making a decision concerning which contraceptive method to use. The seriousness of the disease in question must first be evaluated. When there are reasons to believe that pregnancy would permanently worsen the patient's health or be fatal for her, sterilization of one of the partners should be discussed. When pregnancy would substantially impair the patient's health but would not be life-threatening, long-term methods with high efficacy and safety could be recommended, for example, copper or levonorgestel-containing IUDs or hormonal methods when not contraindicated. Certain diseases do not impose major safety risks with respect to pregnancy. Should that be the case, patients who express the desire to preserve their fertility may use a wide range of methods according to preference and clinical compatibility. Before prescribing, the physician should take a thorough inventory of the patient's medications because certain preparations decrease the effectiveness of hormonal contraception.

Contraceptive Choices in Individual Diseases

Cardiovascular Disease

For a patient with any heart disease, a copper IUD may be the method of first choice because of its high efficacy and lack of systemic effects. The insertion of the IUD should be covered by antibiotics if the patient is at risk for bacterial endocarditis. Patients who receive antiocoagulation therapy can be fitted with a levonorgestrel IUD; the progestagen released suppresses the growth of the endometrium. Combination OCs should not be recommended if the patient is currently suffering from or indicates a personal history of MI, congestive heart failure, stroke, uncontrolled hypertension, or thromboembolism. Women with varicose veins can use OCs. Uncomplicated valvular heart disease, including mitral valve prolapse, is not a contraindication to hormonal contraception. If valvular disease is complicated by pulmonary hypertension, atrial fibrillation, subacute bacterial endocarditis, and signs and symptoms of cardiac congestion, combination OCs must be avoided.

For those with a number of heart conditions, progestagen-only contraception can be used in the form of pills, injections, and subdermal implants. These conditions include a history of thombophlebitis, valvular heart disease (uncomplicated and complicated), and controlled hypertension with systolic blood pressure 140 mmHg/90 mmHg. A history of ischemic heart disease or stroke does not preclude the use of progestagen-only contraception, but it should be used only if other options are not available or acceptable to the patient and if the patient can be properly monitored. In the United States, the product label of progestagen-only contraceptives is as restrictive as that for combination OCs. However, international guidelines permit a wider range of indications for progestagen-only contraception.

Diabetes Mellitus

In diabetes mellitus, the frequency and severity of vascular complications increase with age and in pregnancy. Diabetic patients should be advised of these possibilities and counseled on early family planning decisions. Effective contraception is critical for the health of diabetic patients. The contraceptive method of first choice should be the copper IUD, which is suited for patients with uncomplicated as well as with complicated diabetes mellitus.

The American College of Obstetricians and Gynecologists developed guidelines recommending that use of combined OCs be limited to nonsmoking, otherwise healthy women with diabetes who are younger than 35 years and show no evidence of hypertension, nephropathy, retinopathy, or other vascular diseases.

Combined OCs do not impair the course of either type 1 or type 2 diabetes. The critical question of whether OCs increase the risk of early diabetic renal or retinal complications, or both, has been explored in a retrospective case-control study of two matched groups of patients with type 1, insulin-dependent diabetes mellitus. The study group patients took OCs for at least 1 year; the control group consisted of never-users of OCs. During the observation period, markers of diabetic renal damage and results of eye examinations were not significantly different in the two groups; the longitudinal hemoglobin A1c values were similar for both study and control subjects. The study indicates that the use of OCs by young women with insulin-dependent diabetes mellitus does not pose an additional risk for the development of early diabetic retinopathy or nephropathy. A prospective cohort study of 98,000 women nurses found no increased risk of type 2 diabetes when subjects were taking OCs. A history of gestational diabetes does not preclude the use of hormonal contraception. If the health status and desire of the patient indicate, sterilization should be considered.

Liver Disease

The interaction between the liver and contraceptive hormones is manifold. In experimental animals, conditions resembling peliosis hepatis can be induced by estrogens, and the possibility of liver adenomas in OC users has been considered. The incidence of these tumors is rare, 1 to 3 per 1 million women per year, and the risk attributable to oral contraception is difficult to assess. An increased risk for development of primary hepatocellular carcinoma in OC users has not been proved. In patients with impaired liver function, contraceptive steroids may not be efficiently metabolized, and such patients may have increased circulating levels of these hormones. The clinical impact of these biochemical changes is uncertain. Gallbladder disease has been linked to oral contraception, but epidemiologic evidence has not been consistent.

A copper IUD should be considered the method of first choice for patients with liver problems. As stated in the section "Contraindications," the use of combined hormonal contraception should be avoided in patients with active liver disease, severe cirrhosis, and liver tumors or even a history of liver tumor. Under close supervision, patients with compensated cirrhosis can use progestagen-only contraception. There are no restrictions for the use of any type of contraception for carriers of hepatitis viruses.

Human Immunodeficiency Virus Infection

HIV-positive women have shown less inclination to procreate than healthy women, irrespective of their socioeconomic status and background. Sexually active HIV-infected women who desire contraception should practice procedures that are highly effective in preventing an unintended pregnancy and at the same time protect them from acquiring another STD and prevent transmission of the HIV infection to the woman's sexual partner. These objectives are best achieved by the dual-protection technique, with which the HIV-infected woman uses an effective contraceptive method (OC, medicated IUD, possibly tubal sterilization) and she or her male partner uses a condom.

HIV-positive women who want to become pregnant or are already pregnant should be counseled on the availability of treatment and prevention of vertical transmission of the infection from mother to infant.

Patients with Compromised Mental Health

Patients with reduced or limited mental abilities have a right to a safe sexual life. This has to be balanced with the right of caregivers, for whom a pregnant mentally ill patient can cause substantial distress. Also, one has to take into account a patient's need for adequate parental care. For all these reasons, the choice of contraception is crucial. Before the choice is made, several questions must be answered. Is the patient competent enough to decide upon the right form of contraception? Is she able to use a method consistently and correctly? Are bleeding and hygiene manageable? In no case must the patient be forced to use a
Hormonal contraception is not contraindicated for patients with epilepsy; however, one has to bear in mind that antiepileptic drugs may decrease the effects of contraceptive hormones. Similarly, rifampin decreases the effects of hormonal contraceptives in patients with tuberculosis. In both conditions, the choice of appropriate contraception should be individualized. For example, some women who take antiepileptic medication do well with a relatively higher dose OC. On the other hand, drugs used for the treatment of malaria do not affect contraceptive hormones, and oral contraception is not contraindicated in patients with malaria.

A coincidence of migraine and stroke has been recognized in several epidemiologic studies. A large-scale prospective epidemiologic study in the United States followed up 12,220 subjects between the years 1971 and 1984 and was published in 1997. The results of the study strengthened previous evidence regarding a nonrandom association of migraine and severe nonspecific headaches with a significantly increased risk of stroke, particularly among young women. In women younger than 45 years, all cases of stroke occurred in OC users. However, the study was conducted during a period when use of low-dose OCs was not common. This probably also applies to a case-control study examining the risk of ischemic stroke in young women with migraine. In this study, stroke was strongly associated with migraine with aura (odds ratio 6.2) as well as without aura (odds ratio 3.0). OCs increased the risk of ischemic stroke to 13.9. Another study estimated the odds ratio in migrainoid women using COC as 16.9.

Contraindications to the use of combined hormonal contraception are migraines with aura, migraines without aura if they are unusually severe or last more than 72 hours, migraines treated with ergot preparations, and all types of migraines when other risk factors for stroke are present. These contraindications are included in the British practice guidelines. The American College of Obstetrics and Gynecology recommends methods other than OCs for women with migraines. This prudent approach to combined OCs is warranted because an array of reliable nonhormonal methods is available today. Progestagen-only oral contraception can be tried in patients with simple migraines.

Patients with concomitant diseases who want and need contraception require special care and possibly more frequent follow-up. With the present availability of a wide variety of contraceptives, no health-compromised patient needs to be without protection from pregnancy.
THE FUTURE OF FAMILY PLANNING: NEEDS AND RESEARCH

Family planning in the second part of the 20th century was a remarkable success; almost 60% of couples of reproductive age now use contraception, and the fertility rate worldwide decreased nearly to the replacement level (see Fig. 17-3). Is this a reason for satisfaction? The number of unwanted pregnancies, over 2.5 million in the United States alone and 50 million worldwide, sends us the message that there is ample room for improvement.

Human Immunodeficiency Virus-Acquired Immunodeficiency Syndrome

Today’s major medical problem is HIV infection and AIDS. With respect to reproductive health care, the research challenge is to develop a reliable microbicidal-spermicidal agent that will simultaneously protect against the two dangerous viral infections, HIV and HPV. Another research task is to design ways to prevent the transmission of the HIV infection from mother to fetus. Finally, prevention of pregnancy in women with HIV-AIDS requires education of infected women with regard to an effective method of fertility control and provision of suitable means including financial to do so.

The statistics of the HIV-AIDS epidemic are chilling: HIV-AIDS affects 16 million women and 1.4 million children younger than 15 years worldwide. The yearly death toll for women is 1.3 million and for children younger than 15 years is 500,000. To protect women from HIV-AIDS and to prevent transmission of the infection to infants is an urgent task.
Expanding Contraceptive Choices

There are several goals at the heart of expanding contraceptive choices that include tailoring contraception to the individual needs of the woman or the couple and designing new delivery systems for existing hormones. A meaningful contribution has been the successful completion of clinical trials with a contraceptive patch and the current research on vaginal rings releasing contraceptive hormones. These and other parenteral delivery systems for contraceptive steroids have been described in the appropriate section of this chapter.

With respect to the development of new nonhormonal methods of fertility control, most of the current efforts involve modifications of previous designs.
Departure from 1-Month to 3-Month Regimen

Traditionally, OC treatment was designed for 1-month use. However, a number of women perceive monthly withdrawal bleedings as a nuisance and would prefer to reduce the number of bleeding episodes and symptoms accompanying such episodes. For many years, physicians have prescribed continuous combined OCs to avoid withdrawal bleeding. Currently, a 3-month regimen of ethinylestradiol and levonorgestrel is being investigated in the United States. The effect on the endometrium and evolution of endometrial hyperproliferation at the end of the 3-month dosing period must be investigated and defined.
Contraception for Nursing Women

There is still a need for additional contraceptive options for breast-feeding women. Although lactation reduces fertility substantially, unpredictable breakthrough ovulations do occur, particularly when breast-feeding is not exclusive or is irregular. Pilot studies with breast-feeding women have shown that small amounts of estradiol delivered by transdermal patches significantly reduce pituitary gonadotropins more than in untreated breast-feeding women. The growth of ovarian follicles was also significantly suppressed in the treated women. Before this information can be translated into a practical contraceptive method for lactating women, many questions must be answered, including the long-term effects of low doses of estrogen on the mother, the transfer of estrogen into the breast milk, and possible effects on the infant. For now, barrier and progestagen-only methods remain most reasonable.
Immunocontraception

Since 1975, a WHO research program has devoted considerable effort to developing an anti-hCG antibody that would protect women from pregnancy for 6 to 12 months. Although the research has yielded an impressive amount of basic scientific data, human application had to be discontinued because of unexpected adverse events. New immunologic leads are being pursued. Antisperm vaccines, antiovum vaccines, and anti-GnRH vaccines are also being contemplated but have not crossed from the laboratory into the clinic.
Developing a Male Contraceptive

After years of trying various approaches, the only effective and well-tolerated methods of male contraception are vasectomy and the condom. Attempts have been made to develop systemic male contraception using the same principles as in female contraception, that is, blocking the pituitary gonadotropins in order to reduce sperm production in the testes to the point at which the man becomes infertile. Testosterone enanthate alone suppresses pituitary gonadotropins and interferes with spermatogenesis. Combination of this androgen with a GnRH agonist or a GnRH antagonist achieved an impressive reduction of spermatogenesis without affecting the sexual function of the men studied.

The addition of a progestagen to testosterone has been associated with more rapid and effective suppression of spermatogenesis than with testosterone alone. Therefore, considerable research efforts have been directed toward testing combinations of testosterone with contraceptive progestagens, including levonorgestrel, cyproterone acetate, MPA, norethindrone enanthate, and desogestrel. The major disadvantage of testosterone is its conversion to dihydrotestosterone and the consequent stimulation of the prostate gland. The negative effect of testosterone on lipid metabolism is also of concern. Although treatments with testosterone alone and in combination with either GnRH agonists and antagonists or with various progestagens have contributed substantially to our knowledge of spermatogenesis and its suppression, a practical method of male contraception has not been developed.

However, one approach is promising. The Population Council is conducting clinical testing with steroid hormones of the 19-nortestosterone series, notably with 7-methyl-19-nortestosterone. The 7-methyl group protects the compound from conversion to dihydrotestosterone, therefore, its effects on the prostate gland are limited. However, 7-methyl-19-nortestosterone is 10 times more potent in suppressing pituitary gonadotropins. Because of its lack of oral bioavailability, the compound has been formulated in a subdermal implant.

Human studies have progressed to initial clinical pharmacology testing. One-month dose-response studies have identified the daily amount of 7-methyl-19-nortestosterone that successfully suppresses both luteinizing hormone and follicle-stimulating hormone, and studies of the effect of 7-methyl-19-nortestosterone on spermatogenesis in humans are in progress.
The Future

In the search for a new method of male contraception, it might be necessary to depart from the traditional hormonal approach and look for potential leads in the molecular regulation of sperm biology. One approach would be to interfere with sperm capacitation in the epididymis. Maturation of the sperm surface composition is critical for fertilization of the egg, and any disruption can impede sperm progress through the cells and carbohydrate matrix of the cumulus oophorus and the glycoproteins of the zona pellucida. Decapacitated sperm may attach to the surface of the cumulus but fail to penetrate it.

During epididymal transit, the sperm undergoes maturation, a series of processes that have been only partially elucidated. Incomplete sperm maturation within the epididymis could explain the failure of sperm binding to the zona pellucida in unsuccessful human in vitro fertilizations. A group of newly discovered proteins (HE2 and HE2') that are synthesized in the epididymis and secreted into that tubule might interact with sperm and affect their maturation. If the role of these epididymis-specific proteins in sperm maturation is confirmed and defined, they could be a source of potential contraceptive targets. This approach is an attempt to apply the lessons of molecular cell biology in the clinic.

With respect to hormonal contraception for women, the trend has been to introduce new types of progestagens with minimal metabolic impact and a specific action on the endometrium. Is there really a need for new progestagens? Progestagens of the advanced gonane series, such as norgestimate and desogestrel, already have no negative effects on the metabolism of lipids, proteins, and insulin, and they may be the answer to the quest for a progestagen with minimal metabolic action.

With respect to estrogens, we are still using a compound synthesized in biochemically prehistoric times in 1938. Perhaps we should start looking for a selective estrogen receptor modulator that suppresses the pituitary gland with no or little effect on the endometrium, no effect on the blood clotting mechanisms, and no potential for thromboembolism. To date, no product is available that meets these criteria.

The development of new contraceptive modalities depends on close cooperation between three institutions: academia, government agencies, and the pharmaceutical industry. This is true for the development of any drug, but it is perhaps more important for the development of contraceptives because contraceptive research involves a number of public health issues and, in many instances, financial support for reproductive research depends on public opinion and attitudes.

Chapter 18 - Disorders of the Testes and the Male Reproductive Tract

James E. Griffin
Jean D. Wilson

The testes produce sperm and the hormones that regulate male sexual life; both functions are controlled by the hypothalamic-pituitary system. The pathways for hormone formation and the regulatory control of the testes are similar to those in the ovaries and the adrenal glands, and all steroid hormones work by similar mechanisms. However, the major steroid hormone of the testes, testosterone, has few direct actions; instead, it serves as a circulating prohormone (or precursor) for formation of 5-reduced androgens and estrogens, metabolites that mediate most androgen actions.

The regulation of testicular hormone production and the mechanisms of hormone action are similar at all stages of life, but the physiologic effects of these hormones differ at different times of life; for example, inducing formation of the male urogenital tract during embryogenesis and promoting sexual maturation at the time of puberty. As a result, abnormal testicular function causes different consequences depending on when it develops, from early gestation to old age.
DEVELOPMENT OF THE TESTES

Embryogenesis

Testicular differentiation is controlled by genes on the Y chromosome. The short arm of the Y is invariable in size, whereas in normal men the long arm can vary considerably in length. The short arm contains genes responsible for testicular development, and additional Y-encoded genes are essential for spermatogenesis. The short arm of the Y chromosome is composed of two distinct regions: the so-called pairing segment on the distal end of the short arm is homologous to a region on the end of the short arm of the X chromosome and is responsible for the pairing between the X and Y that is essential for complete segregation of the sex chromosomes during meiosis. Recombination can occur between the shared regions of the X and the Y. Genes and sequences in this region of the X chromosome fail to exhibit typical X linkage, and the pattern of inheritance of such genes is termed pseudoautosomal.

The region of the short arm of the Y chromosome between the pairing segment and the centromere encodes genes that do not recombine with the X chromosome, including the SRY (sex-determining region Y chromosome) gene responsible for testis determination. The SRY gene is Y-chromosome specific, conserved among mammals, and expressed principally in the testes, and female mice carrying an SRY transgene develop into phenotypic males with testes. SRY encodes a protein of the HMG (high-mobility group) box type that probably acts to influence chromatin structure, and other genes in the sex determination cascade, including the steroidogenic factor 1 gene (SF1), Wilms' tumorrelated gene 1 (WT1), the dosage-sensitive sex reversals adrenal hypoplasia congenital gene (DAX1), and the SRY-related genes HMG-box 3 (SOX3) and HMG-box 9 (SOX9) (Fig. 18-1). Mutations in WT1, SF1, SRY or any of the downstream genes under its control can impair testicular development (see Chapter 22).

Testes contain three principal cell types:

1. Germ cells, derived from primitive endodermal cells of the inner cell mass (initially identifiable in the yolk sac).
2. Supporting cells, derived from the coelomic epithelium of the gonadal ridge that differentiate into the Sertoli cells in the testis (or granulosa cells in the ovary).
3. Stromal (interstitial) cells, derived from the mesenchyme of the gonadal ridge that differentiate into Leydig cells.

The primordial germ cells express specific cell markers and are recognizable in the 4.5-day-old human blastocyst. Before day 23 of human gestation, these cells are located in the dorsal and caudal portions of the yolk sac entoderm (Fig. 18-2A). They then migrate by ameboid movement from the gut endoderm through the mesentery to reach the genital ridge (see Fig. 18-2B). The forces that control the migration are unknown, but the germ cells replicate during migration so that more cells reach the genital ridge than were present in the yolk sac. On reaching the genital ridge the germ cells, together with adhering epithelial cells, infiltrate the underlying mesenchyme. This process is identical in male and female embryos and culminates by 5 to 6 weeks of gestation in the formation of the genital blastema containing the three basic cell types. Primordial germ cells that fail to reach the genital ridge degenerate or differentiate into other cell types and may serve as the progenitors of extragonadal germ cell tumors in later life.

Sexual dimorphism of the gonad begins between 6 and 7 weeks of gestation with the development of seminiferous cords in the fetal testis. By contrast, histologic differentiation of the fetal ovary is not apparent until the sixth month of gestation, when granulosa cells organize around the dividing oocytes to form the primary ovarian follicle. The somatic cells of the gonad can undergo partial organization into ovary or testis as specified by the sex chromosomal even when the germ cells are prevented from migrating to the genital ridge, suggesting that some determinants for gonadal development are inherent in the cells of the genital ridge.
Testicular Descent

Histologic development of the testes is largely complete by the end of the third month of gestation, whereas testicular descent from the abdominal cavity to the scrotum occurs later. Between 10 and 15 weeks of human gestation, the testes remain anchored to the future inguinal canal by the caudal ligament of the testis, the gubernaculum, whereas the ovary moves cranially. Simultaneously, the cranial suspensory ligament that anchors the testes to the posterior abdominal wall regresses. The gonadal positions in the two sexes deviate further after 25 weeks of gestation, when the gubernaculum descends into the scrotum and begins to degenerate as it is hollowed out by a diverticulum of the peritoneum, the processus vaginalis.

The actual descent of the testes through the processus vaginalis into the scrotum occurs as intra-abdominal pressure increases as a consequence of the closure of the umbilical cord, descent being completed between 7 months of gestation and shortly after birth. Continued development of the abdominal musculature causes closure of the inguinal rings and obliteration of the processus vaginalis. Conditions that impair development of intra-abdominal pressure, such as congenital defects in the abdominal musculature, are associated with cryptorchidism.

The genetic and endocrine factors that control testicular descent are now understood in large part. The role of androgens has been established by two types of evidence: (1) dihydrotestosterone promotes testicular descent in rats, and (2) the position of the testes in 46,XY subjects with mutations that impair the androgen receptor correlates with the severity of impairment of receptor function. Thus, androgen action may involve the formation, enlargement, or degeneration of the processus vaginalis or the gubernaculum. Androgens may also enhance the release of calcitonin generelated peptide, from the genitofemoral nerve, which in turn may promote descent.

Antimüllerian hormone (AMH) (also called müllerian-inhibiting substance and müllerian duct inhibitor) may also play a role in testicular descent, possibly in the contraction of the gubernaculum. The testes in some men with persistent müllerian duct syndrome are located high in the retroperitoneal space as a result of impaired formation or action of AMH. The INSL3 gene (also designated Ley I-L and relaxin-like factor, RLF), a member of the insulin-like superfamily, controls development of the gubernaculum, and mice with targeted disruption of INSL3 have bilateral cryptorchidism with freely moving intra-abdominal testes. Diethylstilbestrol-induced cryptorchidism in mice is also associated with failure of gubernaculum development and impairment of expression of INSL3. A similar phenotype, namely long gubernacular cords and intra-abdominal testes, results from targeted disruption of the homeobox gene HOXA-10.
STRUCTURAL ORGANIZATION OF THE TESTES

The testes contain a network of tubules for the production and transport of sperm to the excretory-ejaculatory ducts and a system of interstitial or Leydig cells that synthesize androgens. Tight junctions between the Sertoli cells separate the spermatogonia from the primary spermatocytes and form a diffusion barrier that divides the testis into two functional compartments: basal and adluminal. The barrier between these two compartments has limited permeability to macromolecules, analogous to the blood-brain barrier and other epithelial barriers. The basal compartment consists of the Leydig cells, the boundary tissue of the tubule including peritubular myoid cells, and the outer layers of the spermatogenic tubules that contain the spermatogonia. The adluminal compartment consists of the inner two thirds of the tubules, including primary spermatocytes and cells in more advanced stages of spermatogenesis.

The structure and function of the Sertoli cell are closely linked (see Fig. 18-4). The base of the cell is adjacent to the outer basement membrane of the spermatogenic tubule, whereas the inner portion consists of an arborized cytoplasm containing large gaps or lacunae, analogous to the branches of a tree. The mechanism by which the spermatogonia pass through the tight junctional complexes between the Sertoli cells as spermatogenesis commences is not known, but the arborized cytoplasm of the Sertoli cell encompasses the differentiating spermatocytes and spermatids so that spermatogenesis takes place within the Sertoli cell cytoplasm network. Sertoli cells synthesize hormones such as AMH, inhibin, activin, and prodynorphin as well as factors essential for spermatogenesis such as transferrin.

The lipid droplets responsible for the foamy appearance of Leydig cell cytoplasm are composed largely of esterified cholesterol, derived in part from circulating lipoproteins and in part from locally synthesized cholesterol. The esterified cholesterol serves as a reservoir of substrate for testosterone synthesis. After hydrolysis of cholesterol ester, free cholesterol moves to mitochondria under the control of the steroidogenic acute regulatory (StAR) protein, where the initial reaction in testosterone biosynthesis takes place, namely side-chain cleavage of cholesterol to pregnenolone. Pregnenolone in turn is converted to testosterone in the endoplasmic reticulum. The amount of testosterone stored in the Leydig cell is small because newly synthesized testosterone diffuses promptly into the testicular venous blood.
PHYSIOLOGY OF TESTICULAR FUNCTION

Hypothalamic-Pituitary-Testicular Axis

Hypothalamic Hormones

The hypothalamus is connected to the pituitary gland both by a portal vascular system and by neural pathways (Fig. 18-5) (Figure Not Available). The portal vascular system provides a mechanism for the delivery of releasing hormones from the brain to the pituitary gland, the major system by which the brain controls anterior pituitary function. Reverse flow through this hypophyseal-portal circulation may also allow pituitary hormones to reach the brain by a more direct path than through the general circulation. The preoptic area and the medial basal region of the hypothalamus (particularly the arcuate nucleus) contain important centers for control of gonadotropin secretion. Peptidergic neurons in this region secrete gonadotropin-releasing hormone (GnRH), also called luteinizing hormone-releasing hormone (LHRH), in a pulsatile fashion. Neurons from other regions of the brain terminate in this area and influence both the frequency and the amplitude of GnRH secretory pulses through catecholamine-related, dopamine-related, and endorphin-related mechanisms.

GnRH is a decapeptide that is widely distributed in the central nervous system (CNS) and other tissues. However, a physiologic role has not been established for the hormone in sites other than the pituitary. The metabolic clearance rate of GnRH averages about 800 L/min body surface area per day. Increased excretion in urine of immunoreactive GnRH metabolites coincides with pubertal development in boys, and in adult men GnRH levels in urine correlate with those of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Pituitary Hormones

LH and FSH are the primary pituitary hormones that regulate testosterone function. These hormones were named on the basis of their ovarian effects before their roles in testicular function were recognized. LH and FSH are secreted by the same basophilic cells in the pituitary. Like thyrotropin (or thyroid-stimulating hormone) and human chorionic gonadotropin (hCG), LH and FSH are glycoproteins composed of two polypeptide chains designated α and β. The subunits of the four hormones are identical; the individual immunologic and functional characteristics of the hormones are determined by unique subunits. Both subunits are required for full biologic activity.

The structures of the subunits of LH and hCG are similar except that the carboxy end of hCG contains an additional 30 amino acids and additional carbohydrate residues. The disappearance of exogenous LH from blood is described by two linear exponentials with half-times of 40 and 120 minutes, and the metabolic clearance rate is coupled primarily to G₁,4,5-triphosphate systems in the Leydig cell. Frequent pulses favor LH secretion. In some species, GnRH effects can be demonstrated in testes, but GnRH does not appear to have a direct effect on the human Leydig cell.

Mechanism of Action of GnRH-Releasing Hormone and Gonadotropins

GnRH interacts with high-affinity cell-surface receptors coupled to G proteins on the plasma membrane of pituitary gonadotrophs. The acute administration of GnRH stimulates the release of both LH and FSH by a mechanism involving calcium or phosphoinositides as second messengers. GnRH probably also acts long-term to enhance gonadotropin synthesis. The amounts of LH and FSH released in response to GnRH depend on age and hormonal status. In monkeys, the gonadotroph response to GnRH reaches a peak in the first few months of life and then declines and remains low until the onset of puberty, when it again increases to attain an adult response. Before puberty, the secretion of FSH in response to GnRH is greater than that of LH. Slow-frequency GnRH pulses favor FSH secretion, whereas frequent pulses favor LH secretion. In some species, GnRH effects can be demonstrated in testes, but GnRH does not appear to have a direct effect on the human Leydig cell.

The LH receptor on the plasma membrane of Leydig cells is a member of the superfamily of G protein-coupled, seven-transmembrane domain receptors. The binding of LH to the receptor activates signal transduction by both the adenylyl cyclase and phosphoinositide pathways (see Chapter 5). The intracellular loops of the receptor form contact sites for interaction with G proteins. In the testsis, receptor activation is coupled primarily to G_s proteins, leading to stimulation of adenylyl cyclase and formation of cAMP, which binds to the regulatory subunit of protein kinase and causes dissociation of the regulatory subunit and activation of the catalytic subunit. The activated protein kinase operates through unidentified steps to stimulate the synthesis of the enzymes of testosterone biosynthesis. The signal is terminated by endocytosis and degradation of the LH receptor complex.

In the intact testis and in cultured Leydig cells, the number of LH receptors decreases after administration of LH or hCG. The loss in receptor number is dose-dependent, reaches a nadir 24 hours after LH administration, is associated with a decrease in LH receptor messenger ribonucleic acid (mRNA), and returns to control levels within several days. This down-regulation of receptor number is associated with decreased responsiveness (desensitization) to subsequent LH administration. Desensitization cannot be solely the result of the decrease in receptor number and appears to result in part from inhibition of some postreceptor event because cAMP is ineffective in reversing desensitization. Whatever the mechanism, the diminished response of the Leydig cell to LH after administration of LH is a critical component of the regulation of testosterone production.

The primary site of action of FSH is the basal aspect of the plasma membrane of Sertoli cells, where the hormone binds to the FSH receptor, also a member of the G protein-coupled, seven-transmembrane domain receptor family. The second messenger is cAMP, which is also linked to the activation of protein kinase and stimulation of the synthesis of proteins such as androgen-binding protein and the aromatase that converts testosterone to estradiol. The precise role of FSH in the control of spermatogenesis remains uncertain and may vary among species (see later).

FSH plays an indirect role in androgen biosynthesis by inducing maturation of Leydig cells during development, possibly a consequence of the release of a paracrine factor by Sertoli cells; but FSH does not play a major role in the control of Leydig cell function in adults. Like LH and other peptide hormones, FSH regulates the number of its own receptors, but the physiologic significance of this phenomenon is unclear.

Regulation of Secretion of GnRH-Releasing Hormone and Gonadotropins

Episodic secretion of GnRH into the hypophyseal-portal system causes episodic secretion of both immunoreactive and bioactive LH. In adult men, LH secretory pulses occur at a frequency of 8 to 14 per 24 hours and vary in magnitude. Pulsatile secretion of FSH is temporally coupled to that of LH but is lower in amplitude. LH secretion is under negative-feedback control by gonadal steroids at the level of the hypothalamus and the pituitary gland (see Fig. 18-5) (Figure Not Available). Both testosterone and estradiol can effect this inhibition. Testosterone can be converted to estradiol in the brain and pituitary gland, but the two hormones are thought
One major effect of androgen in the CNS is to slow the hypothalamic pulse generator and consequently decrease the frequency of LH pulsatile release.

Endogenous opiates have a role in the negative-feedback actions of androgen and estrogen on pulsatile LH secretion in men. Furthermore, in monkeys with hypothalamic lesions that abolished endogenous GnRH release and in whom normal pulsatile secretion of LH was mimicked by chronic intermittent intravenous GnRH administration, bilateral orchidectomy caused minor elevations of plasma LH levels, whereas castration of monkeys with an intact hypothalamus given similar pulses of GnRH was followed by a marked rise in LH levels, indicating that LH is controlled by the negative feedback of gonadal steroids at the hypothalamic level. Acute infusions of estradiol also lowered LH levels associated with an increased frequency and a decreased amplitude of the LH pulses.

The fact that dihydrotestosterone, which cannot be converted to estrogen, exerts a negative-feedback control on LH secretion indicates that testosterone does not require aromatization to inhibit LH secretion. Testosterone also appears to have a negative-feedback action on LH secretion at the pituitary level because administration of exogenous testosterone to GnRH-deficient men who were given pulsatile LHRH infusions caused a decrease in mean plasma LH levels and in LH pulse amplitude. Hyperprolactinemia suppressed LH secretion, probably by inhibiting the pulsatile secretion of GnRH.

The negative-feedback control of FSH secretion involves peptide and steroid hormones from the testes. Serum FSH concentrations increase in proportion to the loss of germinal elements in the testis, whereas LH levels change little. Inhibin, a peptide secreted by Sertoli cells that inhibits pituitary FSH secretion, is a heterodimer consisting of a 20-kd subunit and a 15-kd subunit. The subunit occurs in two forms, so that there are two inhibins, inhibin A and inhibin B, each 31 kd in size. Inhibin B is thought to be the physiologically important hormone in men. FSH stimulates inhibin production, and both FSH and androgen are involved in normal inhibin production. Dimers of the subunit of inhibin (termed activin) stimulate FSH release, and the pituitary protein follistatin binds and inactivates activin.

Testosterone and estradiol also influence FSH secretion. In castrated rats treated with subphysiologic amounts of testosterone but physiologic amounts of estradiol, plasma FSH levels increase to the castration range but LH concentrations are normal. Indeed, alterations in the ratio of testosterone to estradiol can alter plasma FSH levels. In addition, varying the pattern of GnRH administration to hypogonadotropic men so that the same total dose was administered but with less frequent pulses caused selective increases in FSH levels.

In the rhesus monkey with a hypophysemotropic clamp, administration of inhibin maintained FSH levels in the precastration range when episodic gonadotropin secretion was maintained by intermittent GnRH infusion. Thus, the suppression of FSH secretion by inhibin does not require the action of testosterone and must take place at the level of the pituitary gland.
Androgen Physiology

Testosterone Synthesis and Secretion

The pathways of testosterone synthesis are illustrated in Figure 18-6 (Figure Not Available) and Figure 18-7. As stated earlier, the precursor steroid cholesterol can either be synthesized de novo or derived from the plasma pool by receptor-mediated endocytosis of low-density lipoprotein (LDL), and both sources are important in the human Leydig cell. 26

Figure 18-6 (Figure Not Available) Pathway of testosterone formation in the testis and the conversion of testosterone to active metabolites in peripheral tissues. SIAR, steroidogenic acute regulatory protein. (Revised from Griffin JE, Wilson JD. Disorders of the testes. In BraunwaldE, Fauci AS, Kasper DL, et al [eds]. Harrison’s Principles of Internal Medicine, 15th ed. New York, McGraw-Hill, 2001, pp 21432154.)

The conversion of cholesterol to testosterone involves several enzymatic reactions. The cholesterol side chain is cleaved in two steps to reduce the size from 27 to 19 carbons, and the A ring of the steroid is oxidized to the 4,3-keto configuration. The initial reaction in the process involves the transfer of cholesterol by the SIAR protein to the inner mitochondrial membrane, 26 where it undergoes side-chain cleavage by CYP11A1 to form pregnenolone. The subsequent conversion of pregnenolone to testosterone involves both random and ordered enzymatic reactions.

For the second side-chain cleavage to take place, 17-hydroxylation and cleavage of the 17,20 bond through CYP17 must occur before the reduction of the 17-ketone by 17-hydroxysteroid dehydrogenase III (17-HSD-III). In contrast, oxidation of the A ring by 3-HSD-II can take place at any stage in the process. Thus, the point in the pathway at which A ring oxidation occurs depends on the amounts and affinities of the enzymes for the various substrates and their compartmentalization within the cell. The predominant pathway in the human testis appears to be the 5 pathway (see Fig. 18-7, left side). A ring oxidation being the terminal reaction in the sequence. 26 Although

**Blood samples from the spermatic vein were collected, with the use of local anesthesia, from patients with carcinoma of the prostate, hernia, varicocele, or hydrocele.**

17-hydroxylase and 17,20-lyase were originally regarded as separate enzymes, both activities are the function of a single cytochrome P450 enzyme CYP17. 26

The rate-limiting reaction in testosterone synthesis under most circumstances is the transport of cholesterol to the inner mitochondrial membrane. As mentioned earlier, the acute administration of LH stimulates testosterone synthesis by enhancing the delivery of cholesterol to the mitochondria through SIAR protein 26 for side-chain cleavage by CYP11A1. 26 In the steady state, LH also stimulates testosterone synthesis by enhancing the formation of CYP11A1 and other enzymes in the pathway.

Testosterone is the major product, but dihydrotestosterone, androsterone, 5-androstane-3,17-diol, androstenedione, 17-hydroxyprogesterone, progesterone, and pregnenolone are also formed by the tests in small amounts 26 (Table 18-1). The role of 5-reduced androgens formed in the tests has not been established, the major sites of steroid 5-reduction being extraglandular. The functions in the male of pregnenolone, progesterone, and 17-hydroxyprogesterone are not known.

Androstenedione serves as a substrate for extraglandular estrogen formation (see later).

The concentrations of testosterone in testicular lymph and testicular venous blood are similar, but the flow of testicular lymph is small so that the major route for steroid secretion into the circulation is through venous blood. The mechanism of transport of testosterone and other steroids from the sites of production to blood and lymph is not completely understood. Because only about 25 ng of testosterone is stored in the normal testes, the total testicular content turns over more than 200 times to provide the average of 6 mg secreted into plasma each day by normal men. 26

Gonadotropin Regulation of Testosterone Secretion

Rat Leydig cells have excess or "spare" LH receptors; that is, the physiologic response is maximal when only a fraction of the receptors are occupied by LH. These spare receptors neverthless coupled to cAMP generation so that maximal testosterone biosynthesis occurs with doses of hCG or LH that result in only 10% of maximal cAMP production. 26 Human Leydig cells contain fewer LH receptors than rat Leydig cells, but the fact that the maximal rates of testosterone biosynthesis
per Leydig cell are similar in both species suggests that the major difference is in the number of spare receptors rather than the number of receptors coupled to androgen synthesis.

The decreased response of target cells to LH or hCG after an initial exposure was described earlier and involves both reduced LH receptor number (down-regulation) and some effects distal to receptor binding. The possibility that hCG desensitization is mediated by a local increase in estrogen production by the testes is suggested by the findings that the testicular estradiol level is elevated within 30 minutes after hCG administration and that estrogen antagonists can block hCG-induced desensitization. In mouse Leydig cells, testosterone itself appears to act directly to control the activity of its biosynthetic pathway.

The long-term in vivo response to hCG is complex. Administration of hCG causes an elevated plasma testosterone level within 2 hours in both rats and humans. The plasma level of testosterone reaches a plateau or declines after the initial rise and then starts to increase again by 48 hours, and plasma estradiol levels increase and reach a peak 24 hours after hCG injection, a time corresponding to the nadir between the two testosterone responses.

The concept that the mechanism of this temporary desensitization involves inhibition of the 17,20-lyase reaction is supported by the fact that 17-hydroxyprogesterone increases 24 hours after hCG administration and then declines at 48 hours while testosterone levels are rising. Administration of high doses of hCG to men for long periods results in steady-state elevations of plasma estradiol, 17-hydroxyprogesterone, and testosterone. The increase in total plasma testosterone levels after hCG administration is greater in the morning than in the afternoon, in keeping with the normal circadian rhythm of serum testosterone levels. The higher testosterone levels in the morning in normal men do not correlate with changes in mean LH values but may be the consequence of changes in pulse frequency of LH secretion.

In rats, prolactin receptors are present on Leydig cells, and prolactin potentiates the effect of LH on testosterone synthesis, possibly by enhancing lipoprotein transport into the cells and increasing the availability of cholesterol for steroidogenesis. A role for prolactin has not been shown in human Leydig cell function, and the prolactin receptor is not expressed in human Leydig cells.

A variety of paracrine control mechanisms have been described in the testis, including:

1. Testicular peptides (inhibin, activin).
2. Growth factors (transforming growth factors and , fibroblast growth factor, insulin-like growth factor I [IGF-I]).
3. Immune-derived cytokines (tumor necrosis factor-).
4. Vasoactive peptides (endothelin, angiotensin II, and atrial natriuretic peptide [ANP]).

To date, however, no integrated view of the relevance of these various agents for Leydig cell function or for treatment of testicular defects has emerged.

Testosterone Transport in Plasma

In plasma, testosterone is largely bound to proteins, mainly albumin and sex hormone-binding globulin (SHBG, also called testosterone-binding globulin). SHBG, a -globulin composed of nonidentical subunits, has a molecular mass of about 95 k, contains about 30% carbohydrate, and has one androgen binding site per molecule. SHBG shares sequence homology with the coagulation factor protein S, laminin, and the growth arrest-specific gene (GASG). A variant allele of the SHBG gene is present in 13% of normal persons.

In the blood of normal men, about 2% of testosterone is free (unbound), 44% is bound to SHBG, and 54% is bound to albumin and other proteins. The fraction of testosterone bound to SHBG in serum is proportional to the SHBG level. Albumin has about a 1000-fold lower affinity for testosterone than SHBG, but the concentration of albumin is so much higher that the binding capacities are similar. Furthermore, protein-bound testosterone can dissociate within the capillary bed so that the active fraction is actually larger than the free fraction as estimated by equilibrium dialysis. In fact, nearly all albumin-bound testosterone is available for tissue uptake in vivo so that the bioavailable testosterone in men is about half the total (equal to the free plus the albumin-bound fraction). SHBG-steroid complexes can also bind to receptor sites on the cell surface and increase intracellular AMP levels by some mechanism not involving the intracellular androgen receptor.

Estradiol binds to SHBG with a lower affinity than testosterone, a consequence of which is that SHBG-bound estradiol is taken up by tissues. The multiple isoforms of SHBG arise from differential post-translational processing of the carbohydrate moiety.

The level of SHBG is increased by estrogens, as in normal pregnancy, and is decreased by testosterone administration. The plasma level in normal men is one third to one half that in women, and the level is higher than normal in hypogonadal men. SHBG levels are decreased in hypothyroidism and increased with thyroid hormone excess, possibly because of changes in estrogen formation.

The effects of changes in SHBG levels differ, depending on the physiologic state. In normal men, alterations in SHBG levels have little effect on androgen physiology in the steady state, for example, an increase in plasma SHBG is followed by temporary decreases in free (active) plasma testosterone and an increased rate of LH secretion followed by an increase in testosterone synthesis until the normal level of free hormone is reconstituted. As a consequence, in the steady state both increases and decreases in SHBG levels are compatible with normal rates of androgen synthesis and degradation and normal free hormone concentrations in plasma.

In contrast, changes in the plasma SHBG levels have profound consequences when the level of free hormone is not tightly regulated. Such is the case in two circumstances. First, with disorders of the hypothalamic-pituitary-testicular axis, the ability to regulate the free levels of the hormone is limited and replacement therapy may have to be adjusted when SHBG levels change. Second, and more important, even in men with an intact hypothalamic-pituitary-testicular axis, not all plasma hormones are under such tight regulation as testosterone.

The level of plasma estradiol in men is probably determined by the amount of androgen available as substrate for estrogen formation and by the amount of aromatase activity in extraglandular sites and thus is not regulated directly by the usual feedback mechanisms. Because SHBG binds estradiol less avidly than testosterone or dihydrotestosterone, increases in SHBG cause decreased hepatic clearance of testosterone but have little effect on the hepatic clearance of estradiol. Thus, in normal men, changes in SHBG levels can alter the ratio of androgens to estrogens even when androgen levels themselves are not significantly altered.

Extraadrenal Metabolism of Androgens

As noted earlier, testosterone serves as a circulating precursor or prohormone for the formation of two types of active metabolites, which in turn mediate many androgen actions (see Fig. 18-6) (Figure Not Available). On the one hand, testosterone can undergo irreversible 5-reduction to steroids such as dihydrotestosterone, which are responsible for many aspects of male sexual development and virilization. Dihydrotestosterone in turn can be further metabolized to 17-ketosteroids and polar derivatives excreted in urine. Alternatively, circulating androgens containing a 1,3-keto configuration can be converted to estrogens in the extraglandular tissues of both sexes. Estrogens in some instances act in concert with androgens to influence physiologic processes and in others exert effects that are independent of androgens. Thus, the physiologic actions of testosterone are the result of the combined effects of testosterone itself plus those of estrogen and androgen metabolites of testosterone.

In normal men, small amounts of estradiol (15% to 25% of the total daily production) and dihydrotestosterone are secreted directly by the testis, and small amounts of both can be formed indirectly from adrenal androgen through the sequence androstenedione estrone estradiol or androstenedione androstenedione dihydrotestosterone. The formation of estradiol in normal young men is illustrated diagrammatically in Figure 18-8 (Figure Not Available). Of the average daily
estradiol production of 45 pg, 17 µg is derived from the aromatization of circulating testosterone. 22 µg is formed extraglandularly from the weak estrogen estrone, and 6 µg is secreted directly by the testes. In some instances, these metabolites exert local actions in the tissues in which they are formed; in others, the 5-reduced and estrogenic metabolites can reenter the plasma and act as circulating hormones.

The factors that regulate estradiol and dihydrotestosterone formation are poorly understood. Circulating dihydrotestosterone is formed principally in androgen target tissues. Aromatization takes place in many tissues, the most significant of which is probably adipose tissue; the overall rate of extraglandular aromatization increases with age and body size.

In the past, androgen metabolism was characterized in considerable detail before it was recognized that some testosterone derivatives are themselves active hormones rather than inactive metabolites. For example, for many years it had been known that testosterone is converted in the body to a variety of 5-reduced and 5-metabolites. The finding that 5-dihydrotestosterone is the principal intracellular androgen in target tissues such as the rat prostate and and that dihydrotestosterone is more potent than testosterone in bioassay systems indicated that dihydrotestosterone mediates some androgen actions. The importance of dihydrotestosterone in normal androgen physiology has been confirmed both by physiologic studies and by studies of human mutations that impair dihydrotestosterone formation (see Chapter 22).

Two enzyme activities are responsible for 5-reductase activity in human tissues, one of which is defective in human steroid 5-reductase deficiency. These activities are due to two separate isoenzymes; steroid 5-reductase 1 is encoded by a gene on the short arm of chromosome 5, and the gene for steroid 5-reductase 2 is on the short arm of chromosome 2. The two enzymes have predicted molecular masses of 28 to 29 kd, share similar intron-exon organizations, and contain about 40% hydrophobic amino acids. Each is believed to be an intracellular enzyme. In the lipil biliary, 5-Reductase 2 is defective in subjects with 5-reductase deficiency, and administration to pregnant rats of finasteride, a potent inhibitor of 5-reductase 2, produced a phenocopy of 5-reductase deficiency in male embryos.

5-Reductase activity is under complex regulatory control. In the rat prostate gland, the enzyme activity is up-regulated by androgens, whereas thyroid hormones appear to be the major regulators in liver. In cultured human skin fibroblasts, the enhancement of enzyme activity by androgens appears to be mediated by IGF-1. In intact subjects, the production rate of dihydrotestosterone appears to be determined predominantly by the amount of testosterone available to serve as substrate for the reductases.

The distribution and ontogeny of the two isoenzymes are distinct; 5-reductase 2 is expressed in the male urogenital tract early in embryogenesis, whereas 5-reductase 1 is expressed in skin and liver predominantly after the time of puberty. Within the skin of the scalp, 5-reductase 1 is expressed in sebaceous glands, whereas isoenzyme 2 is the predominant enzyme in the hair follicle. Other steroids with 4,3-keto configurations, including progesterone and aldosterone, also undergo 5-reduction by the enzymes, but a role has not been established for other 5-reduced steroids in human physiology.

Estrogen formation involves hydroxylation, oxidation, and removal of the carbon at position 19 of the steroid molecule and aromatization of the A ring of the steroid. Estrogen formation in testes and in extraglandular tissues is catalyzed by the same enzyme that operates in placenta and ovary. Expression of aromatase in individual human tissues is determined by tissue-specific promoters that give rise to transcripts with different N-terminal noncoding sequences. Testosterone and androstenedione are substrates for aromatase, whereas 5-reduced steroids such as dihydrotestosterone cannot serve as estrogen precursors because reduction of the A ring precludes aromatization. Estrogen formation in the tests is regulated by gonadotropins (see earlier). The rate of the overall aromatase activity in nongonadal tissue is not influenced by castration or adrenalectomy but is enhanced with increasing body weight and with age.

The metabolism of testosterone is illustrated in Figure 18-9. The metabolites are excreted primarily in the urine (>90%), approximately half of the daily turnover being recovered as urinary 17-ketosteroids and the other half as a series of polar compounds, including hydroxylated metabolites and conjugates. Various excretory metabolites are thought to be largely inactive.

Androgen Action

Current concepts of androgen action in target cells are summarized in Figure 18-10. Major androgen functions include regulation of gonadotropin secretion by the hypothalamic-pituitary system, initiation and maintenance of spermatogenesis, formation of the male phenotype during sexual differentiation, promotion of sexual maturation at puberty, and control of sexual drive and potential in men (see Chapter 24).

Testosterone is believed to enter cells by passive diffusion. Inside cells that express 5-reductase, testosterone can be converted to dihydrotestosterone. Testosterone and dihydrotestosterone bind to the same high-affinity androgen receptor, and the hormone-receptor complexes attach to hormone response elements in deoxyribonucleic acid (DNA) to initiate biologic reactions. (See Chapter 5 for a discussion of the ancillary proteins involved in the regulation of transcription by the androgen-receptor complex.) Few of the presumed large number of acceptor sites in DNA have been defined, and the factors that determine the specificity of hormone response are poorly understood. However, interactions between the hormone-receptor complex and the hormone response elements either increase or decrease gene transcription.

The model of androgen action shown in Figure 18-10 is based on studies of androgen metabolism in animals and humans of various ages and on studies of single-gene mutations that impair androgen action. The testosterone-receptor complex regulates gonadotropin secretion and virilization of the Wolffian ducts during male sexual differentiation and is probably responsible for sexual dimorphism of muscle development. The dihydrotestosterone-receptor complex controls external virilization during embryogenesis and the development of most male secondary sexual characteristics during puberty, including androgen-mediated hair growth and loss.

The question of which hormone is involved in spermatogenesis is unresolved. On the basis of studies of androgen metabolism in rodent testis, it is generally believed that testosterone is the active hormone for this function; however, dihydrotestosterone is formed in the spermatogenic tubule and sperm production is impaired in subjects with 5-reductase 2 deficiency, raising the possibility that dihydrotestosterone may play a role in human spermatogenesis.

Androgen receptors are present in highest concentration in androgen target tissues such as the accessory organs of male reproduction and some areas of the brain. Tissues such as skeletal muscle, heart and vascular smooth muscle, placenta have small amounts of receptor, and in the tests androgen
receptors are present in both Sertoli cells and Leydig cells. Whether the presence of androgen receptors identifies a tissue as androgen-responsive is not clear. The amount of receptor present in a tissue may be affected by androgen or estrogen, by age, and by single-gene mutations and genetic polymorphisms.

A single androgen receptor binds both testosterone and dihydrotestosterone, and the receptor is encoded by a gene on the long arm of the X chromosome. The complementary DNA encoding the human androgen receptor predicts a protein of 917 amino acids and a molecular mass of about 99 kd. In its amino acid sequence, the receptor shares a high degree of homology with the progesterone, glucocorticoid, and mineralocorticoid receptors in the hormone and DNA binding domains. The N-terminus is only weakly homologous to comparable regions of other steroid hormone receptors and contains glutamine, proline, and glycine homopolymeric sequences. The length of the glutamine repeat is polymorphic in normal populations, and more than 90% of normal women are heterozygous at this locus. Very long glutamine repeat sequences are associated with a neurologic disease termed spinobulbar muscular atrophy (Kennedy's syndrome). The active form of the androgen receptor is a homodimer that forms as a result of interacting sites in the N-terminal and C-terminal domains of the protein; the homodimer in turn interacts with other proteins to form an active transcription regulatory complex.

If a single receptor mediates the action of both testosterone and dihydrotestosterone, why is dihydrotestosterone formation important for normal androgen action? A partial answer is that the affinity of the human androgen receptor for testosterone is less than it is for dihydrotestosterone, a difference that results in more rapid dissociation for the testosterone-receptor complex. Testosterone-receptor complexes are also less stable and transform to the DNA-binding state less efficiently.

Dihydrotestosterone formation may serve fundamentally to amplify the androgen signal rather than to allow interaction of the hormone-receptor complex with specific DNA target sequences.

Many issues in androgen action remain unresolved. For example, most acceptor sites for binding androgen-receptor complexes in nuclei, the so-called hormone response elements (HREs), are palindromes in DNA sequences located 5' to genes under control of the hormone and recognize specific sequences in the DNA binding domains of the receptors. However, the characterized glucocorticoid and androgen regulatory elements respond in vitro to either hormone-receptor complex, and other factors determine specificity of action for these hormones in vivo, including the site of location of the HRE in relation to the coding sequence under hormonal control, differences in binding affinities of the hormone-receptor complexes to the HREs, and participation of additional transcription regulatory proteins including suppressor proteins in the active transcription complex.

It is noteworthy that in most target tissues (the human and dog prostate glands being notable exceptions) androgen action is limited; for example, under the control of androgen, the penis increases approximately 10-fold in size during male puberty, but when some maximal level is achieved growth ceases regardless of the androgen status of the individual. This cessation of growth corresponds temporally with a decrease in the level of the androgen receptor in the penis, but it is not clear whether the decrease in androgen receptor level is the cause or the consequence of growth cessation.
Estrogen Physiology

As discussed earlier, estrogens may be either secreted directly by the testes or formed in peripheral tissues from 19-carbon precursors. The role of estrogen as an independent hormone in male physiology is incompletely understood but includes closure of the epiphyses, acceleration of the pubertal growth spurt, accrual and maintenance of bone density, influence on gonadotropin secretion, a role in male sexual drive or potencia or both, and control of epididymal function. Estrogen excess in men causes gynecomastia (see later).

These various actions appear to be mediated predominantly through the estrogen receptor. In addition, estrogen interacts with androgen action by mechanisms that are not fully understood. In the prostate, estrogens may enhance androgen action by increasing the number of androgen receptors, whereas under physiologic conditions estrogens do not cause growth of the male breast because androgens appear to act as weak antiestrogens and prevent the binding of estrogen to the estrogen receptor.
Spermatogenesis and Fertilization

Spermatogenic Cycle

Spermatogenesis involves three processes: (1) multiplication of the germ cells, (2) reduction of the number of chromosomes from the diploid to the haploid state (meiosis), and (3) formation of a superstructure that allows sperm motility as well as generation of energy to drive motility. This superstructure also protects the chromosomes against environmental damage and provides sperm with the capacity to penetrate the ovum.\(^{140}\)

After migration of the germ cells to the genital ridge is completed during the second month of gestation (see Fig. 18-2), the total number of spermatogonia is approximately \(3 \times 10^8\) per gonad, and by puberty this number increases to about \(6 \times 10^8\) per testis. As a result of the hormonal events accompanying puberty, a profound cellular proliferation ensues.\(^{141}\) The net result is the production of approximately 1 billion sperm each day from the completion of puberty to extreme old age, a total of more than 1 trillion sperm during the usual male reproductive life span.

Although the process of spermatogenesis is similar among species, there are major histologic differences, including differences between man and other primates. As illustrated in Figure 18-12, each spermatogonium undergoing differentiation after puberty gives rise to 16 primary spermatocytes, each of which then enters meiosis and gives rise to four spermatids and subsequently to spermatozoa. Thus, 64 spermatogonia can develop from each spermatogonium. In the steady state at least 1.5 million spermatogonia begin this cycle each day, and because nearly half of potential sperm production is lost during meiosis, the actual number of spermatogonia that commence meiosis may be closer to 3 million/day.\(^{142}\) The commitment of spermatogonia to differentiation does not occur randomly; instead, because clumps or groups of adjacent cells share a similar if not identical degree of histologic development, contiguous groups of spermatogonia undertake differentiation simultaneously.

During spermatogenesis, cytokinesis is frequently incomplete and cytoplasmic bridges form between differentiating spermatocytes and spermatids. This interconnection facilitates coordinated development of groups of germ cells, the so-called wave or synchrony of histologically distinct stages. Clermont\(^{143}\) identified six typical cellular associations in human seminiferous tubules; thus, one or two generations of spermatids at given steps of spermatogenesis are always associated with one or two generations of spermatocytes and with specific groups of spermatogonia. The succession of these six stages in any one area of tubular epithelium constitutes the cycle of the seminiferous epithelium.\(^{144}\)

The ultrastructural changes during spermatogenesis involve a reorganization of cytoplasm and development of the flagellum (Fig. 18-13). The chromatin becomes progressively more dense, and the nucleus comes to occupy an eccentric position at the cranial pole of the spermatid adjacent to

![Figure 18-12 Cell divisions during spermatogenesis. The overall number of cell divisions is much higher than that during oogenesis.](image)

![Figure 18-13 Schematic diagram illustrating conversion of spermatocyte to spermatid to spermatozoon.](image)

the acrosomal cap. The latter is probably formed from the Golgi apparatus and is believed to be essential for the penetration by the sperm of the zona pellucida of the ovum. The core of the sperm tail develops from a centriole near the Golgi apparatus and consists of nine outer fibers and two inner fibers. Mitochondria form a helix around the cilia from the neck to the annulus of the tail. The terminal region of the tail consists of the axial filament surrounded by the cell membrane; most of the cytoplasm is shed as spermatids are released into the lumen of the tubule.

Spermatogenesis takes approximately 70 days from the beginning of the differentiation of the spermatocyte to the formation of motile sperm.\(^{145}\) The transport of the sperm through the epididymis to the ejaculatory duct requires an additional 12 to 21 days\(^{146}\) and is a journey that involves peristaltic movement, bulk fluid drag, and intrinsic sperm motility. Sperm leaving the testes are relatively immature and have a poor capacity to fertilize. Sperm maturation during passage through the epididymis involves development of the capacity for sustained motility, modification of the structural state of the nuclear chromatin and the tail organelles, and loss of remnant cytoplasm (the cytoplasmic droplet).\(^{147}\) Acrosome acquisition by the sperm of the capacity to fertilize (capacitation) is poorly understood and may be completed in the female genital tract.

Energy to drive motility is derived from the hydrolysis of adenosine triphosphate generated in mitochondria in the middle piece of the tail (see Fig. 18-13). The axial structure of the tail contains a central pair of microtubules surrounded by nine doublet tubules and nine dense fibers; the doublets are attached to the central tubules by a series of radial spokes, to each other by dynein arms, and to the axonemal membrane by so-called Y links. Motility is believed to involve a sliding action of the microtubules, analogous to the interaction of actin and myosin in muscles. The dynein arms contain a powerful adenosine triphosphatase, and sliding is generated by interaction of the dynein arms and is restricted by the radial spokes.\(^{148}\) Mutations that influence the doublet arms, the spokes, or the spoke heads can lead to the immotile cilia syndromes (see later).\(^{149}\)

Control of Spermatogenesis

Spermatogenesis does not occur in the hypophysectomized state, and restoration of spermatogenesis after hypophysectomy and its initiation at puberty require LH and FSH. FSH acts directly on the spermatogenic tubule, whereas LH enhances spermatogenesis indirectly by increasing testosterone formation in Leydig cells.\(^{150}\) FSH and testosterone act in the testis by the same general mechanisms as peptide and steroid hormones in other tissues (see Chapter 4 and Chapter 5). For example, FSH binds to receptors on the surface of Sertoli cells and spermatogonia and stimulates adenylate cyclase, resulting in increased intracellular cAMP levels, activation of protein kinases, and phosphorylation of a variety of proteins.\(^{151}\)

FSH stimulates spermatogenesis at several levels.\(^{152}\) For example, it stimulates mitosis of Sertoli cells, increasing their number during puberty, and promotes maturation and development of tight junctions between Sertoli cells. FSH actions in Sertoli cells include increased production of androgen-binding protein, transferrin, inhibin, aromatase, and plasminogen activators and enhanced uptake of glucose and enhanced conversion of glucose to lactate. FSH receptor mRNA levels vary during different stages of the spermatogenic cycle, suggesting that the levels are regulated and may play a role in spermatogenesis. However, the fact that spermatogenesis and fertility can occur in the presence of loss-of-function mutations that impair FSH and its receptor suggests that the principal role of FSH in spermatogenesis is a quantitative one.\(^{153}\)

Androgen receptors are present in Sertoli cells, Leydig cells, and peritubular myoid cells, and androgen receptor levels in Sertoli cells vary with the stage of spermatogenesis and appear to be under the control of androgen.\(^{154}\) Genetic evidence has provided insight into the role of androgen in spermatogenesis; mouse
The hormonal requirements for the initiation of spermatogenesis in maturing animals differ from those for maintenance in adults or for reinitiation after hypophysectomy. After hypophysectomy in the adult male, spermatogenesis can be restored by treatment with FSH (human menopausal gonadotropin [hMG]) plus hCG. After spermatogenesis is restored, it can usually be maintained by hCG treatment alone. The latter phenomenon, together with the finding that in otherwise normal subjects with suppressed FSH activity spermatogenesis can be restored by LH alone, suggests that FSH is essential for initiation but not maintenance of spermatogenesis. However, FSH may be necessary for quantitatively normal sperm production in men, and a hypophysectomized man with an activating mutation of the FSH receptor had sustained spermatogenesis.

Fertilization

Fertilization normally takes place within the fallopian tube, and spermatozoa usually require a period in the female genital tract before they can fertilize. This functional change, termed capacitation, is believed to consist of at least two components: (1) enhancement of the rate of flagellar beat with acceleration of sperm movement and (2) development of the capacity to undergo an acrosome reaction and consequently allow the plasma membrane of the sperm to fuse with the ovum.

Whether capacitation is an absolute requirement in the human or serves only to enhance fertilizing capabilities is not known. Because fertilization can take place in vitro when sperm and eggs are combined with no preincubation, the minimal time required for some spermatozoa to undergo capacitation must be short.

Capacitation involves a change in the intracellular concentration or metabolism of calcium or cAMP. The acrosome reaction may also involve calcium. Neither the fallopian tube nor the egg itself appears to be essential for the acrosome reaction, which begins as a fusion between the acrosomal membrane and the overlying plasmalemma and is followed by calcium influx into the sperm. Subsequently, the acrosome fragments and disappears. The acrosome is derived from lysosomes, and its disintegration causes release of hydrolytic enzymes and proteases.

The fact that the acrosome reaction is followed within a few hours by a loss of sperm motility means that variability in the timing of capacitation in a sperm population relative to the moment of insemination increases the chance of successful fertilization. Ordinarily, about a fifth of motile spermatozoa recovered from the oviduct at variable times after insemination have undergone the reaction. The net effect of the enhanced motility and the acrosome reaction is that sperm acquire the capacity to penetrate the formidable vestments of the ovum.

One consequence of the sequential acceleration of motility and initiation of the acrosome reaction is that sperm transport to the site of fertilization in the fallopian tube is a culling process. Only a small number of the millions of sperm that are ejaculated reach the site of fertilization. The features that distinguish spermatozoa that reach the ampulla and fertilize the egg are not known, but these sperm are presumed to exhibit the fastest motility and the most delayed initiation of the acrosome reaction.

Understanding of the mechanism of sperm penetration is based largely on studies of fertilization of human eggs in vitro, a situation that may not be identical to the phenomenon in intact humans. Ovulated eggs are surrounded by layers of cumulus cells embedded in a matrix of hyaluronic acid. The mechanism by which sperm penetration through the cumulus is not known. Possibly, hyaluronidase is released by the degenerating acrosome, and the mechanical agitation of the flagellum may disperse the cumulus cells. Under in vitro conditions, prior disposal of the cumulus with hyaluronidase is necessary to allow penetration of the zona pellucida and hence to permit fertilization by the sperm.
Phases of Normal Testicular Function

The phases of normal testicular function can be delineated in terms of the plasma testosterone concentration (Fig. 18-14). In the male embryo, the production of testosterone by the testes begins to rise at the end of the second month of gestation and shortly thereafter reaches a maximal value that is maintained until late in gestation and then decreases. At the time of birth, the plasma testosterone level is only slightly higher in males than in females. Shortly afterward, the plasma testosterone level again commences to rise in the male infant and remains elevated for approximately 3 months, falling to low levels by 1 year. The plasma level then remains low (but higher in boys than in girls) until the onset of puberty, when it again increases in boys and reaches adult levels by about age 17.

Plasma levels remain more or less constant in the adult until middle age and then gradually decline during the later decades of life. Sperm production takes place after puberty. The physiologic events during these various periods differ, as do the consequences of testicular derangements at different stages of life.

Embryonic Male Sexual Differentiation

The process of sexual differentiation is described in Chapter 22. In brief, the embryos of both sexes develop in an identical fashion until the seventh week of gestation. Thereafter, the anatomic development and the physiologic development diverge, with formation of the male or female phenotypes.

As formulated by Jost, normal sexual development in the mammalian embryo depends on three sequential processes. The first involves the establishment of genetic sex, which is defined by the sex chromosome constitution established at the time of conception. The heterogametic sex (XY) in mammals is male, whereas the homogametic sex (XX) is female. In the second phase, the sex chromosomal determine whether the indifferent gonad differentiates into a testis in the male or an ovary in the female. The third step involves the translation of gonadal sex into phenotypic sex and is the direct consequence of the type of gonad formed; that is, testicular secretions determine that the urogenital tract and external genitalia will be male in character.

The internal genitalia in the two sexes are derived from the wolffian and müllerian ducts that exist side by side in early embryos of both sexes. The wolffian ducts serve as the excretory ducts of the mesonephric kidney and are physically attached to the indifferent gonad, whereas the müllerian duct has no continuity with the gonad. In the male, the wolffian ducts give rise to the epididymis, vasa deferentia, seminal vesicles, and ejaculatory ducts and the müllerian ducts disappear. In the female, the fallopian tubes, uterus, and upper vagina are derived from the müllerian ducts and the wolffian ducts disappear.

Thus, masculinization of the fetus requires the action of testicular hormones, whereas the female phenotype develops in the absence of gonadal secretions. Under ordinary circumstances, chromosomal sex, gonadal sex, and phenotypic sex are concordant; that is, chromosomal sex determines gonadal sex and gonadal sex in turn determines phenotypic sex, without deviation from the chromosomal program.

Control over the formation of the male phenotype is vested in the action of three hormones. Two of the three, AMH and testosterone, are secretory products of the fetal testis. AMH, a glycoprotein hormone of the embryonic testis, acts ipsilaterally in the male embryo to suppress the müllerian ducts and consequently prevents development of the uterus and fallopian tubes. Testosterone converts the wolffian ducts into the epididymides, vasa deferentia, and seminal vesicles and is also the precursor for the third fetal hormone, dihydrotestosterone. The latter hormone, which is formed within the urogenital sinus and lower urogenital tract from circulating testosterone, acts in the urogenital sinus to induce formation of the male urethra and prostate and in the genital tubercle, swelling, and folds to cause the midline fusion, elongation, and enlargement that eventuate in the male external genitalia.

Thus, androgens function during fetal life to induce the formation of the accessory organs of male reproduction. Testosterone and dihydrotestosterone act through the same receptor mechanism during embryogenesis and in the adult (see Fig. 18-14). The formation of the male phenotype is largely completed by 12 to 15 weeks of gestation, but at the time of completion of the male urethra, the external genitalia in the two sexes do not differ in size. Descent of the testes and differential growth of the external genitalia in the male take place largely during the second half of gestation.

The control of testosterone formation by the embryonic testis is incompletely understood. By the 13th week of human gestation, testosterone secretion appears to be regulated by LH from the fetal pituitary gland or by placental hCG in the fetal circulation, or by both. The decrease in testosterone synthesis late in gestation correlates both with a decline in the number of LH-hCG receptors in the testis and with a decrease in the level of hCG and LH in the fetal circulation. Castration of the male rhesus monkey during late gestation results in a further decrease in plasma testosterone elevation of plasma gonadotropins. Anencephaly and other forms of congenital hypopituitarism cause the syndrome of microphallus. Taken together, these findings indicate that testosterone production during the second half of gestation is regulated by LH or hCG and that LH production itself is under negative-feedback control by testosterone.

The mechanism by which testosterone production is controlled between gestational weeks 8 and 12, when male phenotypic development takes place in the human embryo, is not clear. In the rabbit embryo, testosterone production during the analogous phase of male development appears to be independent of gonadotropin, but for technical reasons this phase of embryonic development in human gestation has not been adequately examined. The fact that most male infants with anencephaly, congenital hypopituitarism, or both have normal male urothras suggests either that androgen synthesis during early gestation is independent of gonadotropins or that chorionic gonadotropin, which apparently is not present in the rabbit, acts as a fail-safe mechanism to guarantee normal male development in the absence of LH from the fetal pituitary gland. However, the fact that loss-of-function mutations of the LH receptor gene cause impairment of the virilization of the male external genitalia (but not of the wolffian ducts) indicates that LH or hCG plays a role in early androgen synthesis.

In addition to their role in male phenotypic development, androgens secreted during fetal or neonatal life (or both) exert at least two types of effects on the CNS in some species: regulation of the hypothalamic-pituitary system and control of diverse sexually dimorphic behavior patterns. Androgens are presumed to act in brain through the same receptor as in the urogenital tract and other androgen target tissues. Social imprinting also plays a critical role in sex-specific behavior in some species. Male sexual development, apart from spermatogenesis, is remarkably complete during embryogenesis. For example, male infants have periodic erections during the later phases of gestation, which indicates that the complex neurogenic pathways that regulate this process have developed by that time.

The extent to which androgen action in the human CNS influences human sexual behavior has not been established. There is no evidence for permanent imprinting by fetal androgens on the hypothalamic control of gonadotropin production in the human, and it is not established whether gonadal hormones have any direct effect on gender identity or gender behavior apart from their role in anatomic development of the sexual phenotype. Nevertheless, both androgens and cultural factors probably play important roles in the development of characteristic male behavior. Therefore, in making clinical decisions about sex assignment in subjects with ambiguous genitalia, it is important to undertake a thorough diagnostic evaluation and appropriate therapeutic intervention as early as possible, preferably in the newborn nursery, to ensure that the
The neonatal surge in testosterone secretion is the consequence of a rise in plasma gonadotropin levels, but neither the cause of the increase in gonadotropin levels nor the precise function of the temporary increase in testosterone secretion is understood. Serum inhibin levels increase in boys in the first year of life in parallel with testosterone levels. In some species, the neonatal testosterone surge is believed to be responsible for two aspects of male development: (1) permanent virilization of the hypothalamus so that it secretes LH tonically rather than cyclically as in the female and (2) the priming of androgen target tissues for subsequent androgen-mediated growth and maturation in later life.

Blockade of the neonatal activation of the pituitary-testicular axis in male monkeys resulted in subnormal increases in LH and testosterone and impairment of testicular enlargement at the time of puberty. However, in humans there is no evidence that neonatal deprivation or excess of androgen has any permanent effect on hypothalamic-pituitary function. Whether neonatal androgen plays a specific role in the male gender identity or gender role behavior is likewise uncertain. Indirect evidence suggests that neonatal androgen influences the subsequent androgen-mediated growth of the male urogenital tract. Boys who are born with micropenis caused by deficient androgen biosynthesis may have subnormal androgen-mediated growth of the external genitalia if androgen replacement therapy is not started until the time of normal male puberty. However, their response may be normal if androgen is administered temporarily during infancy. Such observations are consistent with the view that late fetal or neonatal androgen primes the male urogenital tract by promoting early growth and potentiating maturational effects of the hormone at puberty.

In the prepubertal years, the plasma levels of gonadotropins and gonadal steroids are low. Maturation of adrenal androgen secretion, termed adrenarche, results in enhanced secretion of dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione in boys as early as age 6 or 7, several years before maturation of the hypothalamic-pituitary-gonadal axis. The secretion of these androgens is probably under the control of corticotropin (also called adrenocorticotropic hormone [ACTH] or adrenocorticotropic) and appears to be independent of activation of the pituitary-gonadal axis. In part, the prepubertal growth spurt and the early development of axillary and pubic hair are mediated by these adrenal androgens, which are believed to bind to the androgen receptor only after conversion to testosterone or dihydrotestosterone in target tissues.

Before the onset of puberty, the low levels of plasma gonadotropins are under feedback control by the small amounts of androgen secreted by the testes, as evidenced by the fact that castration at this time results in a rise in plasma gonadotropins to levels similar to those of the postpubertal castrate. Gonadotropins in children, as in adults, are secreted in a pulsatile fashion, with the pulses occurring at 2- to 3-hour intervals. These facts suggest that the negative-feedback control of gonadotropin secretion is exquisitely sensitive to plasma testosterone levels before puberty and subsequently changes during puberty development.

The factors that determine the onset of puberty are poorly understood and may reside in the hypothalamic-pituitary system, in the testis itself, in the adrenal gland, or at some undefined level (see Chapter 24). The sequence of pubertal maturation has, however, been well characterized. Its onset is heralded by sleep-associated pulses of LH secretion and, to a lesser extent, by increases in the episodic secretion of FSH. Later in puberty, the increased plasma gonadotropin levels become sustained throughout the day, as do the resulting increases in plasma testosterone and dihydrotestosterone levels. The rise in gonadotropin secretion is believed to be the consequence of both an increase in GnRH secretion and an increase in sensitivity of the pituitary to GnRH. Plasma levels of bioactive LH increase even more than those of the immunoreactive hormone.

The pubertal changes in gonadotropin and steroid hormone levels in plasma are compatible with the concept that with maturation, the hypothalamic-pituitary system becomes less sensitive to feedback inhibition by circulating androgens, which results in a higher mean plasma androgen concentration. The maturational change in the hypothalamic-pituitary system appears to be triggered by the attainment of a critical body mass or percent body fat, possibly mediated by an increase in plasma leptin levels.

The pubertal changes in the testes are illustrated in Figure 18-16. In prepubertal testes, the interstitial cells consist of an undifferentiated mesenchyme with immature tubules. After puberty, the cytoplasm of the functioning Leydig cells develops a characteristic foamy appearance and the various stages of spermatogenesis can be delineated within the tubule. Initiation of spermatogenesis early in puberty is associated with a rise in serum inhibin B levels. As indicated by the appearance of sperm in centrifuged urine samples from boys entering puberty, sperm production is an early pubertal event and can occur when testicular growth has just begun.

The anatomic and functional changes of puberty are largely the consequence of the action of testicular androgens. It is probable that all androgenic actions are mediated by dihydrotestosterone or testosterone and that other naturally occurring 19-carbon steroids act as androgens only if they are converted to testosterone or dihydrotestosterone within extraglandular tissues. The physiologic effects of androgens have been classified as either androgenic (maturational of the male urogenital tract and spermatogenesis) or anabolic (promotion of growth in muscle and other somatic tissues). These various effects are mediated by the same androgen receptor.
Androgen is responsible for many effects at puberty. Rugal folds appear in scrotal skin. The testes, penis, and scrotum enlarge, and the penis and scrotum become pigmented. The prostate, seminal vesicles, and epididymis increase in size. Growth of the various accessory organs of reproduction accounts for about a fourth of androgen-mediated nitrogen retention in puberty. One consequence of this growth and maturation process is the transformation of the cuboidal epithelia of the secretory tissues of the urogenital tract into columnar epithelia. The characteristic hair growth of male puberty involves development of the mustache and beard; regression of the scalp line; appearance of truncal, extremity.

TABLE 18-2 — Stages of Puberty

TABLE 18-2

- Pubic Hair Stage
- Genital Stage

Stage 1: Prepubertal. Vellus over the pubes is no further developed than that over the abdominal wall, i.e., no pubic hair.

Stage 2: Scrotum and testes have enlarged, and there is a change in the texture of scrotal skin and some reddening of scrotal skin.

Stage 3: Growth of the penis has occurred, at first mainly in length but with some increase in breadth. There has been further growth of the testes and the scrotum.

Stage 4: The penis is further enlarged in length and breadth, with development of glans. The testes and the scrotum are further enlarged. There is also further darkening of scrotal skin.

Stage 5: Hair is adult in quantity and type, distributed as an inverse triangle. There is spread to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle.

Adulthood.

On average, reproductive capacity is attained between the ages of 16 and 19 years. As indicated in Figure 18-17, most anatomic changes are also completed by this time. However, androgen-mediated growth of body hair is usually not maximal until the middle to late 20s.

The various physiologic actions of androgen during puberty and adulthood can be separated into two general types: permanent and concurrent. Permanent effects encompass anatomic actions that are irreversible and do not regress if androgen production ceases, such as the effects on the larynx. Concurrent effects are those that require a continuing male level of the hormones, such as the enhancement of erythropoietin production and hemoglobin levels. Other physiologic effects of androgen have both permanent and concurrent components; for example, beard growth slows but rarely stops in men who are castrated postpubertally.

Many features of castration have been described in anecdotal

form only, but several aspects have been studied in some detail.

First, postpubertal castration results in a negative nitrogen balance. The source and exact magnitude of the nitrogen loss have not been established, but probable
sites of loss include the secretory tissues of the male urogenital tract and, to some extent, other androgen target tissues such as muscle. Androgen replacement in castrated men restores nitrogen balance and the secretory capacity of the epididymis, seminal vesicles, and prostate.

Second, castration is followed by a progressive decline in male sexual drive so that only rare castrated subjects can have intercourse after a few years. In such individuals, physiologic androgen replacement results in a rapid and predictable restoration of male sexual activity.

Third, two thirds of men subjected to surgical or medical castration experience hot flushes that may persist for 5 years or longer. Long-term consequences of castration in men include osteoporosis, gynecomastia, profound shrinkage (apparent disappearance) of the prostate, and enlargement of the pituitary gland (assumed to be due to hyperplasia of LH-secreting cells).

At the completion of puberty, the plasma testosterone levels have attained the adult male level of 10 to 35 nmol/L (3 to 10 ng/mL), sperm production has reached a steady level, and plasma concentrations of gonadotropins are in the adult range. Thus, the mature feedback regulatory system shown in Figure 18-5 (Figure Not Available) is established and is maintained for approximately 40 years.

Even under the best circumstances, the system can be perturbed, usually temporarily, by a variety of influences at the level of both the testis and the hypothalamic-pituitary system. One of the most important of these influences is scrotal temperature; spermatogenesis is exquisitely sensitive to alterations in temperature, and temporary increases in systemic or local temperature (as in a hot bath) can be followed by temporary decreases in sperm production. Spermatogenesis can also be influenced by diet, drugs, environmental agents, and a variety of psychological stresses. Testosterone production is more stable than spermatogenesis but can also be impeded by drugs (see later).

Old Age

The term male climacteric implies an analogy to the complete cessation of ovarian function in women at the time of menopause. Men do not experience a relatively rapid total cessation of Leydig cell or seminiferous tubule function with old age, nor do men with intact testes experience the hot flashes characteristic of menopause. Male sexual function does decrease with age, but this decline does not appear to coincide with hormonal changes. Nevertheless, in older men carefully screened to exclude major health problems or medication use, serum testosterone levels do decline with age, although most older men still have serum testosterone levels within the range of normal for young men.

The normal circadian rhythm in serum testosterone levels is lost with age, and levels of bioavailable testosterone, namely serum testosterone not bound to SHBG, and Leydig cell reserve, as assessed by response to hCG, are decreased in older men. In a cross-sectional analysis of the Massachusetts Male Aging Study, testosterone parameters began to change around age 40 years; free testosterone levels decreased about 1.2%/year and SHBG levels increased about 1.2%/year, so the total testosterone levels do not reflect the true level of bioavailable testosterone in older men. A longitudinal follow-up of these subjects also showed a fall in total and free testosterone levels of about 1.5%/year. In another study, serum levels of bioavailable estradiol and testosterone both declined with age so that most men older than 65 had low levels of bioavailable testosterone as compared with young men.

When controlled for ejaculatory frequency, sperm density does not change with age, but older men have lower ejaculate volumes, decreased sperm motility, and an increased percentage of abnormal sperm. Total daily sperm production, as assessed histologically, also declines with age. However, most older men have values for these parameters that are within the normal range for young fertile men, and decreased sperm production in older men does not correlate with Leydig cell number. Levels of serum inhibin B decrease after age 35.

Serum LH and FSH levels increase in elderly men in keeping with some decrease in bioavailable testosterone and sperm production. Studies of gonadotropin secretion indicate a decreased LH pulse frequency but no change in pulse amplitude with age. Levels of bioactive and immunoreactive LH are increased to a similar degree in elderly men. These observations suggest that the hypothalamic-pituitary responsiveness to the decreased Leydig cell function is appropriate. In one study, the bioactive pituitary LH reserve was decreased in elderly men, as indicated by the response to GnRH and tamoxifen; in another study, the response to clomiphene citrate was normal. Basal levels of bioactive FSH are similar in young and elderly men, but total levels of FSH are higher in elderly men. Administration of clomiphene citrate increases bioactive and immunoreactive FSH levels to a similar degree.

The modest increase in serum gonadotropin levels with age is less than would be predicted for the decline in bioavailable testosterone levels, possibly a consequence of enhanced negative feedback of androgens. Veldhuis and colleagues have suggested that many of the endocrine changes with age are due to impaired synchrony of neuroendocrine function. The close coupling between sleep stage and nocturnal penile tumescence and episodic LH and testosterone secretion becomes blurred in the elderly. Pulsatile administration of GnRH to older men returns LH pulse frequency and amplitude and plasma LH levels to normal, but plasma testosterone levels do not increase equivalently. These findings suggest that defects may occur in the Leydig cell and in the CNS with aging.

The role of these changes in other aspects of aging is yet to be determined. In healthy men aged 73 to 94 years, levels of total and bioavailable testosterone correlate positively with muscle strength and total body bone mineral density (BMD) and negatively with fat mass. Levels of plasma estrone and estradiol correlate positively with BMD, and the relation between testosterone levels and BMD is independent of estradiol levels. Estrogen appears to play a major role in preventing bone resorption, whereas both estrogen and testosterone regulate bone formation. In other studies, the decline in bioavailable testosterone in elderly men correlated with depressed mood and with changes in cognitive function. The possible relation between testosterone levels and body composition provides some rationale for testosterone replacement in healthy older men with low testosterone levels (see later).
ASSESSMENT OF TESTICULAR FUNCTION

Leydig Cell Function

History and Physical Examination

The assessment of androgen status should include an inquiry about the following:

1. Presence of developmental abnormalities at birth (e.g., hypospadias, microphallus, cryptorchidism) (see later).
2. Timing and extent of sexual maturation at puberty.
3. Rate of beard growth.
4. Current libido, sexual function, muscle strength, and energy.

Inadequate androgen production or action during embryogenesis impairs development of the normal male phenotype, and Leydig cell failure before puberty impairs sexual maturation and causes eunuchoidism, namely an infantile amount and distribution of body hair, poor development of skeletal muscles, and failure of closure of the epiphyses so that the arm span is more than 5 cm greater than height and the lower body segment (heel to pubis) is more than 5 cm longer than the upper body segment (pubis to crown).

Detection of Leydig cell failure that begins after puberty requires a high index of suspicion and appropriate laboratory assessment. One reason for difficulty in detecting this condition is that decreased sexual function in adult men is more common than Leydig cell failure. Erectile dysfunction with preservation of normal libido is usually not due to testosterone deficiency but rather to the adverse effects of systemic disease or of medications prescribed to treat such disease. Likewise, decreased libido may not be recognized by individual patients and may be revealed only by discussion with sexual partners. A second reason is that some manifestations of testosterone deficiency are nonspecific, including depression, loss of drive in the workplace, decreased stamina, increased irritability, hostility, and nervousness.

Another reason that androgen deficiency is missed is that some functions that require androgens for initiation continue unabated with Leydig cell failure and some functions that eventually regress do so slowly. The frequency of shaving may not decrease for many months or years because of slow decline in the rate of beard growth once established. Finally, some consequences of testosterone deficiency such as increased abdominal obesity and decreased muscle mass may not be recognized as out of the range of normal variation.

Assessment of Plasma Luteinizing Hormone, Androgens, and Sex Hormone Binding Globulin

Because the LH level must be interpreted in light of plasma testosterone, it is usually appropriate to measure both hormones by using a pool formed by combining equal quantities of blood obtained from three or four samples at 15- to 20-minute intervals. In this way, only a single pooled sample of plasma is submitted to the laboratory and the averaging of values is accomplished before the assay. Dual-site immunometric assays using an appropriate international standard or reference preparation have largely replaced competitive radioimmunoassays. The usual normal range of plasma LH in adult men is 1.3 to 13 IU/L.

Plasma testosterone is also measured by immunoassay. Like LH, testosterone is secreted in a pulsatile fashion. Because the diurnal variation of plasma testosterone is significant in many men, it is desirable to measure testosterone in the morning along with plasma LH in pooled samples as just described. The normal range in adult men is 10 to 35 nmol/L (3 to 10 ng/mL). The plasma testosterone level is higher in prepubertal boys than girls, the normal range in boys being 0.2 to 0.7 nmol/L (0.05 to 0.2 ng/mL). The start of puberty is marked by a rise in plasma testosterone at night as a consequence of sleep-related nocturnal gonadotropic surges, and daytime levels of plasma testosterone gradually increase with the stages of puberty. In young men, the plasma testosterone is higher in the morning than in the late afternoon. In healthy middle-aged and elderly men, morning testosterone levels tend to remain stable over long periods.

Plasma dihydrotestosterone is also measured by immunoassay. In normal young men, the plasma concentration averages about 10% of the testosterone value.

Testicular function cannot be assessed by measurement of urinary 17-ketosteroids, which are composed of metabolites of testicular and adrenal androgens.

Measurement of the SHBG level is sometimes useful for interpretation of levels of total plasma testosterone. Binding capacity of SHBG can be assessed by the use of radioactive androgen, and the protein is measured by immunoassay.

In most situations, measurement of total testosterone provides an adequate assessment of Leydig cell function. However, in men with altered levels of SHBG (men older than 55 years of age and men with human immunodeficiency virus [HIV], abnormal liver function, or marked obesity), it is appropriate to assess the free or bioavailable testosterone level. Measurement of free testosterone levels by equilibrium dialysis is rarely done, and the analogue free testosterone assay is unreliable because it is influenced by the SHBG level. It is more practical to measure bioavailable (non-SHBG-bound) testosterone; this assay is performed by precipitating SHBG and measuring testosterone in the supernatant.

Alternatively, free or bioavailable testosterone can be estimated from the levels of total testosterone and SHBG, using the affinity constants of binding of testosterone to albumin and SHBG. In most circumstances, these calculated values correspond closely to directly measured levels.

Dynamic Tests of the Hypothalamic-Pituitary-Leydig Cell Axis

To assess Leydig cell function before puberty, it is common to measure the response of plasma testosterone to gonadotropin stimulation as an index of Leydig cell reserve. Normal prepubertal boys respond to 3 to 5 days of injection of hCG at 1000 to 2000 IU/day with an increase of plasma testosterone to about 7 nmol/L (2 ng/mL); the magnitude of the response increases with the initiation of puberty and peaks in early puberty.

In some circumstances, the response of plasma LH to GnRH is measured to assess the functional integrity of the hypothalamic-pituitary-Leydig cell axis. Before puberty, the responses of LH and FSH are similar, and with puberty the LH response to acute administration of GnRH increases whereas the FSH response remains the same. The amount of LH released after acute administration of GnRH is believed to reflect the amount of hormone stored in the pituitary. Administration of 100 µg of GnRH to normal men causes LH levels to increase fourfold to fivefold with a peak level at 30 minutes. However, the range of response is broad, and the peak LH after a single dose of GnRH usually correlates with the basal level.

In men with primary testicular failure, measurement of basal LH is usually sufficient and assessment of the GnRH response adds little information. Men with pituitary or hypothalamic disease may have either a normal or an abnormal LH response to an acute dose of GnRH, and consequently a normal response is of no value in determining the presence of secondary disease or in distinguishing hypothalamic from pituitary disease. A subnormal response to an acute dose indicates that an abnormality exists but provides no evidence concerning the site of the abnormality.

Measurement of long-term GnRH responsiveness is useful for evaluation of men with secondary hypogonadism and a subnormal LH response to an acute dose of GnRH. If daily...
infusions of GnRH for 1 week lead to the development of a normal LH response to an acute dose of GnRH, a hypothalamic cause of the hypogonadism is likely. More often, a hypothalamic or pituitary defect is diagnosed with imaging studies.
Seminal Tube Function

History and Physical Examination

Leydig cell dysfunction usually results in defective spermatogenesis, and men with the clinical features of Leydig cell dysfunction are usually infertile. In contrast, men with primary disorders of the seminiferous tubules can present with infertility as the sole clinical manifestation.

Examination of the testes is an essential portion of the physical examination. The seminiferous tubules account for about 60% of testicular volume. The prepubertal testis is about 2 cm in length (and 2 mL in volume, as assessed by the Prader orchidometer) and increases in size with puberty to reach the adult size by about age 16. When damage to the seminiferous tubules occurs before puberty the testes are small and firm, whereas postpubertal damage characteristically results in small, soft testes.

The normal adult testis is at least 4 cm in length with a volume of 15 to 25 mL. Considerable damage can occur before overall size shrinks below the lower limits of normal. Testis size varies among ethnic groups. Asian men have smaller testes than European men independent of differences in overall body size. Testicular size can be assessed with a ruler or with a Prader orchidometer. Because of the frequent occurrence of varicocele among fertile men and its possible causal role in infertility, the testes should be carefully palpated while the patient is standing.

Seminal Fluid Examination

Routine evaluation of the seminal fluid assesses parameters that do not necessarily reflect the functional capacity of the sperm. Seminal fluid should be obtained by masturbation into a clean glass or plastic container. Collection in a condom or after coitus interruptus may be incomplete and is not recommended. The volume of the normal ejaculate is 2 to 6 mL. The seminal fluid coagulates immediately after ejaculation and then liquefies within 15 to 30 minutes. The specimen should be analyzed within an hour.

Motility is estimated by examining a drop of undiluted seminal fluid and recording the percentage of motile forms. The quality of motility can be graded 1 to 3. Spermatozoa with grade 3 motility move rapidly across the field, grade 2 spermatozoa move aimlessly, and grade 1 spermatozoa have a beating tail but do not move. Normally, 60% or more of sperm should be motile, with an average quality of motility of grade 2.5 or more.

After it liquefies, the semen sample should be mixed well and diluted 1:20 either in water or with dilute sodium bicarbonate containing 1% phenol to immobilize the spermatozoa. A drop of this specimen is placed on a standard blood-counting chamber, and the spermatozoa are counted within five blocks containing 16 squares each. This number multiplied by 10^6 represents the count per milliliter. Sperm density can also be estimated by using an electronic particle counter. The normal value is usually considered to be greater than 20 million/mL, with total sperm per ejaculate greater than 60 million.

Random sperm counts are complicated by the effects of factors such as hot baths, acute febrile illness, and medications. The net result is that it is difficult to define the minimally adequate ejaculate. When 24 to 36 hours of sexual rest is specified and ejaculates are examined at 2-week intervals, average semen quality and sperm output are lower than previously considered normal for fertile men. Three ejaculates are usually required to determine sperm number and cytologic features, and six estimates or more may be necessary for valid assessment if the initial ejaculates are of equivocal quality.

Seminal fluid cytology can provide a useful index of fertility. The seminal fluid smear is prepared similarly to a blood smear but with special stains. Normal spermatozoa have symmetrically oval heads, middle pieces that are larger at the proximal ends and inserted symmetrically into the heads, and tails 7 to 15 times longer than the heads. Some abnormal spermatozoa are present in all semen. The best correlations between histologic abnormalities and infertility occur when a single anomaly (e.g., lack of the acrosome) is found in a large percentage of sperm. More than one abnormality may be present. Although there is no clear definition of the minimal structural features compatible with fertility, 60% or more of the spermatozoa should have normal morphology. Evaluation of sperm structure by electron microscopy, if available, is useful for identifying specific defects in immotile sperm (see later).

Testicular Biopsy

In men with azoospermia, testicular biopsy may be helpful if intracytoplasmic sperm injection (ICSI) is contemplated for treatment of infertility. It is most appropriate to perform such biopsies at the time ICSI is scheduled. Fine-needle aspiration can provide biopsy material and sperm for ICSI. In most men with infertility associated with oligospermia, testicular biopsy is of little value. The diagnosis of Klinefelter's syndrome related to chromosomal mosaicism limited to the testes can be established only by tissue culture and karyotypic analysis of the biopsy material. The histologic features of several testicular disorders are illustrated in Figure 18-16.

Plasma Follicle-Stimulating Hormone and Inhibin B

Levels of plasma FSH usually correlate inversely with spermatogenesis; that is, elevations of FSH occur in men with intact hypothalamic-pituitary axes when there is severe damage to the germinal epithelium. An inverse relationship also exists between levels of plasma inhibin B and FSH in men, including semen donors, infertile men, and men with elevated FSH levels. FSH is measured by immunoradiometric assay using the appropriate international standard or reference preparation. As with LH assays, dual-site immunometric assays are now commonly used and the usual range in normal men is 0.9 to 15 IU/L. Oligospermia caused by primary testicular defects is usually associated with elevated FSH levels.

Chromosomal Analysis

Examination of buccal mucosa cells for the presence of chromatin clumps on the nuclear membrane (the Barr body) provides evidence for the number of X chromosomes. In general, there is one Barr body for every X chromosome in excess of one. The Barr body, which represents the second X chromosome in XX individuals, is identifiable in 20% or more of the nuclei of cells in normal females and in less than 2% of cells of normal males. If buccal mucosa cells are stained with quinacrine or its mustard derivative and examined by fluorescence microscopy, the Y chromosome can be identified. This method provides a rapid and accurate means of determining the sex chromosome complement under some circumstances such as suspected male pseudohernphroditism.

Analysis of the chromosomal karyotype, the most accurate means of determining the chromosome complement, involves culture of peripheral blood leukocytes or of tissue fibroblasts in medium containing an agent such as phytohemagglutinin that induces the cells to divide. A spindle poison such as colchicine, which arrests mitosis at metaphase, is added; the cells are harvested and stained; and the number and histologic characteristics of the chromosomes are assessed in several cells. This technique is valuable for establishing the exact chromosome complement, the presence of mosaicism, the presence of structural chromosome alterations, and the sex chromosome composition. The study of multiple tissues may be necessary to establish chromosome mosaicism. In a given tissue, 20 cells must be examined to exclude with 95% confidence a mosaicism of 15% or greater.
Estrogenic Function

History and Physical Examination

Gynecomastia (enlargement of the male breast), the most consistent feature of feminizing states in men, is the consequence of proliferation of glandular tissue. The physician should seek the presence of gynecomastia by examining the patient while he is in the sitting position; the fingers are used to grasp the glandular tissue. Palpation with the flat part of the hand while the patient is supine may result in failure to detect early or minimal breast enlargement. In obese men, it is important to try to detect the edge of the rim of glandular tissue that separates it from the adipose tissue of the chest wall. Ultrasonography or mammography may be useful in separating true gynecomastia from lipomastia.

Plasma Estrogens

As discussed earlier, most estradiol and estrone in normal men are formed by extraglandular aromatization of circulating androgens. As assessed by immunoassay, plasma estradiol is usually less than 180 pmol/L (50 pg/mL) in normal men and plasma estrone is somewhat higher but usually less than 300 pmol/L (80 pg/mL). A recombinant cell bioassay has been developed to measure estradiol at low levels.

[244]
ABNORMALITIES OF ANDROGEN METABOLISM AND TESTICULAR FUNCTION

Abnormalities of testicular function have different consequences, depending on the phase of sexual life in which they are first manifested. Although there are problems inherent in all classifications and although some assignments are arbitrary, such a categorization of testicular diseases has a sound physiologic rationale. For example, although Klinefelter's syndrome is a disorder of chromosomal sex, it is usually diagnosed in individuals when manifestations become apparent after the time of expected puberty. Although such limitations must be recognized, disorders of the testes can be classified as abnormalities of fetal development, puberty, adult life, and senescence.

Fetal Life

Abnormalities of Male Sexual Differentiation

Disturbances in sexual differentiation can arise from a variety of mechanisms:

1. Environmental insult, as in the ingestion of a virilizing drug during pregnancy.
2. Nonfamilial aberrations of the sex chromosomes, as in 45,X/46,XY chromosomal mosaicism.
3. Developmental birth defects of multifactorial origin, as in most cases of hypospadias.
4. Hereditary disorders resulting from single-gene mutations, as in the testicular feminization syndrome.

The disorders of sexual differentiation and their management are described in Chapter 22, but because 46,XX men and men with Klinefelter's syndrome ordinarily present with problems of undervirilization or infertility, they are also discussed in this chapter.

Cryptorchidism

Descent of the testes is essential to normal function because spermatogenesis requires the lower temperature that is present in the scrotum. Failure can occur at any site in the normal pathway of descent, from high in the abdomen to the scrotum itself. The implications and sequelae of cryptorchidism differ, depending on the site at which descent ceases.

A large portion of the literature in this field is difficult to interpret because of imprecise definitions. Cryptorchidism can be defined as a testis that is not 4 cm or more below the public tubercle in an infant of normal size and subclassified, depending on the location of the maldescended testis, as follows:

1. The intra-abdominal testis (10%) cannot be felt. It is usually located just above the internal inguinal ring. Infants with bilateral intra-abdominal testes can be distinguished from female pseudhermaphrodites by assessment of the chromosomal karyotype and from boys with bilateral anorchia by demonstrating that the plasma testosterone level increases after administration of HCG. Unilateral intra-abdominal testes must be separated from the syndrome of mixed gonadal dysgenesis, in which a testis is present on one side and an intra-abdominal streak gonad is present on the other.
2. The canalicular testis (20%) has traversed the internal inguinal ring and is present in the inguinal canal; it may move intermittently between the canal and the upper scrotum. Such testes are small or would not be able to pass the external inguinal ring. When the testis is in the canal, the aponoeurosis of the external oblique muscle forms a firm barrier that the testis can rarely be palpated.
3. The high scrotal testis (40%) is farther along the pathway of descent but does not reach the bottom of the scrotum. It is characteristically smaller than its normal partner and has a limited range of motion so that it can retract into the groin but not past the internal ring. Retraction may make accurate diagnosis and classification difficult.
4. The obstructed testis (30%) is a fourth category in which failure of descent appears to be due to a physical barrier formed by a cord of fascia between the inguinal pouch and the inlet of the scrotum.

Another category is the ectopic testis. On rare occasions, the testis may deviate from its normal pathway of descent and become ectopic in location. The five most frequent sites of ectopia are the perineum, the femoral canal, the superficial inguinal pouch, the suprapubic area, and the opposite scrotum. Testicular ectopia is believed to be caused by an abnormality of the gubernaculum. In most situations, the higher the location of the testis or the more extreme the ectopia, the more difficult surgical repair becomes.

About 3% of full-term male infants have at least one cryptorchid testis at birth. Completion of descent usually occurs during the first few weeks after birth so that the incidence of cryptorchidism at 6 to 9 months and in adult men is about

0.7% to 0.8%. Accurate diagnosis and classification may require careful, repeated observations by a single observer to be certain that a normally (or partially) descended testis has not retracted into the groin. The concept that spontaneous descent can occur after a few months of age is a misconception that arose because of the failure to recognize that many normal testes are retractile in young boys and that elicitation of the cremasteric reflex can cause at least partial retraction of fully descended testes in three fourths of boys. The incidence of retraction declines with age, and it rarely occurs after midpuberty.

It is important to appreciate that a testis in the superficial inguinal pouch may be a temporarily retracted normal testis, a temporarily retracted high scrotal testis, a transiently palpable canalicular testis, or an obstructed testis and that differentiation among these possibilities is not always simple.

Pathogenesis

The cause of testicular maldescent is not well understood. The cryptorchid testis functions poorly in regard to both androgen secretion and spermatogenesis, but it is not always clear whether the testis functions poorly because of maldescent or fails to descend completely because it was abnormal to begin with. Maldescent of the testis occurs with increased frequency in many congenital defects, including virtually all disorders that impair virilization or prevent development of normal intra-abdominal pressure. Although maldescent is common in individuals with severe impairment of the androgen receptor, mutations of the androgen receptor gene are rare. Likewise, defects of the gubernaculum are common in cryptorchid testes, but mutations of the INSL 5 gene have not been detected in men with idiopathic cryptorchidism.

In some instances, a clear relation exists between maldescent and malfunction of the testis. For example, in the obstructed testis, in which a physical barrier prevents descent, and in syndromes in which intra-abdominal pressure is inadequate because the abdominal muscles are absent or incomplete, such as the prune-belly syndrome, inadequate testicular function in later life is the consequence of impeded descent. Conversely, in all series testes appear to have been abnormal from the first, and it is reasonable to assume that the defect in these instances plays a causal role in the maldescent.

As many as half of boys with a unilateral nonpalpable testis and a contralateral descended testis have an absent (vanishing) testis rather than a cryptorchid testis. The diagnosis of vanishing testis is suggested when compensatory testicular hypertrophy causes the contralateral descended testis to be larger than the mean for the age. Cryptorchid testes can sometimes be identified by magnetic resonance imaging or ultrasonography but definitive diagnosis may require laparoscopy.

Sequelae

About 10% of testicular tumors arise in an undescented testis, whereas cryptorchidism is present in fewer than 1% of adult men. Thus, malignancy is more likely to develop in an undescented testis than in a fully descended one. The greatest risk of malignancy is associated with intra-abdominal testes. Such malignancies commonly involve the germ cells, most commonly seminomas or embryonal cell carcinomas. Surgical correction of cryptorchidism does not remove this risk because
malignancy may develop in a previously cryptorchid testis many years after orchiopexy. Moreover, the contralateral normally descended scrotal testis is the site of development of malignancy in approximately a fifth of tumors associated with unilateral cryptorchidism.

The frequency of malignancy in cryptorchid testes should not be exaggerated because the chance of tumor development in any individual with cryptorchidism is low, but lifelong follow-up is required. Each cryptorchid testis should be surgically placed in a site that allows ready examination, and if this is not possible the cryptorchid testis should be removed. Periodic examination of the testes should be mandatory in the routine care of men with a history of cryptorchidism. In unilateral cryptorchidism, regardless of whether surgical correction has been undertaken, overall androgen production and levels are generally normal, presumably because malfunction of one testis can be compensated by the other testis.

Although as many as 60% of men in whom bilateral cryptorchidism was corrected in childhood can father children, cryptorchidism is associated with defective spermatogenesis. Mean sperm density is lower in adult men after surgical repair of cryptorchid testes in childhood, and spermatogenesis can also be decreased in the normally descended testis in men in whom one testis is cryptorchid. Basal FSH levels and FSH responsiveness to GnRH are higher on average in such men. Considered together, these types of evidence support the concept that testicular malfunction, as evidenced by impaired spermatogenesis, is a major factor in maldescent.

Management

Cryptorchidism should be treated by surgical or medical means, or both, and although correction may not prevent all sequelae, it is generally believed that correction should be undertaken before age 5 years. In the case of intra-abdominal testes (unilateral or bilateral), the issue is to exclude vanishing testes as the cause and bring intra-abdominal testes into the scrotum, where they can be monitored by physical examination. Measurement of levels of serum inhibin B and AMH may be useful in distinguishing bilateral intra-abdominal testes from vanishing testes. The testes that cannot be brought into the scrotum should be removed. Likewise, obstructed testes must be treated surgically.

The unresolved issue concerns the role of medical therapy in boys with canicular or high scrotal testes; in relatively large randomized trials, treatment of such boys with hCG, GnRH, or both agents in seriatiim was said to cause descent of the testes into a normal position in about a fifth of cases. However, the stimulation of apoptosis of germ cells by hCG and GnRH may have long-term deleterious consequences. Apoptosis is increased 1 month after hCG treatment but returns to normal subsequently. In one study, however, the level of apoptosis in the original testicular biopsy correlated many years later negatively with testis volume and positively with serum FSH levels, whereas sperm density was not affected. Treatment of cryptorchid boys with GnRH or hCG before orchiopexy caused a similar decrease in germ cells per tubule. Whether any hormonal treatment of cryptorchidism affects subsequent fertility is not known.
Neonatal Life

It is not clear whether abnormality in the neonatal surge in testosterone secretion results in pathologic consequences in humans. As mentioned earlier, however, temporary inhibition of the pituitary-testicular axis in the neonatal primate is associated with impaired testicular function at puberty.
Puberty

The central issue in dealing with disorders of puberty in both sexes is separating subjects with true absence or precocity of pubertal development from those at the extreme limits of normal variation. Normal puberty in the male is variable in onset, duration, and sequence of events. The spectrum of normal puberty and the disorders of puberty are discussed in detail in Chapter 24. (Feminizing states in prepubertal and pubertal boys can result from either absolute or relative increases in estrogen levels, as discussed later.) However, partial impairments of puberty may not be recognized until adulthood, as in Klinefelter's syndrome (see Chapter 22), in some androgen resistance syndromes in men (see Chapter 22), and in isolated gonadotropin deficiency (see Chapter 24).
Adult abnormalities of testicular function can be due to hypothalamic-pituitary defects, testicular disorders, or abnormalities in sperm transport (Table 18-3). Most such abnormalities are associated with underandrogenization and infertility, but some exhibit isolated infertility. Even partial defects in Leydig cell function can cause infertility because spermatogenesis requires androgen action. Therefore, although the evaluation of infertility differs from that of the underandrogenized man, it is essential to exclude the presence of subtle Leydig cell dysfunction in every man with infertility.

Certain factors or conditions (e.g., hyperprolactinemia, radiation, cyclophosphamide administration, environmental toxins, autoimmunity, paraplegia, androgen resistance) can cause either isolated infertility or a combined defect in testicular function (see Table 18-3). In addition to the manifestations of androgen deficiency described earlier in relation to assessment of Leydig cell function, testosterone deficiency can cause osteoporosis and mild elevations of serum total and LDL cholesterol and triglyceride levels.

Infertility with Impaired Virilization

Disorders of the hypothalamus and pituitary gland can impair secretion of gonadotropins and cause secondary decreases in androgen production and spermatogenesis, either as an isolated defect or as part of more complex pituitary insufficiency (see Chapter 8). Thus, destructive lesions of the hypothalamus and pituitary gland such as infarction, pituitary macroadenomas, metastatic or suprasellar tumors, infections, granulomatous processes, or radiation injury can cause hypopituitarism and lead to a secondary testicular defect. Likewise, isolated, functional impairment of hypothalamic GnRH secretion can occur with fasting or critical illness.

Congenital isolated gonadotropin deficiency occurs in both sporadic and familial forms. The incidence of the disorder is not established, but in most centers it is second only to Klinefelter’s syndrome as a cause of hypogonadism in men. The disorder was originally described by Kallmann as a familial syndrome associated with anosmia and can be manifest in childhood as microphallus or cryptorchidism. Male urethral development is usually complete. Because most penile growth occurs during the latter two thirds of gestation, the presence of microphallus in this disorder has been interpreted as evidence for a role of pituitary gonadotropin in regulating testosterone production during the later portion of gestation. Growth in childhood is normal although bone age is usually retarded.

Most affected individuals are identified because of failure to undergo puberty. Some individuals, particularly familial cases, have associated defects such as cleft lip or palate, or both; hearing defect; colorblindness; and eye movement abnormalities. Less severely affected individuals have only partial defects in the production of FSH or LH. A variant in which Leydig cell function is impaired despite testes of normal or near-normal size was originally known as the fertile eunuch

Infertile man

Gonadotropin therapy to induce fertility. Administration of hCG over the long term also causes serum testosterone levels to increase to normal adult male levels.

In the infant or the young child with microphallus, administration of testosterone for limited periods (3 months) may cause enlargement of the penis to the normal size.

Three forms of therapy have been used for hypogonadotropic hypogonadism:

1. Androgen replacement to virilize.
2. Gonadotropin therapy to induce fertility.

In the infant or the young child with microphallus, administration of testosterone for limited periods (3 months) may cause enlargement of the penis to the normal size. The more severe the deficiency, the longer GnRH must be administered to correct gonadotropin secretion. Isolated gonadotropin deficiency can be inherited as an autosomal dominant, autosomal recessive, or X-linked trait. The X-linked form with anosmia is the best characterized. The neurons that secrete GnRH originate in the olfactory placode of the fetus and migrate into the brain with the olfactory, terminalis, and vomeronasal nerves. A defect in the KAL gene in the X-linked disorder impairs the migration of these nerves and thus causes GnRH deficiency, the olfactory disturbance, and hypoplasia of the olfactory bulbs. The genetic locus has been assigned to Xp22.3, and the gene encodes a protein, anosmin, that has homology to neural cell adhesion molecules. In a study of 104 individuals with isolated gonadotropin deficiency, Oliveira and colleagues identified KAL mutations in 3 of 21 familial and in 4 of 39 sporadic cases but in no instance in the absence of anosmia and concluded that the majority of mutations do not involve KAL.

In the presence of olfactory disturbances, other midline defects, a positive family history, or a combination of these factors, the diagnosis of the KAL disorder is not difficult to establish either in an infant with microphallus or in an under-virilized adult. In men with anosmia or hyposmia, defects of the rhinencephalon may be demonstrated by magnetic resonance imaging. In older individuals without midline abnormalities or anosmia and with uninformative family histories, the diagnosis can be made (after the presence of a pituitary tumor is excluded) by documenting a normal acute response to GnRH administration after a week of GnRH treatment. This approach is rarely followed in practice. In the middle teen years, separation of individuals with hypogonadotrophic hypogonadism from those with delayed puberty may require prolonged observation (see Chapter 24).

Additional mutations that cause gonadotropin deficiency encompass a variety of different mechanisms. One involves a mutation on the X chromosome that causes the X-linked form of adrenal hypoplasia congenita in which adrenarcheal insufficiency is associated with hypogonadotropic hypogonadism and which is due to mutations or deletions of the DAX1 gene (see earlier), which encodes a member of the nuclear hormone receptor family of transcription regulatory factors that are expressed in the hypothalamus, pituitary gland, adrenal glands, and gonads. The fact that the response of LH to GnRH is variable suggests underlying defects in both the hypothalamic and pituitary gland.

One individual with adrenal hypoplasia congenita virilized in response to hCG, but 3 years of combination therapy with hCG and HMG did not induce spermatogenesis. The adrenarcheal insufficiency is manifested during infancy, and the hypogonadotropic hypogonadism is recognized at the time of expected puberty, although rarely both may be incomplete or late in onset.

Mutations in the GnRH receptor can cause an autosomal recessive form of congenital isolated gonadotropin deficiency unassociated with anosmia. The phenotype is variable, even within a given family, with some patients having partial responses to GnRH and partial hypogonadism. One family exhibited a decrease in the amplitude of LH pulses.

A functional form of hypogonadotropic hypogonadism has been described in a family with a mutation in the LH gene. The proband did not undergo spontaneous puberty and had low plasma testosterone and elevated immunoreactive LH levels, but testosterone levels increased after administration of exogenous LH and hCG. A missense mutation in the LH gene impaired binding of LH to the LH receptor. Heterozygous male carriers for the mutation may have low testosterone levels and impaired fertility.

Similarly, a partial deletion of the coding sequence of the FSH gene caused a truncation of the molecule and hypogonadism in one man. Serum FSH was undetectable, and LH levels were elevated despite the low testosterone level, suggesting that the absence of FSH impaired Leydig cell function.

Hypogonadotropic hypogonadism also occurs in the Prader-Willi syndrome (obesity, short stature, mental retardation, and hypotonia) caused by partial deletions or uniparental disomy of chromosome 15.

Three forms of therapy have been used for hypogonadotropic hypogonadism:

1. Androgen replacement to virilize.
2. Gonadotropin therapy to induce fertility.

In the infant or the young child with microphallus, administration of testosterone for limited periods (3 months) may cause enlargement of the penis to the normal range without affecting linear growth or causing other significant virilization. In the older child or the adult, long-acting testosterone esters are administered parenterally, as with other forms of hypogonadism (see later). As in other forms of androgen deficiency, the closer to the time of onset of normal puberty that replacement therapy is begun, the more effective the promotion of normal virilization.

Administration of hCG over the long term also causes serum testosterone levels to increase to normal adult male levels. In men with severe (prepubertal) hypogonadotropic hypogonadism, however, the induction of fertility usually requires the administration of FSH, in the form of human menopausal gonadotropin, in addition to hCG. The response to gonadotropin therapy is not influenced by prior testosterone therapy but is a function of the initial testis size, men with testes less than 4 mL in volume responding less favorably. Once a normal sperm count is achieved, it may be maintained by use of hCG or, occasionally, by testosterone esters. In rare cases of partial defects in gonadotropin secretion, spermatogenesis can be promoted by testosterone therapy alone. The long-term administration of GnRH in a pulsatile manner to men with hypogonadotropic hypogonadism results in normal plasma testosterone levels, normal pulsatile secretion of LH, normal mean levels of plasma LH and FSH, and, in most, mature sperm in the ejaculate.

Acquired isolated gonadotropin deficiency can be caused by pathologic states that impair the hypothalamus or pituitary secondarily. For example, elevated plasma cortisol levels, as in Cushing's syndrome, can depress LH secretion independently of a space-occupying lesion of the pituitary. Likewise, chronic administration of exogenous glucocorticoids can lower testosterone levels by inhibiting GnRH secretion.
by impairing GnRH release. Administration of low doses of bromocriptine to men with microadenomas caused an initial increase in plasma LH level and a subsequent increase in serum testosterone level. The preferred treatment is bromocriptine or cabergoline (see Chapter 8).

Hemochromatosis causes iron deposition in the pituitary gland and testes, and about half of affected men have hypogonadism, usually accompanied by testicular atrophy. Abnormal testicular function in this disorder may result in part from the associated liver disease, but most testicular dysfunction is due to hypogonadotropic hypogonadism. The pituitary nature of the hypogonadism was recognized because of the lack of response of LH to GnRH administration and the normal response of plasma testosterone to hCG. A primary testicular abnormality may also occur. Acquired transfusional iron overload can cause similar abnormalities of the pituitary-testicular axis. In both states, reduction of iron stores may result in recovery of gonadotropin secretion.

Hypothalamic or pituitary injury can occur after head trauma even in the absence of fracture, and the most common manifestation is deficiency of gonadotropins and human growth hormone, although multiple deficiencies can be present. Clinical evidence of hormone deficiency may be apparent immediately after injury or not until years later. In conditions in which testosterone levels are decreased despite normal LH levels, the mechanism is less clear. Men with massive obesity have decreased SHBG levels and decreased levels of total and bioavailable testosterone that return toward normal with weight loss. For example, in men with a body mass index greater than 40, free testosterone levels, LH, and LH pulse amplitude are decreased, implying malfunction of the hypothalamic-pituitary system. Obesity may be the cause of decreased testosterone levels in the pickwickian syndrome. Men with temporal lobe seizures may also have hormonal findings consistent with hypogonadotropic hypogonadism. Finally, acquired hypogonadotropic hypogonadism may be idiopathic.

Abnormalities of testicular function in the adult can be grouped into developmental and structural defects of the testes, acquired testicular defects, abnormalities associated with systemic or neurologic diseases, and androgen resistance.

The preferred treatment is bromocriptine or cabergoline (see Chapter 8). The more severe defects in LH receptor function result in an autosomal recessive form of male pseudopseudohernaphroditism in which 46,XY individuals have a female phenotype, a blind-ending vagina, and inguinal testes with absence of Leydig cells (Leydig cell hypoplasia) (see also Chapter 22). Less severe impairments of LH receptor function are associated with variable defects, including a male phenotype and microphallus. Testosterone levels are low in the presence of elevated gonadotropins. In most subjects, the phenotypic defects correlate with both the basal level of the LH receptor and the response of plasma testosterone to hCG, but in one individual with a male phenotype associated with a deletion of exon 10 of the LH receptor gene, serum testosterone levels increased after treatment with hCG.

Klinefelter's Syndrome.

The most common developmental defect of the testis is Klinefelter's syndrome (see also Chapter 22). The disorder is characterized by small, firm testes; various degrees of impaired sexual maturation; azospermia; gynecomastia; and elevated gonadotropin levels. The underlying abnormality is the presence of an extra X chromosome, the usual chromosomal karyotype being either 47,XXX (classic form) or 46,XY/47,XXX (mosaic form). The incidence is approximately 1 in 500 males.

Prepubertal boys with Klinefelter's syndrome have small testes with a decreased number of spermatogonia but are endocrinologically normal; the diagnosis at this age may be made on the basis of the cognitive features (see later). The diagnosis is usually made after the time of expected puberty because of gynecomastia or underandrogenization and later by infertility (Table 18-4). Damage to the seminiferous tubules and azoospermia are consistent features of the 47,XXX variety. The small, firm testes usually less than 2 cm in length and less than 4 mL in volume. Histologic changes in the testes include hyalinization of the tubules, absence of spermatogenesis, and an apparent increase in the number of Leydig cells (see Fig. 18-17 C).

Mean body height is increased because of a longer lower body segment; the presence of this feature before puberty suggests that it is not secondary to androgen deficiency but is probably related to the underlying chromosomal abnormality. Gynecomastia occurs in about 85% of affected individuals, develops during adolescence, is usually bilateral and painless, and may become disfiguring.

Klinefelter's syndrome can cause learning disabilities and poor impulse control. These tendencies may explain the increased frequency of the disorder among men in mental and penal institutions. Indeed, although many men with the disorder have above average or superior intelligence, poor school performance is common, with decreased verbal scores and a higher incidence of dyslexia and attention-deficit disorder.

The risk of breast cancer is increased, presumably because of the presence of gynecomastia, and there is an increased prevalence of extragonadal germ cell tumors in the mediastinum and brain. Autoimmune disorders appear to be more common, perhaps related to the altered levels of gonadal hormones.
Varicose veins, venous stasis ulcers, and thromboembolic disease are also more common. Levels of plasminogen activator inhibitor 1 were reported to be elevated in subjects with Klinefelter's syndrome with leg ulcers but not in those without leg ulcers. Forty percent of men with Klinefelter's syndrome have taurodontism, an abnormality of the dental pulp that predisposes to early tooth decay. Most have a male psychosexual orientation and function sexually as men. The syndrome may go undiagnosed in the majority of affected men, even as adults.

46,XY/47,XXY mosaicism is the cause of about one fourth of cases of Klinefelter's syndrome, as estimated by chromosomal karyotypes of peripheral blood leukocytes. The true prevalence may be underestimated because chromosomal mosaicism can be present in the testes in individuals in whom the chromosomal karyotype of peripheral leukocytes is normal. As summarized in Table 18-4, the manifestations of the mosaic form are usually less severe, and the testes may be normal in size. The endocrine abnormalities are also less severe, and gynecomastia and azoospermia are less common, with occasional men being fertile. Additional karyotypic variations of Klinefelter's syndrome have been described (see Chapter 22).

The 47,XXY form of Klinefelter's syndrome is due to mectic nondisjunction of the chromosomes during gametogenesis. About 40% of the responsible meiotic nondisjunction occur in the father and 60% occur in the mother. Advanced maternal age is a predisposing factor in the latter cases. In contrast, mitotic nondisjunction after fertilization of the zygote causes the mosaic form and can arise in either a 46,XY zygote or a 47,XXY zygote.

Characteristic endocrine changes include elevation of plasma FSH and LH levels. FSH shows the best discrimination, and little overlap occurs with normal individuals, a consequence of the consistent damage to the seminiferous tubules. In the late teens, the plasma testosterone level may be normal. By the middle 20s, the plasma testosterone level averages half the normal value, but the range is broad and overlaps the normal range. Mean plasma estradiol levels are elevated, and SHBG levels are about twice normal. The net result is a variable degree of feminization and insufficient androgenization.

The feminization, including development of gynecomastia, is thought to depend on the ratio of circulating estrogen to androgen (see later). Before puberty, plasma gonadotropin levels and the response to GnRH are normal, but by the time of expected puberty plasma gonadotropins and the response to GnRH are elevated. Older men with untreated Klinefelter's syndrome may have an enlarged or an abnormal sella turcica, presumably secondary to impairment of gonadal steroid feedback and gonadotrope hyperplasia.

Optimally, affected boys should be identified in childhood to allow treatment of the testosterone deficiency early before it has an effect on BMD and to prevent adverse psychological effects of incomplete sexual maturation. The commencement of testosterone replacement before age 20 results in a normal BMD, whereas institution of therapy in older individuals does not enhance BMD. Androgen replacement has no effect on fertility but has the same general benefits as in other forms of male hypogonadism. Plasma LH levels usually return to normal with therapy, sometimes after many months. Men with rare spermatozoa in the ejaculate or with spermatids or more advanced stages of spermatogenesis on biopsy may achieve fertility with in vitro fertilization using ICSI (see later). However, as many of 15% of the sperm produced by men with the disorder contain a 24,XY chromosome composition, which may result in an increased incidence of the disorder in offspring.

XX Male Syndrome.

The XX male syndrome, a variant of Klinefelter's syndrome, occurs in about 1 in 20,000 male births. The tests are small and firm, generally less than 2 cm long; gynecomastia is usual; the penis is normal to small in size; and azoospermia and hyalinization of the seminiferous tubules are present. Affected individuals have male psychosexual identification and absence of female internal genitalia. The mean plasma testosterone level is low, and levels of plasma estradiol and gonadotropins are high. The phenotype differs from that of Klinefelter's syndrome in that the average height is less than that of normal men, the incidence of cognitive impairment is not increased, and hypospadias or ambiguous genitalia may be present.

Four theories were proposed to explain male development in the absence of a Y chromosome: (1) mosaicism in some tissues for a Y-chromosomecontaining cell line, (2) a gain-of-function mutation for some autosomal gene, (3) deletion or inactivation of some gene or genes that normally suppress testicular development, and (4) interchange of a portion of the Y chromosome with the X chromosome. Evidence has now been obtained for the presence of mechanisms 1, 2, and 4 in men with this disorder. Y-chromosome sequences are detectable in approximately 80% of 46,XX men and are usually located in the distal region of the X chromosome. Thus, the etiology in most XX males is analogous to that in the sxd mouse, in which a fragment of the X chromosome has been translocated to the X chromosome.

Mosaic involving an intact Y chromosome was present in 1% of the cells in one individual.

The other third of 46,XX men are Y-negative and lack sequences for SRY. The Y-negative group is more likely to have ambiguity of the external genitalia, whereas the Y-positive group has the Klinefelter phenotype. The translated region of the Y can be quite small and involve only the SRY gene itself. The SRY-negative variant is sometimes familial and may occur in families with true hermaphroditism, suggesting that these disorders are due to variable manifestations of the same genetic defect. Such a defect could either be autosomal or X-linked. One 46,XX male had a duplication of the 509X gene (a downstream gene involved in SRY-mediated testicular differentiation), indicating an autosomal mechanism.

In one SRY-positive man with genital ambiguity, the presence of a duplication of the 509X gene, a downstream target of SRY in testicular differentiation, indicated autosomal inheritance. Most SRY-positive 46,XX males do not have genital ambiguity, and in one SRY-positive man with genital ambiguity more than 90% of the of the Y fragment containing SRY was located on the inactive X chromosome in blood lymphocytes. In parallel studies of a 46,XX man with no ambiguity, the Y fragment was located predominately in the active X chromosome. These findings document the complexity and heterogeneity of the disorder. The management is similar to that for Klinefelter's syndrome.

Acquired Defects

Mumps.

The most common cause of acquired testicular failure in the adult is viral orchitis. Mumps virus is most frequent, but echovirus, lymphocytic choriomeningitis virus, and group B arboriviruses also cause orchitis. The disorder is due to infection of the tissue by the virus rather than to indirect effects of infection. Orchitis is common in mumps, occurring in as many as a fourth of adult men with the disease. In about two thirds of cases it is unilateral. It usually develops 4 to 8 days after the onset of parotitis but occasionally precedes it. After the acute inflammatory phase, the tests gradually decreases in size, although swelling can persist for months. The tests may return to normal size and function or undergo atrophy. The atrophy results from both the direct effects of the virus and ischemia caused by pressure and edema within the taut tunica albuginea. The histologic features of the atrophic tests include progressive tubular sclerosis and hyalinization. The degree of atrophy is not necessarily proportional to the severity of the orchitis. It is usually apparent within 1 to 6 months after the orchitis subsides, but the full extent of damage may not be evident for many years. Atrophy occurs in approximately a third of men with orchitis and is bilateral in about a tenth. The hormonal changes associated with gynecomastia related to mumps orchitis include normal estrogen and decreased testosterone production.

The frequency with which mumps results in infertility is not known. Almost 50% of men with unilateral mumps orchitis have sperm densities of less than 10 million/mL in the first 3 months, but the sperm count returns to normal within 1 to 2 years in about 75%. In contrast, semen parameters return to normal in less than a third of men with bilateral orchitis.

The initial treatment is bed rest and scrotal support. If pain is severe, administration of prednisone can reduce swelling and pain. Glucocorticoid therapy does not appear to have a beneficial effect on the return of the sperm count to normal. In one study, treatment with interferon shortened the duration of symptoms and...
Effects on plasma LH levels.

Both spermatogenesis and testosterone production are sensitive to radiation; impaired secretion of testosterone appears to result from decreased testicular blood flow. The incidence of radiation-associated damage to Leydig cells is directly related to the dosage and inversely related to age at treatment. Most prepubertal boys have normal plasma testosterone levels and normal pubertal maturation after receiving 12 Gy of radiation to the testes, but the presence of an increased LH level in some suggests that compensatory changes are involved in the achievement of normal testosterone levels. In most prepubertal boys, radiation doses greater than 20 Gy cause permanent testosterone deficiency. In contrast, radiation doses above 30 Gy cause testosterone deficiency in only half of adolescent boys and young adults. (Also see “Infertility with Normal Virilization.”)

Drugs.

Drugs can cause underandrogenization and infertility in several ways: direct inhibition of testosterone synthesis, blockade of the peripheral actions of androgen, and enhancement of estrogen levels. In addition, agents such as propranolol and guanethidine can impair erectile function in men whose hypothalamic-pituitary-testicular axis is normal.

Two drugs that in high doses block testosterone synthesis are spironolactone and cyproterone, both of which interfere with the late reactions in testosterone biosynthesis. Spironolactone appears to impair CYP17 activity. Plasma testosterone levels do not change appreciably, however, during usual therapeutic regimens.

The antifungal agent ketoconazole blocks testosterone synthesis, also by inhibiting CYP17 activity. The decrease in testosterone after a single dose of ketoconazole is transient, with the nadir occurring within 4 to 8 hours and testosterone returning to baseline within 24 hours as ketoconazole levels fall. However, with doses of ketoconazole greater than 400 mg/day, depression of plasma testosterone levels may be sustained. Impairment of libido is common in men with epilepsy, partly as a consequence of medication.

Enzyme-inducing antiepileptic drugs such as phenytoin and carbamazepine lower bioavailable testosterone, raise plasma SHBG and LH levels, and decrease the metabolic clearance of testosterone. The effect is more pronounced with multiple-drug regimens. Valproic acid does not appear to have as severe an adverse effect in this regard.

Independent of its effects on the liver, ethanol ingestion reduces testosterone levels acutely and chronically. The result of inhibition of testosterone synthesis. The inhibition of steroidogenesis appears to occur at the 3-β-HSD reaction as the result of a decrease in the concentration or availability of the pyridine nucleotide cofactors for the reaction, an effect probably mediated by the ethanol metabolite acetaldehyde. The fact that ethanol lowers testosterone levels without causing appropriate elevations of plasma LH suggests that hypothalamic-pituitary function is also impaired. Ethanol can also impair spermatogenesis.

Antineoplastic and chemotherapeutic agents, especially cyclophosphamide, commonly induce infertility (see later). Combination chemotherapy for acute leukemia, Hodgkin's disease, and other malignancies may also impair Leydig cell function. This toxic effect on the Leydig cell seems to be produced primarily by alkylating agents. Treatment with alkylating agents during the prepubertal years does not interfere with testicular function in later life, but elevated LH levels develop in many men after treatment, implying the presence of subclinical Leydig cell dysfunction. Treatment of adult men with alkylating agents does not alter LH or testosterone levels. High-dose interleukin-2 therapy for metastatic cancer causes a transient reduction in serum testosterone levels.

Plasma testosterone levels may be low in men ingesting large amounts of marijuana, heroin, or methadone. Plasma LH is usually normal, suggesting combined hypothalamic-pituitary and testicular defects. Hyperprolactinemia may contribute to the lowering of testosterone levels.

Elevated plasma estradiol and decreased plasma testosterone levels may occur in men taking digitalis preparations, the mechanism being unclear.

Drugs can interfere with gonadotropin production either as the result of a direct inhibition (as in medroxyprogesterone acetate administration) or as a secondary consequence of enhanced prolactin secretion (as with phenothiazine therapy). Medroxyprogesterone may also impair testosterone secretion at the testicular level.

Several drugs inhibit androgen action by competition at the receptor level. Although spironolactone can inhibit testosterone synthesis, in the usual dosage regimens it acts primarily by antagonizing the binding of androgen to the androgen receptor, which leads to gynecomastia and impotence.

Cyproterone also acts as an androgen antagonist. The most commonly administered androgen antagonist is cimetidine. Gynecomastia can occur in men who are treated with the drug, and decreased sperm density and elevated basal testosterone levels are accompanied by impairment of the LH response to GnRH.

Ranitidine appears to be a less potent antiandrogen. Omeprazole can also cause gynecomastia and impotence.

Environmental Toxins.

Prolonged exposure to lead results in direct testicular toxicity and an impaired pituitary response of plasma LH.

Autoimmune Disorders.

Testicular failure can occur as part of a generalized autoimmune disorder in which multiple primary endocrine deficiencies coexist and circulating antibodies to the basement membrane of the testes are present (see Chapter 37).

Granulomatous Disease.

The testes can also be involved in granulomatous disease. Testicular atrophy occurs in 10% to 20% of men with lepromatous leprosy as the result of invasion of the tissue and in some instances of paratesticular structures as well) by the bacilli. The result is a decreased plasma testosterone level and elevated plasma LH and FSH levels. Destruction of the testis is less common with other systemic granulomatous diseases.

Abnormalities of the hypothalamic-pituitary-testicular axis occur in a number of systemic diseases. Given the chronic ill health and generalized wasting that may coexist, it is often difficult to distinguish specific effects of the underlying condition (e.g., renal failure from those of malnutrition. The inflammatory cytokines interleukin-1, tumor necrosis factor, and interleukin-6 lower testosterone and have variable effects on plasma LH levels. In in vitro preparations, these agents inhibited several steroidogenic enzymes and SIAR protein.
Renal Failure.

About 50% of men undergoing dialysis for renal failure experience decreased libido and impotence associated with impairments in both spermatogenesis and testosterone biosynthesis. The defect in spermatogenesis varies from partial to total destruction of the germ cells. The decrease in plasma testosterone and increase in plasma LH and FSH levels indicate a defect at the testicular level. Plasma testosterone production rates are decreased, and the response of plasma testosterone to hCG is subnormal. After dialysis, plasma testosterone levels and testosterone production rates improve but usually not to the normal range.

Hyperplactinemia occurs in 25% of men who undergo long-term dialysis. In contrast, successful renal transplantation results in a return of testosterone and prolactin levels to normal and a slight decrease in LH and FSH levels. Most men experience improved sexual function after transplantation, and half have sperm densities of more than 10 million/ml.

Hepatic Diseases.

Cirrhosis of the liver can impair testicular function apart from the direct toxic effects of ethanol. Gynecomastia and testicular atrophy occur in half of men with cirrhosis, and 75% of men with hepatic cirrhosis are impotent. Decreased spermatogenesis and peritubular fibrosis are present in about 50% of patients. Plasma estradiol levels are usually elevated, and plasma testosterone levels are decreased. The net result is a ratio in serum of unbound estradiol to unbound testosterone that is about 10 times normal. Levels of SHBG are about twice normal. The metabolic clearance and production rates of testosterone are decreased, and estradiol production is increased.

Extraluminal conversion of androgens, primarily adrenal androgens, to estradiol and estrone is increased about three-fold, presumably because of decreased hepatic extraction of androgens. Basal levels of LH and FSH range from normal to moderately elevated. In men with low testosterone levels pulsatile LH secretion is impaired, implying a defect at the hypothalamic-pituitary level, whereas dynamic tests of the pituitary-testicular axis and hCG responsiveness tests point to a testicular defect.

Gonadotropin levels decrease as liver function fails. The reason for abnormal testicular and hypothalamic-pituitary function is uncertain. Elevated estrogen levels can cause both defects. Testosterone therapy has been tried. Although estradiol levels increase (in correlation with the severity of the cirrhosis) after androgen therapy, there may be normal or increased testosterone excretion, the estrogen/testosterone ratio may become normal, and gynecomastia may regress. Men with alcoholic cirrhosis may experience spontaneous recovery of sexual function with abstinence from alcohol despite persistent liver abnormalities. Men with alcoholic cirrhosis and testicular atrophy, however, are less likely to experience improvement in sexual function with abstinence from alcohol. Sexual function and testosterone levels are also decreased in men with other forms of liver disease. The hormonal abnormalities in the pituitary-testicular axis can be reversed by liver transplantation.

Sickle Cell Anemia.

Sexual maturation can be impaired in boys with sickle cell anemia. Furthermore, in adult men with sickle cell anemia, secondary sexual characteristics are subnormal in most and testicular atrophy occurs in about a third. Testicular biopsy in two men revealed maturation arrest of spermatogenesis. The defect may be either testicular or hypothalamic.

Chronic Illness.

Abnormal Leydig cell function, frequently accompanied by decreased sperm counts, occurs in many systemic diseases including protein-calorie malnutrition, advanced Hodgkin's disease and cancer before chemotherapy, cystic fibrosis, chronic pulmonary disease, and amyloidosis. Such disorders usually cause a low plasma testosterone level and either a normal or slightly increased plasma LH level, suggesting combined hypothalamic-pituitary and testicular defects. The low plasma testosterone level is not the result of plasma factors that inhibit its binding to SHBG and hence is not analogous to that in the euthyroid sick syndrome (see Chapter 10). Indeed, because mean plasma SHBG levels are elevated, bioavailable testosterone may be lower than total testosterone. These changes in testosterone and LH may be nonspecific effects of illness because similar changes occur after myocardial infarction, and severe burns.

Thyrotoxicosis.

The changes in the hypothalamic-pituitary-testicular axis in thyrotoxicosis may be secondary to increased estrogen levels and include decreased sperm count and semen volume, increased plasma total testosterone level, and normal levels of unbound testosterone. The testosterone response to hCG is blunted, and basal LH levels are increased.

Immune Disorders.

Immune disease may cause testicular dysfunction, and primary or secondary hypogonadism is common in men with acquired immunodeficiency syndrome (AIDS), about half of whom have low testosterone levels with normal or appropriately increased plasma LH. Although the disease may involve the testes directly, the hormonal changes suggest a nonspecific response to systemic illness and perhaps the toxic effects of immune cytokines. Many HIV-positive men who progress to AIDS have a transient state of increased LH and normal testosterone levels before testosterone levels become low. Serum SHBG levels are increased in HIV-positive men independent of CD4 count but bioavailable testosterone levels decrease progressively as CD4 counts decline. Levels of bioavailable testosterone decline in men with AIDS before wasting occurs.

The current practice is to provide androgen replacement in men with AIDS when testosterone deficiency becomes manifest. Testosterone replacement in such men results in an increase in lean body mass, improved quality of life, and increased muscle strength. Men with rheumatoid arthritis may have low serum testosterone, particularly during disease flares and while they are receiving glucocorticoids. In contrast, testosterone levels are usually normal in men with long-standing, stable rheumatoid arthritis.

Neurologic Disease.

Neurologic disease can cause testicular abnormalities. Men with myotonic dystrophy usually have small testes, low plasma testosterone levels, and elevated plasma LH and FSH levels. Spinobulbar muscular atrophy (Kennedy's syndrome) is a form of adult-onset degenerative motor neuropathy associated with gynecomastia, testicular atrophy, a hormonal profile suggestive of androgen resistance (see later), and an expansion of the homopolymeric glutamine repeat region in the amino-terminal end of the androgen receptor gene. Although the effects are variable, spinal cord lesions that cause quadriplegia or paraplegia initially cause diminished plasma testosterone levels that usually return toward normal, but semen parameters may be permanently abnormal. Some paralyzed men retain the capacity to have erections and ejaculate, depending on the extent of involvement of the lumbosacral spinal cord.

Men with trisomy 21 (Down's syndrome) have impairment of both germinal and Leydig cell function and elevation of FSH and LH levels.

Androgen Resistance.

Partial androgen resistance can cause underandrogenization and infertility in men with normal external genitalia. In such men, androgen resistance is manifested by increased testosterone production, elevated plasma LH levels in some, and abnormal androgen receptors in cultured genital skin fibroblasts. The presence of elevated testosterone or LH levels, or both, is not a reliable predictor of which men have a receptor defect. Testicular biopsy reveals maturation arrests or germinal
cell aplasia similar to that shown in Figure 18-16D and E. In some families, affected men have had gynecomastia and undervirilization but, in some, preserved fertility.\(^{112}\) Point mutations have been identified in the androgen receptor in men with the isolated infertility and undervirilized, fertile male phenotypes (see Chapter 22).\(^{113}\)

Infertility with Normal Virilization

Isolated infertility with normal Leydig cell function is caused by a separate group of disorders. Isolated infertility can be due to defects in the hypothalamic-pituitary system, the testis, or the sperm transport system (see Table 18-3).\(^{114}\)

Hypothalamic-Pituitary Disorders

Isolated FSH deficiency has been reported in men in whom virilization and plasma LH and plasma testosterone levels were normal but plasma FSH levels were persistently low.\(^{115}\) Plasma FSH levels in such men may increase or remain undetectable after GnRH administration. One man with no FSH response to GnRH had a point mutation in the FSH gene.\(^{116}\) In some men with chronic untreated or undertreated congenital adrenal hyperplasia related to CYP21 deficiency, suppression of gonadotropin secretion by adrenal androgens causes infertility.\(^{117}\) This diagnosis is suggested by the presence of small testes, normal to elevated levels of testosterone, and suppressed levels of gonadotropins and is confirmed by finding elevated plasma levels of 17-hydroxyprogesterone and androstenedione (see Chapter 14 and Chapter 22).

When androgens are administered in pharmacologic doses to normal men, gonadotropins are suppressed and about 50% of the men have azoospermia (see Chapter 17). Although men who present with isolated infertility are unlikely to be receiving testosterone replacement therapy, the use of androgens by weight-lifters and body-builders is common. Self-prescribed regimens may include parenteral testosterone esters and a variety of oral and parenteral substituted androgens, often termed anabolic steroids (see later). Supraphysiologic androgen administration can cause reversible azoospermia in normal men.\(^{118}\)

Testicular Disorders

Developmental and Structural Defects

Germinal Cell Defects.

Also known as the Sertoli cell only syndrome, germinal cell aplasia is a poorly understood defect of the testis. The disorder encompasses histologic features that can have several causes, one of which may be a single-gene defect. Other men with typical histologic and clinical features have a history of viral orchitis, cryptorchidism,\(^{119}\) alcoholism,\(^{120}\) or androgen resistance.\(^{121}\) Testicular biopsy reveals complete absence of germinal elements (see Fig. 18-16F). The clinical features include azoospermia, normal virilization, absence of gynecomastia, normal to small testes, and normal chromosomal complement. Plasma testosterone and LH values are usually normal, and plasma FSH values are high.

The concept of germinal cell aplasia became even more complex with the recognition that one or more Y chromosome determinants other than the SRY gene are essential for spermatogenesis.\(^{122}\) Some men have a deletion of the long arm of the Y chromosome that includes an azoospermia factor (AZF) that maps to Yq11.23-12.\(^{123}\) As many as 18% of men with azoospermia (occasionally severe oligospermia) have chromosome microdeletions in this region.\(^{124}\) Testicular histology varies from germinal cell aplasia to maturation arrest, and the plasma FSH values are high.

Candidate genes for AZF have been identified by positional cloning; the first is a family of genes termed Y-located RNA recognition motif (YRMR) genes\(^{125}\) that encode RNA-binding proteins. The YRMR genes are expressed in germ cells, but the fact that multiple genes exist in this family makes it hard to assess their function.

The second AZF candidate, termed DAZ (deleted in azoospermia), also encodes a testis-specific RNA recognition motif.\(^{126}\) In one study, microdeletions in the AZF region were present in a third of men with idiopathic azoospermia and a fourth of men with oligospermia of unknown origin.\(^{127}\) These microdeletions include the DAZ and YRMR regions and additional sequences.\(^{128}\) Microdeletions were present in 7% of 46,XY men with known causes of infertility.\(^{129}\)

A mutation in the FSH receptor gene in several Finnish families is associated with variable defects in spermatogenesis and infertility.\(^{130}\)

Histologic findings in men with azoospermia include hypospermatogenesis or spermatogenic arrest (see Fig. 18-16F). Familial male infertility with hypospermatogenesis or maturation arrest can be inherited as X-linked\(^{131}\) or autosomal recessive traits.\(^{132}\) In most men, however, the family history is uninformative\(^{133}\) and the cause of infertility is unknown. In both familial and sporadic cases, meiosis is defective.

Cryptorchidism.

Unilateral cryptorchidism, even when corrected before puberty, is associated with abnormal semen in many individuals (see earlier). This finding suggests that the testicular abnormality is bilateral even in unilateral cryptorchidism.

Varicocele.

Varicocele is believed to be the most common treatable cause of male infertility, possibly of causative importance in a third of infertile men.\(^{134}\) Varicocele is caused by retrograde flow of blood into the internal spermatic vein and results in a progressive, often palpable, dilation of the pampiniform plexus of veins. It is thought to be due to incompetence of the valve between the internal spermatic vein and the renal vein and is more common (85%) on the left. The incidence of varicocele is about 10% to 15% in the general population and 20% to 40% in men with infertility. The findings on semen analysis are usually nonspecific, but sperm density is often decreased with medium or large varicocoeles.\(^{135}\)

Most men with varicocele are fertile and have no detectable abnormality of the hypothalamic-pituitary-testicular axis. The leading theory concerning the adverse effect is that varicocele leads to an increased scrotal (and testicular) temperature, and the elevated scrotal surface temperatures in men with both unilateral and bilateral varicoceles can improve after surgical repair.\(^{136}\) The tests on the side of the varicocele may be small.\(^{137}\) Men with varicocele can also have unrelated causes of infertility.\(^{138}\) Of men with varicocele and sperm counts less than 5 million/mL, about a fifth have microdeletions in the Y chromosome.

On average, semen quality improves after surgical repair of varicoceles, but the effect on fertility is inconsistent in that impregnation rates after varicocele repair are probably less than 50%. In one large study of almost 100 men there was an association between subsequent fertility and preoperative sperm density, and the men with preoperative sperm densities greater than 10 million/mL had a 70% impregnation rate after repair.\(^{139}\)

Immotile Cilia Syndrome.

The immotile cilia syndrome is a hereditary disorder characterized by defective motility of the cilia in the airways and elsewhere in the body and either immotile or poorly motile sperm.\(^{140}\) The disorder is usually inherited as an autosomal recessive trait. In the airways, defective cilia cause chronic sinusitis and bronchiectasis and the immotile sperm cannot fertilize. Kartagener's syndrome is a subclass of the syndrome and is associated with situs inversus.

The structural abnormalities that impair motility of cilia can be defined by electron microscopy and include missing or abnormally short dynein arms, short spokes with no central sheath, missing central microtubules, and displacement of one of the microtubule doublets. Cilia from epithelia and sperm from the same individual usually exhibit the same defects, but some mutations can apparently result in immotile sperm without impairment of cilia in the lung.\(^{141}\) In evaluating sperm for structural
abnormalities, the physician should take care to examine a number of axonemes and to confirm the structural defect because axonemal structure can vary in normal respiratory cilia and sperm. The infertility should be treatable, at least theoretically, by empirical methods (see later).

Acquired Defects

Mycoplasma Infection.

A role for Mycoplasma (Ureaplasma urealyticum) in infertility is inferred because infections are common in women whose infertility is associated with a “male factor,” suggesting that genital tract mycoplasma infection may cause male infertility.  Other evidence suggests that the severity of mycoplasma infection in men does not correlate with any specific alteration in sperm density or morphology.  Other evidence suggests that the presence of mycoplasma in the lower urogenital tract may represent silent colonization rather than infection.

Radiation.

Radiation can cause isolated infertility, with damage sometimes being demonstrable after only 0.15 Gy (15 rad). Doses higher than 1 Gy (100 rad) can cause extreme oligospermia or azoospermia, and higher doses decrease sperm counts and damage spermatids. A return to baseline sperm density takes 9 to 18 months after doses of 1 Gy (100 rad) or less, 30 months for doses of 2 to 3 Gy (200 to 300 rad), and 5 years or more for doses of 4 to 6 Gy (400 to 600 rad).  Fracionated radiation may have a more profound effect on the testes than single doses.

Permanent infertility can occur after radiation for malignant lymphoma of the abdomen despite shielding of the testes.  Administration of radioactive iodine to men for thyroid cancer can also impair spermatogenesis and elevate plasma FSH levels; recovery occurs in about 2 years.  Prior suppression of testicular function by administration of testosterone or GnRH, or both, does not protect the testes from radiotherapy (or cytotoxic drugs).

Drugs.

The principal drugs that cause isolated infertility are alkylating agents such as cyclophosphamide.  Spermatocytes and spermatogonia may disappear completely, causing the picture of germinal aplasia with only Sertoli cells lining the tubular lumen. Serum FSH levels can increase fivefold and serve as a marker for germ cell loss; levels of inhibin B decline.  Serum LH and testosterone levels usually remain within normal limits. Cessation of cyclophosphamide therapy is followed by return of spermatogenesis within 3 years in about half of azoospermic men.  Vinblastine, doxorubicin, procarbazine, and cisplatin are also toxic to the germinal epithelium.

Combination regimens such as mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) have an even more profound impact on spermatogenesis.  The combination of doxorubicin, bleomycin, vinblastine, and dacarbazine is less toxic than MOPP.  Combination chemotherapy that includes cyclophosphamide or procarbazine causes postpubertal azoospermia in about half of prepubertal boys, whereas etoposide in combination chemotherapy causes less toxicity.

Chemotherapy-induced azoospermia after treatment with vinblastine, bleomycin, and cisplatin for testicular cancer is usually reversible within 2 years of stopping treatment,  but cisplatin is thought to be the primary mediator of the toxicity.

Sulfasalazine and methotrexate can also cause oligospermia and infertility.

Environmental Toxins.

Because of the potential toxicity of physical and chemical agents, the occupational and recreational history should be carefully evaluated in all men with infertility.  Known environmental toxins include chemicals such as the nematocide dibromochloropropane and related compounds, ethylene glycol, cadmium, lead, and organic chloride compounds.  In a large meta-analysis of studies of normal men, sperm density was said to have declined from 113 million/mL in 1940 to 66 million/mL in 1990.  This report has subsequently been confirmed and refuted (reviewed in reference ). Environmental toxins that might act as estrogens or antiandrogens have been proposed as the cause. Cigarette smoking may also contribute to decreasing sperm density.

Autoimmunity.

Although autoimmunity may cause combined underandrogenization and infertility, the usual manifestation is isolated infertility, and antibodies to the basement membrane of the seminiferous tubules or to the sperm themselves may be responsible. Antisperm antibodies of the immunoglobulin A (IgA) class may prevent the penetration of cervical mucus by sperm.  IgG and IgA antibodies may impair the acrosome reaction and the binding of sperm to the zona pellucida of the oocyte.

Therapy usually involves in vitro fertilization (see later). Development of antisperm antibodies is not always a primary phenomenon because the antibodies have been identified in men with both bilateral and unilateral obstruction of the vas deferens and after vasectomy.

Defects Associated with Systemic Diseases

Temporary impairment of semen quality, particularly decreased sperm density, is common after acute febrile illness.  This is one reason that several semen analyses must be obtained in the work-up for men with infertility to be confident that true basal parameters have been determined (see earlier). Men with celiac disease have a distinct testicular abnormality, namely, endocrine features typical of androgen resistance with elevated plasma testosterone and LH levels.

Improvement in gluten enteropathy may reverse the androgen resistance-like state.

As discussed earlier, spinal cord injury is commonly associated with isolated infertility.

Androgen Resistance

Androgen resistance may cause infertility without underandrogenization (see earlier).  It was originally thought on the basis of functional studies that androgen receptor defects might account for 10% to 20% of idiopathic azoospermia or severe oligospermia, but loss-of-function mutations in the androgen receptor gene are present in only about 2% of such men.  Expansion of the CAG repeat sequence in the N-terminal region of the androgen receptor (see earlier) appears to be more common in men with azoospermia or severe oligospermia.

Impairment of Sperm Transport

Disorders of sperm transport may cause as much as 6% of male infertility.  Such disorders can be unilateral or bilateral, congenital or acquired. Infertility in men with unilateral obstruction may be due to antisperm antibodies. Obstructive azoospermia at the level of the epididymis also occurs in association with chronic infections of the paranasal sinuses and lungs.

In polycystic kidney disease, dilated cysts of the seminal vesicles may obstruct semen transport.  Tuberculosis, leprosy, and gonorrhea can obstruct the ejaculatory system, and sperm transport can be obstructed by deep midline müllerian cysts.  Congenital defects of the vas deferens can cause azoospermia or oligospermia in sons of women given diethylstilbestrol during pregnancy.

Congenital bilateral absence of the vas deferens is common in men with cystic fibrosis, and mutations in the gene responsible, the transmembrane conductor regulator (CFTR) gene, can cause bilateral absence of the vas deferens without other manifestations of the disease.  Congenital unilateral absence of the vas deferens may be an incomplete form of the bilateral disorder.  Thus, congenital absence of the vas deferens and cystic fibrosis are variable manifestations of mutations of the same gene.
Idiopathic Infertility

In large series, known causes were identified for only about 60% of cases of infertility in males, with the remainder classified as idiopathic (Table 18-5). Because at best only about half of fertile men with a varicocele achieve fertility after surgical repair, it is likely that even a larger fraction of infertile men have idiopathic infertility. Some may have androgen resistance, and as many as a fifth may have disorders involving the \( \text{AZF} \) gene (see earlier). Others have oligosperma or azoospermia with normal plasma LH and testosterone but elevated FSH levels in the absence of cryptorchism, radiation, or drug exposure.

Studies of such men indicate that isolated FSH elevation may be associated with a decreased GnRH pulse frequency and that FSH levels may be corrected with pulsatile GnRH therapy. Men with oligosperma and normal FSH levels may also have altered pulsatile secretion of gonadotropins and testosterone, and testosterone production rates are said to be low in selected infertile men with isolated FSH elevations and normal total serum testosterone. Whether these abnormalities are of causative significance is unknown.

A subset of men with severe idiopathic oligospermia associated with a decreased ratio of serum testosterone to estradiol have shown an increase in sperm density after treatment with an aromatase inhibitor. Testicular biopsies of men with idiopathic infertility have shown increased apoptosis associated with maturation arrest and hypospermatogenesis, decreased expression of the c-kit receptor, and increased mutations consistent with abnormal DNA repair mechanisms.

Management of Infertility

The management of infertility is usually unsatisfactory because the number of potentially correctable causes is small. When appropriate, however, associated hormonal disorders and coexisting medical conditions may be treated and offending drugs can be discontinued.

Although claims of success have been made for a variety of empirical therapies for infertility with oligospermia, most such claims fail to take into account the spontaneous fertility rate in untreated oligospermic men (25% in 1 year). The fact that treatment-independent pregnancy occurs in all forms of human infertility (male and female factors) makes it necessary for all therapies to be evaluated by randomized clinical trials. When several forms of empirical therapy—including testosterone rebound, nonaromatizable androgen (mesterolone), gonadotropin, antiestrogen (clomiphene), antibiotics, bromocriptine, varicocele repair, artificial insemination, and no therapy—were compared in one large retrospective analysis of oligospermic men, none were effective.

In Vitro Fertilization

The only effective empirical therapy for male infertility is in vitro fertilization. Standard techniques of in vitro fertilization require about 500,000 motile sperm/mL of ejaculate. Although the fertilizing capacity of sperm from men with abnormal sperm parameters is diminished, conventional techniques can result in 10% or more live births per attempt in men with mild to moderate abnormalities. Such rates are threefold to fivefold higher than natural impregnation rates in such men. However, standard in vitro fertilization is ineffective in men with more severe defects in spermatogenesis. In the Melbourne experience, fertilization rates were low in men with severe oligospermia, poor motility, and increased numbers of abnormal forms.

Intracytoplasmic Sperm Injection

Better results have been obtained with the development of intracytoplasmic sperm injection (ICSI)namely, fertility rates of 50% or more using poor quality semen, including decreased sperm number, impaired motility, increased abnormal forms, and combined defects. In men with obstructive azospermia in whom sperm must be aspirated from the epididymis, fertilization rates are nearly normal.

In the past, men with nonobstructive azoospermia, typically with elevated plasma FSH levels, were not treatable. Such patients include men with maturation arrest, postcryptorchidism tubular atrophy, mumps orchitis, and Klinefelter's syndrome. However, when minute amounts of sperm could be identified by testicular biopsy, fertilization and impregnation have been achieved with rare spermatooza or spermatids retrieved from such biopsy specimens using ICSI. ICSI should not be undertaken until men with abnormal semen undergo a complete work-up so that hypogonadotrophic hypogonadism or some other treatable condition is not missed. Furthermore, ICSI may increase the chances of transmitting the father's disorder to offspring, as has been reported in men with Klinefelter's syndrome and men with AZF mutations.
Old Age

The role of the decrease in total and bioavailable testosterone and the increase in estradiol in the decline of male sexual function with aging is not clear (see the following). However, this changing hormonal milieu may be involved in the pathogenesis of breast enlargement in elderly men and in the development of prostatic hyperplasia.

Prostatic Hyperplasia

Enlargement of the prostate to the extent that it obstructs urethral outflow is common in elderly men. The gland weighs a few grams at birth, and at puberty androgen-mediated growth causes the prostate to reach the adult size of about 20 g by age 20. This growth is accompanied by transformation of the cuboidal epithelium of the acini to a columnar, secretory epithelium and by initiation of secretion of the prostatic component of the ejaculate. The weight of the gland remains stable for about 25 years.

Beginning in the fifth decade of life, a hyperplastic phase of prostatic growth ensues in most men. The second growth phase, unlike the earlier growth, which involves the gland diffusely, typically begins in the periurethral region as a localized proliferation of glandular and stromal elements. The hyperplasia may remain limited in scope, but in many men growth continues and eventually compresses the remaining normal portion of the prostate. The progressive increase in gland size can cause lower urinary tract symptoms and urinary obstruction, but the correlation between symptoms and anatomic changes can be unpredictable. On the one hand, hyperplasia primarily of the periurethral region can obstruct urine outflow in the absence of gross prostatic enlargement; on the other hand, men with gross enlargement of the gland may be asymptomatic.

The second growth spurt, like the growth at puberty, requires a functioning testis. Dihydrotestosterone formed within the prostate from testosterone mediates the embryonic development, pubertal growth, and hyperplastic growth of the prostate. Administration to animals of a 5-reductase inhibitor to block dihydrotestosterone formation caused involution of the prostate despite elevation of testosterone levels within the gland. Furthermore, although plasma testosterone may decline with age, the level of dihydrotestosterone in the hyperplastic gland either remains constant or increases.

Prostatic hyperplasia also occurs in the aging male dog, and most research on its pathogenesis has been done in that species. Administration to the castrated dog of androgens that cause an increase in the prostatic dihydrotestosterone level caused prostatic enlargement comparable to that seen in the naturally occurring disorder. Estrogen acts synergistically with dihydrotestosterone to enhance prostatic growth in the dog because estrogen increases the amount of androgen receptor in the tissue. Thus, two hormones participate in the development of prostatic hyperplasia in the dog; dihydrotestosterone is responsible for prostate growth, and estradiol enhances dihydrotestosterone action.

Three types of evidence suggest that dihydrotestosterone and estradiol are also involved in human prostatic hyperplasia:

1. Either surgical or pharmacologic castration causes a decrease in the size of the hyperplastic prostate gland, indicating that continuing androgen action is essential to maintain the hyperplastic state.
2. Inhibition of prostatic 5-reductase with agents such as finasteride causes a profound decrease in prostatic dihydrotestosterone levels and a 20% to 30% decrease in prostate volume after 3 to 6 months of therapy. This effect is maintained for up to 4 years and is associated with few side effects.
3. There is a temporal relation between the development of prostatic hyperplasia and the increase in plasma estradiol with age, but a causal relation between estradiol and human prostatic hyperplasia has not been established.

Demonstration that hormones play a role in prostatic hyperplasia does not necessarily provide insight into its pathogenesis because their action could be permissive rather than causal, and the reason that the disorder varies so markedly in its manifestations is unclear. Similarly, the therapeutic role of 5-reductase inhibitors is not established because there is a strong placebo effect on urinary symptoms, there is no clear-cut relation between symptoms and urine flow, and the natural history of the disorder particularly how to predict which subset of men will develop significant obstruction is not understood. As a consequence, although a variety of minimally invasive or medical therapies are now available, the indications for surgical or medical management, compared with watchful waiting, are sometimes unclear.

Prostatic Cancer

The endocrine aspects of prostatic cancer are discussed in Chapter 39.
Disorders of All Ages

Testicular Tumors

Tumors of the testes occur with an incidence of 2 to 3 per 100,000 men per year in the United States and account for about 1% of cancer deaths in men. The incidence in most Western countries has risen since the 1930s, particularly in adults, but mortality rates have declined. The frequency shows a trimodal curve, with peaks in childhood (embryonal carcinomas and teratocarcinomas), young adulthood, and old age (seminomas). The incidence in blacks is a sixth or less that in whites, but overall the tumors are the second most common malignancy (after leukemia) in men between ages 20 and 35 years. The tumors are commonly bilateral (either simultaneous or sequential, e.g., a seminoma developing in one testis many years after the removal of the other).

Occurrence is familial in 1% to 2% of cases. The presence of an isochromosome of the short arm of chromosome 12 is characteristic of germ cell tumors of all subtypes.

Several factors predispose to testicular malignancy. Men with cryptorchidism have a fivefold increased risk of development of such tumors, men with intra-abdominal testes being more at risk than those with high inguinal testes, so that in one series 10 of 131 men with testicular cancer had antecedent maldescent. Three fourths of tumors associated with maldescent are seminomas, the remainder being other germ cell tumors.

Early orchiopexy facilitates detection, but whether it reduces the incidence of tumor development is not clear. Testicular malignancy may be more frequent in individuals with abnormal sexual development (i.e., 45,X/46,XY mixed gonadal dysgenesis or 46,XY testicular feminization) than with other forms of testicular maldescent. Occupational exposure to extremely high or low temperature can increase the risk. Estrogen administration to pregnant women may be a predisposing factor in male offspring, and Down's syndrome, Klinefelter's syndrome, and HIV infection are associated with an increased incidence.

Most testicular tumors in men with congenital adrenal hyperplasia related to steroid 21-hydroxylase (CYP21) deficiency consist of adrenal cell rests, are dependent on cortisol for growth and secretion, and occur in men who are inadequately treated and hence have elevated plasma corticotropin levels. However, the tumors can be difficult to separate histologically from interstitial cell tumors.

**Diagnosis**

Most testicular cancers produce local symptoms, but delay in making a diagnosis is common because of oversights by both physicians and patients. Testicular cancers usually occur before age 45, and men should be educated about the need to seek prompt medical advice for any change in a previously normal testis, including enlargement, pain or a feeling of heaviness, swelling, or other unusual findings. Pain occurs in half of affected men, and to reduce delay physicians should consider any testicular mass to be a tumor until proved otherwise and to obtain surgical consultation if symptoms and signs persist.

**Classification**

The most widely used classification is that of Mostofi (Table 18-6) and is based on the cell type from which the tumor originates.

**Germ Cell Tumors**

Germ cell tumors are the most common types.

Seminomas are characterized by large cells with clear cytoplasm in a delicate fibrovascular stroma infiltrated with lymphocytes; the granulomatous reaction around the tumor can be so intense as to suggest a graft-versus-host reaction. These tumors account for at least half of all testicular neoplasms and can be subdivided into spermatocytic seminomas, which occur in older men and are associated with a 90% to 95% 5-year survival, and anaplastic seminomas, which have a poor prognosis.

Embyronal carcinomas are the most common testicular tumors in boys, resemble embryonal carcinomas of the ovary, and are associated with 5-year survivals of about 70% in infants and 25% in adults.

Choriocarcinomas contain syncytiotheliotrophic cells and usually occur in the second and third decades of life; the prognosis is poor.

Teratomas contain at least two germ cell layers and may be either benign or malignant; they are second in frequency to embryonal carcinomas in childhood and are unusual in adults.

Tumors that contain combinations of germ cell types account for 40% of germ cell tumors; the biology of such tumors is determined by the least differentiated (most malignant) element. Of mixed tumors that contain cells of germinal and stromal origin, perhaps the most distinctive is the gonadoblastoma, which consists of germ
cells, sex cords, and, usually, Leydig cells. Gonadoblastomas usually occur in dysgenetic testes containing a Y chromosome and synthesize androgen.

Germ cell tumors of all types can also originate in extragonadal sites, including the mediastinum and the brain. These extragonadal tumors are presumed to arise from aberrant migration of germ cells early in embryogenesis; from some common precursor stem cell line that normally gives rise to germ cells, thymus, and pineal gland; or from migration of transformed gonadal germ cells.

Testicular germ cell tumors usually occur as a nodule or painless swelling of the testis but may be identified as the result of metastases or because of the peripheral manifestations of hCG secretion by the tumor. After diagnosis, the tumors are staged either by surgical exploration or by computed tomographic scanning or magnetic resonance imaging. Stage I is limited to the testes, stage II involves metastases to infradiaphragmatic lymph nodes but not beyond, stage III involves supradiaphragmatic lymph nodes, and stage IV involves extralymphatic metastases.

Germinomas can secrete several distinct tumor cell markers into plasma, including hCG and its subunit, -fetoprotein, lactate dehydrogenase, carcinoembryonic antigen, and placental alkaline phosphatase. Virtually all germ cell tumors synthesize hCG and its subunits, but the hormone is secreted in large amounts only by some nonseminoma germ cell tumors (choriocarcinomas, teratocarcinomas, and yolk sac tumors). -Fetoprotein is a marker of tumors containing yolk sac elements, and teratomas can secrete carcinoembryonic antigen. An elevated level of one of these tumor markers in the plasma of a patient whose tumor has been classified as a pure seminoma usually indicates that the tumor is actually a combination tumor. These markers are particularly useful for following the response to therapy. Secreted hCG may be endocrinologically active and cause enhanced formation of testosterone and, more important, of estradiol by the testes. The net result can be a feminizing syndrome and inhibition of the secretion of LH and FSH by the pituitary (see later).

The treatment of germ cell tumors constitutes a major triumph of cancer therapy. Appropriate therapeutic strategies include debulking of the tumor mass, resection of involved lymph nodes, administration of chemotherapy (usually combinations of cisplatin, vinblastine, etoposide, and bleomycin), radiation, and monitoring of tumor cell markers. The cure rates for patients with seminomas are approximately 90% for stage I disease, and individuals with stage III nonseminoma tumors, which were previously uniformly lethal, now have good survival rates.

Because young men with germ cell tumors may have infertility related to castration, radiation, chemotherapy, or a combination, cryopreservation of semen before treatment has been advocated as a means of preserving fertility, but many men have adequate sperm production after chemotherapy. Treatment is associated with a small risk of recurrence and the development of secondary solid tumors and leukemia and with the late sequelae of chemotherapy such as nephrotoxicity and neurotoxicity.

Stromal Cell Tumors

Stromal tumors (Leydig cell tumors, Sertoli cell tumors) account for 1% to 2% of testicular tumors, and both cell types may coexist within the same tumor. Rarely, adrenal rest tumors occur in the testes. As would be expected, Leydig cell tumors commonly secrete testosterone and thus may cause virilization in prepubertal boys (precocious pseudopuberty); many of the tumors secrete estradiol as well and cause mixed signs of feminization and virilization during the prepubertal years and feminizing signs in adult men. The hormones from such tumors can suppress levels of endogenous gonadotropins and testosterone and can cause azoospermia and decreased size of the contralateral testis. Because the tumors may be so small as to be recognized only by ultrasonography, documenting that the testis is the site of increased estrogen production may require selective catheterization of the testicular veins.

Sertoli cell tumors show a bimodal age distribution, most patients being younger than 1 year or between ages 20 and 45 years. The tumors are frequently bilateral and familial (usually as a component of the Peutz-Jeghers syndrome). Gynecomastia occurs in about 25% of patients, and estrogen secretion can impair spermatogenesis and cause shrinkage of the contralateral testis. Leydig cell hyperplasia can occur in the area around the tumor, implying either that the tumor is of mixed cell origin or that Sertoli cells secrete some factor that stimulates Leydig cell development. Complete cure and regression of feminizing signs usually follow surgical resection. Approximately 10% of stromal tumors are malignant.

Rate Tissue Tumors

Adenocarcinoma of the rete testis is rare but tends to be highly malignant.

Summary

Testicular tumors can enhance production of estradiol and testosterone by more than one mechanism. When tumors produce steroid hormones autonomously, plasma gonadotropin levels and androgen secretion by uninvolved portions of the testes are depressed, and azoospermia is common. When hCG is secreted by the tumor, production of estradiol and testosterone is increased in unaffected areas of the testes, and azoospermia is uncommon. Furthermore, occasional chorionicarcinomas that cannot synthesize steroids de novo nevertheless convert circulating androgens to estrogens. When hormones are formed directly or indirectly by the tumors, the response varies depending on the pattern of hormones produced and the age of the subject.
ABNORMALITIES IN ESTROGEN METABOLISM

Gynecomastia

Administration of large amounts of estrogen to men, as for carcinoma of the prostate or in preparation for sex change surgery, causes a variety of side effects, including fluid retention and congestive heart failure, hypertension, electrocardiographic changes, myocardial infarction, and thromboembolic disease. At lower levels, as can occur with estrogen-secreting testicular tumors, estrogen excess suppresses gonadotropin secretion, secondarily impairs testosterone production, and inhibits spermatogenesis. However, the most common manifestation of estrogen excess in men is gynecomastia (breast enlargement).

Sexual dimorphism in breast development at the time of puberty is due to the ovarian secretion of estrogen, and estrogen excess at any stage of life can cause breast enlargement in men. In the absence of a progestagen, the breast acini and lobules do not undergo complete female development, probably explaining why galactorrhea is unusual in men.

Clinical Features

At the clinical level, gynecomastia is complicated by problems of definition. The common view has been that any palpable breast tissue in men is abnormal except for three situations: transient gynecomastia of the newborn, pubertal gynecomastia, and gynecomastia that occasionally occurs in elderly men. However, this view was challenged by Nuttall and Niewoehner and Nuttall, who reported that 36% of normal adult men and two thirds of hospitalized men have palpable breast tissue. The prevalence may have increased because of some unrecognized cause.

A confounding problem is that it can be difficult to distinguish enlargement of breast tissue from lipomastia, in which enlargement is caused by adipose tissue. True gynecomastia can be separated from lipomastia by mammography or sonography. Autopsy data are not of much help in establishing the frequency of gynecomastia because they do not provide information about what fraction of gynecomastialactive or inactivestheoretically palpable. For the purposes of this discussion, breast enlargement in men (other than in the three so-called physiologic states) may be indicative of an underlying endocrinopathy and deserves at least a limited evaluation.

Histopathology and Etiology

Gynecomastia is frequently asymmetrical, and unilateral gynecomastia can be temporary in that one breast may enlarge months or years before the other. The process begins with proliferation of the stroma and the duct system, which elongates, buds, and duplicates. With time, progressive fibrosis and hyalinization are accompanied by regression of epithelial cells so that the ducts decrease in number. On correction of the cause, resolution involves reduction in size and cell content of the epithelium followed by gradual disappearance of the ducts, leaving hyaline bands that may persist or eventually disappear.

Gynecomastia is generally viewed as the consequence of absolute or relative estrogen excess, and it can be classified as either physiologic or pathologic (Table 18-7).

Physiologic Gynecomastia

During three phases of male life, breast enlargement can be a normal finding.

Gynecomastia in the Newborn

Enlargement of the breast in the newborn is probably due to maternal or placental estrogens, or both. The swelling may or may not be associated with milk production and usually disappears in a few weeks but can persist longer.

Adolescent Gynecomastia

Transient enlargement of the breast occurs in about 40% of adolescent boys. The median age at onset is 14 years, the breasts may be asymmetrical and tender, and by age 20 only a small number of men have palpable vestiges of gynecomastia. The most severe disorder, termed pubertal gynecomastia (breast tissue > 4 cm), may persist into adulthood and is more commonly associated with an underlying endocrinopathy.

The cause of pubertal breast enlargement is uncertain. Plasma estradiol levels in boys normally reach the adult range before plasma testosterone, and by age 20 only a small number of men have palpable vestiges of gynecomastia. The most severe disorder, termed pubertal gynecomastia, may persist into adulthood and is more commonly associated with an underlying endocrinopathy.

Pathologic Gynecomastia

Relative estrogen excess

Congenital defects

Congenital anorchia

Klinefelter’s syndrome

Androgen resistance (testicular feminization and Reifenstein’s syndrome)

Defects in testosterone synthesis

Secondary testicular failure (viral orchitis, trauma, castration, neurologic and granulomatous diseases, renal failure)

Increased estrogen production

Increased testicular estrogen secretion

Testicular tumors

Bronchogenic carcinoma and other tumors producing hCG
Women with complete testicular feminization and men with Reifenstein's syndrome have normal or elevated production of estrogen (hypospadias and gynecomastia) or men with undervirilization or infertility, or both. Phenotypic women with testicular feminization. If the impairment of receptor function is less complete, the phenotype is that of men with Reifenstein's syndrome and male testosterone levels but who are resistant to their own and to exogenous androgens.

Hereditary defects in the X-linked gene that encodes the androgen receptor cause a spectrum of syndromes of incomplete virilization in 46,XY men who have testes. Estrogen/androgen ratios.

Serum testosterone and estrogen levels begin to decline as plasma LH, which also causes enhanced estradiol secretion by the testes. Testicular function becomes progressively impaired with time, so that after age 15 years, the causes of elevated plasma estradiol are complex.

Pathologic Gynecomastia

Pathologic gynecomastia can be due to a relative (as in testosterone deficiency) or absolute increase in estrogen formation (as in Leydig cell tumors), to drugs, or to unknown causes.

Relative Estrogen Excess

Failure of testosterone synthesis or action causes elevated plasma gonadotropin levels, and relative estrogen excess ensues because of the extraglandular aromatization of adrenal androgens and on occasion a secondary increase in testicular estrogen secretion. Plasma FSH and LH levels are high, and the average plasma testosterone level is half normal, although some have normal testosterone levels. Variations in plasma levels of testosterone and estradiol are associated with variable degrees of androgenization and feminization in the disorder.

Congenital Defects

Congenital Anorchia.

Congenital anorchia is a rare, often familial disorder in which the testes are missing in phenotypically normal 46,XY males. Affected individuals are thought to have bilateral cryptorchidism at birth, but no tests are located on surgical exploration of the abdomen. Because testicular hormones are necessary for male phenotypic development and because the penis is normal in this disorder, it is believed that testes are present and function normally until late in embryonic life and then regress for unknown reasons. Approximately half of anorchid men develop gynecomastia.

In some anorchid men, Leydig cells secrete small amounts of testosterone into the circulation even if testes cannot be found at surgery. Other men with congenital anorchia have profound testosterone deficiency and a small amount of estradiol formed by the indirect pathway androstenedione estrone estradiol in extraglandular aromatization of adrenal androgens and on occasion a secondary increase in testicular estrogen secretion. These findings imply that the critical factor for feminization is not the absolute level of estrogen but rather some ratio of testosterone to estradiol to induce breast enlargement in the absence of disease.

Other men with congenital anorchia have profound testosterone deficiency and a small amount of estradiol formed by the indirect pathway. Phenytoin, theophylline, diazepam, marijuana, heroin) appear to block estrogen action by competing with estradiol for binding to the estrogen receptor.

Klinefelter's Syndrome

Approximately half of nonmosaic and a third of a mosaic men with Klinefelter's syndrome have gynecomastia after the expected time of puberty. Plasma FSH and LH levels are high, and the average plasma testosterone level is half normal, although some have normal testosterone levels. Variations in plasma levels of testosterone and estradiol are associated with variable degrees of androgenization and feminization in the disorder.

The causes of elevated plasma estradiol are complex. Early in adolescence, plasma testosterone is usually in the normal male range as the result of elevated plasma LH, which also causes enhanced estradiol secretion by the testes. Testicular function becomes progressively impaired with time, so that after age 15 years, serum testosterone and estrogen levels begin to decline and the end stage resembles anorchia (see earlier). Diminished estrogen clearance may further increase estrogen/androgen ratios.

Androgen Resistance (Testicular Feminization and Reifenstein's Syndrome)

Hereditary defects in the X-linked gene that encodes the androgen receptor cause a spectrum of syndromes of incomplete virilization in 46,XY men who have testes and male testosterone levels but who are resistant to their own and to exogenous androgens. In the most severe form, affected individuals are phenotypic women with testicular feminization. If the impairment of receptor function is less complete, the phenotype is that of men with Reifenstein's syndrome (hypospadias and gynecomastia) or men with undervirilization or infertility, or both.

Women with complete testicular feminization and men with Reifenstein's syndrome have normal or elevated production
rates for testosterone and estradiol, presumably because of increased secretion by the testes in response to elevated plasma gonadotropin levels. FSH and LH levels are elevated because of resistance at the hypothalamic-pituitary level to negative-feedback control by testosterone. However, there is no direct relation between the rates of estrogen secretion in these disorders and the degree of feminization that results, probably because the degree of feminization is influenced by other factors such as the severity of the androgen resistance and the variable elevation of plasma androgen levels.

Defects in Testosterone Synthesis.

Five inherited defects impair testosterone synthesis and prevent normal virilization of the male embryo. Each of the defects involves a critical biochemical step in the conversion of cholesterol to testosterone. The completeness of the defects and the severity of clinical manifestations vary, but feminization is common in two of the disorders, 3-HSDII deficiency and 17-HSDIII deficiency.

Feminization in these disorders can arise from more than one mechanism. For example, normal or low levels of plasma estrogen can cause feminization in the presence of diminished androgen production, analogous to the situation in congenital anorchia. Alternatively, estrogen production may be increased because of increased availability for extragonadal aromatization of steroids such as androstenedione that accumulate proximal to the enzymatic block. Partial deficiency of 17-HSDIII and late-onset 3-HSDII deficiency are rare causes of gynecomastia in otherwise phenotypically normal men.

Testicular Failure

Viral orchitis is the most common cause of testicular failure after puberty, and mumps is the most frequent etiology (see earlier). In men with gynecomastia and bilateral testicular atrophy related to orchitis, testosterone production is severely impaired, whereas production of estradiol and estrone is normal, arising almost entirely from extraglandular sources. 

The second most common cause of acquired testicular atrophy in the adult is trauma, and gynecomastia can result. Trauma to the testes can be associated with elevated levels of plasma estradiol many years later. Neurologic disease, including myotonic dystrophy and spinal cord injury, can also cause testicular atrophy. 

Testicular atrophy, decreased plasma testosterone levels, elevated gonadotropin levels, and gynecomastia are also common in proximate block.

Gynecomastia is present in approximately half of men undergoing hemodialysis for renal failure. Plasma LH and FSH levels are elevated, the plasma testosterone level is low, and plasma prolactin levels are elevated. Estradiol levels may also be high (see earlier).

Increased Estrogen Production

Estrogen production in men can increase because of (1) increased testicular secretion, (2) increased availability of substrate for extraglandular formation, or (3) increased activity of extraglandular aromatase itself.

Increased Testicular Estrogen Secretion (see Fig. 18-18 B)

Testicular Tumors.

Testicular tumors can feminize in three ways.

First, germinal cell tumors (embryonal carcinomas, choriocarcinomas, teratomas, and rarely seminomas) can produce hCG or fragments of hCG, which can act in uninvolved areas of the testes to stimulate the synthesis of estradiol and testosterone, which in turn suppress plasma LH and FSH.

Second, stromal cell tumors (Leydig and Sertoli cell tumors) can secrete testosterone and estradiol autonomously. About 20% of men with Leydig cell tumors have gynecomastia, and gynecomastia may be even more common with Sertoli cell tumors. 

Feminization can occur before such tumors are detectable by physical examination, but even small tumors can usually be identified by ultrasonography. Similarly, in choriocarcinomas and in hepatocellular carcinomas, aromatase in the tumor tissue can convert circulating adrenal and testicular androgens to estrogens.

Third, some Sertoli cell tumors stimulate adjacent Leydig cells to secrete androgens that serve as substrate for aromatase in the tumor cells. (See earlier for discussion of diagnosis and management of testicular tumors.)

Bronchogenic Carcinoma.

Lung cancer can cause an increase in hCG levels in plasma, and gynecomastia in this condition correlates with the amount of estradiol secreted by the testes. Indeed, hCG secretion by any tumor, such as by transitional cell tumors of the urinary tract, can cause feminization.

True Hermaphroditism.

In true hermaphroditism (see Chapter 22), both the ovarian and the testicular components of the gonads are endocrinologically active and cause a mixed pattern of feminization and virilization at puberty. Gynecomastia is due to gonadal estrogen secretion (see Fig. 18-18 B), presumably by the ovarian elements of the ovotestes.

Increased Substrate for Peripheral Aromatase (see Fig. 18-18 C)

Adrenal Disease.

In feminizing adrenal carcinoma, estrogen production is usually due to massive increases in the levels of the adrenal androgens androstenedione and DHEA, which serve as substrates for extraglandular aromatization. In rare instances, adrenal tumors secrete estrogen. 

Feminization in boys with congenital adrenal hyperplasia (as in CYP21 or CYP11A2 deficiency) is usually the consequence of increased production of androstenedione by the adrenal glands and hence of increased substrate for peripheral aromatase. In some instances, decreased testosterone levels may play a role in the gynecomastia. Increased androstenedione is also the usual cause of feminization in men with 17-HSDIII deficiency.

Androgen Administration.

Administration of testosterone to children commonly causes gynecomastia, correlating with an increase in estrogens, whereas replacement with conventional doses in adult men increases plasma estradiol but rarely causes gynecomastia. In contrast, testosterone administration to men with impaired liver function can cause
profound increases in plasma estradiol levels. In addition, administration of supraphysiologic amounts of aromatizable androgens can increase estradiol levels as much as sevenfold in normal men, and gynecomastia is common in users of anabolic steroids. In probing patients’ histories for possible causes of gynecomastia, it should be remembered that some androgens are not aromatizable or are weak substrates for the enzyme (see the following).

Liver Disease.

Liver disease is a common cause of feminization. Gynecomastia is thought to be largely a result of over-production of estrone. However, the liver is not the direct source of the estrogen, which are mainly due to decreased hepatic catalysis of androstenedione and the consequent increased availability of androstenedione for extrahepatic aromatization. In carcinoma of the liver, feminization can be the consequence of increased aromatase activity in the tumor itself.

Starvation.

Gynecomastia was common in American prisoners of war during World War II. About a third of the cases occurred during refeeding after release, other instances were associated with temporary improvements in the food supply during imprisonment, and most regressed within a few months. The pathophysiology of starvation gynecomastia may be similar to that with liver disease (see earlier).

Thyrotoxicosis.

Thyrotoxicosis can cause gynecomastia. Elevation of plasma estradiol levels is probably due to increased androstenedione production rates and increased formation of estrogen in extraglandular sites.

Increase in Extraglandular Aromatization (See Fig. 16-13B)

Increased activity of aromatase enzymes in peripheral tissues can increase estrogen production as much as 50-fold, and in at least one family the trait appeared to be inherited in an autosomal dominant pattern through three generations, being manifested in females by precocious puberty and macromastia and in males by gynecomastia. A characteristic feature is that the onset of gynecomastia correlates with the onset of adrenarche and occurs before the time of normal puberty. A similar trait is present in the Sebright bantam chicken, in which an autosomal dominant gene increases extraglandular aromatization more than 100-fold.

Drugs

Drugs can cause gynecomastia by direct action as estrogens, by enhancement of testicular production of estrogens, by inhibition of testosterone synthesis or action, or by unknown mechanisms.

Estrogens and Estrogen Mimetics

Estrogens given to men in any form can cause gynecomastia, as in the treatment of prostatic cancer with diethylstilbestrol and of transsexual men with estrogens. Young men and boys are particularly sensitive to estrogens, and gynecomastia can develop as a result of industrial exposure or dermalointments containing estrogens. Identifying the source may require a high index of suspicion, as in the case of a barber who massaged the scalps of customers with ointment containing estrogen, factory workers who manufacture oral contraceptives, children of workers in a diethylstilbestrol manufacturing plant who absorbed the drug from the clothing of their fathers,

and offspring of women who use topical estrogen preparations. Sufficient estrogen to induce gynecomastia can be absorbed by men during sexual intercourse with partners who use vaginal creams containing estrogens. In the United States, no federal regulations cover estrogens in cosmetics, and estradiol levels may be as high as 18 ng/ml in creams and 50 mg/dl in lotions.

Epidemics of gynecomastia among children have resulted from the ingestion of milk or meat from estrogen-treated cows, raising the possibility that long-term exposure to small amounts of estrogens may be a cause of idiopathic gynecomastia. Sources may include meat and dairy products from animals treated with estrogens other than diethylstilbestrol, endogenous estrogens in animal tissues, or plant or fungal estrogens in foods.

About 10% of men given digitalis for a year had gynecomastia; however, abnormal liver function is common in such men, and gynecomastia is said to correlate better with congestive heart failure than with administration of digitalis. Nevertheless, digitalis preparations associated with gynecomastia also have estrogenic effects on the vaginal epithelium in postmenopausal women. Digitalis binds to the estrogen receptor and may act as a direct estrogen agonist.

Drugs That Enhance Endogenous Estrogen Formation

Administration of hCG can cause gynecomastia as a consequence of increased estradiol secretion by the testes. Clomiphene citrate (both an estrogen agonist and antagonist) has been used to treat gynecomastia in boys, but paradoxically it can cause gynecomastia on withdrawal, presumably by increasing LH secretion and consequently increasing estradiol secretion by the testes.

Drugs That Inhibit Testosterone Synthesis or Action

The antifungal drug ketoconazole and other imidazoles block steroid hormone synthesis.

Gynecomastia is presumably due to altered ratios of estradiol to testosterone.

Antineoplastic agents can cause long-term impairment of testosterone synthesis, presumably through toxic effects on Leydig cells; such damage may occur when the therapy is for systemic neoplasms (e.g., alkylating agents for Hodgkin’s disease) or for testicular cancers. The cause of gynecomastia has not been elucidated, but it may be due to elevated plasma gonadotropin levels secondary to testicular damage and enhancement of testicular estrogen synthesis.

Gynecomastia is common in men treated with spironolactone. At low doses, the drug prevents the binding of androgen to its receptor, and at high dose it inhibits testosterone synthesis.

Antiangiogens, including cyproterone, flutamide, zanoterone, and bicalutamide, inhibit testosterone binding to the receptor and can cause gynecomastia.

Gynecomastia is a common side effect of treatment with cimetidine, which also blocks the binding of androgen to the androgen receptor and may inhibit the catabolism of estradiol. Gynecomastia is less common in subjects receiving ranitidine. Suggestive evidence for induction of gynecomastia by an environmental antiandrogen has come from studies of an epidemic of temporary gynecomastia that affected Haitian refugees in five detention centers in the United States in 1981. The detouring agent used in these centers binds to the androgen receptor and acts as an antiandrogen in rats. All antiandrogens are believed to impair the feedback control of gonadotropin production and cause elevation of plasma LH, which in turn increases estradiol secretion from the testes.

Drugs That Act by Unknown Mechanisms

A variety of drugs cause gynecomastia by unknown mechanisms. For example, gynecomastia occurred in boys and in men given human growth hormone. Many drugs are associated with gynecomastia with a frequency that is probably not coincidental; these include busulfan, calcium channel-blocking agents, angiotensin-converting enzyme inhibitors, diazepam, isoniazid, methyl dopa, omeprazole, penicillamine, tricyclic antidepressants, and a variety of antimicrobial agents, particularly protease inhibitors used for the treatment of HIV. Some of these agents may act by altering liver function. Both marijuana and

A detailed physical examination including the testes (the finding of small testes bilaterally suggests testicular insufficiency, and asymmetrical testes raise the

The extent to which minor endocrine disorders are not recognized with current methodologies is uncertain. The fact that gynecomastia can develop as the result of subtle environmental exposure to estrogens or antiandrogens (as described earlier) raises the possibility that a large fraction of idiopathic gynecomastia may be the consequence of unrecognized exposure to endocrine disruptors. The critical clinical point is that, whatever the cause, the diagnosis of idiopathic gynecomastia carries no known import related to health.

Lack of Role of Prolactin in Gynecomastia

Plasma prolactin levels are usually normal in men with gynecomastia of diverse causes, and men who have prolonged elevation in plasma prolactin secondary to use of psychotropic drugs do not commonly have gynecomastia. Consequently, prolactin is not believed to play a direct role in the disorder. This conclusion is in keeping with the fact that prolactin is not a growth hormone for the breast. Furthermore, when gynecomastia develops in men with prolactin-secreting tumors of the pituitary gland and high plasma prolactin levels or in men taking psychotropic agents, the gynecomastia is probably the consequence of secondary testicular failure as a result either of the effects of the tumor mass or of inhibition of LH secretion by prolactin.

Diagnosis

The dilemma is to distinguish men with significant endocrine disease from those with idiopathic gynecomastia. In general, only men with symptomatic gynecomastia are evaluated; however, if there is a question about whether the gynecomastia is real, the issue is best solved by mammography or ultrasonography.

Most of the known causes of gynecomastia can be identified by a work-up that includes the following:

1. A careful drug history that encompasses potential environmental and indirect exposures to endocrine substances.
2. A detailed physical examination including the testes (the finding of small testes bilaterally suggests testicular insufficiency, and asymmetrical testes raise the possibility of testicular tumors).
3. Evaluation of liver function.
4. A limited endocrine work-up, including (a) measurement of plasma DHEAS or urinary 17-ketosteroids (usually elevated in adrenal feminizing states), (b) measurement of plasma estradiol (helpful if elevated but usually normal), (c) assessment of plasma hCG (sometimes elevated with testicular tumors), and (d) measurement of plasma LH and testosterone.

If these parameters are normal, as is frequently the case, the usual recourse is to observe the patient without treatment. If the symptoms persist or worsen and if the enlargement is progressive, a more extensive evaluation may have to be undertaken.

Treatment

The difficulty in treating gynecomastia is inherent in its natural history. If the feminizing process persists for a long period, the initial glandular hyperplasia is replaced by progressive fibrosis and hyalinization that do not regress after the source of excess estrogen is corrected. Consequently, surgery remains the mainstay of therapy and is frequently indicated for psychological and cosmetic reasons. Such surgery is usually accomplished through a circumareolar approach.

Medical management is most successful when it is addressed to gynecomastia of recent onset or to prevention of its development. Testosterone administration has inconsistent effects in Klinefelter’s syndrome but can cause dramatic improvement in other forms of testicular failure (e.g., anorchia, viral orchitis).

Several drugs have been tried for gynecomastia, including the antiestrogens tamoxifen and clomiphene, the aromatase inhibitor testolactone, and danazol, a weak androgen that inhibits gonadotropin secretion. In one study, tamoxifen was about twice as effective in treating idiopathic gynecomastia as danazol; in another study, tamoxifen was uniformly effective in treating the gynecomastia induced by antiandrogen treatment in men with prostatic carcinoma. Treatment with dihydrotestosterone (which cannot be aromatized to estrogen) was also reported to provide symptomatic improvement.

Perhaps the most effective therapy for gynecomastia is to prevent its development by radiating the breasts before the institution of estrogen therapy in men with prostatic carcinoma or of antiandrogen therapy in male sex offenders. This therapy is about 90% effective, and the complication rate is low.
Impairment of Estrogen Formation or Action

The study of men with single-gene mutations that impair estrogen formation or action has provided insight into the role of estrogen in male physiology. These forms of estrogen deficiency are rare, but the fact that the phenotypes in the two disorders are similar establishes the importance of this role.

Aromatase Deficiency

Aromatase deficiency is the consequence of autosomal recessive loss-of-function mutations in the CYP19 gene. In the two reported men with this disorder, childhood development was considered normal but skeletal growth continued into the 20s despite pubertal maturation and resulted in tall stature. This growth pattern was associated with failure of epiphyseal closure, marked delay in bone age, and osteopenia.

One man had undetectable estrogen in plasma and elevated levels of testosterone, dihydrotestosterone, and gonadotropins; testicular volume was normal, and semen analysis was declined. The other affected man was evaluated because of tall stature, infertility, and skeletal pain associated with severe osteopenia; the testicular volume was 8 mL bilaterally, the sperm density was very low with many immotile sperm, and testicular biopsy revealed a maturation arrest at the spermatocyte stage. The etiology of the infertility in the latter patient was not clear because a brother was infertile in the presence of a normal CYP19 gene, suggesting that the infertility in this family may be due to some other disorder. The man responded dramatically to estradiol therapy with an increase in bone density to the normal range, resolution of bone pain, and lowering of elevated levels of total and LDL cholesterol and triglycerides.

These men had different homozygous missense mutations in the CYP19 gene that caused single amino acid substitutions and resulted in the formation of mutant enzymes with 0.2% to 0.4% of the activity of normal enzyme.

Estrogen Receptor Deficiency

An autosomal recessive, loss-of-function mutation in the estrogen receptor gene has been described in a man with tall stature, unfused epiphyses, osteopenia, and acanthosis nigricans. Virilization was normal, and he had a normal level of plasma testosterone. Plasma levels of estradiol, estrone, FSH, and LH were elevated, and semen analysis revealed a normal sperm density but decreased sperm motility. Serum lipoprotein levels were normal, but the presence of hyperinsulinemia and impaired glucose tolerance indicated insulin resistance. He did not respond to treatment with high-dose, transdermal estradiol sufficient to raise the plasma free estradiol 10-fold above normal, as indicated by no change in plasma gonadotropins or in bone density after 6 months. He was homozygous for a missense mutation in exon 2 of the estrogen receptor gene that resulted in a premature termination codon and hence precluded the formation of functional receptor.

In summary, the evidence from these rare disorders of estrogen formation and action indicates that estrogen plays a major role in controlling skeletal maturation and both the accrual and maintenance of bone mass in men. In both conditions, there was no pubertal spurt in growth; growth was instead steady and continued in association with failure of epiphyseal closure. Despite testosterone levels that were normal or increased, gonadotropin levels were elevated. These findings are in accord with studies of aromatase inhibitors, which indicate that estrogens are important for feedback control of gonadotropin secretion at the level of the pituitary and the hypothalamus. Abnormalities of carbohydrate and lipid metabolism in these patients appear to be inconsistent. The fact that gender identity and gender role behavior are male in both conditions indicates that estrogen does not play a critical role on these parameters.
HORMONAL THERAPY

Androgen Therapy

When administered by mouth, testosterone is absorbed into the portal blood and degraded by the liver so that only a small fraction reaches the systemic circulation. Parenterally injected testosterone is also rapidly absorbed and degraded. As a consequence, effective androgen therapy requires either administration of testosterone in a slow-release form (transdermal or micronized oral preparations) or administration of chemically modified analogues. Such chemical alterations either retard absorption or catabolism to maintain effective blood levels or enhance the androgenic potency of each molecule so that physiologic effects can be achieved at a lower plasma level of drug.

Three general types of modification of testosterone are clinically useful:

1. Esterification of the 17-hydroxyl group (type A).
2. Alkylation at the 17 position (type B).
3. Modification of the A, B, or C rings, particularly substitutions at the 1, 2, 9, and 11 carbons (type C) (Fig. 18-19).

Most agents actually contain combinations of ring structure alterations and either 17 alkylation or esterification of the 17-hydroxyl group.

Esterification of testosterone with various carboxylic acids decreases the polarity of the steroid, makes it more soluble in the fat vehicles that are used for injection, and hence slows release of the injected steroid into the circulation. The esters of 19-nortestosterone have particularly slow release and turnover rates. The longer the carbon chain in the ester, the more fat soluble the steroid becomes and hence the more prolonged the action. For example, testosterone propionate must be injected daily, whereas testosterone cypionate and testosterone enanthate can be administered every 2 or 3 weeks. Even more slowly hydrolyzed esters are under investigation.

![Figure 18-19 Types of androgen preparations available for clinical use. Type A derivatives are esterified in the 17 position. Type B steroids have alkyl substitutions in the 17 position. Type C derivatives involve a variety of alterations of ring structure that enhance activity, impede catabolism, or influence both functions. Most androgen preparations involve combinations of type AC or type BC changes.](Image)

Figure 18-19

such as testosterone buciclate, which is administered every 12 weeks, and testosterone undecanoate, which is administered every 6 weeks. Testosterone cypionate or enanthate was for many years the treatment of choice for male hypogonadism.

Although testosterone esters can be detected in plasma, they must be hydrolyzed before the hormone acts so that the effectiveness of therapy can be monitored by assaying the plasma level of testosterone after administration. Most esters must be injected, but twomethanolone acetate and testosterone undecanoate can be administered by mouth. Testosterone undecanoate is absorbed through the lymphatic system into the systemic circulation, and physiologic blood levels of testosterone can be achieved at doses of approximately 120 mg/day. Because of rapid turnover, testosterone undecanoate must be administered two to three times a day. The reason for the oral effectiveness of methenolone acetate (and of mesterolone) is not entirely clear.

The use of transdermal testosterone formulations makes it possible to sustain serum testosterone levels in the normal male range while avoiding the necessity for parenteral administration. These formulations include a scrotal patch, two nonscrotal patches, and a gel. The scrotal patch Testoderm is designed to deliver either 4 or 6 mg of testosterone over 24 hours and takes advantage of the fact that absorption across the scrotal skin is efficient in the absence of permeation enhancers. After application in the morning, serum levels peak in 2 to 3 hours and are maintained throughout the day.

The nonscrotal patches, Androderm and Testoderm TTS, differ in recommended application sites and times to peak serum levels, but both provide physiologic testosterone levels throughout the day. Androderm, available in 2.5- and 5-mg doses, is applied at bedtime; peak levels are achieved in 8 hours, and the application site must be rotated to avoid skin irritation. Testoderm TTS delivers 5 mg of testosterone from a larger surface area, is applied in the morning, results in a maximal serum level in 2 to 3 hours, and appears to cause minimal skin irritation. In a randomized comparative study, Androderm therapy did not cause the temporary supraphysiologic levels of estradiol and of total and bioavailable testosterone that occur after injections of testosterone enanthate. The transdermal preparation resulted in more normal testosterone levels, less frequent suppression of plasma LH, and less frequent elevation of plasma hemoglobin levels.

A transdermal 1% testosterone gel has been developed for the application of 50 to 100 mg of testosterone to the shoulders or abdomen each morning, the usual dose being 50 mg. The absorption of testosterone appears to be largely independent of the surface area to which it is applied, and steady-state serum levels are achieved within a few days. The hands must be washed carefully after each application to avoid inadvertent transmission of the hormone, but the application site should not be washed for 6 hours to maintain absorption efficiency. Application site skin-to-skin transfer may occur with close physical contact. In comparison with the 5-mg nonscrotal patch, 50 mg of testosterone gel causes somewhat higher serum testosterone levels.

Administration of a 5-mg preparation of testosterone cypoxodrin sublingually three times a day also results in normal plasma testosterone levels in hypogonadal men. 17-Alkylated androgens, such as methyltestosterone and methandienolone, are effective by mouth because alkylated steroids are absorbed into the portal circulation, are slowly catabolized by the liver, and reach the systemic circulation in effective amounts. For this reason, 17-methyl or 17-ethyl substitution is present in most orally active androgens. Because 17-alkylated androgens are believed to act within the cell as such (i.e., the alkyl groups are not removed), because assays are not routinely available for monitoring blood levels, and because they can cause abnormal liver function, these steroids have a limited role in medicine.

Other alterations of the ring structure either alter the metabolism or enhance the potency of a given molecule. For example, the potency of fluoxymesterone, 19-nortestosterone, and 1-methylsubstituted steroids may be enhanced because they are poor precursors for estrogen formation in extraglandular tissues. Similarly, 19-nortestosterone is a more potent androgen than testosterone because its more planar ring structure, like that of dihydrotestosterone, fits more tightly into the binding site of the androgen receptor. 7-Methyl-19-nortestosterone cannot be 5-reduced and may be useful when androgen replacement is needed with minimal effects on the prostate.

As with 17-alkylated steroids, androgens with ring alterations are not converted to testosterone in vivo, and specific assays for each must be used to monitor blood levels. One orally effective androgen, mesterolone, is neither esterified nor alkylated in the 17 position and cannot be aromatized to estrogens in peripheral tissues. Consequently, effective androgen replacement can be achieved by oral administration without causing abnormalities of liver function; unfortunately, the steroid is ineffective in regulating gonadotropin secretion and consequently is a poor agent for routine androgen replacement therapy.
The subcutaneous implantation of testosterone-filled silicone elastomer (Silastic) capsules results in slow release of hormone into plasma for long periods. However, this is impractical because of the large size of such capsules. When large amounts of testosterone are given by mouth in microcrystalline form (200 to 400 mg/day), physiologic blood levels can be achieved, but the preparation has to be taken several times a day and these doses induce hepatic drug-metabolizing enzymes, the long-term effects of which are uncertain.

**Androgens for Normal Men**

When the plasma testosterone level is raised above the normal range, both the basal levels of LH and FSH and the peak levels after GnRH administration are diminished. As a consequence, the testicular volume is decreased about 20%, sperm production is uniformly decreased by 90% or more, and the volume of the ejaculate remains unchanged. Acne is common, and the serum estradiol level increases twofold.

Administration of usual replacement doses of testosterone enanthate (100 mg/week) to normal men caused significant decreases in triglycerid and total body fat and increases in BMD in the spine, effects that are probably the consequence of the temporary increases in testosterone levels above the normal range after the injections. Administration of six times this dose (600 mg/week) of testosterone enanthate to normal men caused an increase in fat-free body mass, triceps and quadriceps muscle size, and muscle strength.

In a similar study, there was no change in levels of prostate-specific antigen (PSA). In a dose-response study in healthy young men, testosterone enanthate caused increases in fat-free body mass, muscle strength, and hemoglobin levels and decreases in fat mass and HDL cholesterol levels, beginning with a dose that was just above replacement levels (125 mg/week). Sexual function, visual-spatial cognition, mood, and PSA levels did not change at any dose.

**Androgens for Hypogonadal Men**

The aim of androgen therapy in hypogonadal men is to restore or normalize male secondary sexual characteristics (beard, body hair, external genitalia) and male sexual behavior to promote normal male somatic development (hemoglobin, voice, muscle mass, nitrogen balance, and epiphyseal closure). Because a reliable assay for plasma testosterone is widely available for monitoring therapy, the treatment of androgen deficiency is straightforward and almost universally successful.

The parenteral administration of a long-acting testosterone ester, such as 100 to 300 mg of testosterone enanthate at 1- to 3-week intervals, results in a sustained increase in plasma testosterone concentration to the normal male range or slightly above. The usual replacement regimen is 200 mg every 2 weeks. Similar effects are obtained with the transcutaneous administration of testosterone.

Such regimens usually reduce the plasma LH level (if elevated) and maintain serum testosterone within the normal range. Serum testosterone should be measured after 4 to 6 weeks of therapy to assess adequacy of dosage; the trough level is measured in men receiving intramuscular testosterone, and midmorning levels are assessed in men receiving transdermal formulations. If the hypogonadism is primary and of long duration (as in Klinefelter's syndrome), suppression of the plasma LH value to the normal range may not occur for many weeks, if at all. In postpubertal testicular failure, even of many years' duration, resumption of normal sexual activity is usual after adequate replacement, primarily because of increased libido and increased frequency of erections.

Androgen therapy does not restore spermatogenesis in hypogonadal states, but the volume of the ejaculate, derived largely from the prostate and seminal vesicles, and other secondary sexual characteristics return to normal. Treatment of hypogonadal men with testosterone replacement in growth of the prostate to the same degree as that of age-matched controls. Testosterone replacement in such men can cause dramatic changes in body composition, strength, and BMD, although maximal effects may not be seen for as long as 2 years. Improvement in BMD in BMD involves both trabecular and cortical bone and is independent of the age at which replacement is started.

In men of all ages in whom hypogonadism develops before expected puberty (such as in hypogonadotropic hypogonadism), it is appropriate to bring plasma testosterone into the adult range slowly. When therapy is begun at the time of expected puberty, the normal events of male puberty proceed in the usual fashion. If therapy is delayed until after the time of expected puberty, the degree of virilization is variable, but many such men undergo a late but relatively complete anatomic and functional male maturation. Intermittent androgen therapy is sometimes given to prepubertal hypogonadal boys with microphallus to stimulate penile growth.

In boys of pubertal age with either isolated hypogonadotropic hypogonadism or primary testicular deficiency, the initial administration of small doses of testosterone esters follows by a gradual increase to doses of 100 to 150 mg/m² of body surface area per month results in a normal pubertal growth spurt. Penile growth, deepening of the voice, and appearance of other secondary sexual characteristics usually commence during the first year of treatment. Puberty in normal boys extends over several years, and treatment that is designed to replicate normal development cannot shorten the process greatly.

In postpubertal testicular failure, even of many years' duration, resumption of normal sexual activity involves both trabecular and cortical bone and is independent of the age at which replacement is started.

**Androgens for Healthy Older Men with Decreased Bioavailable Testosterone Levels**

Because many of the changes in body composition, libido, and erectile function with aging also occur with male hypogonadism, androgen administration has been evaluated in healthy older men. The criterion for inclusion in such studies is a low level of total testosterone or of bioavailable (nonSHBG-bound) testosterone.

In one study of older men with a total serum testosterone less than 14 nmol/L (<420 ng/dL), administration of testosterone enanthate at 100 mg/week returned plasma testosterone levels to normal, increased lean body mass and hemoglobin levels, and decreased total and LDL cholesterol levels.
levels of bioavailable testosterone, treatment with testosterone enanthate at 200 mg every 2 weeks increased muscle strength and hemoglobin levels without increasing PSA levels. 672 In a larger, long-term placebo-controlled study of older men, the use of a testosterone patch increased BMD significantly in the men with low levels of total testosterone but had minimal effects in men with normal levels of total testosterone. 673 674 Lean body mass and hemoglobin levels were increased and fat mass was decreased in all men receiving testosterone. The PSA levels increased by 0.5 ng/mL and then were stable after 6 months.

Although these studies suggest that such treatment is beneficial in men with low plasma testosterone, many questions are still unanswered. 675 For example, it will be necessary to perform long-term studies to be certain that the risk-to-benefit ratio is favorable before such treatment can be recommended routinely.

**Use of Androgens for Purposes Other Than Replacement Therapy**

Administration of testosterone to hypogonadal men has systemic effects in addition to those on the male urogenital tract, including reduction in the urinary excretion of nitrogen, sodium, potassium, and chloride and induction of weight gain. A major component of androgen-induced weight gain and nitrogen retention involves an increase in skeletal and muscle mass. In several species, including humans, the skeletal muscles that support the forelimbs, namely the muscles of the pectoral and shoulder region, show the greatest response, but most muscles probably respond to androgen administration. Such muscles enlarge because of formation of new myofilaments along the myofibrils and because of division of the enlarging myofibrils; the net consequence is an increase in the diameter of muscle fibers and fibrils. 676

The effects of androgens on muscle are not due to different actions of the same hormone but represent the same action in different tissues. It is theoretically possible that a steroid might be devised that would be taken up by or retained selectively by muscle, 677 but no anabolic hormone devoid of androgenic effects has been found. Indeed, all anabolic agents tested in men so far are also androgens and in appropriate doses could be used for androgen replacement. Androgens have been tried in a variety of clinical situations other than hypogonadism with the hope that improvement in nitrogen balance and muscle development could outweigh any deleterious side effects.

**Attempts to Improve Nitrogen Balance in Catabolic States**

After injury, infection, or surgery, the breakdown of body protein is accelerated, and as a consequence excess nitrogen is excreted in the urine. During the recovery phase, nitrogen deficits are replaced. Anabolic steroids can improve the nitrogen balance during the first few days after relatively minor operations in well-nourished individuals, 678 but the decrease in nitrogen loss is minimal and does not appear to be of therapeutic benefit. Likewise, any effect of androgens on weight in undernourished, debilitated, or elderly men is complicated by the fact that many such men, including some men with AIDS, also have secondary testosterone deficiency (see earlier). 679

There is no convincing evidence that testosterone supplementation improves strength or outcome in wasting disorders in the absence of androgen deficiency. 680 Androgens are also of no proven value in the management of nitrogen accumulation in chronic renal failure.

**Androgens and Athletic Performance**

The use of androgens by athletes who believe that athletic performance will be improved constitutes a widespread form of drug abuse. Weight-lifters and body-builders began to use them in the 1950s, and the practice spread to all levels of athletic competition from high school to professional. Several lines of evidence suggest that androgens may have a beneficial effect on strength:

1. In a meta-analysis of 16 studies in athletes, Elashoff and colleagues 681 concluded that androgen administration to trained athletes results in about 5% improvement in strength.
2. Forbes deduced that administration of a total dose of about 20 g of exogenous androgen causes an increase of about 18 kg of lean body mass.
3. Griggs and colleagues 682 reported that large amounts of testosterone increase muscle protein synthesis and muscle mass in normal men.
4. Bhasin and co-workers 683 showed that pharmacologic amounts of testosterone esters increase lean body mass, muscle size, and strength.

Considered together, these studies support the views of athletes and their trainers that such agents are effective in adult male athletes. Although controlled studies have not been carried out in women and boys, it is clear on the basis of uncontrolled studies in the German Democratic Republic that the agents are even more effective in these groups. 683

Unfortunately, the side effects of the drugs are also more striking in women and children. The doses of androgens taken by athletes are often 10 to 100 times ordinary replacement doses. At these doses, androgens may promote anabolism by functioning as antagonists to the catabolic effects of glucocorticoids and hence promote nitrogen retention independent of the androgen receptor.

The question of efficacy, interesting though it may be, is independent of the side effects of the drugs. Because many athletes take oral agents such as nandrolone phenpropionate and stanozolol along with testosterone esters by injection, the potential toxic side effects are formidable.

**Stimulation of Erythropoiesis**

The difference in the hematocrit between men and women is the result of enhancement of erythropoietin formation and erythropoiesis by testosterone. After castration of men, red blood cell mass decreases 10%, red blood cell diameter decreases 40%, and osmotic fragility increases. Occasionally, the resulting anemia may be severe. In normal men given pharmacologic doses of testosterone esters, the average increase in hemoglobin is about 10 g/L (1 g/dL). As a consequence, androgens have been used in the treatment of refractory anemia. 684

The mechanism by which androgens stimulate erythropoietin formation by the kidneys involves the same receptor mechanism that has been documented for other androgen actions, and all androgens have the capacity to enhance erythropoiesis. In humans, some erythropoietin is synthesized outside the kidneys, and the presence of renal tissue is not an absolute requirement for stimulation of erythropoiesis by androgens. 685 686 Androgen has been given to treat anemias associated with bone marrow failure but has been used infrequently since erythropoietin became available for therapy.

Occasional dramatic increases in hemoglobin level occur when administration of androgens to individuals with bone marrow failure. 687 In unselected patients who were treated with androgens, approximately 50% appeared to respond. 688 Improvement appears to be more common when the bone marrow is hypoplastic or when there is myelofibrosis than when the marrow is hypercellular. Furthermore, in a prospective randomized trial of androgen therapy in patients with aplastic anemia, the use of oral androgens at high dosages (1 mg/kg body weight per day) was associated with hematologic improvement and increased survival, primarily in the less severe cases. 689

Androgens have also been used for the anemia of renal failure. Androgen-induced increases in erythropoietin and hemoglobin levels are less marked in the anephric state, as would be expected if the beneficial effect were due to increased erythropoietin formation. 686 688 In most studies, androgen therapy increased the hemoglobin level (10 to 50 g/L [1 to 5 g/dL]) and red blood cell volume (325 to 350 mL), provided that dialysis was adequate and stores of iron and folate were normal. 690 691 Whether the benefits of such treatment outweigh the potential adverse effects is unclear, 692 and the use of androgens for this purpose has largely been replaced by erythropoietin therapy.

**Hereditary Angioneurotic Edema**

In this autosomal dominant disorder, the serum inhibitor of the first component of complement is nonfunctional or absent and unopposed activation of the complement cascade generates factors that enhance the permeability of vessels and produce attacks of angioedema. A variety of 17-alkylated steroids can increase the activity of
the inhibitor in serum and restore the complement components that are depleted secondarily in the disorder.  
Orally active androgens are effective, and steroids such as danazol that are weak androgens appear to be as effective as or more effective than potent androgens.

The response in men and women appears to be the same. Because 17-alkylated androgens (but not testosterone or testosterone esters) cause elevations of several plasma glycoproteins, including haptoglobin, protein-bound sialic acid, plasminogen, and the inhibitor of the first component of complement, the beneficial effect of oral androgens in this disorder is probably the result of the side effect of 17-alkylated steroids on liver function rather than androgen action per se. No reports of the effect of testosterone esters in angioneurotic edema have been published.

Short Statute

Androgens have been used in the management of growth retardation of various causes other than pituitary insufficiency. Their administration before the epiphyses close accelerates linear growth, and the mean height age may be advanced more than skeletal age. Administration of androgens for short periods (6 months or less) has no permanent effects on hypothalamic-pituitary or gonadal maturation. The acceleration of growth may be due to increased levels of plasma growth hormone, but such treatment does not appear to increase final height. Indeed, such therapy in short children before the age of 9 years may actually have a deleterious effect on adult height.

Carcinoma of the Breast

See Chapter 39.

Side Effects of Androgens

Some side effects of androgens are due to physiologic actions of the hormones (through the androgen receptor) but in an inappropriate setting. For example, the virilizing actions are desirable in hypogonadal men but undesirable in women and young boys. In some older hypogonadal men, androgen therapy may cause previously unrecognized prostate cancer to become clinically apparent. Other side effects are the results of actions of androgen metabolites, and because different androgens are metabolized differently, the side effects vary. Testosterone can be metabolized in estrogens and can have feminizing as well as virilizing effects, whereas 5-reduced androgens such as dihydrotestosterone cannot be converted to estrogens and consequently do not have feminizing effects.

Normal people vary in the frequency of side effects, just as there is variability in the degree of virilization of males at puberty. There are also age differences in the occurrence of some side effects. For example, androgens in children may cause premature closure of the epiphyses, may induce gynecomasia, or may produce virilization, even when used in small amounts and for limited periods. The incidence of side effects may also be increased by coexisting clinical conditions. Hepatoma may occur more frequently after androgen treatment of individuals with Fanconi's anemia, sodium retention is worse in patients with congestive heart failure, and feminizing side effects are more prominent in men with hepatic cirrhosis.

A physiologic effect of androgen administration is an increase in the hematocrit, and some men develop polycythemia with such treatment. In one retrospective study, nine of nine older men with high hematocrit values had cerebrovascular events after discontinuation of testosterone therapy.

In a randomized study, significant increases in hematocrit values were more common in men given testosterone esters than a testosterone patch and the increase in hematocrit was related to age, bioavailable testosterone levels, and estradiol levels.

Virilizing Side Effects

All androgens involve the risk of virilizing women and children of both sexes. Coarsening of the voice, hirsutism, and menstrual irregularities are common. If treatment is discontinued as soon as these effects are noticed, the manifestations may slowly subside. With prolonged treatment, male-pattern baldness, hirsutism, coarsening of the voice and enlargement of the cricoïd cartilage, and hypertrophy of the clitoris become largely irreversible.

Feminizing Side Effects

The feminizing side effects of androgens are poorly understood. Testosterone can be converted (aromatized) in peripheral tissues to estrogens and can have feminizing effects, whereas 5-reduced androgens such as dihydrotestosterone cannot be converted to estrogens and consequently do not have feminizing effects.

The conversion of all androgen analogues to estrogens has not been documented, it is presumed that most, if not all, C19 steroids with a 3-keto configuration can be converted to estrogens and that feminization is the effect of estrogenic metabolites of the parent steroids. Administration of testosterone esters to men increases plasma estrogen levels. The most common manifestation of feminization, development of gynecomasia, is unpredictable and in adult men usually occurs only after high-dose androgen therapy. However, in children given androgens, gynecomasia is common (see earlier).

Toxic Side Effects

Some degree of sodium retention is a common consequence of androgen therapy. The amount of retained sodium is usually minor but can cause edema in the presence of underlying heart disease or renal failure.

17-Alkylated androgens impair liver function as evidenced by elevation of plasma alkaline phosphatase and conjugated bilirubin levels during therapy. Such changes are rare in men given parenteral testosterone esters. The predominant effect on hepatic function appears to be at the site of transport of metabolites from hepatocyte into bile. The clinical consequences of abnormal liver function probably depend on the previous integrity of the liver, but jaundice can occur in the absence of preexisting liver disease because of a hypersensitivity reaction. The changes in liver function induced by 17-alkylated drugs include increases in a variety of plasma proteins and decreased conjugation of adrenal steroids.

The most serious complications of oral androgen use are development of peliosis hepatitis (blood-filled cysts in the liver) and hepatoma. These disorders are more common in patients with aplastic anemia but also occur in persons given oral androgens for other reasons, including hypogonadism. Although they are usually benign and regress after discontinuation of the drugs, the tumors may undergo malignant transformation.

Occasional hyperlipidemia has been reported with oral androgens. All androgens including testosterone cause decreases in serum HDL cholesterol levels, and testosterone is the major cause of the differences in serum levels of HDL between men and women. 17-Alkylated androgens may cause a further suppression of HDL and raise LDL levels, but replacement with physiologic levels of testosterone in hypogonadal men does not suppress HDL cholesterol below levels seen in normal men. Sleep apnea has been reported in occasional men given pharmacologic amounts of testosterone esters, possibly the consequence of increased collapse of the upper airways during sleep. Obese men at risk for sleep apnea should be monitored for related symptoms when receiving testosterone therapy. Priapism has occurred in men treated with testosterone enanthate.
Gonadotropin Therapy

Gonadotropin treatment can establish or restore fertility in men who have gonadotropin deficiency either as an isolated disorder or as a part of more extensive anterior pituitary failure. Because men with hypogonadotropic hypogonadism may become resistant to gonadotropins after long-term treatment (presumably as the result of the development of neutralizing antibodies), the customary strategy is to treat such individuals initially with testosterone esters as described earlier and to reserve gonadotropin therapy until fertility is desired. Prior androgen therapy does not impair subsequent gonadotropin induction of spermatogenesis in men with hypogonadotropic hypogonadism.

Two gonadotropin preparations are available: hMG and hCG. The usual preparation of hMG (menotropins), purified from the urine of postmenopausal women, contains 75 IU of FSH and 75 IU of LH per vial. There are several sources of hCG, which is available in vials containing 5000 to 20,000 IU. The hCG is devoid of FSH activity and resembles LH in its ability to stimulate Leydig cells. Because of the expense of hMG, treatment is usually begun with hCG alone, and hMG is added later to stimulate the FSH-dependent stages of spermatid development.

A high ratio of LH to FSH activity and a long duration of treatment are necessary to bring about the maturation of prepubertal testes. In hypophysectomized adult men with long-term suppression of spermatogenesis, it is not predictable whether administration of preparations with both FSH and LH activities is necessary to initiate spermatogenesis. However, after spermatogenesis has been restored in hypophysectomized patients or initiated in hypogonadotropic hypogonadal men by combined therapy, sperm production can usually be maintained by hCG alone.

In men with hypogonadotropic hypogonadism, the dose of hCG required to maintain a normal plasma testosterone level varies from 1000 to 6000 IU/week. Most regimens for the induction of spermatogenesis involve starting with doses of 2000 IU three times or more a week until most of the clinical parameters, including normal male plasma testosterone values, indicate an optimal effect. During initial treatment, the testis volume may reach only 8 mL. Then hMG is added, with as little as 12.5 IU of FSH being required three times a week to complete the development of spermatogenesis and cause further growth of the testes. Optimal spermatogenesis may require treatment for 12 to 24 months.

In most men with hypogonadotropic hypogonadism and no history of cryptorchidism, such a regimen brings sperm counts to the fertile range; for those in whom sperm production is not sufficient for fertility, in vitro fertilization may be successful. The addition of hMG may not be necessary in individuals with partial hypogonadotropic hypogonadism who presumably have some endogenous FSH secretion. Anti-hCG antibodies may develop after long-term hCG treatment, but development of resistance to the action of the hormone is less common.

Recombinant human FSH (rhFSH) is similarly successful in inducing puberty and spermatogenesis in gonadotropin-deficient adolescent and adult men but is ineffective in the treatment of idiopathic infertility.

Treatment with hCG has been used to attempt to promote permanent descent of inguinal testes into the scrotum. Although there are discrepancies among studies because of varying definitions of cryptorchidism, such therapy appears to be successful in about a fifth of patients and makes it possible to identify unambiguously the cryptorchid boys who should be treated surgically (see earlier). Such therapy is associated with a variety of virilizing and feminizing side effects in boys because of enhancement of the testicular production of estradiol and testosterone (see Chapter 24).
Gonadotropin-Releasing Hormone Therapy

GnRH agonists can produce diametrically opposite effects depending on the mode of administration. When given in a pulsatile fashion to mimic physiologic secretory patterns, such therapy enhances gonadotropin secretion. In contrast, the tonic administration of the same agonist inhibits gonadotropin secretion and causes a physiologic (reversible) castration ([741] [742] (see discussion of antiandrogens later). In addition, antagonists have been designed that have no agonist action, regardless of the pattern of administration. ([742]

Agonistic effects are of benefit in hypogonadotropic hypogonadism and cryptorchidism. Because the most common cause of isolated gonadotropin deficiency is defective synthesis or release of GnRH, this agent is the most physiologic treatment of the disorder. In such individuals, the long-term pulsatile administration of GnRH through a portable infusion pump induces normal pubertal development. Normal levels of plasma testosterone, LH, and FSH can be attained with small doses of gonadorelin administered subcutaneously every 90 to 120 minutes. ([743] [744]

Pulsatile GnRH therapy does not appear to have advantages over gonadotropin therapy in men with hypogonadotropic hypogonadism. ([745] GnRH and its analogues have also been used to treat boys with cryptorchidism. The success (or failure) rates for descent of inguinal testes in boys so treated appear to be comparable to those achieved with gonadotropins (see earlier). ([746]
Antiandrogens and 5-Reductase Inhibitors

Agents that block the synthesis or action of androgens are used for treatment of hyperplasia and carcinoma of the prostate, acne, male-pattern baldness, virilizing syndromes in women, precocious puberty in boys, and male sex offenders.

Inhibitors of Testosterone Synthesis

The most effective inhibitor of testosterone synthesis is either GnRH itself or a GnRH agonist or antagonist (see Chapter 8 for details). These agents cause a decline in the plasma levels of LH and testosterone and induce a pharmacologic (and reversible) castration. Such therapy provides a medical alternative to castration for producing androgen deprivation in men with prostatic cancer and produces fewer deleterious side effects than estrogen therapy. \[747\]

In individuals with prostatic carcinoma, such agents are usually administered in conjunction with androgen receptor antagonists, which block the action of androgens of adrenal origin, to produce total androgen deprivation. \[747\] In contrast, monotherapy with GnRH analogues is effective in individuals with precocious puberty. \[748\] Some men with paraphilias, \[750\] and selected men with prostatic hyperplasia. \[752\] These agents are administered parenterally. The frequency of administration and dosage vary with the agent, but long-acting agents such as depot leuprolide acetate are effective when given at monthly intervals in doses of 7.5 mg. \[754\] Vasomotor symptoms characteristic of the castrated state are common and may be severe; management of the latter symptoms is frequently unsuccessful, but they may respond to megestrol acetate. \[756\]

The progestagen medroxyprogesterone acetate inhibits testosterone biosynthesis by at least two mechanisms; at low concentrations it inhibits synthesis directly, and at higher concentrations it inhibits LH secretion. \[757\] Dosages of 400 mg/week by parenteral injection induce a pharmacologic castration and have been used successfully in some men with paraphilia. \[759\]

Antifungal agents of the imidazole class, such as ketoconazole and itraconazole, secondarily block cytochrome P450 enzymes in steroid hormone biosynthesis, effects that have been used to induce androgen deprivation in some prostate cancer. \[760\] Gastrointestinal side effects, short duration of action, and inhibition of the biosynthesis of adrenal steroids limit the usefulness of these agents.

Spironolactone, an aldosterone antagonist (see Chapter 14 and Chapter 15), is also a weak inhibitor of the binding of androgen to the androgen receptor and impairs androgen biosynthesis. In some women with hirsutism, the drug decreases the growth rate and mean diameter of facial hair; \[761\] because it may cause menstrual irregularity, it is commonly given together with an oral contraceptive. \[762\] In efficacy studies, spironolactone was about as effective as finasteride in improving hirsutism scores. \[763\]

5-Reductase Inhibitors

Because the conversion of testosterone to dihydrotestosterone is essential for certain androgen actions, inhibition of steroid 5-reductase selectively blocks androgen action in the tissues (e.g., prostate, certain hair follicles) in which continuing production of dihydrotestosterone is essential. The azasteroid finasteride is an orally active inhibitor that preferentially blocks steroid 5-reductase 2 but may also inhibit enzyme 1. \[764\] At ordinary dosages, the agent causes a profound decline in dihydrotestosterone levels in serum and prostate but has little if any effect on serum testosterone or LH levels. It also has no significant effect on potency or libido. \[765\]

In men with prostatic hyperplasia, finasteride at a dosage of 5 mg/day causes a consistent decrease in prostate size and improvement in urine flow and symptoms in a third, and thus provides an alternative to surgery in men with moderate disease manifestations. \[766\] Finasteride is also effective at a dose of 1 mg/day for male-pattern baldness. \[767\] Additional 5-reductase inhibitors, including agents specific for the individual isozymes, are under development.

Androgen Receptor Antagonists

Several anilide derivatives block the binding of androgen to its receptor. Bicalutamide, a nonsteroidal antianrogen that blocks binding of dihydrotestosterone to the androgen receptor, is devoid of other hormonal activity and has a half-life that allows once-daily oral dosing. Bicalutamide appears to have a low incidence of adverse effects. \[768\] Flutamide, given at doses of 750 mg/day, is converted in vivo to 2-hydroxyflutamide, a potent antienrogen, but because of rapid turnover must be administered three times daily. \[769\] Nilutamide has similar effects at doses of 300 mg/day. \[770\]

In normal men, all three agents block the inhibitory feedback of androgen on LH production and result in an increase in the frequency of LH secretory bursts and hence an increase in serum LH and testosterone. The rise in serum testosterone serves to limit the antianrogenic effectiveness. Consequently, they are most useful in inhibiting androgen action in castrated men, in men in whom LH is inhibited (e.g., in men receiving GnRH agonists), or in women (in whom LH production is not under androgenic control). The principal use is for treatment of prostatic cancer, usually in conjunction with GnRH blockade or estrogen. \[771\]

In men with advanced prostate cancer, bicalutamide and flutamide, each used in combination with a GnRH analogue, have similar effects. \[772\] If the agent crossed the placenta, it would be expected to cause male pseudohemaphroditism in male embryos and consequently should always be given to women in conjuction with an oral contraceptive. Flutamide can cause diarrhea and hepatotoxicity, and nilutamide is associated with side effects similar to those seen with disulfiram (Antabuse) and visual disturbances.

The progestagen cyproterone acetate is an antianrogen antagonist that also suppresses the secretion of gonadotropins and thus interferes with testosterone production. \[773\] The principal effect is believed to be competition with dihydrotestosterone for binding to the androgen receptor. \[774\] In castrated animals, dosages about five times that of testosterone blocked androgenic responses by about 50% and with larger dosages the antagonism was almost complete. \[775\] The administration of cyproterone acetate at 100 mg/day to normal men caused a 50% decrease in serum levels of LH and FSH and a 75% decrease in serum testosterone. \[776\] The agent has been used for the treatment of acne, male-pattern baldness, and hirsutism and virilizing syndromes in women \[777\] and to induce chemical castration in men with paraphilias. \[778\] The agent has orphan drug status in the United States. The fact that it can cross the plaencta and induce male pseudohemaphroditism in male embryos \[779\] and that its use has been associated with severe liver damage, including development of hepatocellular carcinoma, \[780\] limits its usefulness.
Aromatase Inhibitors and Antiestrogens

Aromatase Inhibitors

Second-generation aromatase inhibitors that are both selective and potent include letrozole and anastrozole, both of which are orally active and can be administered once daily. At a dose of 1 mg/day, anastrozole lowered plasma estradiol in men by about half and caused reciprocal increases in plasma LH and testosterone levels, and letrozole had similar effects in male monkeys.

Although not approved for these indications, such agents may be useful in the treatment of familial testotoxicosis in boys, selected cases of gynecomastia, and the aromatase excess syndrome. Potential adverse effects include asthenia, nausea and vomiting, and headache.

Estrogen Receptor Antagonists (see Chapter 39)

Of the two estrogen receptors identified, current antagonists were designed to block the receptor, and it is assumed that dual or selective -receptor antagonists would have different consequences. Tamoxifen at a dose of 20 mg/day was reported to provide resolution in about 75% of cases of idiopathic gynecomastia, and 16 of 18 men with mastalgia or gynecomastia associated with spironolactone therapy for hepatic cirrhosis improved significantly with a dose of 20 mg of tamoxifen twice a day. Similar beneficial effects of tamoxifen have been reported in flutamide-induced gynecomastia and in the gynecomastia that follows castration or leuprolide therapy. A variety of side effects have been reported, including development of fatty liver.

Erectile dysfunction (ED), previously referred to as impotence, is the inability of the male to attain or maintain a penile erection sufficient for satisfactory sexual intercourse. Sexual dysfunction is a more general term that also includes libidinal, orgasmic, and ejaculatory dysfunction in addition to the inability to attain or maintain penile erection. [1]
MALE SEXUAL DYSFUNCTION

PREVALENCE AND INCIDENCE RATES

The best data on the prevalence of ED in men have emerged from two cross-sectional studies that have used probability sampling techniques, namely the Massachusetts Male Aging Study (MMAS) and the National Health and Social Life Survey (NHSLS). The MMAS was a cross-sectional, community-based random sample epidemiologic survey in which 1709 men in the greater Boston area, 40 to 70 years of age, were first surveyed between 1987 and 1989. Of these, 847 men were resurveyed between 1995 and 1997. This survey revealed that 52% of men between the ages 40 and 70 were affected by ED to some degree; 17.2% of surveyed men reported minimal ED, 25.2% moderate ED, and 9.6% complete ED.

The NHSLS was a national probability survey of English-speaking Americans, 18 to 59 years of age living in the United States in 1992. In this survey, 7% of men between 18 to 29 years of age, 9% between 30 and 39 years of age, 11% between 40 and 45 years, and 18% between 50 and 59 years reported ED, based on self-reports of difficulty in obtaining or maintaining erections.

These two landmark studies and data from several other studies suggest ED is a common problem affecting 20 to 30 million men in the United States alone. The prevalence of ED increases with age; it affects fewer than 10% of men younger than 45 years of age but 75% of men older than 80 years of age. Men with other medical problems, such as hypertension, diabetes, cardiovascular disease, and end-stage renal disease, have a significantly higher prevalence of ED compared with healthy men.

There is a paucity of longitudinal data on the annual incidence rates of ED in men. Most of the available information has been derived from two studies. In the MMAS, of the 1297 men 40 to 70 years of age who were originally surveyed in 1987 to 1989, follow-up information was gathered from 847 men between 1995 and 1997. In this study, the crude incidence rate of ED in white men in the Boston area was 25.9 cases per thousand man-years. The incidence rates increased from 12.4 cases per thousand man-years for men aged 40 to 49 years to 29.8 cases per thousand man-years for men aged 50 to 59 years, and 46.4 per thousand man-years for men aged 60 to 69 years.

In another study, incidence rates were derived from a survey of 3250 men, 6 to 83 years of age, seen at a preventive medicine clinic between 1987 and 1991. This study found the incidence rates of ED to be fewer than 3 cases per 1000 man-years among men younger than 45 years of age and 52 cases per thousand man-years among men 65 years of age or older. On the basis of these two studies, it is estimated that there are 600,000 to 700,000 new cases of ED each year in the United States alone.
REGULATION OF MALE SEXUAL FUNCTION AND PHYSIOLOGY OF PENILE ERECTION

Sexual function is a complex, multifunctional biologic process that comprises central mechanisms for regulation of libido and arousability as well as local mechanisms for the generation of penile tumescence, rigidity, orgasm, and ejaculation. Androgen-deficient men have decreased overall sexual activity but can achieve normal erections in response to visual erotic stimuli. These observations have led to the prevalent dogma that libido is testosterone-dependent and that the local mechanisms for penile erection are androgen-independent. There is emerging evidence that testosterone is a regulator of nitric oxide synthase (NOS) activity in the cavernosal smooth muscle. Therefore, it is possible that physiologically normal testosterone concentrations might be required for optimal penile rigidity. Orgasm and ejaculation are not androgen-dependent and can occur without a full penile erection.

Normal penile erection requires coordinated involvement of intact central and peripheral nervous systems and the corpora cavernosa and spongiosa as well as a normal arterial blood supply and venous drainage (Fig. 19-1) (Figure Not Available). The cavernosal arteries and their branches (the helicine arteries) provide blood flow to the penis. Helicine arteries deliver blood into the cavernosal sinuses. Dilatation of the helicine arteries increases the blood flow and pressure in the cavernosal sinuses. Relaxation of the cavernosal smooth muscle that surrounds the cavernosal sinuses along with increased blood flow results in pooling of blood in the cavernosal spaces and penile engorgement. The expanding corpora cavernosa compress the veins against the rigid tunica albuginea, restricting the venous outflow from the cavernosal spaces. This facilitates entrapment of blood in the cavernosal sinuses and achievement of a rigid erection.

The erectile state of the penis is determined by the tone of the corporal smooth muscle cells. When the cavernosal smooth muscle cells are relaxed, the tone is low and the penis is engorged with blood and erect. Conversely, when the cavernosal smooth muscle tone is high, the penis is flaccid. The smooth muscle tone in the corpora cavernosa is maintained by agonist-stimulated release of intracellular calcium into the cytoplasm and influx of calcium through membrane channels. An increase in intracellular calcium through its binding to calmodulin activates myosin light chain kinase, resulting in phosphorylation of myosin light chain, actin-myosin interactions, and muscle contraction. The transmembrane and intracellular calcium flux in the cavernosal smooth muscle cells is regulated by a number of cellular processes and signaling molecules such as potassium ion (K⁺) flux through potassium channels, connexin 43-derived gap junctions, norepinephrine, prostaglandin E₁, and nitric oxide (NO).

Movement of K⁺ across the membrane determines the membrane potential of the cavernosal smooth muscle cells; at least four subtypes of potassium channels mediate this K⁺ efflux. The adjacent smooth muscle cells are interconnected in a syncytium through connexin 43-derived gap junctions. Therefore, changes in K⁺ channel activity in one myocyte affect the membrane potential of adjacent cells, resulting in rapid transmission of electrical and biochemical signaling throughout the syncytium.

The vascular smooth muscle contraction in the corpora cavernosa is regulated by the noradrenergic pathway. Norepinephrine binds to adrenergic receptors, resulting in generation of diacylglycerol and inositol triphosphate (IP₃). Diacylglycerol activates protein kinase C, which in turn can inhibit K⁺ channels, whereas IP₃ increases intracellular calcium and calcium influx through the membrane. The net increase in intracellular calcium promotes actin-myosin interaction, resulting in smooth muscle contraction.

PGE₂, activation of its receptor results in generation of cyclic adenosine monophosphate (cAMP), which activates protein kinase A (PKA). Activated PKA stimulates K⁺ channels, resulting in K⁺ efflux from the cell. In addition, PKA-mediated processes also result in a net decrease in intracellular calcium, favoring smooth muscle cell relaxation. Nitric oxide, through stimulation of synthesis of intracellular cyclic guanosine monophosphate (cGMP), also decreases intracellular calcium and K⁺ efflux.

The relaxation of the cavernosal smooth muscle trabeculae is under the regulation of the autonomic nervous system. A number of cholinergic, adrenergic, and noradrenergic, noncholinergic (NANC) mediators regulate cavernosal smooth muscle relaxation. The NANC mediators include vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and nitric oxide. Nitric oxide is derived from the nerve terminals innervating the corpora cavernosa, the endothelial lining of penile arteries and cavernosal sinuses, and is an important biochemical regulator of cavernosal smooth muscle relaxation. Nitric oxide also induces arterial dilatation. The actions of nitric oxide on the cavernosal smooth muscle and the arterial blood flow are mediated through the activation of guanylyl cyclase and production of cyclic GMP. The latter acts as an intracellular second messenger and causes smooth muscle relaxation by lowering intracellular calcium.

A class of enzymes, called cyclic nucleotide phosphodiesterases, degrades cGMP into an inactive form, GMP. Researchers have now identified at least 11 different isoforms of cyclic nucleotide phosphodiesterases. These isoforms are widely distributed throughout the body; the predominant isoform of this enzyme in the cavernosal smooth muscle is cyclic nucleotide phosphodiesterase type 5 (PDE5).

Hydrolysis of cGMP by this enzyme results in reversal of the smooth muscle relaxation and reversal of penile erection. Sildenafil (Viagra, Pfizer) is a potent and selective inhibitor of type 5 PDE activity that prevents breakdown of cGMP and thereby enhances penile erection.

Figure 19-1: Anatomy and mechanism of penile erection. The corpora cavernosa are made up of trabecular spaces that are surrounded by cavernosal smooth muscle. Helicine arteries provide the arterial supply to the cavernosal spaces. The dorsal nerve provides the sensory innervation to the penis. During erection, the relaxation of the trabecular smooth muscle and the increased blood flow result in engorgement of the sinusoidal spaces in the corpora cavernosa. The expansion of the sinusoids compresses the venous return against the tunica albuginea, resulting in entrapment of blood. This imparts rigidity to the tumescent penis. (Adapted from Lue T. Erectile dysfunction. N Engl J Med 2000; 342:1802-1813.)
PHYSIOLOGIC, LIFESTYLE, AND PSYCHOSOCIAL CORRELATES AND RISK FACTORS FOR ERECTILE DYSFUNCTION

Epidemiologic studies indicate that the best predictors of the risk of ED are age, a history of diabetes mellitus, hypertension, medication use, and cardiovascular disease. Advancing age is an important risk factor for ED in men: fewer than 10% of men below age 40 years and more than 50% of men older than age 70 years are anticipated to be affected by ED. In both studies mentioned earlier (MMAS and NHSLS), the prevalence of ED increased with each decade of life.

Among the chronic diseases associated with ED, diabetes mellitus is the most important risk factor. In the MMAS, the age-adjusted risk for development of complete ED was three times higher in men with history of treated diabetes mellitus than in men without such a history. Of men with diabetes mellitus, 50% are expected to experience ED at some time during the course of their illness. In the MMAS, treated heart disease, treated hypertension, and hyperlipidemia were associated with significantly increased risk of ED. Among men with treated heart disease and hypertension, the probability of ED was more than two times greater for smokers than for nonsmokers. Smoking also increases the risk of ED in men taking medications for cardiovascular diseases. Cardiovascular disorders, including hypertension, stroke, coronary artery disease, and peripheral vascular disease, are all associated with increased risk of ED.

Several reviews have emphasized the relationship of prescription medications and the occurrence of ED. In the MMAS, the use of antihypertensive agents, cardiac medication,

Figure 19-2 Biochemical mechanisms of penile smooth muscle relaxation. A, Relaxation of the cavernosal smooth muscle is regulated by intracellular cyclic adenosine monophosphate (cAMP) and cyclic guanidine monophosphate (cGMP). The intracellular second messengers, by activation of specific protein kinases, cause sequestration of intracellular calcium (Ca^{2+}), closure of calcium channels, and opening of potassium (K^+) channels. This results in a net decrease in intracellular calcium, causing smooth muscle relaxation. Nitric oxide, released by noradrenergic, noncholinergic nerve endings (NANC), stimulates guanyl cyclase. By inhibiting phosphodiesterase type 5 (PDE5), sildenafil increases the amount of intracellular cGMP. Prostaglandin E, (PGE), stimulates generation of cAMP. Papaverine inhibits PDE, PDE, and PDE and thereby increases the amount of intracellular cAMP. AMP, adenosine monophosphate; GTP, guanosine triphosphate; IP, inositol 1,4,5-triphosphate; NO, nitric oxide; PKA, protein kinase A; PKG, cGMP-specific protein kinase. B, Interconnection of cavernosal smooth muscle cells in the penis. The smooth muscle cells in the corpora cavernosa are interconnected through connexin 43-derived gap junctions. Therefore, alterations in action potential and potassium channel activity in any myocyte affect the adjacent myocytes. (A and B, Adapted and redrawn from Melman A, Christ GJ. Integrative erectile biology: the effects of age and disease on gap junctions and ion channels and their potential value to the treatment of erectile dysfunction. Urol Clin North Am 2001; 28:217-231.) and oral hypoglycemic drugs was associated with an increased risk of ED. Thiazide diuretics and psychotropic drugs used in the treatment of depression may be the most common drugs associated with ED, simply because of the high prevalence of their use. A variety of drugs, however, including almost all antihypertensive agents, digoxin, histamine-2 receptor antagonists, anticholinergics, cytotoxic agents, and androgen antagonists, have been implicated in the pathophysiology of ED.
PATIENT EVALUATION

History

The diagnostic work-up of the patient with ED should start with an evaluation of general health (Table 19-1). The general medical history should be directed at identifying etiologic factors as well as factors that might affect the selection and response to therapy. The presence of diabetes mellitus, coronary artery disease, peripheral vascular disease, and hypertension may suggest a vascular cause. A history of stroke, spinal cord or back injury, multiple sclerosis, or dementia may point to a neurologic disorder. Also relevant is any history of pelvic trauma, prostate surgery, or priapism.

The social history must include ascertainment of recreational drug abuse particularly tobacco, use of cocaine, marijuana and alcohol. Information about medications, particularly antihypertensive agents, antiandrogens, antidepressants, and antipsychotic drugs is important because almost 25% of all cases of impotence can be attributed to medications. Psychiatric illnesses (e.g., depression, psychosis) or drugs used to treat these disorders may be associated with sexual dysfunction.

A detailed sexual history, including the nature of relationships, partner expectations, situational erectile failure, performance anxiety, and marital discord, needs to be elicited (see Table 19-1). It is important to distinguish between an inability to achieve erection, changes in sexual desire, failure to achieve orgasm and ejaculation, and dissatisfaction with the sexual relationship. The physician should inquire about the onset, quality, and duration of erections and the presence of nocturnal and early morning erections.

Physical Examination

A directed physical examination should assess secondary sex characteristics, the presence or absence of breast enlargement, and testicular volume. An evaluation of femoral and pedal pulses can provide clues to the presence of peripheral vascular disease (see Table 19-1). The neurologic examination focuses on the presence of motor weakness, perineal sensation, anal sphincter tone, and bulbocavernosus reflex. The examination of the penis notes any unusual curvature, palpable plaques, or superficial lesions.
Self-Reporting Questionnaires

Over the last decade, there has been a general shift in most male sexual dysfunction clinics away from expensive, time-consuming, and invasive techniques (e.g., dynamic infusion cavernosometry, penile duplex Doppler ultrasonography, and Rigiscan studies) toward the use of simple, noninvasive, self-reporting questionnaires. These questionnaires have been found to be of value because many men with ED, for a variety of reasons, do not voluntarily come forward to their physicians and state their sexual complaints. Many men with ED feel embarrassed, whereas others consider ED an inevitable concomitant of the aging process. Some physicians themselves feel uncomfortable while discussing issues of such personal nature; this creates an atmosphere that is not conducive to effective communication. These self-reporting questionnaires can help break the ice and facilitate communication. These instruments are widely available and easy to complete, and they can complement or enhance the work-up of sexual dysfunction.

The International Index of Erectile Function (IIEF) is a multidimensional scale consisting of 15 questions that address relevant domains of male sexual function. The IIEF has been validated in several languages, used in many multinational clinical trials, and has been found to have adequate sensitivity and specificity for detecting treatment-related changes, including response to oral erectogenic agents in men with ED.

Considerable effort has been invested in the development of abbreviated questionnaires that take less time than the IIEF but more concisely address similar aspects of male sexuality (e.g., Sexual Health Inventory for Men Questionnaire [SHIM]).
Laboratory Tests

The diagnostic evaluation of a man with ED starts with general health evaluation. This may include measurements of hemoglobin, white blood cells, blood glucose, aspartate transaminase (AST), alanine transaminase (ALT), bilirubin, alkaline phosphatase, blood urea nitrogen (BUN), and creatinine.

Measurement of serum total testosterone concentrations can help detect androgen deficiency. Although there is no consensus on this issue, it is important to exclude androgen deficiency in men presenting with ED because this deficiency may be a manifestation of serious underlying illness, such as a pituitary tumor or human immunodeficiency virus (HIV) infection. In addition, testosterone replacement is desirable in men with androgen deficiency not only for restoration of sexual function but also for maintaining bone mineral density, muscle mass and protein metabolism, and a sense of well-being.

If the history, physical examination, and ED questionnaire do not identify any obvious medical concerns warranting further work-up, a more cost-effective approach for a busy practitioner is to prescribe a trial of oral medication (e.g., sildenafil) if there are no contraindications (e.g., nitrate use). See algorithm A.
Evaluation of Penile Vasculature and Blood Flow

Several tests are available to assess the integrity of penile vasculature and blood flow. Of these, the penile brachial blood pressure index is a simple and specific, but not a very sensitive, indicator of vascular insufficiency. It is of historical interest but is rarely used today.

Intracavernosal injection of a vasoactive agent such as PGE₁ can be used as both a diagnostic and potential therapeutic modality. This procedure can show whether the patient will respond to this therapeutic modality and can facilitate patient education about the procedure and its potential side effects. Failure to respond to intracavernosal injection sometimes suggests vascular insufficiency or a venous leak that might need further evaluation and treatment.

Most men with ED do not need duplex color sonography, cavernosography, or pelvic angiography. These procedures should be reserved for patients in whom the results of these tests would alter the management or prognosis and only by physicians with considerable experience in their use. For instance, angiography may be useful in a young man with arterial insufficiency associated with pelvic trauma. Similarly, suspicion of congenital or traumatic venous leak in a young man presenting with ED would justify cavernosography. In each instance, confirmation of the vascular lesion might lead to consideration of surgery. Duplex ultrasonography can provide a noninvasive evaluation of vascular function.
Nocturnal Penile Tumescence

Although recording of formal nocturnal penile tumescence (NPT) in a sleep laboratory for successive nights can help differentiate organic from psychogenic impotence, this test is expensive and labor-intensive and is not required in most men with ED. In most cases, formal NPT studies are reserved for medical-legal documentation.

The introduction of portable Rigiscan devices in 1985 has provided clinicians with a reliable means of continuously monitoring penile tumescence and rigidity at home. The patient wears this multicomponent device at bedtime for two to three nights. Two wiregauge loops are placed around the base and tip of the penis to record changes in penile circumference and rigidity. Data are stored and then downloaded via a software program that allows for sophisticated interpretation.

NPT testing is not needed for most men with ED. It is recommended only for patients with a high clinical suspicion of psychogenic ED or situational problems or to document preoperatively poor penile rigidity. For most cases, a careful history eliciting nighttime or early morning erections provides a reasonable correlation with formal NPT and Rigiscan studies.
Diagnostic Tests to Exclude Androgen Deficiency and Hypothalamic-Pituitary Lesions

There is considerable debate about the usefulness and cost-effectiveness of hormonal evaluation and the extent to which androgen deficiency should be investigated in men presenting with ED. Of all men with ED, 8% to 10% have low testosterone levels; the prevalence of androgen deficiency increases with advancing age. The prevalence of low testosterone levels is not significantly different in men who present with ED and in an age-matched population. Urologic studies report that in 6% to 8% of men with ED there is an endocrine basis to the condition. These data are consistent with the proposal that ED and androgen deficiency are two common but independently distributed disorders.

Yet, it is important to exclude androgen deficiency in this patient population. Androgen deficiency is a correctable cause of sexual dysfunction, and some men with ED and low testosterone levels do respond to testosterone replacement. Hypogonadism can have additional deleterious effects on the patient’s health; for instance, hypogonadism might contribute to osteoporosis, loss of muscle mass and function, and increased risk of disability, falls, and fracture. In addition, in cross-sectional epidemiologic studies, low testosterone levels are associated with increased risk of midsegment obesity, insulin resistance, type 2 diabetes mellitus, and coronary artery disease; however, we do not know whether testosterone replacement can reduce visceral fat and improve insulin sensitivity and cardiovascular risk in middle-aged men with midsegment obesity. Regardless of the presence of sexual dysfunction, androgen deficiency should be corrected by appropriate hormone replacement therapy. Further, androgen deficiency may be a manifestation of a serious underlying disease, such as HIV infection or a hypothalamic-pituitary space-occupying lesion.

In large studies, only a small fraction of men with ED and low testosterone levels have been found to have space-occupying lesions of the hypothalamic-pituitary region. In one large survey, all of the hypothalamic-pituitary lesions were found in men with serum testosterone levels below 150 ng/dL. Therefore, the cost-effectiveness of the diagnostic work-up to rule out an underlying lesion of the hypothalamic-pituitary region can be increased by limiting the work-up to men with serum testosterone levels less than 150 ng/dL.
TREATMENT

The selection of the therapeutic modality should be based on the underlying etiology, the patient's preference (goal-directed approach), the nature and strength of relationship with the man's sexual partner, and the absence or presence of underlying cardiovascular disease and other co-morbid conditions. In current practice, it is common to employ a step approach that first utilizes minimally invasive therapies that are easy to use and produce fewer adverse effects and then progresses to more invasive therapies that may require injections in some circumstances or surgical interventions after the first-line choices have been exhausted (Table 19-2). The physician needs to discuss the risks, benefits, and alternatives of all the diagnostic procedures and therapies with the couple.

It is intuitive that, in the execution of good medical practice, all associated medical disorders need to be optimized. In men with diabetes mellitus, efforts to optimize glycemic control are instituted, although improving glycemic control may not necessarily improve sexual function. In men with hypertension, control of blood pressure is optimized, and, if possible, the therapeutic regimen may need to be modified to discontinue antihypertensive drugs that impair sexual function. This strategy is not always possible because almost all antihypertensive agents have been associated with sexual dysfunction; the frequency of this adverse event is less with angiotensin-converting enzyme (ACE) inhibitors than with other agents.

All patients with ED can benefit from psychosexual counseling. Unfortunately, many couples are reluctant to pursue this avenue. When there is latent marital discord, the sensitive and astute clinician should direct affected couples appropriately.

First Line Therapies

Psychosexual Counseling

Counseling can be of benefit in both psychogenic and organic causes of sexual dysfunction (see Table 19-2). It can help decrease performance anxiety and increase the patient's ability to cope with the problem. Involving the partner in the counseling process can help dispel misperceptions about the problem, decrease stress, enhance intimacy and ability to talk about sex, and increase the chances of successful outcome of therapy. Counseling sessions are also helpful in uncovering conflicts in relationships, psychiatric problems, alcohol and drug abuse, and significant misperceptions about sex. Although psychobehavioral therapy has been claimed to relieve depression and anxiety, there is a striking paucity of outcome data on the effectiveness of this therapeutic modality.

Sildenafil

Sildenafil (Viagra) is the first effective oral agent for the treatment of ED. It was introduced to the United States market in March 1998, and since that time millions of tablets have been dispensed. Sildenafil is a selective type 5 PDE inhibitor that is a safe and effective first-line, oral treatment for ED (Table 19-3 and Table 19-4). Therefore, sildenafil action requires an intact nitric oxide response as well as constitutive synthesis of cGMP by the smooth muscle cells of the corpora cavernosa. By selectively inhibiting cGMP catabolism in the cavernosal smooth-muscle cells, sildenafil restores the natural erectile response to sexual stimulation but, importantly, does not produce an erection in the absence of sexual stimulation. The fidelity of the nitric oxide production pathway and sexual stimulation are both necessary requirements for sildenafil to induce an erection.

Efficacy

The efficacy of sildenafil was demonstrated in a randomized dose-response study in which 532 men with organic, psychogenic, or mixed ED were randomized to receive placebo or 25, 50, or 100 mg of sildenafil for 24 weeks. In this dose-response study, patients taking sildenafil performed better in terms of increased rigidity, frequency of vaginal penetration, and maintenance of erection. Increasing doses of sildenafil were associated with higher mean scores for the questions assessing frequency of penetration and maintenance of erections after sexual penetration.

In a follow-up dose escalation study, 329 men were randomly assigned to receive placebo or 50 mg of sildenafil for 12 weeks. At each follow-up, the dose of sildenafil was increased or decreased by 50%, depending on the therapeutic response.

<table>
<thead>
<tr>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Sildenafil (Viagra) is absolutely contraindicated in men taking long-acting or short-acting nitrate drugs on a regular basis.</td>
</tr>
<tr>
<td>2. If the patient has stable coronary artery disease, is not taking long-acting nitrates, and uses short-acting nitrates only infrequently, the use of sildenafil should be guided by careful consideration of risks.</td>
</tr>
<tr>
<td>3. All men taking nitrates should be warned about the risks of the potential interaction between nitrates and sildenafil. The patients should also be warned that concurrent recreational use of inhaled nitrates or “poppers” may result in marked hypotension that may be serious or even fatal.</td>
</tr>
<tr>
<td>4. Sildenafil is contraindicated within 24 hours of ingestion of any form of nitrate.</td>
</tr>
<tr>
<td>5. In men with preexisting coronary artery disease, the physician should assess the risks of inducing cardiac ischemia during sexual activity before prescribing sildenafil. This assessment may include a stress test.</td>
</tr>
</tbody>
</table>
6. Men who are taking a combination antihypertensive medication should be warned about the possibility of sildenafil-induced hypotension. This is of particular concern in men with congestive heart failure who have borderline low blood volume or who are receiving complex regimens that include vasodilators or diuretics.

Sildenafil Guidelines in Men with Coronary Artery Disease

In a separate randomized clinical trial, 268 men with diabetes mellitus and ED received either placebo or sildenafil for 12 weeks. Fifty-six percent of men receiving sildenafil reported improved erections compared with 10% of those receiving placebo (P < .001). The rate of men reporting at least one successful attempt at intercourse was 61% for the sildenafil group versus 22% for the placebo group. The study demonstrated that sildenafil was an effective treatment for ED in patients with diabetes mellitus.  

Sildenafil is also effective in men with ED due to a variety of other causes, including spinal cord injury and postradical prostatectomy. In general, baseline sexual function correlated positively with response to sildenafil, and patients with diabetes mellitus or previous prostate surgery responded less well than patients with psychogenic or vasculogenic ED. Because there is no baseline characteristic that predicts the likelihood of failure to respond to sildenafil therapy, a therapeutic trial of sildenafil is warranted in all patients except in those in whom it is contraindicated.  

Adverse Effects Associated with Sildenafil Therapy

In clinical trials, the adverse effects that have been reported with greater frequency in sildenafil-treated men than placebo-treated men include headache, flushing, dyspepsia, respiratory tract disorders, and visual disturbances (see Table 19-4). Sildenafil does not affect semen characteristics. No cases of priapism were noted in any of the pivotal clinical trials.

Hemodynamic Effects of Sildenafil Cite

In postmarketing surveillance, several instances of myocardial infarction and sudden death were reported in men using sildenafil. Forty-four of the 120 deaths reported by the U.S. Food and Drug Administration, from March to November 1998, occurred in temporal relation to the ingestion of sildenafil; 16 of these deaths occurred in individuals who were taking nitrates. Because most men presenting with ED also have high prevalence of cardiovascular risk factors, it is unclear whether these events were causally related to the ingestion of sildenafil, underlying heart disease, or both.  

In a rigorously controlled study, oral administration of 100 mg sildenafil to men with severe coronary artery disease produced only small decreases in systemic blood pressure and no significant changes in cardiac output, heart rate, coronary blood flow, or coronary artery diameter. This led the American Heart Association to conclude that the preexistence of coronary artery disease by itself does not constitute a contraindication for the use of sildenafil.  

Sildenafil Guidelines in Men with Coronary Artery Disease

Before sildenafil is prescribed to a patient, it is crucial to assess cardiovascular risk factors (see Table 19-3). If the patient has hypertension or symptomatic coronary artery disease, the treatment of those clinical disorders must be addressed first. The physician must inquire about the use of nitrates because sildenafil is absolutely contraindicated in individuals taking any form of nitrates; sildenafil should not be used within 24 hours of the use of nitrates.  

In men with preexisting coronary artery disease, sexual activity can induce coronary ischemia; these individuals should undergo assessment of exercise tolerance. One practical way to assess exercise tolerance is to have the patient climb one or two flights of stairs. If the patient can safely climb one or two flights of stairs without angina or excessive shortness of breath, he can probably engage in sexual intercourse with a stable partner without similar symptoms. Exercise testing before prescribing sildenafil may be indicated in some men with significant heart disease to assess the risk of inducing cardiac ischemia during sexual activity.  

In men with congestive heart failure, men receiving vasodilator drugs, or taking complex regimens of antihypertensive drugs, it is advisable to monitor blood pressure after initial administration of sildenafil.  

A number of reviews have been published on the safety of sildenafil therapy.  

Drug-Drug Interactions

Sildenafil is metabolized mainly by the P450 2C9 and the P450 3A4 pathways. Cimetidine and erythromycin, inhibitors of P450 3A4, increase the plasma concentrations of the drug. Protease inhibitors may also alter the activity of the P450 3A4 pathway and can affect the clearance of sildenafil.  

Conversely, sildenafil is an inhibitor of the P450 2C9 metabolic pathway, and its administration has the potential to affect the metabolism of drugs metabolized by this system, such as warfarin and tolbutamide. The most serious interactions of sildenafil occur with nitrates. The vasodilator effects of nitrates are augmented by sildenafil; this effect also applies to inhaled forms of nitrates such as amyl nitrate or nitrites sold under the street name "poppers." Concomitant administration of the two drugs can cause a potentially fatal decrease in blood pressure.  

Therapeutic Regimens

In most men with ED, sildenafil can be started at an initial dose of 50 mg. In patients with significant coronary artery disease, an initial trial of 25 mg of sildenafil may be appropriate. If this dose does not produce any adverse effects, the dose can be titrated to 100 mg. Further dose adjustment should be guided by the therapeutic response and the occurrence of adverse effects. Typically, unit doses higher than 100 mg are not recommended. Sildenafil is taken at least 1 hour before...
sexual intercourse and not more than once in any 24-hour period.

Cost-Effectiveness of Sildenafil

A number of studies have evaluated the economic cost of treating ED in men in managed care organizations. These analyses, using prevalence-based cost-of-illness approach, have concluded that sildenafil and vacuum constriction devices are the most cost-effective of all the available therapeutic options in managed care setting and should be considered first-line strategies.

Vacuum Devices for Inducing Erection

Commercially available vacuum devices consist of a plastic cylinder, a vacuum pump, and an elastic constriction band. The plastic cylinder fits over the penis and is connected to a vacuum pump. The negative pressure created by the vacuum within the cylinder draws blood into the penis, producing an erection. An elastic band slipped around the base of the penis traps the blood in the penis, and an erection is maintained as long as the rubber band is retained around the base. The constriction band should not be left in place for more than 30 minutes.

These devices are safe, relatively inexpensive, and reasonably effective. They can impair ejaculation, however, resulting in entrapment of semen, and are difficult and awkward for some patients to use. Some couples dislike the lack of spontaneity engendered by the use of these devices. Partner cooperation is usually important for their successful use.

Testosterone Replacement in Androgen-Deficient Men with Erectile Dysfunction

Testosterone replacement in healthy, young, androgen-deficient men restores sexual function. In healthy young men, relatively low normal levels of serum testosterone can maintain sexual function. In male rats, a decrease in serum testosterone concentrations to castrate levels is associated with marked impairment of all measures of mating behavior. Testosterone replacement of castrated male rats to levels that are at the lower end of the adult male range normalizes all measures of mating behavior. In general, supraphysiologic doses of testosterone do not further improve sexual function. Although increasing testosterone levels above the physiologic range may increase arousability, this outcome has not been conclusively demonstrated.

As previously stated, androgen deficiency and ED are two common but independently distributed clinical disorders in middle-aged and older men that often coexist in the same patient. Of men presenting with ED, 8% to 10% have low testosterone levels. The prevalence of low testosterone levels is not significantly different between middle-aged and older men with impotence and those without impotence. Testosterone administration is unlikely to improve sexual function in men with normal testosterone levels. Therefore, indiscriminate use of testosterone replacement in all older men with ED is not warranted. However, it is important to exclude testosterone deficiency in older men presenting with ED. Androgen deficiency may be a manifestation of an underlying disease such as a pituitary tumor. Additionally, therapies directed just at ED in men do not correct androgen deficiency, which, if left uncorrected, would have deleterious effects on bone, muscle, energy level, and sense of well-being.

Many, but not all, of the men with ED and low testosterone levels experience improvements in libido and overall sexual activity with androgen replacement therapy. The response to testosterone supplementation, even in this group of men, is variable because of the coexistence of other disorders, such as diabetes mellitus, hypertension, cardiovascular disease, and psychogenic factors. A meta-analysis of the usefulness of androgen replacement therapy has concluded that testosterone administration is associated with greater improvement in sexual function than that associated with placebo in men with ED and low testosterone levels.

In middle-aged and older men, ED is often a multifactorial disorder. Common causes of ED in men include diabetes mellitus, hypertension, medications, peripheral vascular disease, psychogenic factors, and end-stage renal disease. Many of these factors often coexist in the same patient. Therefore, it is not surprising that testosterone treatment alone may not improve sexual function in all men with androgen deficiency.

Testosterone treatment does not improve sexual function in impotent men with normal testosterone levels. It is not known whether testosterone replacement improves sexual function in impotent men with borderline serum testosterone levels.
Second-Line Therapies

Intracavernosal Therapies

An intracavernosal system for delivery of alprostadil called MUSE (medicated urethral system for erection, VIVUS) was released in 1997. Alprostadil is a stable, synthetic form of PGE$_1$, which causes an increase in cAMP levels and thereby promotes cavernosal smooth muscle relaxation and penile erection.

Alprostadil, when applied into the urethra, must be absorbed through the ventral side of the tunica albuginea and into the corpus cavernosum to cause an erection. High concentrations of PGE$_1$ must be used to maintain efficacy.

Typically, the clinician applies the initial MUSE dose of 500 µg in the office to observe any changes in blood pressure or urethral bleeding secondary to misapplication of the MUSE device into the urethra. Depending on the erectile response, the clinician can either increase the alprostadil dose to 1000 µg or decrease the dose to 250 µg.

Common side effects of transurethral alprostadil are penile pain and urethral burning in up to 30% of patients. Initial randomized, placebo-controlled studies reported 40% to 60% success rates, defined as having at least one successful sexual intercourse during a 3-month study period.

The use of intracavernosal injections of vasoactive agents has been a cornerstone of the medical management of ED since the early 1980s. Patients are taught how to self-inject a vasoactive agent into the corpus cavernosum with a 27- or 30-gauge needle up to 3 times a week for sexual intercourse. Erections occur typically 15 minutes after intracorporal injection and ideally last 45 to 90 minutes. When titration is correct, the success rate of this therapy in producing a rigid erection is 80% to 90%. Early studies with intracavernosal injection therapy report patient and partner satisfaction rates of 70% and 67%, respectively.

The main adverse effects include penile pain, occurrence of hematoma, formation of corporal nodules, and the possibility of prolonged erections (priapism if longer than 4 hours). Despite the effectiveness of this approach in producing rigid erections, most patients do not relish injecting a needle into the penis; therefore, it is not surprising that long-term drop-out rates approach 60% to 70%.

Intracavernosal injection therapy can be used as first-line therapy but is often reserved for patients who have failed medical therapy or for those who need more control over their erections. The use of a constriction device (Actis, VIVUS) at the time of application of transurethral alprostadil has been shown to increase efficacy. VIVUS is currently investigating a combination of alprostadil and prazosin (an -blocking agent) to further promote cavernosal smooth muscle relaxation and erectile response.

<tr>
<td>2. Physicians who wish to prescribe intracavernosal injections must have contingency plans and a designated urologist to handle emergencies related to complications such as priapism.</td>
<td></td>
</tr>
<tr>
<td>3. It is advisable to administer the first injection in the physician’s office and to observe the blood pressure and heart rate response. This provides an excellent opportunity for educating the patient, observing adverse effects, and determining whether the patient will respond to this form of therapy.</td>
<td></td>
</tr>
<tr>
<td>4. The dose of the vasoactive substance should be adjusted to achieve an erection that is sufficient for sexual intercourse but that does not last more than 30 minutes.</td>
<td></td>
</tr>
<tr>
<td>5. The patient should be advised that priapism and fibrosis are potential complications of intracavernosal therapy.</td>
<td></td>
</tr>
<tr>
<td>6. After the injection, the patient should compress the injection site to minimize the risk of hematoma formation and subsequent fibrosis.</td>
<td></td>
</tr>
<tr>
<td>7. If the erection does not abate in 30 minutes, the patient should be instructed to take a pseudoephedrine tablet or an intracavernosal injection of phenylephrine. If this is not effective, the patient should either call a designated urologist or come to the emergency department.</td>
<td></td>
</tr>
<tr>
<td>8. Intracavernosal therapy is not suitable for patients with psychiatric disorders, hypercoagulable states, or sickle cell disease and for those who are receiving anticoagulant therapy.</td>
<td></td>
</tr>
</tbody>
</table>

Three different agents are commonly used alone or in combination by clinicians who prescribe injection therapy for the treatment of ED:

1. **Papaverine (PGE$_1$)**: Papaverine, a nonspecific PDE inhibitor, which increases both intracellular cAMP and cGMP. As a single agent, it is efficacious and inexpensive and needs no refrigeration. It does not cause penile pain but tends to induce priapism and fibrosis with long-term use.

2. **Phentolamine**: Phentolamine is a competitive , -adrenergic and , -adrenergic antagonist that contributes to smooth muscle relaxation. As a single agent, it is minimally efficacious but is commonly used in combination to potentiate papaverine and/or PGE$_1$ action.

In an attempt to maximize efficacy and minimize side effects, many clinicians use a combination of PGE$_1$, papaverine, and phentolamine as a tri-mix, which allows the use of a lower dose of each agent. A common mixture is 2.5 mL papaverine (30 mg/mL), 0.5 mL phentolamine (5 mg/mL), and 0.05 mL alprostadil (500 mg/mL). The reliable patient can titrate the intracavernosal dose from 0.2 to 0.5 mL to optimize his erectile response.

The biggest concern with intracavernosal injection therapy is priapism. Early studies with intracavernosal injection therapy report patient and partner satisfaction rates of 70% and 67%, respectively.
Third-Line Therapy: The Penile Prosthesis

In the early part of the 20th century, the treatment of ED was virtually nonexistent. It was the introduction of the semirigid and inflatable penile prostheses in the early 1970s that initiated the great strides that have been made in recent years in the treatment of ED. To some, penile prostheses are considered invasive and costly, but for many patients with advanced organic disease who are unresponsive to any contemporary form of therapy, have significant structural disorders of the penis (e.g., Peyronie’s disease), or have suffered corporal loss from cancer or traumatic injury, prostheses remain a highly effective and predictable method for restoring erectile function.

Implantation surgery usually takes less than an hour and in most cases can be done as an outpatient procedure with general or regional anesthesia. Recent studies have reported that more than 80% of patients and 70% of partners are pleased with their prosthesis and the togetherness that it brings to their relationship.

Penile implants are paired supports that are placed one in each of the two erectile bodies. There are two basic types: (1) hydraulic or fluid-filled (inflatable) implants and (2) semirigid implants, which are bendable but always remain firm in the penis.

With a number of recent modifications incorporating newer materials and designs, the chance of mechanical malfunction is only 5% to 10% in the first 10 years. Penile prostheses have a higher reliability rate than any other mechanical device implanted in the human body. The most feared complication by surgeons with prosthesis implantation is infection, which occurs in 1% to 3% of cases, but this can be higher in revision surgery, especially in diabetic patients.
Oral Therapeutic Agents under Development

It has been clearly established, in North America at least, that the preferred route of administration for an ED treatment is by mouth. The huge success of sildenafil attests to the demand for an effective oral erectogenic agent. Research and development in this field by other pharmaceutical enterprises has introduced a number of new PDE type 5 inhibitors with supposedly increased potency and fewer side effects.

PDEs have a ubiquitous presence in the human body. PDE type 5 inhibitors are recognized to enhance the effects of sexual stimulation through nitric oxide increases in cGMP in the penis. Besides acting in the corpus cavernosum of the penis, PDE type 5 inhibition is active in skeletal muscle, vascular smooth muscle, platelets, and visceral smooth muscle. It is the PDE type 5 inhibition cross-reacting in other tissues that causes most of the recognized side effects (e.g., headache, gastroesophageal reflux, muscle cramps, visual acuity changes).

The efficacy and side effects of PDE inhibitors are a function of pharmacologic specificity and bioavailability. Vardenafil (Bayer) and Cialis (Lilly-ICOS) are two new PDE type 5 inhibitors with better tissue specificity and pharmacokinetic profiles than sildenafil and are in advanced stages of clinical development (Table 19-6). Because of their reported increased selectivity, overall efficacy, and decreased number of adverse effects in Phase II and III studies, they show clinical promise. Their availability in the United States market is anticipated.

The PDE type 5 inhibitors are recognized to act as peripheral conditioners (i.e., enhance a local pathway to cause an erection). Another exciting area of research are drugs that initiate erections by actions directed within the central nervous system. Apomorphine SL (TAP Pharmaceuticals, Inc.) is an aporphine (not an opiate) that acts as a dopaminergic agonist. It is effective centrally at picomolar concentrations and has actions on the paraventricular and supraoptic nuclei of the midbrain. It has been reformulated for sublingual absorption with an onset of action within 15 to 20 minutes. Adverse effects include nausea, vomiting, and, rarely, syncope. Ongoing clinical research studies and experience from Europe since its approval in June 2001 may bring it to the United States in the near future.

Another central initiator of erection in early development is -melanocyte-stimulating hormone (melanotan-II). It not only has dopaminergic agonist activity but also has beneficial effects on libido.

In a double-blind, placebo-controlled crossover study, there was significant improvement in Rigiscan events, penile rigidity, and sexual desire in 10 patients with documented ED risk factors who were taking melanotan-II compared to those taking placebo. Nausea was the most common adverse event.

IC₅₀ is the concentration of a given agent to inhibit 50% of a given phosphodiesterase.
Gene Therapy and Erectile Dysfunction

Gene therapy can be defined as the introduction of genetic material (ribonucleic acid [RNA] or deoxyribonucleic acid [DNA]) into an appropriate cell type, thus altering gene expression of that cell in order to produce a therapeutic effect. The goal of gene therapy for ED is to introduce novel genetic material into an appropriate cell in an attempt to restore normal cellular and physiologic function.

Gene therapy has been proposed as a viable treatment option for diseases that have a vascular origin, such as arteriosclerosis, congestive heart failure, and pulmonary hypertension. This, by biologic extension, suggests that gene therapy may also be employed to treat vascular diseases of the penis; ED in most cases is a manifestation of vascular disease.

One advantage of applying gene therapy for the treatment of ED is the easily accessible external location of the penis. Hence, a tourniquet can be placed around the base of the penis and the desired gene can be administered directly into the corpora cavernosa without entering the systemic circulation. Further, in the penis only a small number of cells need to be transfected because smooth muscle cells of the corpus cavernosum are interconnected by gap junctions that allow second messenger molecules and ions to be transferred to a number of interconnected smooth muscle cells, thus causing physiologically relevant changes in erectile function. Moreover, the vascular smooth muscle cells of the penis have a relatively low turnover rate, thus allowing a desired gene to be expressed for long periods of time.

The concept of gene therapy for ED treatment focuses on preventing cavernosal tissue degradation and increasing cavernosal smooth muscle tone. Smooth muscle relaxation is the necessary step for achieving a normal erection. Therefore, molecules, enzymes, or growth factors that influence the signal transduction pathway of corporal smooth muscle relaxation represent potential targets for ED gene therapy. Nitric oxide has been recognized to be the principal mediator of penile erection. However, other diverse mediators, such as the prostaglandins, VIP, and CGRP, play a role in erectile physiology.

Garban and associates first demonstrated that gene therapy could be performed in the penis by using naked complementary DNA (cDNA) encoding the penile inducible NOS gene, leading to physiologic benefit in the aging rat. Christ and colleagues later showed that injection of hSlo cDNA, which encodes the human smooth muscle maxi-K⁺ channel, into the rat corpora cavernosa can increase gap junction formation and enhance erectile responses to nerve stimulation in the aged rat. More recently, Bivalacqua and colleagues used an adenoviral gene transfer approach in which an adenoviral construct encoding the eNOS and CGRP genes were shown to reverse age-related ED in rats.

In these studies, cytomegalovirus and Rous sarcoma adenoviruses were utilized, and both eNOS and CGRP expression were sustained for at least 1 month in the corpora cavernosa of the rat penis. Five days after transfection with the AdCMVeNOS or AdRSVeNOS viruses, aged rats had significant increases in erectile function, as determined by cavernosal nerve stimulation and pharmacologic injection with the endothelium-dependent vasodilator acetylcholine and the type 5 PDE inhibitors zaprinast and sildenafil.

Lue and colleagues demonstrated that intracavernous injection of adeno-associated virus brain-derived neurotrophic factor could improve erectile function after cavernosal nerve injury. This neurotrophic factor purportedly restored neuronal NOS in the major pelvic ganglion, thus enhancing the recovery of erectile function after bilateral cavernous nerve injury. These early but innovative studies provide evidence that in vivo gene transfer can have beneficial physiologic effects on penile erection; this approach still requires a significant amount of basic research before in vivo gene therapy techniques can be applied to humans.
FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction is a multicausal and multidimensional medical problem that adversely affects physical health and emotional well-being. There has been a conspicuous paucity of basic science research on female sexuality. Thus, our knowledge and understanding of the anatomy and physiology of normal female sexual response and the pathophysiology of female sexual dysfunction are limited. On the basis of our understanding of the physiology of the male erectile response, recent advances in technology, and heightened interest in women's health, the study of female sexual function and dysfunction is evolving.

PREVALENCE AND INCIDENCE RATES

Sexual dysfunction in women is age-related, progressive, and highly prevalent, affecting 30% to 50% of American women. In the National Health and Social Life Survey, which included 1749 women, 43% of adult women had complaints of sexual dysfunction. Although this study had a large sample size, with minority representation, and used modern probability sampling, it was limited by its cross-sectional design. In addition, the NHLSLS did not include women over age 60 years and did not make any adjustment for menopausal status or medical risk factors.

Another study that surveyed 448 women over 60 years of age demonstrated that two thirds of these women were sexually inactive, 12% of married women had difficulty with intercourse, and 14% experienced pain with intercourse. Sexual activity was strongly correlated with marital status. Women over age 60 years were less likely to have sex if their partners were in poor health and if they had feelings of low self-worth.

The incidence rates of sexual dysfunction in women are not known. The same disease processes and risk factors that are associated with ED in men such as aging, hypertension, cigarette smoking, and hypercholesterolemia, are also associated with sexual dysfunction in women.
PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE CYCLE

Masters and Johnson first characterized the female sexual response as consisting of four successive phases: excitement, plateau, orgasm, and resolution. During sexual arousal, the clitoris and the labia minora become engorged with blood and vaginal and clitoral length and diameter increase. These authors observed that the labia minora increase in diameter by two to three times during sexual excitement and consequently become everted, exposing their inner surface.

Kaplan proposed the aspect of "desire," and the three-phase model, consisting of desire, arousal, and orgasm. In this model, desire is the factor that incites the overall response cycle. This three-phase model is the basis for the Diagnostic and Statistical Manual (DSM IV) definitions of female sexual dysfunction, and the recent reclassification system proposed by the American Foundation of Urologic Disease (AFUD) Consensus Panel in October 1998.

Others have suggested that sexual function should be viewed as a circuit, with four main domains: libido, arousal, orgasm, and satisfaction. Each of these four domains may overlap and feed back negatively or positively upon the other three domains.
PELVIC ANATOMY IN WOMEN

An understanding of female pelvic anatomy and physiology is essential for the evaluation and treatment of female sexual dysfunction. Although the female pelvis is composed of a continuum of organs interrelated in structure and function, it is helpful to group the pelvic organs into two categories: the external and internal genitalia.

The organs of the external genitalia are collectively known as the vulva, which is bound anteriorly by the symphysis pubis, posteriorly by the anal sphincter and laterally by the ischial tuberosities. The vulva consists of the labia, interlabial space, clitoris and vestibular bulbs.

The internal genitalia consist of the vagina, uterus, fallopian tubes, and ovaries.

Vagina

The vagina is a midline cylindrical organ that connects the uterus with the external genitalia. It usually measures 7 to 15 cm in length, depending on the position of the uterus. It can easily dilate and expand for intercourse and childbirth. Anteriorly, two pleats of sensitive tissue, the labia minora (inner lips), surround the opening of the vagina and are protected by the larger folds known as the labia majora (outer lips). The labia minora enclose an area called the vestibule, which contains the clitoris, the urethral opening and vaginal opening. The portion of the labia minora that covers the clitoris is known as the prepuce, or clitoral hood.

The wall of the vagina consists of three layers: (1) an inner aglandular mucous membrane epithelium; (2) an intermediary, richly supplied, vascular muscularis layer; and (3) an outer adventitial supportive mesh. Vaginal mucosa is a mucus type, stratified, nonkeratinized, squamous cell epithelium that undergoes hormone-related cyclical changes during the menstrual cycle. The middle muscularis layer is highly infiltrated with smooth muscle and an extensive tree of blood vessels, which engorges during sexual arousal. The surrounding outer fibrosa layer provides structural support to the vagina.

The vagina has many rugae, which are necessary for distensibility of the organ and are more prominent in the lower third of the vagina. Smaller ridges increase frictional tension during intercourse.

Blood Supply to the Vagina

The vascular system of the vagina consists of an extensive anastomotic network of blood vessels throughout its length. The main arterial supply to the vagina arises from vaginal branches of the uterine arteries, pudendal arteries (vaginal branches), and ovarian arteries.

Innervation of the Vagina

The autonomic innervation of the vagina originates from two separate plexuses: the superior hypogastric and the pelvic. Sympathetic fibers originate in the lateral gray column of T1-L2 and form the hypogastric plexuses. Parasympathetic fibers originate in the intermediolateral cell column of S2-S4 and synapse in the pelvic plexus. Sympathetic and parasympathetic nerve fibers leave the pelvic plexus and travel within the uterosacral and cardinal ligaments, along with the vessels, to supply the proximal two thirds of the vagina and the corporal bodies of the clitoris.

Somatic motor fibers originate from the anterior horns of sacral cord levels S2-S4 and travel within the pudendal nerve to innervate the bulbocavernosus and ischiocavernosus muscles. Sensory fibers innervating the introitus and perineum travel within the perineal and posterior labial nerves to the pudendal nerve (Fig. 10.3). Immunohistochemical studies have revealed an abundance of nerve fibers in the distal vagina, as compared with the more proximal part. This area of increased innervation, which plays an important role in sexual function, can be damaged during performance of bladder suspension procedures and vaginal hysterectomies.

Physiologic Changes in the Vagina during Sexual Arousal

During sexual arousal, genital vascongestion occurs as a result of increased blood flow. The vaginal canal is lubricated by secretions from uterine glands, and by a transudate that originates from the subepithelial vascular bed. This is passively transported through the subepithelial spaces, which are sometimes referred to as "intercellular channels." ENGORGEMENT of the vaginal wall raises pressure inside the capillaries and increases the transudation of plasma through the vaginal epithelium. This vaginal lubricative plasma flows through the epithelium onto the surface of the vagina, initially forming sweat-like droplets that coalesce to form a lubricative film that covers the vaginal wall.

Additional moistening during intercourse comes from secretions of the paired, greater vestibular or Bartholin’s glands, although some believe that these glands have a more primal function of emitting an odoriferous fluid to attract the male. In addition to its lubrication, the vagina lengthens and dilates during sexual arousal as a result of relaxation of the smooth muscle in its wall. In human and animal models, sexual stimulation results in increased vaginal blood flow and decreased vaginal luminal pressure.
Clitoris

The clitoris is an erectile organ similar to the penis and arises from the same embryologic structure, the genital tubercle. It is composed of three parts: the outermost glans or head, the middle corpus or body, and the innermost crura. The glans and body of the clitoris are 2 to 4 cm long, and the crura are 9 to 11 cm. The clitoris consists of fused midline erectile bodies (corpora cavernosa) that give rise to bilateral crura. The glans clitoris is visible as it emerges from the labia minora. The labia minora bifurcate to form the upper prepuce anteriorly and the lower frenulum posteriorly.

The clitoris consists of fused midline erectile bodies (corpora cavernosa) that give rise to bilateral crura. The glans clitoris is visible as it emerges from the labia minora.

Each corpus cavernosum is ensheathed by a thick, fibrous connective tissue structure, the tunica albuginea, that covers the lacunar sinusoids, which are surrounded by a trabecula of vascular smooth muscle and collagen fibers. The two separate crura of the clitoris, formed from the separation of the most proximal parts of the corpora in the perineum, attach bilaterally to the undersurface of the pubis along the ischiopubic rami.

The main arterial supply to the clitoris is via the iliohypogastric-pudendal arterial bed. With sexual stimulation, increased blood flow to the clitoral cavernosal arteries results in increased clitoral intracavernous pressure and tumescence and protrusion of the glans. Studies show that, unlike the penis, the clitoris lacks a subalbugineal layer between the erectile tissue and the tunica albuginea layer. In the male, this layer possesses a rich venous plexus that, during sexual excitement, expands against the tunica albuginea, reducing venous outflow and making the penis rigid. The absence of this venous plexus in the clitoris allows this organ to achieve tumescence, but not rigidity, during sexual arousal.

Duplex ultrasound of the clitoris reveals that during sexual simulation the clitoris increases in length and diameter and blood flow almost doubles.
Vestibular Bulb

The vestibular bulbs are 3-cm-long, paired structures that lie along the sides of the vaginal orifice, directly beneath the skin of the labia minora (Fig. 19-3A and B). Although they are homologous to the corpus spongiosum of the penis and are composed of vascular smooth muscle, they are distinct, in that they are separated from the clitoris, urethra, and vestibule of the vagina. Recent cadaver dissections reveal that in young premenopausal women, the bulbs lie on the superficial aspect of the vaginal wall and do not form the core of the labia minora. Furthermore, there are considerable age-related variations in the dimensions of the erectile tissue between young premenopausal specimens and older, postmenopausal specimens. (118)

The main arterial supply to the vestibular bulbs is via bulbar, inferior perineal, and posterior labial branches of the internal pudendal artery (see Fig. 19-3). The somatic sensory innervation of the labia minora travels via the perineal and posterior labial branches of the pudendal nerve. Autonomic innervation consists of sympathetic and parasympathetic fibers that travel with the vessels to reach the vestibular bulb.

In the labia minora, blood flow increases during sexual stimulation, particularly to the vestibular bulbs. This causes a twofold to threefold increase in diameter and eversion of the labia with exposure of its inner surface.
Uterus

The uterine and cervical glands secrete mucus during sexual arousal to lubricate the vagina. Uterine and other pelvic surgical procedures can have a significant impact on female sexual response and function. The innervation of the uterus is closely proximate to the bladder and vagina, and pelvic dissection, as it is currently performed, can adversely affect a woman's later sexual health by damaging the uterine innervation. Surgical menopause brought on by hysterectomy and oophorectomy affects sexual function by multiple mechanisms. Even hysterectomy alone, without the removal of the ovaries, can result in sexual dysfunction. Symptoms that women commonly experience postoperatively after hysterectomy include decreased desire, decreased arousal, decreased genital sensation, and orgasmic dysfunction.

The anatomic and physiologic basis for sexual dysfunction after hysterectomy is poorly understood. Understanding of female neurovascular anatomy is limited but vital to the understanding of normal sexual arousal and function. The sexual dysfunction symptoms women experience after hysterectomy are probably the result of nerve or vascular injuries as well as the loss of ovarian estrogens and androgens. Removal of the uterus and ligation of the arterial supply at the uterine pedicles can result in ovarian atrophy as well as fibrosis of vaginal wall and clitoral cavernosal smooth muscle. Disruption of the pelvic autonomic and cervical plexuses as well as the uterosacral and cardinal ligaments, which are associated with autonomic nerve fibers, results in difficulties in genital arousal and orgasm. This is an area of current focus and research, and in the future, perhaps women will be offered nerve-sparing pelvic procedures similar to those now routinely performed in men.
Pelvic Floor Muscles

The pelvic floor is a collection of tissues that span the opening within the bony pelvis. In addition to supporting the abdominal and pelvic organs and maintaining continence of urine and stool, the pelvic floor allows for intercourse and parturition. The pelvic floor musculature in particular, the pelvic diaphragm that is formed by the levator ani muscles, the urogenital diaphragm, and the perineal membrane is important for pelvic support. The perineal membrane that consists of the ischiocavernosus, bulbocavernosus, and superficial transverse perineal muscles is closely related to the vestibular bulbs and clitoris and plays a role in sexual response. These muscles, when voluntarily contracted, can intensify orgasm of both the female and her mate partner.

The levator ani muscle has two different parts, the pubococcygeus and the iliococcygeus. These muscles can be palpated during pelvic examination as a distinct ridge just above the hymenal ring along each lateral wall of the pelvis. The function of this group of muscles is to pull the rectum, vagina, and urethra anteriorly toward the pubic bones to compress the lumen closed. Nonvoluntary pelvic floor spasm associated with vaginal penetration, or even examination with a speculum, is referred to as vaginismus. This disorder prevents sexual intercourse and is associated with dyspareunia and other sexual pain disorders. If the opposite problem exists, consisting of laxity and hypotonia of the pelvic floor musculature due to aging, menopause, or childbirth, for instance, symptoms of vaginal hypoanesthesia, coital anorgasmia, as well as incontinence during sexual intercourse or orgasm can develop. Women with pelvic floor disorders often have coexisting urologic and sexual dysfunction complaints. As a result of this overlap, all women who present with voiding dysfunction should be questioned about their sexual function as well.
NEUROGENIC MEDIATORS OF FEMALE SEXUAL RESPONSE

Within the central nervous system, the medial preoptic, anterior hypothalamic region and related limbic-hippocampal structures are responsible for sexual arousal. Upon activation, these centers transmit electrical signals through the parasympathetic and sympathetic nervous system. The neurogenic mechanisms modulating vaginal and clitoral smooth muscle tone, and vaginal and clitoral vascular smooth muscle relaxation are currently under investigation.

Noradrenergic, Noncholingeric (NANC)-Mediated Responses

Immunohistochemical studies in human vaginal tissues have shown the presence of nerve fibers containing neuropeptide Y (NPY), VIP, NOS, CGRP and substance P. Preliminary studies suggest that VIP and nitric oxide are involved in modulating vaginal relaxation and secretory processes. In the clitoris, nitric oxide has been identified in human tissue and is thought to be the primary mediator of clitoral and labial engorgement. Organ bath analysis of rabbit clitoral cavernosal smooth muscle strips demonstrates enhanced relaxation in response to sodium nitroprusside and L-arginine (both nitric oxide donors), which supports this hypothesis (Berman et al, unpublished data). Recently, PDE type 5, the enzyme responsible for degradation of cGMP, has been isolated in human clitoral, vestibular bulb, and vaginal smooth muscle culture and is inhibited by sildenafil citrate. Human and rabbit vaginal smooth muscle cells, treated with the nitric oxide donor sodium nitroprusside, in the presence of sildenafil have enhanced intracellular cGMP synthesis and accumulation. PGE1 and forskolin also produce a marked increase in intracellular cGMP.

In organ bath studies, sildenafil causes dose-dependent relaxation of female rabbit clitoral and vaginal smooth muscle strips (Berman), further suggesting a role for nitric oxide as a mediator of clitoral cavernosal and vaginal wall smooth muscle relaxation. The exact identity of the relaxant NANC neurotransmitter, however, remains unclear. VIP is a NANC neurotransmitter that, like nitric oxide, may play a role in enhancing vaginal blood flow, lubrication, and secretions. The vagina is heavily innervated with VIP-immunoreactive nerve fibers in close relation to the epithelium and blood vessels. In organ bath studies, VIP also causes dose-dependent relaxation of rabbit clitoral cavernosal and vaginal smooth muscle tissue, suggesting a similar role for endogenous VIP as a NANC neurotransmitter in clitoral and vaginal tissues (Berman et al, unpublished data).
Alpha₁-Adrenergic and Alpha₂-Adrenergic Responses

In men, adrenergic receptors exist in the brain centers and are associated with penile erection, libido, and ejaculation. Agents that affect these receptors have been extensively studied and used in the treatment of male ED. -Adrenergic agonists such as norepinephrine activate sympathetic nerve terminals, resulting in contraction of penile trabecular smooth muscle and detumescence. In addition, α₂ agonists cause similar responses. Activation of β receptors results in a decrease in intracellular adenosine 3′5′-monophosphate concentrations and in potent contraction in blood vessels. -Adrenergic mediators also appear to play a physiologic role in female sexual arousal.

Preliminary organ chamber experiments using rabbit vaginal tissue suggest that adrenergic mechanisms modulate smooth muscle tone. Exogenous norepinephrine (α₁ and α₂ agonist) causes dose-dependent contraction of vaginal smooth muscle and α₁ (prazosin and tamsulosin) and α₂ (delequamine) selective antagonists inhibit the contraction (Berman et al, unpublished data). These observations suggest that adrenergic nerves mediate contractile response. Furthermore, there appears to be a difference in the quality of the contractile responses in upper and lower vaginal segments, which is consistent with their different innervation and embryologic origin.
HORMONAL REGULATION: THE ROLES OF ESTROGEN AND TESTOSTERONE

Estrogen

Estrogen plays a significant role in regulating female sexual function. Estradiol affects cells throughout the peripheral and central nervous systems and influences nerve transmission. A decline in serum estrogen levels results in thinning of vaginal mucosal epithelium and atrophy of vaginal wall smooth muscle. Decreased estrogen levels also result in a less acidic environment in the vaginal canal. These changes, associated with estrogen deficiency, can predispose women to vaginal infections, urinary tract infections, incontinence, and sexual dysfunction.

In animal models, estradiol administration results in expanded touch receptor zones along the distribution of the pudendal nerve, suggesting that estrogen affects sensory thresholds. In postmenopausal women, estrogen replacement restores clitoral and vaginal vibration and pressure thresholds to levels close to those of premenopausal women. Estrogens also have vasoprotective and vasodilatory effects, which result in increased vaginal, clitoral, and urethral arterial flow, resulting in maintenance of the female sexual response by preventing atherosclerotic compromise to pelvic arteries and arterioles.

With menopause and the decline in circulating estrogen levels, a majority of women experience some degree of change in sexual function. Common sexual complaints include loss of desire, decreased frequency of sexual activity, painful intercourse, diminished sexual responsiveness, difficulty achieving orgasm, and decreased genital sensation. Masters and Johnson first published their findings of the physiologic changes occurring in menopausal women that related to sexual function in 1966. We have since learned that symptoms related to alterations in genital sensation and blood flow are, in part, secondary to declining estrogen levels and that there is a direct correlation between the presence of sexual complaints and levels of estradiol below 50 pg/mL. Some of the symptoms associated with menopause, such as vaginal dryness and diminished genital sensation, improve with estrogen replacement. However, some postmenopausal women continue to experience lack of sexual interest, fantasy and satisfaction, flat mood, and diminished well-being despite appropriate estrogen replacement; these symptoms are often attributed to androgen deficiency. As discussed later, it remains unclear whether physiologic testosterone replacement can improve sexual function in older women or whether this symptom complex is even due to androgen deficiency.

Estrogen also plays a role in regulating vaginal and clitoral NOS expression, the enzyme responsible for the production of nitric oxide. Aging and surgical castration result in decreased vaginal and clitoral NOS expression and apoptosis of vaginal wall smooth muscle and mucosal epithelium. Estrogen replacement restores vaginal mucosal health, increases vaginal NOS expression, and decreases vaginal mucosal cell death. These findings suggest that medications such as sildenafil, which mediate vascular and nonvascular smooth muscle relaxation via nitric oxide, may have a potential role in the treatment of female sexual dysfunction, in particular that associated with sexual arousal disorder.
Testosterone deficiency in the pathophysiology of female sexual dysfunction remains controversial. Most commercial assays for the measurement of total and free testosterone levels were developed to measure the much higher circulating concentrations in men; these assays lack the sensitivity and precision required to measure the low levels prevalent in androgen-deficient women. Because of the paucity of normative data on serum total and free testosterone concentrations in healthy, menstruating women, there is no consensus on the thresholds that can be used to define androgen deficiency in women. Until recently, the available testosterone formulations were designed to deliver the much higher dose required in hypogonadal men. However, two new formulations, the testosterone transdermal matrix patch for women and the testosterone gel are now undergoing phase 1 and phase 2 studies. There is agreement that androgens, by acting within the brain, influence sexual behavior, although a woman’s libido is also determined by environmental, emotional, cultural, and hormonal factors. The effects of androgens in the brain are mediated, in part, directly through the androgen receptor and through aromatization of testosterone to estradiol. Androgen receptors have been identified in the cortex, pituitary, hypothalamus, preoptic region, thalamus, amygdala, and brain stem. In addition, both testosterone and estrogen have been shown to exert nongenomic effects in the central nervous system.

Testosterone might have additional effects on the genitalia in women. Androgen receptors have been reported in the vaginal wall, leading to speculation that testosterone might induce vaginal smooth muscle relaxation. We do not know whether NOS activity in the clitoris is under testosterone regulation as it is in the cavernosal smooth muscle in the penis.
CLASSIFICATIONS AND DEFINITIONS OF FEMALE SEXUAL DYSFUNCTION (1998)

The Sexual Function Health Council of the American Foundation for Urologic Disease convened the AFUD Consensus Panel, an interdisciplinary conference panel, consisting of a multinational group of experts in female sexual dysfunction. The panel included specialists from many relevant disciplines, including endocrinology, family medicine, gynecology, nursing, pharmacology, physiology, psychiatry, psychology, rehabilitation medicine, and urology. The panel's objective was to evaluate and revise existing definitions and classifications of female sexual dysfunction. Specifically, medical risk factors and etiologic mechanisms of female sexual dysfunction were incorporated with the preexisting psychologically based definitions to generate an updated, unified classification system.

The AFUD Consensus Panel classified female sexual dysfunction into several categories, described next (Table 19-7).

Hypoactive Sexual Desire Disorder

Hypoactive sexual desire disorder refers to the persistent or recurring deficiency (or absence) of sexual fantasies or thoughts and/or desire for or receptivity to sexual activity that causes personal distress. This disorder may result from psychological or emotional factors or may be secondary to physiologic problems (e.g., hormone deficiency) and medical or surgical interventions. Any disruption of the female hormonal milieu caused by natural menopause, surgically or medically induced menopause, or endocrine disorders can result in inhibited sexual desire.

In 1998, the Sexual Function Health Council of the American Foundation for Urologic Disease convened a consensus panel that proposed a new classification for female sexual dysfunction. (see text for definitions).
Sexual Aversion Disorder

Sexual aversion disorder is the persistent or recurrent phobic aversion to and avoidance of sexual contact with a sexual partner that causes personal distress. This disorder is generally a psychologically or emotionally based problem that can result from experiences such as physical or sexual abuse, or childhood trauma.
Sexual Arousal Disorder

Sexual arousal disorder refers to the persistent or recurring inability to attain or maintain adequate sexual excitement that causes personal distress. It may be experienced as lack of subjective excitement or lack of genital (lubrication or swelling) or other somatic response.

Disorders of arousal include, but are not limited to, lack of or diminished vaginal lubrication, decreased clitoral and labial sensation, decreased clitoral and labial engorgement, or lack of vaginal smooth muscle relaxation. These conditions may occur as a result of psychological factors; however, often there is a medical/physiologic basis, such as diminished vaginal or clitoral blood flow, previous pelvic trauma, pelvic surgery, or medications.
Orgasmic Disorder

The orgasmic disorder refers to the persistent or recurrent failure, difficulty, or delay in attaining orgasm following adequate sexual stimulation and arousal that causes personal distress. This may be a primary condition (never achieved orgasm) or a secondary condition that may occur as a result of surgery, trauma, or hormone deficiency. Primary anorgasmia can be secondary to emotional trauma or sexual abuse; however, other medical problems as well as medications (e.g., serotonin reuptake inhibitors) can contribute to or exacerbate the problem.
Sexual Pain Disorders

Three sexual pain disorders are described:

1. **Dyspareunia.** Dyspareunia refers to the recurrent or persistent genital pain associated with sexual intercourse. Dyspareunia can develop secondary to medical problems such as vestibulitis, vaginal atrophy, or vaginal infection. It can be either physiologically or psychologically based, or due to a combination of the two.

2. **Vaginismus.** Vaginismus refers to the recurrent or persistent involuntary spasms of the musculature of the outer third of the vagina that interferes with vaginal penetration, and causes personal distress. Vaginismus usually develops as a conditioned response to painful penetration, or secondary to psychological and emotional factors.

3. **Other sexual pain disorders.** Recurrent or persistent genital pain induced by noncoital sexual stimulation can be caused by anatomic and inflammatory conditions, including infections (e.g., HSV), vestibulitis, prior genital mutilation, trauma, and endometriosis.

Each of these categories can be further subtyped according to whether the disorder has been lifelong or acquired; generalized or situational; and organic, psychogenic, or mixed in its pathophysiology. The etiology of any of these disorders may be multifactorial, and often the disorders overlap. At present, sexual arousal disorder is the focus of clinical and basic science research as well as treatment interventions. Human and animal models have been established to assess sexual arousal and validated sexual arousal instruments are now available.

An emerging hypothesis is that decreased sexual arousal, as manifested by diminished genital engorgement, may be related to inadequate pelvic arterial blood flow. Decreased genital blood flow ultimately leads to fibrosis of vaginal wall and clitoral cavernosal smooth muscle. Women with sexual arousal disorder complain of diminished vaginal lubrication, pain with intercourse, decreased vaginal and clitoral sensation, and difficulty achieving orgasm. Because different domains of sexual function in women are interlinked, enhancement of sexual arousal by improvements in vaginal lubrication, clitoral and labial engorgement, and genital sensation would be expected to secondarily improve orgasmic ability as well as libido. The potential role of pharmacotherapy for the treatment of female sexual arousal complaints remains poorly understood.
ETIOLOGY OF FEMALE SEXUAL DYSFUNCTION

The causes of sexual dysfunction in women are complex and multifactorial. Even in women with a known organic disease, additional medical, psychosexual, and relational factors are operative that complicate the management of these patients. Similarly, although the vasculogenic, neurogenic, psychogenic, and hormonal factors are discussed separately to highlight their contributions to the pathophysiology of sexual dysfunction, in reality it is often difficult to clinically establish causal roles of vasculogenic and neurogenic factors in individual patients. Furthermore, hormone deficiencies may secondarily lead to anatomic, vascular, and neural changes that, in turn, may cause sexual aversion because of pain.

Vasculogenic Causes

High blood pressure, high cholesterol levels, smoking, and heart disease are associated with ED in men and with sexual dysfunction in women. The recently named clitoral and vaginal vascular insufficiency syndromes are directly related to diminished genital blood flow secondary to atherosclerosis of the iliohypogastric/pudendal arterial bed. Traumatic injury to this structure from pelvic fractures, blunt trauma, surgical disruption, or chronic perineal pressure from bicycle riding can result in diminished vaginal and clitoral blood flow. Histomorphometric evaluation of clitoral erectile tissue from atherosclerotic animals demonstrates clitoral cavernosal artery wall thickening, loss of corporal smooth muscle, and increase in collagen deposition.

In human clitoral tissue, there is a similar loss of corporal smooth muscle with replacement by fibrous connective tissue in association with atherosclerosis of clitoral cavernosal arteries. It is possible that the atherosclerotic changes that occur in clitoral vascular and trabecular smooth muscle may interfere with normal relaxation and dilation responses to sexual simulation.
Neurogenic Causes

The same neurogenic disorders that cause ED in men can also cause sexual dysfunction in women. These include spinal cord injury; diseases of the central or peripheral nervous system, including diabetes; and complete upper motor neuron injuries that affect the sacral spinal segments. Women with incomplete injuries retain that capacity for psychogenic arousal and vaginal lubrication. Women with spinal cord injury have significantly more difficulty in achieving orgasm than do normal controls.
Hormonal Causes

Dysfunction of the hypothalamic-pituitary axis, surgical or medical oophorectomy, premature ovarian failure, old age, and chronic birth control use are associated with reductions in free testosterone levels and with sexual dysfunction in some women. However, a direct cause-and-effect relationship between hormonal deficiency and sexual dysfunction is difficult to establish because of the coexistence of a number of complex, confounding factors. Estrogen deprivation causes a significant decrease in the clitoral intracavernosal, vaginal, and urethral blood flow. Thus, a decline in circulating estrogen levels can produce significant adverse effects on structure and function of the vaginal and clitoral tissues, including diffuse clitoral fibrosis, thinned vaginal epithelial layers, and decreased vaginal submucosal vasculature; these changes can affect sexual function. Conversely, estrogen administration in postmenopausal women and in women after oophorectomy improves the integrity of vaginal mucosal tissue and has beneficial effects on vaginal sensation, vasocongestion, and secretions, which lead to enhanced arousal.

Although oophorectomized women have often been the subjects in studies of the role of sex steroids in the pathophysiology of female sexual dysfunction, there are several inherent limitations of the use of this patient population. Most of these patients have some underlying pelvic disease that led to oophorectomy in the first place. In most women who have undergone oophorectomy, the uterus has been removed. Hysterectomy can be associated with substantial changes in pelvic and vaginal anatomy that can affect sexual responses. If oophorectomized women do not receive estrogen replacement therapy, they experience vaginal atrophy that can secondarily affect sexual function. It should be recognized that correction of the pelvic pathology by surgical oophorectomy and hysterectomy can, in some women, improve sexual function. For instance, in one retrospective study, a significant proportion of women reported improved sexual function after hysterectomy, although women whose ovaries had been removed were less likely to report improvement than women whose ovaries had not been removed.

The decline in serum testosterone concentrations begins in the fourth decade and is age-related; thus, serum testosterone concentrations in a 60-year old woman, on average, are about half those in a 30-year old woman. In contrast to the rapid decline in estrogen production that occurs at menopause, however, serum testosterone concentrations do not fall abruptly during the menopausal transition. A large epidemiologic study demonstrated that serum testosterone levels either do not change or may even increase in the perimenopausal years. Using a scale that determines well-being and sexual function, these investigators found that 83% of postmenopausal women had scores indicating sexual dysfunction; however, sexual dysfunction did not correlate with androgen levels. Therefore, sexual dysfunction in healthy, postmenopausal women cannot be attributed to androgen deficiency alone.

Because the postmenopausal ovary continues to produce androgens, oophorectomy significantly lowers androgen levels in premenopausal as well as in postmenopausal women.

Estrogen administration reduces free testosterone levels by multiple mechanisms. Estrogen therapy reduces trophic luteinizing hormone (LH) secretion, thus decreasing ovarian androgen production; in addition, estrogens stimulate hepatic sex hormone-binding globulin (SHBG) production, resulting in lower free testosterone levels.
Musculogenic Causes

The pelvic floor muscles, in particular the levator ani and perineal membrane, participate in female sexual function and responsiveness. The perineal membrane, consisting of the bulbocavernosus and ischiocavernosus muscles, when voluntarily contracted, contributes to and intensifies sexual arousal and orgasm. In addition, the bulbospongiosus and ischiocavernosus muscles are responsible for the involuntary rhythmic contractions during orgasm. The levator ani also modulates motor responses during orgasm as well as vaginal receptivity. A hypertonic levator ani can contribute to the development of vaginismus, causing dyspareunia and other sexual pain disorders. When the levator ani is hypotonic, vaginal hypoanesthesia, coital anorgasmia, and urinary incontinence can develop during sexual intercourse or orgasm.
Psychogenic Causes

In women, despite the presence or absence of organic disease, emotional and relational issues significantly affect sexual arousal. Self-esteem, body image, and the quality of the relationship with partner affect a woman’s ability to respond sexually. In addition, depression and other mood disorders are often associated with female sexual dysfunction. Furthermore, the medications commonly used to treat depression can significantly affect the female sexual response.

The most frequently used medications for uncomplicated depression are the serotonin reuptake inhibitors (SSRIs). Women receiving these medications often complain of decreased desire, reduced arousal and genital sensation, and difficulty achieving orgasm. Several studies have documented improvements in SSRI-induced sexual dysfunction in women after administration of sildenafil.
CLINICAL EVALUATION OF THE FEMALE SEXUAL RESPONSE

In the clinical setting, female sexual responses have been difficult to quantify objectively. Female sexual arousal results in a combination of vasocongestive and neuromuscular events, which include increased clitoral, labial, and vaginal wall engorgement as well as increased vaginal luminal diameter and lubrication. Muscle tension, respiratory rate, heart rate, and blood pressure steadily rise during arousal, finally reaching their peak during orgasm. In contrast to the male erectile response, genital changes that occur during female sexual arousal not only are difficult to measure but also are often not readily visible or recognized by the patient. Previously described techniques for evaluating physiologic changes during female sexual arousal have been performed primarily by psychotherapists and physiologists and have focused primarily on estimating vaginal engorgement. The clinical utility of these physiologic measurements remains unknown.

Medical Evaluation

A comprehensive approach to the evaluation of physiologic changes during sexual arousal involves a full history and physical examination, including a pelvic examination and, when clinically indicated, a hormonal profile (i.e., follicle-stimulating hormone [FSH], total testosterone). Increased FSH levels can help document ovarian failure and menopausal status and can aid in differentiating primary ovarian dysfunction from disorders of the hypothalamus and pituitary gland. Measurements of LH levels in women do not add a great deal of information to that obtained from FSH measurements but can provide confirmatory data. Total testosterone levels, measured by an assay that has adequate sensitivity and precision, are needed to determine whether sexual dysfunction is due to androgen deficiency.

Estradiol levels vary greatly in women, depending on the phase of the menstrual cycle; very low levels can confirm ovarian failure but provide little additional information beyond what can be inferred from menstrual history and FSH levels. In women with hypogonadotropic hypogonadism, measurement of serum prolactin and a magnetic resonance imaging (MRI) study of the hypothalamic-pituitary region may be needed to exclude the presence of a space-occupying lesion. In addition, these patients may need evaluation of other pituitary hormones to exclude deficiencies of other trophic hormones.

It is important to exclude systemic illness and medical conditions that disrupt the hypothalamic-pituitary axis such as HIV infection, end-stage renal disease, chronic obstructive lung disease, menopause, prior chemotherapy or bilateral salpingo-oophorectomy. Complete blood counts and a chemistry panel should be part of the general health evaluation. Medications that adversely affect sexual function should be addressed and changed if possible (Table 19-8).

Evaluating the female sexual response in the clinical setting both validates the patient's problem and potentially aids in diagnosis of organic disease, such as vascular insufficiency, a hormonal abnormality, or a neurologic disorder. Current investigations seek to define ranges of normal and the possible relevance to therapeutics for the following parameters:

1. Genital blood flow (clitoral, labial, urethral, and vaginal peak systolic velocities and end-diastolic velocities can be measured with duplex Doppler ultrasound).
2. Vaginal lubrication, as reflected by pH.
3. Vaginal compliance and elasticity (pressure-volume changes).
4. Genital sensation and vibration perception thresholds.
Psychosocial and Psychosexual Assessment

In addition to the medical evaluations, all patients should be evaluated for emotional and relational issues. This includes the context in which the patient experiences her sexuality, her self-esteem and body image, and her ability to communicate her sexual needs with her partner. This is an integral component of the female sexual function evaluation. Emotional and/or relational issues should be addressed before treatment and, certainly, before treatment efficacy is determined. If ongoing therapy is desired or required, it should also be provided.

Several instruments are available for assessment of self-reported sexual function, in particular sexual arousal. These self-report measures can be useful in clinical screening of patients and in clinical trials.

The Brief Index of Sexual Function Inventory (BISF-W), for example, is a validated 21-item self-reported listing of sexual interest, activity, satisfaction, and preference and discriminates between depressed, sexually dysfunctional, and healthy patients. The BISF-W is sensitive to the effects of androgen replacement in oophorectomized women.

The Female Sexual Function Index has also been used in clinical studies and practice. Its self-report measures have been found to have a high degree of reliability and validity. This instrument can discriminate between women with sexual dysfunction and age-matched controls.

Daily diaries and sexual event logs have also been used in clinical trials. Subjective sexual response data reflect the personal experience of the patient, an important variable to evaluate because the ultimate goal is to enhance the personal sexual experience of the woman. Intervention is not considered successful unless the woman is able to experience sexual arousal, pleasure, and satisfaction. Thus, it is important to determine whether physiologic changes or improvement in blood flow translate into a better sexual experience.
TREATMENT

Treatment of female sexual dysfunction is gradually evolving as more clinical and basic research studies are targeting this problem. Medical management remains in the early experimental phases. Most treatment modalities being used by patients and physicians are based on empirical observations and are neither supported by rigorous clinical trial data nor approved by the U.S. Food and Drug Administration. Although it is premature to make general evidence-based recommendations for the treatment of female sexual dysfunction, it is important to recognize that not all female sexual complaints are psychological and that there are potential therapeutic options that might be useful in individual patients.

Estrogen Therapy

Estrogen replacement therapy is often indicated in menopausal women (either spontaneous or surgical). Aside from relieving hot flashes and preventing osteoporosis, estrogen therapy probably results in improved clitoral sensitivity and in decreased pain and burning during intercourse. Although cross-sectional epidemiologic studies had previously reported lower prevalence of cardiovascular disease among estrogen users, a recent randomized placebo-controlled trial was unable to demonstrate beneficial effects of estrogen replacement in secondary prevention of heart disease in postmenopausal women.

The role of estrogen replacement in the primary and secondary prevention of heart disease in women remains unclear and is the focus of ongoing investigation. In women with established heart disease, estrogen replacement has not been shown to improve cardiovascular outcomes. In the HERS study, event rates were higher in women given estrogen replacement than in women given placebo. In menopausal women or in oophorectomized women, local or topical estrogen application relieves symptoms of vaginal dryness, burning, and urinary frequency and urgency. A vaginal estradiol ring (Estring) delivers low-dose estrogen locally and may benefit breast cancer patients and other women who are unable to take oral or transdermal estrogen.
Androgen Formulations

Testosterone supplementation is associated with increased well-being, energy, and appetite and with improved somatic and psychological scores in surgically menopausal women. In one study, such women, who were given supraphysiologic doses of testosterone enanthate by intramuscular injection alone or in combination with estrogen, experienced a greater increase in sexual desire, fantasies, and arousal than women who received estrogen alone. In another study, combined administration of testosterone and estradiol implants increased sexual activity, satisfaction, pleasure, and frequency of orgasm more than estrogen implants alone. The dose of testosterone used in each of these studies was supraphysiologic.

A later study evaluated the effects of physiologic testosterone replacement in women who had undergone hysterectomy and oophorectomy and who were receiving stable estrogen replacement (at least 0.625 mg of conjugated equine estrogen daily orally). These women were randomized to receive either placebo patches or testosterone patches designed to achieve nominal delivery of either 150 µg (one active and one placebo patch) or 300 µg (two active patches) of transdermal testosterone daily for 12 weeks each. The highest dose of testosterone resulted in a mean serum free testosterone slightly above the physiologic range and significantly increased scores for frequency of sexual activity, pleasure, and orgasm. It also increased sexual fantasies, masturbation, and positive well-being.

Objectively, testosterone supplementation has been reported to increase vaginal vascongestion, as measured by vaginal plethysmography during exposure to a potent visual stimulus in a small number of women with hypothalamic amenorrhea. Dehydroepiandrosterone (DHEA) replacement of 50 mg/day for 4 months in women with adrenal insufficiency increased sexuality and well-being. It is unclear whether these effects were secondary to direct effect of DHEA on the brain or to an indirect effect via an increase in androgen synthesis. In contrast, a cross-sectional study of perimenopausal women did not show correlation between sexual function and androgen levels. Although pharmacologic doses of testosterone undoubtedly improve overall sexual function, we do not know whether physiologic testosterone replacement can produce clinically meaningful changes in health-related outcomes.

All androgens carry the risk of inducing virilization in women. Early reversible manifestations include acne, oiliness of skin, hirsutism, and menstrual irregularities. Long-term side effects such as male-pattern baldness, hirsutism, voice changes, and hypertrophy of the clitoris are largely irreversible. There is also evidence that testosterone supplementation in supra-physiologic doses decreases high-density-lipoprotein (HDL) cholesterol levels. Women with history of breast cancer should not be prescribed testosterone because testosterone is converted to estrogen by the aromatase enzyme. Surprisingly, the reported prevalence of virilizing side effects, even with the use of supraphysiologic doses of testosterone in surgically menopausal women, has been relatively low.

17-Methyltestosterone is commonly used in combination with estrogen in menopausal women for sexual dysfunction. There are conflicting reports regarding the benefit of methyltestosterone for treatment of inhibited desire or vaginismus in premenopausal women. The suggested dose of methyltestosterone for premenopausal and postmenopausal women ranges from 0.25 to 1.25 mg/day. The dose should be adjusted according to symptoms, free testosterone levels, and cholesterol, triglyceride HDL levels, and liver function tests. The potential side effects include weight gain, clitoral enlargement, increased facial hair, and hypercholesterolemia. The pharmacokinetics and clinical efficacy of this formulation have not been rigorously studied.

Two novel testosterone formulations are currently in early phases of clinical development. A transdermal matrix testosterone delivery system (patch) for women that is applied twice a week is being investigated. Each patch provides a nominal delivery of 150 µg of testosterone daily. Thus, two patches applied simultaneously twice a week can achieve a daily delivery of 300 µg of testosterone, approximating the daily production rates of testosterone in healthy women. The skin tolerability of the patch is excellent. Initial pharmacokinetic studies have demonstrated that each 150-µg patch increases serum total testosterone concentrations by 25 to 30 ng/dL on average in healthy menstruating women and in surgically postmenopausal women. A testosterone gel for women is in initial stages of development. Each milligram of testosterone applied to the nongenital skin can increase serum testosterone concentration by 7 to 8 ng/dL.

Data from clinical trials thus agree that supraphysiologic doses of testosterone improve several aspects of sexual function in oophorectomized women with sexual dysfunction; however, we do not know whether physiologic testosterone that raises serum testosterone levels from low normal to high end of the normal range in women can produce clinically meaningful improvements in sexual function in postmenopausal women.
Sildenafil

Functioning as a selective type 5 (cGMP-specific) PDE inhibitor, this medication decreases the catabolism of cGMP, the second messenger in nitric oxide-mediated relaxation of clitoral and vaginal smooth muscle. Sildenafil may prove useful alone or perhaps in combination with other vasoactive substances for treatment of female sexual dysfunction. Phase II clinical studies assessing safety and efficacy of this medication for use in women are now in progress. Two studies have demonstrated that sildenafil is successful in treating female sexual dysfunction associated with aging and menopause and secondary to SSRI use. [137][166]
Therapeutic Agents under Development

A number of drugs that have previously been used for the treatment of ED in men are now being investigated in women with sexual dysfunction. In the absence of efficacy data from randomized clinical trials, it is premature to make general recommendations about their use at this time.

L-Arginine functions as a precursor to the formation of nitric oxide, which mediates the relaxation of vascular and non-vascular smooth muscle. Although L-arginine has not been tested in clinical trials in women, preliminary studies in men appear promising. A combination of L-arginine and yohimbine (an α2-adrenergic blocker) is currently being investigated for use in women.

An intraurethral formulation of PGE1, absorbed via the mucosa (MUSE), is now available for male patients. A similar application of PGE1, delivered intravaginally, is under investigation for use in women.

Currently available in an oral preparation, phentolamine functions as a nonspecific α-adrenergic blocker and causes vascular smooth muscle relaxation. A pilot study in menopausal women with sexual dysfunction demonstrated enhanced vaginal blood flow and subjective arousal with the medication.

Apomorphine is a short-acting dopamine agonist that facilitates erectile responses in both normal men and men with ED. This drug is being tested in women with sexual dysfunction.
SUMMARY

The ideal approach to female sexual dysfunction is a collaborative effort between therapists and physicians and should include a complete medical and psychosocial evaluation as well as inclusion of the partner or spouse in the evaluation and treatment process. Although there are significant anatomic and embryologic parallels between men and women, the multifaceted nature of female sexual dysfunction is distinct from that of the male. The context in which a woman experiences her sexuality is equally, if not more, important than the physiologic outcome she experiences, and these issues need to be determined before beginning medical therapy or attempting to determine treatment efficacies. Even in women with identifiable organic disease, there are often psychosocial, emotional, or relational factors that contribute to sexual dysfunction. For this reason, a comprehensive approach, addressing both psychological as well as physiologic factors is instrumental to the evaluation of female patients with sexual complaints.

Whether sildenafil or other vasoactive agents are demonstrated to be effective in women with arousal disorder remains to be seen. There is a pressing need for more clinical and basic science research. Until more definitive efficacy data from randomized clinical trials become available, the treatment of women with sexual dysfunction should be individualized and preceded by a discussion of the uncertainty about beneficial effects and the potential for known and unknown adverse effects of drug therapy.

Chapter 20 - Endocrine Changes in Pregnancy

Glenn D. Braunstein

PLACENTAL DEVELOPMENT

Normal placentation requires a coordinated series of events, beginning with fertilization. The fertilization rate following unprotected regular intercourse during a single menstrual cycle is 2350%. However, in approximately one-third of conceptions there is either failure of implantation or clinical or subclinical spontaneous abortion.

For the first 5 days, preimplantation development takes place within the fallopian tube. During this period, the zygote undergoes cleavage division and, at least through the eight-cell stage, the blastomeres remain totipotent. In the 16-cell stage, differentiation of the innermost cells into the inner cell mass and the surrounding cells into the trophectoderm occurs. The inner cell mass develops into the fetus, and the trophectoderm gives rise to the placenta and membranes. On approximately day 5 or 6 after fertilization, the blastocyst enters the uterus, but implantation does not occur for another 1 to 2 days. Implantation occurs after the zona pellucida disappears from around the embryo.

Implantation is a complex process that involves apposition of the microvilli present on the trophectoderm cells with microvilli on the endometrial cells, followed by removal of fluid between the cells through pinocytosis by the endometrial cells, a process stimulated by progesterone. Progesterone synthesis by the corpus luteum is stimulated and sustained during this time and for the first 6 to 7 weeks of pregnancy by secretion of human chorionic gonadotropin (hCG) by the trophoblast cells. The hCG is first detected in the maternal serum 6 to 9 days after conception. Attachment of the embryo is enhanced through the expression of a variety of adhesion molecules, including mucins, integrins, and trophinin, a trophoblast-specific cell membrane adhesion protein.

After the trophoblast attaches to the endometrium, the embryo invades the endometrium through a complex process involving matrix metalloproteinases and differentiation of the trophectoderm into cytotrophoblasts or syncytiotrophoblasts. The syncytiotrophoblasts are multinucleated cells formed by the fusion of cytotrophoblasts. The cytotrophoblasts form a column of cells that invade the endometrium, form anchoring villi, and enter the maternal vasculature, eventually replacing the endothelial layer of the endometrial and myometrial spiral arterioles with a layer of cytotrophoblasts (vascular trophoblasts). This process converts the high-resistance, low-capacity uterine vessels into low-resistance, high-volume vessels, essential for growth of the placenta and fetus. At the site of implantation, the endometrial cells undergo decidualization, enlarging and increasing their metabolic activity with enhanced production of protease inhibitors, extracellular matrix proteins, cytokines, and growth factors that modulate the extent of trophoblast invasion and influence trophoblast function.

The trophoblast cells secrete several angiogenic proteins, including vascular endothelial growth factor, platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF), which stimulate blood vessel development within the villi. The syncytiotrophoblasts form an outer layer of cells in the chorionic villi, between the cytotrophoblast cells and the maternal blood space on the exterior surface. Only three tissues separate the fetal blood from maternal blood: (1) the endothelium of the fetal vessels in the villi, (2) connective tissue, and (3) the trophoblasts; this form of placenta is referred to as hemochorial. Thus, in addition to hCG secretion, which is responsible for maintaining early pregnancy, and progesterone secretion, required for continuation of pregnancy after the luteal-placental shift, the syncytiotrophoblasts provide the major site for transportation of oxygen and nutrients to and removal of waste from the fetus.

Substances are transferred across the placenta through transcellular pathways that include carrier-mediated transport (e.g., immunoglobulin G through the Fc receptor) and simple extracellular diffusion. The degree of transplacental passage of a hormone from the mother to the fetus through diffusion depends on (1) the rate of placental blood flow, (2) the maternal concentration of the free or readily dissociatable hormone, and (3) the molecular mass, lipid solubility, charge, and degree of placental metabolic degradation of the hormone. Maternal-to-fetal transfer occurs for hormones smaller than 700 daltons, but the placenta is not permeable to hormones larger than 1200 daltons (Table 20-1). The syncytiotrophoblasts provide a tight barrier to most substances, although they are able to transport some substances, such as maternal-fetal transfer of hCG, progesterone, and human placental lactogen (HPL). The placenta is highly permeable to substances with a molecular mass of less than 1200 daltons, such as glucose and amino acids.

hCG during the first trimester but not during the subsequent trimesters. [13]
MATERNAL ADAPTATIONS TO PREGNANCY

Myriad physiologic changes take place beginning shortly after implantation. During early pregnancy, these effects are hormonally mediated. In the second and third trimesters, the uteroplacental vascular system and mechanical factors associated with the enlarging gravid uterus combine with the hormonal milieu to alter the function of every system.

General Adaptations

Weight gain averages 12.5 kg, of which the fetus accounts for about 3.4 kg, the placenta 0.65 kg, amniotic fluid 0.8 kg, uterus 1 kg, breasts 0.4 kg, blood 1.5 kg, extravascular fluid 1.5 kg, and maternal fat stores approximately 3.3 kg. The volume of the uterine cavity increases from about 10 mL to an average of 5 L at term, and blood flow through the uteroplacental circulation reaches 450 to 650 mL/minute.

In order to maintain appropriate perfusion of the mother and fetal-placental unit, blood volume increases throughout pregnancy and at term is 40% to 45% higher than in the nonpregnant state. Both the plasma volume and red cell mass increase. The plasma volume increases about 45% to 50% as a result of aldosterone-stimulated sodium and water retention; the red cell mass increases approximately 20% because of increased production resulting from a twofold to threefold increase in erythropoietin secretion. The net effect is a decrease in the hematocrit by about 15% at term.

The renal blood flow and glomerular filtration rate (GFR) increase rapidly and peak during the second trimester, and there is a 50% increase in creatinine clearance, resulting in a reduction in serum creatinine. Atrial natriuretic peptide (ANP) levels increase during pregnancy and may in part be responsible for the increased renal blood flow, GFR, 24-hour urine volume, and naturesis. An alteration in the osmotic thresholds for the release of vasopressin and activation of the hypothalamic thirst centers, possibly caused by an extragonadal effect of hCG, lead to an approximately 4% reduction in serum osmolality (10 mOsm/kg). Several hemodynamic changes are induced by the low-resistance, high-capacity uteroplacental vessels, which in many respects act like an arteriovenous malformation; the increased blood volume; and the large quantities of estrogens, progesterone, and angiotensin present during pregnancy. The changes include an increase in the heart rate by 10 to 15 beats/minute, a 30% to 50% increase in cardiac output resulting from increased stroke volume in early pregnancy and heart rate during the third trimester, a reduction in diastolic blood pressure with little or no change in systolic pressure, and an approximately 20% reduction in peripheral vascular resistance.

The pulmonary vascular resistance is reduced by about a third. Pregnancy is also associated with increases in pulmonary tidal volume by about 30%, which results in a respiratory alkalosis that is compensated by increased bicarbonate excretion by the kidneys; in minute ventilatory volume by 30% to 40%; and in minute oxygen uptake. There are no changes in respiratory rate, maximum breathing capacity, or forced or timed vital capacity. However, there is an approximately 40% reduction in the expiratory reserve because of the elevation of the diaphragm by the enlarged uterus.

Gastrointestinal tract function is altered during pregnancy. Gastric emptying time is decreased by more than 50% at term and the lower esophageal sphincter tone is reduced, which, together with the displacement of the abdominal contents by the pregnant uterus, results in a marked increase in gastroesophageal reflux disease. Motility of the intestine is also reduced, contributing to the constipation that is common during pregnancy. Decreased motility of the gallbladder leads to an increased gallbladder volume and reduced emptying of bile after meals, which results in a more lithogenic bile and an increase in cholelithiasis during pregnancy.
Maternal Endocrine Alterations

Pituitary Gland

The anterior pituitary gland enlarges by an average of 36% during pregnancy, primarily because of a 10-fold increase in lactotroph size and number. This enlargement results in an increase in height and convexity of the pituitary on magnetic resonance imaging. There are reduced numbers of somatotrophs and gonadotrophs and no changes in corticotrophs or thyrotrophs. The posterior pituitary gland diminishes in size during pregnancy.

The marked increase in estrogen levels during pregnancy enhances prolactin synthesis and secretion, and maternal prolactin serum levels increase in parallel with the enlargement of the lactotrophs. At term, the mean serum prolactin concentration is 207 ng/mL (range 35 to 600 ng/mL), in contrast to a mean of 10 ng/mL in nonpregnant premenopausal women. Prolactin is also present in the amniotic fluid and appears to be primarily of decidual origin because the decidua actively synthesizes prolactin. Amniotic fluid prolactin levels are 10 to 100 times higher than in the maternal circulation in early pregnancy, and maternal bromocriptine ingestion does not reduce the amniotic fluid prolactin levels but does reduce the maternal and fetal serum concentrations. Prolactin levels return to the baseline of nonpregnancy approximately 7 days after delivery in the absence of breast-feeding. With breast-feeding, the basal prolactin levels remain elevated for several months but gradually decrease; however, with suckling, there is a brisk rise in prolactin levels within 30 minutes.

Growth hormone (GH) levels in maternal serum throughout pregnancy are unchanged, although the source of immunoreactive GH during gestation does change. Relaxin, secreted by the corpus luteum of pregnancy, and estrogens stimulate GH secretion during early pregnancy. Pituitary GH messenger ribonucleic acid (mRNA) and GH secretion decrease after the 25th week of pregnancy, and beginning in the fourth month of gestation, the placental syncytiotrophoblast secretes a variant of GH in a nonpulsatile pattern. In concert with the different sources of GH during the first and second halves of pregnancy, the GH response to provocative stimuli differs in each half. Insulin hypoglycemia or arginine infusion results in an enhanced GH response during the first half of gestation, and there is a decreased response during the second half with respect to the response in nonpregnant women.

Maternal serum concentrations of insulin-like growth factor I (IGF-I) are elevated during the second half of pregnancy, probably through the combined effect of the placental GH variant and HPL, which is evolutionarily related to both GH and prolactin. HPL has somatotropic biologic activity, and its serum concentration increases throughout pregnancy, paralleling that of IGF-I. In turn, it is likely that the suppression of pituitary GH synthesis and secretion is due to the high IGF-I concentrations, which in late pregnancy are five times higher than those in nonpregnant women.

Although the placenta synthesizes and secretes biologically active gonadotropin-releasing hormone (GnRH), pituitary gonadotropin production decreases throughout pregnancy, as indicated by a marked reduction in gonadotropin immunoreactivity in the gonadotrophs beginning at 10 weeks of gestation as well as a reduction in serum levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). This suppression is probably mediated through the elevated blood levels of ovarian and placental sex steroid hormones along with placental production of inhibin. The suppression is incomplete because administration of exogenous GnRH leads to release of gonadotropins, although the response is blunted in comparison with that of nonpregnant women and does not return to normal until a month after birth.

Mean thyrotropin (hTSH, or thyroid-stimulating hormone) concentrations during the first trimester are significantly lower than in the second and third trimesters or in the nonpregnant state. Much of this early decrease may be accounted for by the intrinsic thyrotropic activity of hCG. The maximal biologic thyrotropic activity in maternal serum corresponds to the peak concentration of hCG at 10 to 12 weeks after the last menstrual period, at a time when there is a reciprocal relationship between the rising hCG levels and falling hTSH concentrations. The only time during pregnancy when the free thyroxine concentration in the maternal serum is elevated corresponds to the time of peak hCG and lowest hTSH, suggesting that the depressed hTSH is the result of feedback suppression by thyroxine. Despite the lower mean hTSH during early pregnancy, the hTSH response to exogenous thyrotropin-releasing hormone (TRH) is normal.

Maternal adrenocorticotrophic hormone (ACTH, or corticotropin) levels rise during pregnancy, increasing fourfold over concentrations in the nonpregnant state between 7 and 10 weeks of gestation. There is a further gradual rise to weeks 33 to 37, at which time a mean fivefold increase over prepregnancy values is found, followed by a 50% drop just before parturition and a marked 15-fold increase during the stress of delivery. The ACTH concentration returns to the prepregnancy level within 24 hours of delivery. Both the pituitary gland and the placenta serve as the source of the circulating ACTH during pregnancy, and exogenous corticotropin-releasing hormone (CRH) stimulates the release of ACTH from both tissues in a dose-dependent manner. Biologically active CRH is synthesized and secreted by the placenta and, to a lesser extent, by the decidual and fetal membranes, but in contradistinction to the inhibitory effect on pituitary CRH, glucocorticoids stimulate the expression of placental CRH.

Of interest, there appears to be a "disconnect" between CRH and ACTH during pregnancy. One would expect biologically active CRH to stimulate ACTH production. However, the qualitative patterns of CRH production, which shows an exponential rise during the sixth month of gestation, and ACTH secretion, which demonstrates a more gradual rise during pregnancy, are quite different. In addition, the lack of a significant correlation between maternal plasma CRH and ACTH during pregnancy suggests that factors such as the elevated levels of free cortisol in the maternal serum may modulate the response to CRH. Both the circadian rhythm and the ability to respond to stress are maintained throughout pregnancy; however, the ACTH response to exogenous CRH during the third trimester is blunted while the responsiveness to vasopressin is maintained, suggesting that the elevation of CRH in the maternal serum down-regulates the responsiveness to CRH.

Arginine vasopressin (AVP) concentrations in the maternal serum are similar to those in nonpregnant women. During pregnancy, however, there is increased synthesis of AVP, which is offset by the increased metabolic clearance of the hormone through destruction by a trophoblast-derived cysteine aminopeptidase (vasopressinase), whose levels rise throughout pregnancy in parallel with the increase in trophoblastic mass. As previously noted, there is a reduced osmolar set-point for thirst and the release of AVP related to the 10 mOsml/kg average decrease in plasma osmolality during pregnancy, possibly reflecting an
extragonadotropic effect of hCG. Taking into account the reduced set-point, the AVP response to dehydration and water loading is normal.

Oxytocin levels progressively increase in the maternal blood and parallel the increase in maternal serum estradiol and progesterone. The levels increase further with cervical dilation and vaginal distention during labor and delivery, stimulating uterine smooth muscles and enhancing fetal ejection.

Uterine oxytocin receptors also increase throughout pregnancy, resulting in a 100-fold increase in oxytocin binding at term in the myometrium.

**Thyroid Gland**

The thyroid gland enlarges by an average of 18% during pregnancy. The enlargement is associated with an increase in the size of the follicles with increased colloid and enhanced blood flow. This enlargement may be a response to the thyrotropic effect of hCG and asialo-hCG, which may also account for some of the increase in serum thyroglobulin concentrations noted during pregnancy. There is enhanced uptake by the maternal thyroid gland, which undoubtedly reflects the combined effects of hCG stimulation and reduction of the blood levels of iodide by enhanced renal iodide clearance.

The rising estrogen concentrations during pregnancy induce increased hepatic synthesis of thyroxine-binding globulin (TBG) as well as enhanced sialylation of TBG, which decreases its metabolic clearance rate. The results are a twofold increase in TBG and increased total thyroxine ($T_4$) and triiodothyronine ($T_3$) levels in maternal serum throughout pregnancy, whereas for the majority of gestation the free $T_4$ and free $T_3$ concentrations remain normal. There are no significant changes in the levels of thyroxine-binding prealbumin, but albumin levels are decreased because of the increase in vascular volume.

**Parathyroid Glands**

During pregnancy, approximately 30 g of calcium is transferred from the maternal compartment to the fetus, with most of the transfer occurring during the last trimester. Maternal total serum calcium levels decrease during pregnancy, with a nadir at 28 to 32 weeks related to the decrease in albumin levels that accompanies the increase in vascular volume. However, the albumin-adjusted total calcium and the ionized calcium concentrations actually rise slightly above the level in the nonpregnant state. The urinary calcium excretion rate increases in parallel with the increased GFR, and intestinal calcium absorption undergoes a twofold increase.

Although some studies have suggested that parathyroid hormone (PTH) levels increase during pregnancy, measurements of intact PTH levels by two-site immunometric assays indicate that they are within the normal, nonpregnancy range throughout pregnancy. In contrast, the circulating concentrations of PTH-related protein (PTHrP) increase throughout pregnancy. Many normal tissues produce this protein and the source of the elevated levels during pregnancy is unclear, although the two most likely sites are the mammary tissue and the placenta. This protein is probably involved in placental calcium transport.

The serum levels of 25-hydroxyvitamin D are unchanged during pregnancy, but the estrogen-induced rise in vitamin D-binding globulin results in a twofold increase in 1,25-dihydroxyvitamin D concentrations in maternal serum. There is also a rise in the biologically active free fraction of 1,25-dihydroxyvitamin D, which may reflect both increased maternal renal 1-hydroxylase activity and the synthesis and secretion of 1,25-dihydroxyvitamin D by the placenta.

This increase in the active metabolite of vitamin D may be responsible in part for the enhanced intestinal calcium absorption.

**Pancreas**

Hyperplasia and hypertrophy of the beta cells in the islets of Langerhans are probably the result of stimulation by estrogen and progesterone. During early pregnancy, the glucose requirements of the fetus lead to enhanced transport of glucose across the placenta by facilitated diffusion, and maternal fasting hypoglycemia may be present. Although basal insulin levels may be normal, there is hypersecretion of insulin in response to a meal. Because the half-life of insulin is not altered during pregnancy, this increase represents an increase in synthesis and secretion. The results are enhanced glycogen storage and decreased hepatic glucose production.

As pregnancy progresses, the levels of hPL rise, as do the levels of glucocorticoids, leading to the insulin resistance found during the last half of pregnancy. Thus, in late pregnancy, glucose ingestion results in higher and more sustained levels of glucose and insulin and a greater degree of glucagon suppression than in the nonpregnant state.

**Adrenal Glands**

As a result of the hyperestrogenemia of pregnancy, hepatic production of cortisol-binding globulin is increased. The increased production results in a doubling of the maternal serum levels cortisol-binding globulin, which in turn results in decreased metabolic clearance of cortisol and a threefold rise in total plasma cortisol by week 26, when the levels reach a plateau until they rise at the onset of labor. The rate of cortisol production is increased, and the plasma free cortisol concentrations are also increased. The enhanced cortisol production is due to an increase in the maternal plasma ACTH concentrations and hyperresponsiveness of the adrenal cortex to ACTH stimulation during pregnancy.

Cortisol secretion follows that of ACTH, and the diurnal rhythm is maintained during pregnancy. Despite the elevated free cortisol levels, pregnant women do not develop the stigma of glucocorticoid excess, possibly because of the antiglucocorticoid activities of the elevated concentrations of progesterone.

Plasma renin substrate levels are increased as a consequence of the effects of estrogen on the liver. Renin levels are also increased, and increased renin activity results in increased levels of angiotensin II, which lead to an eightfold to 10-fold increase in aldosterone production and serum aldosterone levels.

Despite their basal elevations, the various components of the renin-angiotensin-aldosterone system demonstrate normal responses to positional changes, sodium restriction, and sodium loading. The elevated aldosterone levels do not lead to an increase in serum sodium, a decrease in serum potassium, or an increase in blood pressure, which again may reflect the high progesterone concentrations, which are capable of displacing aldosterone from its renal receptors. Another mineralocorticoid, 11-deoxycortisol, shows a sixfold to 10-fold increase in concentration at term.

Elevated levels of this hormone are due to estrogen-induced extraglandular 21-hydroxylase of progesterone produced by the placenta.

Levels of androstenedione and testosterone, whether they are of adrenal or ovarian origin, are elevated because of the estrogen-induced increase in hepatic synthesis of sex hormone-binding globulin. However, the free androgen levels remain normal or low. The adrenal production rates of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are increased twofold, but the maternal serum concentration of DHEAS is reduced to one-third to one-half the nonpregnancy levels because of the enhanced 16-hydroxylation and placental utilization of 16-hydroxydehydroepiandrosterone sulfate in estrogen formation.

Adrenal medullary function remains normal throughout pregnancy. Thus, 24-hour urine catecholamine and plasma epinephrine and norepinephrine levels are similar to concentrations in the nonpregnant state.
PLACENTAL HORMONE PRODUCTION

Steroid Hormones

Placental steroidogenesis takes place in the syncytiotrophoblast, and synthesis and secretion of estrogens and progesterone increase throughout pregnancy in concert with the increase in the trophoblast mass (Fig. 20-2). The placenta has reduced levels of, or lacks several enzymes important for, the de novo production of estrogens and progesterone and thus is dependent on precursors of both maternal and fetal origin. This dependence has led to the concept of the maternal-fetal-placental unit. These interactions are outlined in Figure 20-3.

Progestrone

Although the trophoblast can synthesize cholesterol from acetate, the amount of an essential enzyme needed for cholesterol synthesis, hydroxymethylglutaryl-CoA reductase, in placental microsomes is low because of the inhibitory effects of the high intracellular concentrations of cholesterol that result from progestrone inhibition of cholesterol esterification. Therefore, steroid synthesis by the placenta is dependent on the delivery of low-density lipoproteins (LDLs) and very-low-density lipoproteins (VLDLs) from the maternal circulation. The syncytiotrophoblast contains receptors for LDLs, VLDLs, and high-density lipoproteins (HDLs). Receptor-mediated uptake of LDL cholesterol is stimulated by estrogens, as is the activity of the cholesterol side-chain cleavage enzyme (CYP11A1), which converts cholesterol to pregnenolone.

Progestrone is synthesized in the trophoblast from pregnenolone by a placental isoform of 3-hydroxysteroid dehydrogenase (3-HSD-I). Approximately 90% of the progesterone synthesized is secreted into the maternal compartment, and at term the mean maternal serum concentration is about 150 ng/mL. The fetal compartment is not essential for progesterone production. Hence, progesterone production continues after fetal death.

Progesterone appears to have multiple functions during pregnancy, the most important being preparation of the uterus for implantation and maintenance of the pregnancy. The corpus luteum is the primary source of progesterone during the first 8 to 10 weeks of pregnancy, after which ovarian progesterone production declines and placental synthesis and secretion become the major source of the hormone (the luteal-placental shift).

Luteectomy, or removal of the ovary containing the corpus luteum, within the first 35 days after conception leads to abortion, but the pregnancy generally continues if these procedures are performed 40 or more days after conception. This indicates that placental progesterone production is sufficient to maintain the pregnancy even before the luteal-placental shift. Administration of the progesterone receptor antagonist mifepristone during the first 49 days after conception results in abortion, again demonstrating that progesterone is essential for the maintenance of early pregnancy.

Progesterone also serves as an important substrate for fetal adrenal glucocorticoid and mineralocorticoid synthesis and maintenance of myometrial quiescence, possibly through inhibition of prostaglandin formation. A possible role for the high concentrations of progesterone present at the trophoblast-decidua junction is suppression of cell-mediated rejection of the fetus, which expresses paternal antigens, by maternal T lymphocytes.

Estrogens

The trophoblast lacks 17-hydroxylase and 17,20-lyase (CYP17) activities and therefore cannot directly convert progesterone to estrogen. Pregnenolone produced in the placenta enters the fetal compartment, where it is taken up by the fetal zone of the adrenal cortex, which also synthesizes pregnenolone from fetal LDL cholesterol. Pregnenolone is conjugated with sulfate by fetal steroid sulfotransferase in the fetal liver and adrenals to form pregnenolone sulfate and is converted in the fetal adrenals to 17-hydroxy-pregnenolone sulfate and then DHEAS by 17-hydroxylase and 17,20-lyase (CYP17) activities.

VLDLs, and high-density lipoproteins (HDLs). Receptor-mediated uptake of LDL cholesterol is stimulated by estrogens, as is the activity of the cholesterol side-chain cleavage enzyme (CYP11A1), which converts cholesterol to pregnenolone.

DHEAS enters the fetal circulation and undergoes hydroxylation in the fetal liver to form 16-hydroxy-DHEAS, which is converted to 16-DHEA in the placenta through the action of placental sulfatase. Further metabolism in the trophoblast by 3-HSD-I, 17-hydroxysteroid dehydrogenase (17-HSD), and aromatase (CYP19) leads to the generation of estradiol, which is quantitatively the major estrogen in the maternal circulation during pregnancy. The maternal liver actively conjugates estradiol with glucosiduronate and sulfate, which are excreted into the urine. Approximately 90% of the estradiol present in the maternal serum and urine is derived from fetal precursors, and therefore measurement of estradiol levels in serum or urine serves as an index of fetal well-being.

The DHEAS enters the fetal circulation and undergoes hydroxylation in the fetal liver to form 16-hydroxy-DHEAS, which is converted to 16-DHEA in the placenta through the action of placental sulfatase. Further metabolism in the trophoblast by 3-HSD-I, 17-hydroxysteroid dehydrogenase (17-HSD), and aromatase (CYP19) leads to the generation of estradiol, which is quantitatively the major estrogen in the maternal circulation during pregnancy. The maternal liver actively conjugates estradiol with glucosiduronate and sulfate, which are excreted into the urine. Approximately 90% of the estradiol present in the maternal serum and urine is derived from fetal precursors, and therefore measurement of estradiol levels in serum or urine serves as an index of fetal well-being.

During pregnancy, estrogens have several actions. They accomplish the following:

1. Enhance receptor-mediated uptake of LDL cholesterol, which is important for normal placental steroid production.
2. Increase uteroplacental blood flow.
3. Increase endometrial prostaglandin synthesis.
4. Prepare the breasts for lactation.

However, estrogen action does not appear to be essential in maintaining pregnancy because a fetus with deletion of the gene encoding placental sulfatase cannot...
remove the sulfate moiety from 16-hydroxy-DHEAS and therefore has maternal estrogen levels approaching only about 10% of normal. Similarly, pregnancies complicated by fetal aromatase deficiency may continue to term, again suggesting that the high concentrations of estrogens found in normal pregnancy are not necessary.
Protein Hormones

Human Chorionic Gonadotropin

Chemistry

Human chorionic gonadotropin (hCG) is a glycoprotein composed of two disissimlar subunits, and, which are non-covalently linked through hydrophobic bonding. This molecule shares structural homology with the other glycoprotein hormones, human luteinizing hormone (hLH), hFSH, and hTSH. These hormones have subunits that contain the same sequence of 92 amino acids and differ only in their carbohydrate composition; the subunits differ in both amino acid and carbohydrate structure and are responsible for the biologic and immunologic specificity of the heterodimeric (intact) hormones. The 22,000-dalton subunit of hCG is composed of 145 amino acids. Approximately 80% of the first 115 amino acids are homologous to those in the subunit of hLH. hCG has an additional 24 amino acids on its carboxyl-terminal end that enhance its biologic activity.

Both subunits of hCG contain two oligosaccharide chains attached to asparagine residues through N-glycosidic linkages, and the subunit contains in addition four O-serine-linked oligosaccharide units in the carboxyl-terminal peptide. The carbohydrate composition of hCG contains microheterogeneity and affects hormone clearance and biologic activity. The tertiary structure of hCG is determined by the carbohydrate composition and multiple disulfide bonds within each subunit. The subunit contains five disulfide bonds; the subunit has six. In each of the subunits, three of the disulfide bonds form a cystine knot, similar to that found in PDGF- and transforming growth factor (TGF-).

The free subunit has a 41-minute fast T$_{1/2}$ and a 76-minute slow T$_{1/2}$ of 4 hours, and the free subunit has a 13-minute fast T$_{1/2}$ and a 76-minute slow T$_{1/2}$. After it is secreted, hCG exhibits a biexponential clearance from the circulation with a fast half-time (T$_{1/2}$) of 6 hours and a slow T$_{1/2}$ of close to 36 hours. In contrast, the free subunit has a 41-minute fast T$_{1/2}$ and a slow T$_{1/2}$ of 4 hours, and the free subunit has a 13-minute fast T$_{1/2}$ and a 76-minute slow T$_{1/2}$. Approximately 22% of the intact hormone appears in the urine unchanged; the rest undergoes metabolic degradation (Fig. 20-5). One of the early steps is proteolytic cleavage ("nicking")

The single subunit gene, located on chromosome 6, is actively expressed in both the cytotrophoblast and syncytiotrophoblast. In contrast, the subunit is encoded by a cluster of six genes located on chromosome 19 in proximity to the hLH- gene. Three of the hCG- genes are actively transcribed during pregnancy, primarily in the syncytiotrophoblast, which thus has the ability to synthesize and secrete free subunits and intact hCG. After synthesis of the protein core, each subunit is glycosylated, undergoes further post-translational modification through trimming of the carbohydrate, and then combines to form intact hCG.

Secretion of hCG differs from that of many of the other placental proteins, whose secretory pattern parallels that of the trophoblastic mass. hCG is first detected in maternal serum 6 to 9 days after conception. The levels rise in a logarithmic fashion, peaking 6 to 10 weeks after the last menstrual period, followed by a decline to a nadir at 18 weeks, with subsequent levels remaining constant until delivery. The placenta also secretes free subunits. During the first 13 weeks of pregnancy, relatively more subunit is synthesized than subunit, and throughout the remainder of pregnancy the opposite occurs. In addition, a hyperglycosylated form of subunit (big hCG) that is unable to combine with free subunit is secreted into the maternal serum.

The physiologic factors that regulate hCG secretion in vivo are unknown. Much of the data concerning factors that stimulate or inhibit hCG synthesis and secretion have been derived from in vitro studies and is difficult to extrapolate to the in vivo situation. There is strong circumstantial evidence that GnRH, synthesized in both the cytotrophoblast and syncytiotrophoblast, may be an important factor in hCG secretion. This peptide is identical to hypothalamic GnRH and stimulates placental hCG production both in vitro and in vivo, whereas GnRH antagonists decrease basal hCG secretion.

Immunohistochemical staining for GnRH in placental tissue is highest at 8 weeks of gestation and lower afterward. Roughly paralleling the pattern of hCG production, as do the circulating levels of GnRH measured in maternal serum. In addition, the placenta contains GnRH receptors. Placental GnRH release is stimulated by cyclic adenosine monophosphate (cAMP), prostaglandin E$_2$, prostaglandin F$_2$, epinephrine, epidermal growth factor, insulin, and vasoactive intestinal peptide (VIP), factors also noted to increase hCG secretion in vitro.

Two other peptides synthesized by the cytotrophoblast, activin and inhibin, also modulate GnRH and hCG secretion; activin increases both, and inhibin inhibits the action of GnRH on the syncytiotrophoblast. Increases in hCG production have also been found after trophoblast exposure to FGF, calcium, glucocorticoids, and phorbol esters. Decreased production occurs with TGF-$
\beta$, follistatin, and progesterone. The decidua may also influence hCG production through paracrine mechanisms. Decidual interleukin-1 stimulates hCG secretion in cultured trophoblasts, while decidual prolactin and an 8- to 10-kd decidual protein inhibit hCG production.

Finally, hCG may autoregulate its own production to some extent. hCG receptors are present on the surface of trophoblastic cells, and the addition of hCG to placental cells in culture stimulates cAMP production as well as proliferation and differentiation of the cytotrophoblasts into syncytiotrophoblasts. Both hCG mRNA and hCG production are stimulated by analogues of cAMP or agents that activate adenylyl cyclase, probably through a protein kinase. Thus, the net effect of an increase in syncytiotrophoblast mass and cAMP would be enhancement of hCG secretion.

The placenta is not the only site of hCG synthesis. Immunoreactive hCG has been found by immunocytochemistry or by immunooassay of extracts of a wide variety of normal tissues, including spermatozoa, testes, endometrium, kidney, liver, colon, gastric tissue, lung, spleen, heart, fibroblast, brain, and pituitary gland.

and the hormone has been shown to be synthesized in some fetal tissues. The pituitary gland appears to be the major source of hCG or an hCG-like material present in nonpregnant individuals. Immunoreactive and bioactive hCG has been partially purified from pituitary glands; the material is secreted in vitro by fetal pituitary cells and is shown by immunocytochemistry to be present in gonadotroph-type cells that do not contain hLH or human FSH.

Immunoreactive hCG has been measured in sera from normal, nonpregnant individuals, with the highest concentrations found in postmenopausal women. In postmenopausal women, this material is secreted in a pulsatile fashion in parallel with hLH pulses, and during the normal menstrual cycle the immunoreactive hCG shows a midcycle peak concomitant with the LH peak. In both men and postmenopausal women, GnRH stimulates secretion of the hormone, whereas its secretion is inhibited by oral contraceptives in women and by a GnRH agonist in gonadal men.

Both gestational and nongestational trophoblastic tumors secrete hCG and its free subunits. The sources of hCG secretion in nongestational trophoblastic neoplasms are the syncytiotrophoblastic cells and in seminomas are the trophoblastic giant cells. In many instances, the tumors produce incomplete forms of hCG or its subunits, and differences in carbohydrate content from the hCG in pregnancy have been especially apparent. A wide variety of nontrophoblastic tumors also secrete hCG, although the predominant moiety appears to be the free subunit of hCG.
The presence of hLH-hCG receptors on the corpus luteum. The parallel rise of progesterone and hCG in early pregnancy. The early production of hCG by the implanting trophoblast. Approximately 20% of patients with complete moles develop persistent trophoblastic disease, whereas only 2% to 4% of patients develop persistent disease after partial molar pregnancy. Persistent trophoblastic disease also can occur after a normal term pregnancy as well as pregnancies that end in spontaneous

Nicked hCG is unstable and dissociates into free subunit and nicked free subunit. The latter is further metabolized, primarily in the kidney, to produce the core fragment, which is composed of the subunit amino acids 6 to 40 disulfide bridged to amino acids 55 to 92, trimmed of a portion of carbohydrate, and has a molecular mass of 10,479 daltons. This fragment is the major form of immunoreactive hCG present in the urine in pregnancy. In normal pregnancy, the urine also contains variable quantities of the hyperglycosylated form of subunit, free subunit, free subunit, nicked hCG, nicked free subunit, carboxyl-terminal fragments of the subunit, and fragments of the subunit.

Physiologic Functions

Most, if not all, of the physiologic functions of hCG occur after interaction of the hormone with the hLH-hCG receptor. The receptor gene is located on chromosome 2 and encodes for a G protein-coupled receptor with seven hydrophobic transmembrane domains and a large extracellular amino terminus that binds to hCG (and hLH). The receptor is part of superfamily of receptors, including those for hFSH, hTSH, hPG, VIP, PTH, and receptors for a variety of biogenic amines and neurotransmitters. The hCG-receptor interaction results in increased cAMP production and, in some tissues, increased phosphoinositide turnover.

Because of the close structural homology of the hLH-hCG receptor with the other glycoprotein hormone receptors, hCG may interact with the hFSH and hTSH receptors and thus has weak intrinsic hTSH and hFSH biologic activity. As previously noted, the hTSH-like activity of hCG is clinically manifested during normal pregnancy by the reciprocal decrease in maternal hTSH at the time of the hCG peak between 6 and 12 weeks after the last menstrual period. It is especially important in patients with hydatidiform moles and other forms of trophoblastic disease in which hCG levels may exceed 100,000 IU/L and result in clinical thyrotoxicosis.

One of the major functions of hCG during pregnancy is the "rescue" of the corpus luteum during the conception cycle. During a menstrual cycle without conception, progesterone concentrations in the serum increase for the first 6 to 7 days of the luteal phase, followed by a 3- to 4-day plateau and then a decrease resulting in shedding of the endometrial lining. After conception and implantation, the corpus luteum continues to secrete progesterone and 17-hydroxyprogesterone for another 4 to 6 weeks. The maternal serum progesterone and 17-hydroxyprogesterone concentrations then decrease, indicating a marked diminution in corpus luteum function. The fall in 17-hydroxyprogesterone concentrations continues, but the drop in progesterone levels is only transient. This marks the transition from dependence of ovarian progesterone production to placental progesterone secretion (the luteal-placental shift). As previously noted, luteectomy during the first 50 days after the last menstrual period is associated with a decline in progesterone levels and expulsion of the products of conception. After a therapeutic abortion, progesterone levels also drop rapidly.

Thus, the fetal-placental unit is responsible for the signal to maintain the corpus luteum. The data supporting the idea that hCG is that physiologic signal include the following:

1. The presence of hLH-hCG receptors on the corpus luteum.
2. The early production of hCG by the implanting trophoblast.
3. The dose-dependent increase in cAMP, progesterone, and estradiol from luteal cells cultured in vitro after exposure to hCG.
4. The parallel rise of progesterone and hCG in early pregnancy.
5. The enhanced progesterone secretion and prolongation of the menstrual cycle in nonpregnant women given exogenous hCG during their luteal phase.

The inability of hCG to prolong the life of the corpus luteum of pregnancy beyond the sixth to eighth week of pregnancy appears to be due to homologous desensitization of the adenylate cyclase system and the inhibitory effects of the high estrogen levels on progesterone synthesis through inhibition of 3-hydroxysteroid dehydrogenase and 5α-isomerase in the corpus luteum.

Another physiologic role for hCG is in the differentiation of fetal male genitalia through stimulation of the LH-hCG receptors on the fetal testicular Leydig cells during the period when differentiation of Wolffian duct structures and development of the external genitalia occur. The maximum testosterone production per unit weight of the testes coincides with the maximum binding of 125I-labeled hCG to the fetal testicular receptors at 10 to 12 weeks of development, and fetal Leydig cells produce cAMP and testosterone in vitro after exposure to hCG. The hCG concentrations in fetal serum parallel the fetal testicular testosterone levels at a time when the amount of fetal pituitary LH is not sufficient to stimulate the testosterone production.

There are several other possible actions of hCG during normal pregnancy. In vitro, hCG stimulates the differentiation of cytotoxic lymphoblasts to syncytiotrophoblast and hence may play an important paracrine role in regulating syncytiotrophoblast mass and production of trophoblast hormones.

Additional data supporting this autoregulatory effect of hCG include the in vivo stimulation of placental synthesis of cAMP, activation of glycogen phosphorylase, and incorporation of radiolabeled galactose and leucine into placental proteins upon exposure to hCG. The fetal zone of the adrenal releases DHEAS in response to hCG exposure in vitro, and therefore hCG may have androgenic effects in concert with fetal pituitary ACTH and placental ACTH.

It has also been suggested that hCG plays a role in the immunosuppression that occurs during pregnancy. Many early studies on this topic were hampered by the use of impure preparations of hCG or the presence of preservatives such as phenol that may alter the end-points of the test systems used to define immunosuppression. In addition, the immunosuppressive effects may be due to gonadal steroid secretion in response to the hCG in the in vivo models used in some of the studies. Relaxin secretion from the corpus luteum is stimulated by hCG both in vivo and in vitro.

Finally, the decrease in osmotic threshold for thirst and AVP release during pregnancy is clearly related to hCG. Whether this decrease is due to a direct effect of hCG or an indirect effect through stimulation of gonadal steroids or interaction with hLH-hCG receptors present in vascular smooth muscle is unclear.

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) includes complete and partial hydatidiform moles, choriocarcinoma, and placental-site trophoblastic tumor. Complete molar pregnancy is the most common variety, occurring in 1 to 2 in 1000 pregnancies. Patients usually present with vaginal bleeding, a uterus that is larger than expected for the duration of pregnancy, amenorrhea, and excessive vomiting. Pathologically, trophoblast hyperplasia, marked edema of the choriocarcin, and absence of fetal tissues are observed. In contrast, partial moles demonstrate focal trophoblast hyperplasia and villous swelling and often have fetal tissues with congenital malformations. Approximately 20% of patients with complete moles develop persistent trophoblastic disease, whereas only 2% to 4% of patients develop persistent disease after partial molar pregnancy. Persistent trophoblastic disease also can occur after a normal term pregnancy as well as pregnancies that end in spontaneous

Hormones. Amsterdam, Elsevier Science, 1988, p 33.)
or induced abortion.

Choriocarcinoma is the most aggressive malignant form of persistent trophoblastic disease and may involve complications from local uterine disease, such as bleeding and rupture of the uterus, or from the effects of metastases, especially those involving the liver, lungs, and brain. The least common form of GTD is placental-site trophoblastic tumor, which is derived from the intermediate trophoblast and is often associated with vaginal bleeding and amenorrhea. 161

All of these neoplasms secrete hCG, free subunit, and often additional forms of these molecules. With the exception of placental-site trophoblastic tumor, which secretes relatively low amounts of hCG, the serum and urine concentrations of hCG roughly parallel the tumor burden and also provide prognostic information. Thus, hCG measurements in concert with clinical and radiologic findings, especially vaginal ultrasonography findings, are useful for making the diagnosis of GTD.

Hydatidiform moles are initially treated with uterine dilatation and evacuation with or without adjunctive single-agent chemotherapy with methotrexate or actinomycin D. Approximately 90% of patients with low-risk, persistent trophoblastic disease are cured by single-agent chemotherapy; 75% of patients with high-risk, metastatic disease are cured by multi-agent chemotherapy, including etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine. Serial hCG measurements are invaluable for monitoring as they accurately reflect the effect of therapy on the tumor. 162

Human Placental Lactogen

Also called choric somatomammotropin, hPL is a single-chain, nonglycosylated polypeptide composed of 191 amino acid residues and two disulfide bridges, with a molecular mass of 21,600 daltons. 163 It is closely related chemically and biologically to both GH (85% amino acid homology) and prolactin (13% amino acid homology) 164 The hGH-hPL gene cluster is located on the long arm of chromosome 17 and consists of five genes coding for pituitary hGH (hGH-N), one for placental hGH (hGH-V), and three for placental hPL (hPL-L, hPL-A, and hPL-B, of which only hPL-A and hPL-B are transcribed). 165

hPL is synthesized and secreted by the syncytiotrophoblast and is detected in maternal serum between 20 and 40 days of gestation. 166 The maternal serum levels rise rapidly and peak at 34 weeks, followed by a plateau. 167 168 Both the serum concentrations and placental hPL mRNA concentrations are closely correlated with placental weight and syncytiotrophoblastic mass. 169 170 The maternal serum concentrations at term average between 6 and 7 µg/mL; at that time, on the basis of the 9- to 15-minute T½ of disappearance from the circulation, the placental production rate of hPL is in excess of 1 g/day. 171 The fetal serum levels are 1/50 to 1/100 of the maternal levels. 167

The physiologic in vivo regulation of hPL synthesis and secretion, other than the constitutive production related to placental mass, is unknown. Several studies have examined the possible role of nutrients in hPL secretion in pregnant women. Neither acute hyperglycemia nor hypoglycemia appeared to alter the hPL concentrations, although prolonged glucose infusions decreased and prolonged fasting increased the concentrations. 172 173 174 Arginine infusions, dexamethasone administration, and changes in plasma free fatty acid levels did not affect the maternal hPL concentrations. 175 176 Glucose, estrogen, glucocorticoids, progestagens, epinephrine, oxytocin, TRH, GnRH, and l-dopa have been examined in vitro systems and found to be without consistent effects. 177 178 179 180

Angiotensin II, IGF-I, phospholipase A, 181 and arachidonic acid, and epidermal growth factor stimulated hPL release in vitro. 182 183 184 Epidermal growth factor probably enhances production through promotion of cytotrophoblast-to-syncytiotrophoblast differentiation. 185 186 Apolipoprotein AI also stimulated hPL synthesis and release through CAM-dependent and arachidonic acid-dependent pathways. 187 188 189 Because changes in the maternal plasma apolipoprotein AI concentrations parallel those of hPL during pregnancy, it is likely that this apoprotein, alone and as part of circulating HDL, is important in the secretion of hPL. 190

hPL has a number of biologic activities that are qualitatively similar to those of hGH and prolactin and can bind to both the hGH and prolactin receptors. 191 In various bioassay systems, hPL had weak somatotrophic and lactogenic effects 192 193 194 It appears to be a major regulator of IGF-I production, and during pregnancy, hPL concentrations are correlated with those of IGF-I. 195 196 197 hPL also affects the metabolism of maternal nutrients. It stimulates pancreatic islet insulin secretion, both directly and after carbohydrate administration, 198 199 200 and is a diabetogenic factor during pregnancy through its promotion of insulin resistance. It enhances lipolysis, leading to a rise in free fatty acids, which may in part be responsible for the insulin resistance. 201

The various biologic activities of hPL have led to the hypothesis that the role of hPL during pregnancy is to provide the fetus with a constant supply of glucose and amino acids. 202 The hPL-stimulated lipolysis allows the mother to utilize free fatty acids for energy during fasting, allowing glucose, amino acids, and ketone bodies to cross the placenta for use by the fetus. In addition, hPL has actions in the fetus, promoting amino acid uptake by muscle and stimulating protein production, IGF-I production, and glycogen synthesis. 203

Despite the proposed importance of hPL in maternal and fetal metabolic homeostasis during pregnancy, its absence does not appear to impair pregnancy. Deficient or absent hPL production related to gene defects has been described in several women who experienced normal pregnancies and delivered normal infants. 204 205 206

Placental Growth Hormone

Placental GH, hGH-V, is synthesized and secreted by the syncytiotrophoblast. 207 208 Alternate splicing of the hGH-V gene results in two nonglycosylated isoforms with molecular masses of 22 and 26 kD. 209 210 The 22-kD variant may also be glycosylated and circulate as a 26-kD protein. 211 HGH-V is detected in the maternal plasma from 10 weeks of gestation and peaks during the third trimester 212 213 214 (Fig. 20-7). 215

HGH-V has somatotropic activity and stimulates IGF-I production, and the increase in IGF-I concentrations may in turn be responsible for the suppression of maternal pituitary hGH secretion 216 217 218 (see Fig. 20-7). Unlike pituitary hGH, hGH-V is not secreted in a pulsatile fashion, nor is it released from the trophoblast by growth hormonereleasing hormone (GHRH), but it is inhibited by glucose. 219 It has been estimated that at term, 85% of the GH biologic activity in maternal serum is due to hGH-V, 12% to hPL, and only 3% to pituitary hGH. 220 Within 48 hours of delivery, pituitary hGH secretion returns to normal.

Human Chorionic Corticotropin

The syncytiotrophoblast synthesizes an ACTH-like peptide, human chorionic corticotropin (HCC), as well as several proopiomelanocortin-derived peptides, including α-lipotropin, endorphin, and –melanocyte-stimulating hormone. 221 222 223 The maternal serum concentrations of ACTH increase as pregnancy progresses, and the elevation of free cortisol levels during pregnancy may be related in part to both placental hCC and pituitary ACTH production. 224

HCC secretion is stimulated by CRH, which is probably the most important factor regulating the local production of the peptide through paracrine or autocrine mechanisms, or both, because it is also produced by both the cytotrophoblast and the syncytiotrophoblast. 225 Unlike the situation with the pituitary, glucocorticoids and oxytocin also stimulate HCC release from placental cells. 226 227 Indeed, the resistance of maternal plasma ACTH concentrations to suppression after...
glucocorticoid administration may reflect the placental hCC contribution to the total pool of circulating immunoreactive ACTH.

### Hypothalamic Peptides

#### Corticotropin-Releasing Hormone

Both the cytotrophoblast and the syncytiotrophoblast synthesize and secrete GnRH, which has the same chemical structure.

In vitro, GnRH production by placental explants or purified trophoblasts is stimulated by prostaglandins, epinephrine, insulin, epidermal growth factor, VIP, estradiol, and estriol, and secretion is reduced by inhibin, progesterone, and -opioid and -opioid agonists. The syncytiotrophoblast contains low-affinity GnRH receptors, whose concentrations parallel the hCG secretory pattern.

Because GnRH stimulates hCG secretion by placental explants and purified trophoblast cells in vitro, with the response of early to midtrimester placentas being greater than that of term trophoblast, it is reasonable to conclude that GnRH is an important autocrine or paracrine regulator of hCG secretion.

#### Other Peptides

A substance with GHRH-like activity has been found in the placenta. It has unknown physiologic significance because there is no convincing evidence that a chorionic thyrotropin exists, and hCG appears to be the major trophoblastic thyrotropin-like substance.

### Immunoreactive Somatostatin

This pattern has led to the speculation that somatostatin inhibits hPL production and that the loss of inhibition allows the placenta to secrete increasing quantities of hPL. The finding of somatostatin receptors in the placenta adds some indirect support to this hypothesis. However, somatostatin does not inhibit hPL (or hGH-V) production by placental cells exposed to the peptide in vitro.

A substance with GHRH-like activity has been found in the placenta. However, because exposure of placental cells to hypothalamic GHRH does not result in stimulation of hPL or hGH-V secretion, it is unlikely that human placental GHRH is physiologically important.

### Growth Factors

Many growth factors, growth factor-binding proteins, and growth factor receptors have been identified in the placenta. These include IGF-I, IGF-II, relaxin, epidermal growth factor, PDGF, nerve growth factor, FGF, TGF-α, inhibin, activin, and folliculoostatin.

As reviewed earlier, a number of these factors have been implicated in the autocrine or paracrine regulation of placental hormone synthesis and release and placental angiogenesis, and they may have important actions in fetal development. In addition to the placenta, the human endometrium is a rich source of growth factors, cytokines, and vasoactive neuropeptides that are important for uteroplacental function.

Chapter 21 - Endocrinology of Fetal Development

Delbert A. Fisher

The unfolding of our understanding of mammalian pregnancy and fetal development represents one of the dramatic chapters of scientific progress during the past half-century, but we are only beginning to understand the complex genetic, growth factor, and hormonal interactions involved in implantation, placentation, embryonic and fetal development, parturition, and fetal adaptation to extrauterine life. An array of homeobox genes program embryogenesis and fetal development in concert with autocrine, paracrine, and endocrine networks of chemicals, hormones, and growth factors that provide the cellular communication coordinating maternal-placental-fetal interactions and fetal maturation. An important concept that has emerged is that the fetal-placental endocrine milieu is unique and the insights from studies of endocrine and growth factor systems of mature species are not directly applicable to the fetal environment.

Unique features of the placental-fetal endocrine environment (Table 21-1) include the growing spectrum of placental hormones and growth factors and a variety of transient fetal endocrine adaptations to the intrauterine environment. The fetal adrenal cortex, the para-aortic chromaffin system including the paired organs of Zuckerkandl, and the intermediate lobe of the pituitary are prominent among these. Vasotocin, the parent neurohypophyseal hormone in submammalian species, is expressed transiently during fetal life, and calcitonin, a largely vestigial hormone in adult mammals, plays a significant role in fetal calcium and bone metabolism.

In addition, the active adrenal glucocorticoid, cortisol, and the major thyroid hormone, thyroxine (T4), are largely inactive during much of fetal life because of the preferential synthesis of inactive moieties. Hormones and growth factors that play prominent roles in the fetus include catecholamines, parathyroid hormone-related protein (PTHrP), antimüllerian hormone, insulin-like growth factor II (IGF-II), transforming growth factor (TGF-), and the neuroregulins. In the perinatal period, cortisol serves to modulate the functional adaptations requisite for extrauterine survival. In addition, hormonal imprinting during the fetal-perinatal period conditions the adult functional characteristics of selected endocrine systems.

This chapter reviews the current status of our understanding of the fetal-placental endocrine and growth factor milieu, maturation of the fetal endocrine systems, and adaptations of the fetal endocrine system to extrauterine life.
PLACENTA

The fetal milieu depends on a functioning placenta, which develops in parallel with the fertilized ovum. By 6 to 7 days after conception, the blastocyst consists of an outer layer of trophoblast cells and an inner cell mass destined to become the embryo. The trophoblast cells have implanted in the endometrium and within 10 days have developed two distinct layers, an inner cytotrophoblast layer and an outer layer of continuous cytoplasm, the syncytiotrophoblast, which forms the early fetal-maternal interface. Pockets of cytotrophoblast cells in the mature placenta serve as a reservoir of stem cells for continuing syncytiotrophoblast development.

The predominantly syncytiotrophoblastic placenta grows progressively throughout gestation. As the placenta develops, the chorionic villi containing the fetal capillaries extend into the maternal lakes of blood within the maternal decidua. Within the villi three layers of fetal tissue separate the fetal circulation from the maternal circulation: the cytotrophoblast-syncytiotrophoblast layer, the fetal mesenchyme layer of extraembryonic connective tissue, and the fetal capillary endothelium. The syncytiotrophoblast is the major site of diffusion between the maternal lakes of blood in the placenta and the fetal capillaries.

![Figure 21-1](image)

**Figure 21-1** Diagrammatic representation of a chorionic villus extending into the maternal blood lake and showing fetal capillaries in the fetal mesenchyme. The villus is sheathed by the syncytiotrophoblast. The residual sparse areas of cytotrophoblast provide cells to renew and maintain the syncytiotrophoblast layer. The villus is surrounded by maternal blood in the maternal intervillous space. The placenta serves as an important endocrine organ. Hormones are produced by cytotrophoblast and syncytiotrophoblast cells. Neuropeptides appear to modulate syncytiotrophoblast production of placental protein hormones, and decidual prostaglandins and cytotrophoblast growth factors may participate in regulation of syncytiotrophoblast steroid hormone production. See text for details.

- Neuropeptides and fetal water metabolism
- Parathyroid glands and placental calcium transport
- Catecholamine and vasopressin responses to hypoxia
- Cortisol programming for extrauterine exposure
- Catecholamine and cortisol control of extrauterine adaptation
- Perinatal hormonal imprinting

**Placental Hormone Transfer**

The placenta regulates maternal-fetal molecular exchange, and thin areas of the syncytiotrophoblast adjacent to the fetal capillaries seem to be specialized for this function. However, the fetal endocrine milieu is largely independent of maternal hormones because the placenta is impermeable to most peptide hormones.

There are two major routes for the transfer of molecules across the placenta: an extracellular route through fluid-filled intercellular channels and a transcellular route. The rate of extracellular diffusion is related to the luminal diameter of the intercellular or paracellular channels and to the molecular weight (molecular radius or size) and lipid solubility or hydrophilicity of the transferred molecule. The placenta is more permeable to lipid-soluble molecules, and the permeability for both lipid-soluble and lipid-insoluble molecules decreases with increasing molecular weight. The transfer or diffusion of L-glucose is believed to be accomplished by extracellular diffusion.

The placental transfer of a number of hormones is summarized in Table 21-2. The differences in placental structure among species have a limited influence on
placental hormone transfer, and data derived from some animal and primate species are included. Hormones larger than 0.7 to 1.2 kDa have little or no access to the fetal compartment. The exception is immunoglobulin G, which is actively transported from mother to fetus during the latter half of gestation. 9

Placental cell membranes contain a variety of receptors for polypeptide hormones and growth factors, including insulin, the IGFs, and epidermal growth factor (EGF). These receptors bind and in some instances degrade their respective ligands but do not facilitate placental transfer.

Hormones that traverse the placenta by the transcellular route and are metabolized en route include cortisol, estradiol, thyroid hormones, and catecholamines. The placental cells contain an active 11-hydroxysteroid dehydrogenase (11-HSD) that catalyzes the conversion of most of the cortisol to inactive cortisone. Placental 17-hydroxysteroid dehydrogenase is considered to prevent passage of excessive estrogens to the fetus by catalyzing inactivation of estradiol to estrone. Placental tissue also contains an iodothyronine inner ring monodeiodinase, which deiodinates most of the T4 to inactive reverse triiodothyronine (rT3) and converts active 3,5,3’-triiodothyronine (T3) to inactive diiodothyronine. Catecholamine-degrading enzymes in placental tissue include both monoamine oxidase and catechol-O-methyltransferase, and both metanephrine and dihydroxymandelic acid metabolites of catecholamines are present in placental homogenates.

Placental Hormone Production

The placenta functions as a major endocrine organ, providing a secondary source of hypothalamic, pituitary, adrenal, and gonadal hormones and growth factors (Table 21-3). The syncytiotrophoblast manufactures steroid and protein hormones; after the eighth week of pregnancy, it is the most active fetal or maternal endocrine organ. The steroid hormones are produced from both fetal and maternal substrates. The protein hormones are synthesized in the rough endoplasmic reticulum of the syncytiotrophoblast from amino acids of maternal origin. Secretion is predominantly into the maternal circulation, but significant amounts reach the fetal compartment. The cytotrophoblast produces a variety of neuropeptides and growth factors, and decidua tissue is a major source of prostaglandins and relaxin.

The network of peptides expressed by the placenta provides an autocrine-paracrine system regulating the fetal-maternal unit. Local placental control systems resemble a miniature hypothalamic-pituitary-target organ network. Maternal and fetal hormones in the placental circulation may also regulate placental hormone production. In addition to the local effects, a number of placental hormones are involved in modulation of maternal and fetal homeostasis during pregnancy (see Fig. 21-1).

Placental Estrogen

The human placenta near term secretes large amounts of estrogens, including estrone, estradiol, and estriol. Excretion rates of these steroids during the latter third of pregnancy are approximately 2, 1, and 30 to 40 mg/day, respectively, whereas total estrogen production in nonpregnant women is less than 1 mg/day. This production is due to the combined effects of the fetal adrenal gland and the placenta, first characterized by Diczfalusy as the human fetoplacental unit. Most of the estrogen is secreted into the maternal circulation, but fetal concentrations and levels in amniotic fluid are high.

The major substrates for placental estrogen synthesis are dehydroepiandrosterone (DHEA) and androstenedione. These relatively inactive adrenal steroids are derived from both fetal and maternal adrenal glands. The fetal zone of the adrenal cortex is deficient in an enzyme with 3-hydroxysteroid dehydrogenase (3-HSD) and isomerase activities but has high steroid sulfokinase activity. Thus, the conversion of pregnenolone to progesterone is limited and the major product of fetal adrenal steroidogenesis is DHEA sulfate (DHEAS), which is transported to the liver for 16-hydroxylation. DHEAS and 16-hydroxy-DHEAS are hydrolyzed in the

---

The major substrates for placental estrogen synthesis are dehydroepiandrosterone (DHEA) and androstenedione. These relatively inactive adrenal steroids are derived from both fetal and maternal adrenal glands. The fetal zone of the adrenal cortex is deficient in an enzyme with 3-hydroxysteroid dehydrogenase (3-HSD) and isomerase activities but has high steroid sulfokinase activity. Thus, the conversion of pregnenolone to progesterone is limited and the major product of fetal adrenal steroidogenesis is DHEA sulfate (DHEAS), which is transported to the liver for 16-hydroxylation. DHEAS and 16-hydroxy-DHEAS are hydrolyzed in the
Glucocorticoids, however, have no effect on placental CRH or corticotropin (ACTH) activity. Estrogens also augment maternal glucocorticoid suppression in pregnancy suggest that the placenta may be involved in regulation of the maternal pituitary-adrenal axis during pregnancy.

Compared with corticotropin, -endorphin and -MSH are released from placenta in larger amounts. Thus, control and processing of placental POMC are different than in the anterior pituitary.

The human placenta synthesizes a pro-opiomelanocortin (POMC) and contains the POMC-derived peptides corticotropin (adrenocorticotropic hormone [ACTH] or hGH-like effects mediated by somatomedins during pregnancy.

produce identical hPL molecules. Placental tissue also expresses pituitary PRL and one of the hGH genes. The PRL, hGH, and hPL genes are also closely related. Evolution of pseudogenes.

substrate flow.

progesterone production.

The general control of the synthesis and secretion of these placental hormones is not well understood, and inhibits maternal cell-mediated immune responses to foreign (fetal) antigens. Despite the predominant secretion of progesterone into the maternal circulation, fetal blood progesterone levels are twofold to threefold higher than maternal values because of lower metabolic clearance of progesterone by the fetus. The significance of this progesterone to the fetus is not clear.

The principal substrate for placental progesterone synthesis is circulating maternal LDL and very-low-density lipoprotein (VLDL) cholesterol; de novo placental synthesis of cholesterol from acetate is limited. Placental progesterone production is largely independent of the maternal pituitary or adrenal glands, and fetal death in utero has little acute effect on maternal progesterone levels. Progesterone production is regulated by the number of LDL receptors and thus placental mass.

The major factor in control of placental progesterone production appears to be the expression of steroidogenic enzymes, including CYP11A1 and 3HSD, in cytotrophoblast cells. The type I 3HSD enzyme is expressed in placenta, whereas type II activity is expressed in adrenal and gonadal tissues. Expression of messenger ribonucleic acid (mRNA) for all the placental steroidogenic enzymes is stimulated by cyclic adenosine monophosphate (cAMP), which appears to be produced constitutively in mature cytotrophoblast cells. There is some evidence that endogenous steroids may modulate placental progesterone production.

The production of progesterone is approximately 200 mg/day during the third trimester, a value some 10-fold higher than that during the midluteal phase of the normal menstrual cycle; 90% of this amount is secreted into the maternal circulation. Progesterone acts on the uterine musculature to maintain a state of quiescence and inhibits maternal cell-mediated immune responses to foreign (fetal) antigens. Despite the predominant secretion of progesterone into the maternal circulation, fetal blood progesterone levels are twofold to threefold higher than maternal values because of lower metabolic clearance of progesterone by the fetus. The significance of this progesterone to the fetus is not clear.

Placental Poly peptide Hormone

The placenta produces several pituitary-like hormones. The most abundant are human chorionic gonadotropin (hCG) and human placental lactogen (hPL), also called human chorionic somatomammotropin. HCG is a glycoprotein of 36 to 40 kd with structural, biologic, and immunologic similarities to the pituitary gonadotropins and thyrotropin (also called thyroid-stimulating hormone [TSH]); hCG also has weak thyrotropic hormone-like activity. hPL is a 191-amino-acid protein with 96% homology to human growth hormone (hGH). It has 3% or less of the growth-promoting bioactivity of hGH and equivalent prolactin (PRL)-like effects. hCG is secreted predominantly during the first half of gestation, and hPL is secreted mainly during the second half.

The control of the synthesis and secretion of these placental hormones is not well understood, but hormone secretion is related to placental mass and continues in the absence of the fetus. Luteinizing hormone-releasing hormone (LHRH, also called chorionic gonadotropin-releasing hormone), EGF, activin, and hCG increase hCG synthesis in placental tissue in vitro, whereas inhibin and progesterone suppress synthesis. It is likely that hCG plays a role in the maintenance of the corpus luteum early in pregnancy as well as stimulation of the fetal testes and stimulation of placental progesterone production. hCG has weak thyrotropic-like activity; there is less than 0.5 mU of thyrotropin per unit of hCG, and hCG produces minimal, but sometimes significant, thyroid hyperactivity and hyperthyroidism during normal pregnancy. hPL has weak hGH-like and PRL-like bioactivities and may exert an anti-insulin effect on maternal carbohydrate and lipid metabolism, thereby increasing maternal glucose and amino acid levels and augmenting maternal-to-fetal substrate flow. In addition, hPL appears to be an important stimulus of fetal growth.

The same gene is responsible for the subunit expressed in the placenta for hCG and in the pituitary for production of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyrotropin. There is also a single gene for the subunit of LH, whereas there are seven genes or pseudogenes, or both, for the hCG subunit. The hCG and LH subunits have similar structures, and it appears that the hCG gene arose from the LH gene and that the hCG gene family is early in the process of evolution of pseudogenes.

The PRL, hGH, and hPL genes are also closely related. The PRL gene is presumed to be the ancestral gene; hGH evolved nearly 400 million years ago, whereas hPL evolved within the last 10 million years. The hGH gene cluster includes five similar gene loci, two for hGH and three for hPL; these loci have 93% sequence homology in mRNA and probably evolved by repeated duplication over time. Only two of the hPL sequences are expressed in the placenta, and they produce identical hPL molecules. Placental tissue also expresses pituitary PRL and one of the hGH genes (hGHV), and placental hGH may contribute to the maternal hGH-like effects mediated by somatomedins during pregnancy.

The human placenta synthesizes a pro-opiol melanocortin (POMC) and contains the POMC-derived peptides corticotropin (adrenocorticotropic hormone [ACTH] or adrenocorticotropin), lipotropin and lipotropin, -endorphin, -melanocyte-stimulating hormone (-MSH), and three forms of endorphin. Corticotropin-releasing hormone (CRH) is also produced by the placenta, and CRH stimulates corticotropin production from perfused human placental fragments, suggesting a possible paracrine role for placental CRH in modulating corticotropin production in the placenta. Glucocorticoids, however, have no effect on placental CRH or corticotropin release, and otoxin (OT) stimulates placental POMC release but has no effect on pituitary release of corticotropin.

Compared with corticotropin, -endorphin and -MSH are released from placenta in larger amounts. Thus, control and processing of placental POMC are different than in the anterior pituitary. The increased plasma levels of POMC-derived peptides in pregnant women and the resistance of maternal placenta corticotropin to glucocorticoid suppression in pregnancy suggest that the placenta may be involved in regulation of the maternal pituitary-adrenal axis during pregnancy.

Inhibin and activin are produced by placental tissue. The mRNAs for inhibin subunits (α, β, and γ) are present in the placenta, and inhibit A (α) and activin A (α,α)
Activin A is present in cord serum only at term, whereas activin B is present in fetal blood and amniotic fluid before birth; activin B is largely absent from maternal serum. The role of these hormones during pregnancy is not clear. Inhibin production in placenta is stimulated by hCG, FSH, EGF, and prostaglandins. Inhibin suppresses hCG production, whereas activin can stimulate growth hormone-releasing hormone (GHRH), LHRH, progesterone, and prostaglandin production by placental cells in culture. A paracrine role for these hormones in the placenta is suggested.

Activin A and B, two forms of inhibin, are present in placenta. Activin A is produced by decidual cells, while B is produced by syncytiotrophoblast cells. Activin is thought to play a role in the regulation of placental function, including the regulation of angiogenesis, trophoblast invasion, and maternal-fetal immune tolerance. Activin A may also have a role in the regulation of maternal metabolism, including glucose metabolism.

The significance of activin in the placenta is not yet fully understood. Further research is needed to elucidate the specific roles of activin A and B in placental function and to determine how these factors interact with other signaling molecules to regulate placental development and function.
development is not clear.

EGF and TGF- mRNA and proteins have been demonstrated in pools of placental tissue from early, middle, and late gestation. Placental levels of TGF- protein are relatively high throughout gestation (90 to 180 ng/mg protein), whereas EGF values are low (3 to 9 ng/mg protein). The placenta is richly endowed with receptors that bind both EGF and TGF-. TGF- mRNA is localized in the maternal decidua early in gestation in the mouse and is present in fetal tissues. EGF induces differentiation of human trophoblast to syncytiotrophoblast, and this differentiation is associated with increased production of hCG and hPL. These studies have suggested that TGF- or EGF, or both, may influence placental maturation and function.

Transforming growth factor has been purified from human placenta, and precursor mRNA is present in placental tissue. In addition, placental growth factor, PTHrP, platelet-derived growth factor, vascular endothelial growth factor, endothelin-1, tumor necrosis factor, oncomedullin, erythropoietin, and several colony-stimulating factors and receptors have been demonstrated in placental tissue and conditioned media. These factors are also postulated to have autocrine-paracrine roles in placental growth and function.
ECTOPIC FETAL HORMONE PRODUCTION

Ectopic Fetal Polypeptide Hormone

Kidney, liver, and testes from 16- to 20-week-old human fetuses produce immunoreactive and bioactive hCG in vitro. Kidney tissue produces nearly half as much hCG (per milligram of protein) as placenta; liver activity is lower. Corticotropin-like immunoreactivity is present in relatively high concentrations in neonatal rat pancreas and kidney. This material is presumably derived from a POMC parent molecule.
Extraneural Fetal Neuropeptide

Hypothalamic neuropeptides are present in a variety of adult tissues, particularly in the pancreas and gut. In the fetus, hypothalamic neuropeptides are also present in the gut and tissues derived from it. High concentrations of TRH and somatostatin immunoreactivity have been reported in neonatal rat pancreas and gastrointestinal tract tissues, whereas hypothalamic concentrations of these immunoreactive substances are low. These neuropeptides have immunoreactive and chromatographic properties similar to those of the synthetic hypothalamic peptides. Other peptides cleaved from pre-pro-TRH are present in perinatal rat pancreas. In addition, encephalotomy does not alter the circulating TRH levels in the neonatal rat, whereas significant reductions are produced by pancreatectomy. TRH production by monolayer cultures of fetal rat pancreatic cells is stimulated by serotonin and inhibited by carbachol; catecholamines, -aminobutyric acid, and histamine have no effect. Specific neurotransmitter control has been postulated. In the sheep fetus, thyroid hormones modulate pancreatic and gut TRH levels, which suggests thyroid hormone control of extrahypothalamic TRH gene transcription or translation in the fetus.

TRH and somatostatin are present in the human neonatal pancreas and in blood of the human newborn. It seems likely that both hormones are derived mostly from extrahypothalamic sources. The presence of TRH at high concentrations in fetal ovine blood and the control of fetal pancreatic, placental, and blood TRH levels by thyroid hormones suggest a role for extrahypothalamic TRH in the control of fetal pituitary thyrotropin secretion before the near-term maturation of hypothalamic TRH. Infusion of TRH into the fetal sheep also evoked behavioral arousal, caused increased body and eye movements, and stimulated fetal breathing. The role of extraneural somatostatin in the fetus is undefined.

There is a general tendency toward hypersecretion of fetal pituitary hormones during the last half of gestation, and pituitary hormones found at high levels in cord blood from aborted human fetuses and premature human infants include hGH, thyrotropin, corticotropin, -endorphin, -lipotropin, LH, and FSH. Development of hypothalamic-pituitary control is complex, involving maturational events in the cortex and midbrain, the hypothalamus and hypothalamic-pituitary portal vascular system, peripheral endocrine systems, and the placenta itself, including hormone, growth factor, and neuropeptide production. The fetal pituitary hyperfunction appears to be related more to relatively delayed maturation of the central nervous system and hypothalamic control with unrestrained secretion of stimulating hypothalamic hormones than to the action of placental neuropeptides.
FETAL ENDOCRINE SYSTEMS

Anterior Pituitary and Target Organs

Development

The human fetal forebrain is identifiable by 3 weeks of gestation, the diencephalon and telencephalon by 5 weeks. Rathke’s pouch, the buccal precursor of the anterior pituitary gland, separates from the primitive pharyngeal stomodeum by 5 weeks of gestation. [95] The neural components of the transducer system (the hypothalamus, the pituitary stalk, and the posterior pituitary) are largely developed by 7 weeks of gestation, and the bony floor of the sella turcica is present by this time, separating the adenohypophysis from the primitive gut. Capillaries develop within the proliferating anterior pituitary mesenchymal tissue around Rathke’s pouch and the diencephalon by 6 weeks of gestation, and intact hypothalamic-pituitary portal vessels are present by 12 to 17 weeks. [94] Maturation of the portal portal vascular system continues, and the system becomes functionally intact during the period of histologic differentiation of the hypothalamus and development of the portal vascular extension into hypothalamic tissue; this maturation process extends to 30 to 35 weeks of gestation.

The hypothalamic cell condensations, which represent the hypothalamic nuclei, and the interconnecting fiber tracts are demonstrable histologically by 15 to 18 weeks of gestation. [94] Hypothalamic cells and diencephalic fiber tracts for the hypothalamic neuropeptides somatostatin, CRH, GH, and LHRH are also visible by this time. Concentrations of dopamine, TRH, LHRH, and somatostatin are significant in hypothalamic tissue by 10 to 14 weeks of gestation. Specialized anterior pituitary cell types, including lactotropes, somatotropes, corticotropes, thyrotropes, and gonadotropes, can be recognized in the anterior pituitary between 7 and 16 weeks of gestation. Anterior pituitary hormones (including hGH, PRL, thyrotropin, LH, FSH, and corticotropin) are detectable by radioimmunoassay between 10 and 17 weeks of gestation. Thus, the anatomy and biosynthetic mechanisms that make up the hypothalamic-pituitary neuroendocrine transducer appear to be functional by 12 to 17 weeks of gestation in humans.

This embryonic process is regulated by a series of homeodomain proteins or transcription factors that have been characterized by mutation analysis, gene transfection, and gene knockout studies. [95] Mutations of the homeobox genes sonic hedgehog (SHH) and ZIC2 have been identified in patients with familial and sporadic holoprosencephaly. HESX1 homeobox gene mutations have been shown in siblings with septo-optic dysplasia in association with midline brain defects and pituitary hypoplasia. Other genes involved in hypothalamic development include SF1 and LHX4. Early pituitary homeodomain factors include the Rathke pouch homeobox gene (RPX), LHX3, and LHX4. The later factors PROP1 and PIT1 program development and function of the pituitary cells producing GH, TSH, and PRL. Mutations in PROP1 and PIT1 have been described in patients with familial hypopituitarism and are fully addressed in Chapter 8. [102] [95] [97] [94] (Fig. 21-3).

Human Pituitary Growth Hormone and Prolactin

The human fetal pituitary gland can synthesize and secrete hGH by 8 to 10 weeks of gestation. [95] Pituitary hGH content increases from about 1 nmol (20 ng) at 10 weeks to 45 nmol (1000 ng) at 16 weeks of gestation. Fetal plasma hGH levels in cord blood samples are in the range 1 to 4 nmol/L during the first trimester and increase to a mean peak of approximately 6 nmol/L at midgestation. Plasma hGH levels fall progressively during the second half of gestation to a mean value of 1.5 nmol/L at term. [94] Pituitary hGH mRNA and hGH content generally parallel the increase in plasma hGH concentration between 16 and 24 weeks of gestation. [95] This pattern of ontogenesis of plasma hGH reflects a progressive maturation of hypothalamic-pituitary and forebrain function. The responses of plasma hGH to somatostatin and GHRH and to insulin and arginine are mature at term in human infants. [95] Plasma hGH levels are low in anencephalic infants.

The high plasma hGH concentrations at midgestation after the development of the pituitary portal vascular system may reflect unrestrained secretion. [94] Studies of 9- to 16-week-old human fetal pituitary cells in culture have shown a predominant response to GHRH and a limited effect of somatostatin, which suggests that the inhibitory action of somatostatin develops later in gestation. [97] This interpretation has been substantiated by in vivo studies in the sheep fetus, which have shown a failure of somatostatin to inhibit GHRH-stimulated GH release early in the third trimester and maturation of the inhibitory effect of somatostatin near term. [94] Thus, a predominant GHRH enhancement and limited somatostatin inhibition of hGH secretion at midgestation are presumably associated with a limited capacity for inhibition of hGH release by somatotropin feedback. In addition, there may be unrestrained hGH secretion at the pituitary cell level or immaturity of limbic and forebrain inhibitory circuitry that modulates hypothalamic function, or both. Whatever the mechanisms, control of hGH secretion matures progressively during the last half of gestation and the early weeks of postnatal life so that mature responses to sleep, glucose, and -dopa are present by 3 months of age.

The ontogenesis of fetal plasma PRL differs significantly from that of hGH (Fig. 21-4). Levels are low until 25 to 30 weeks of gestation and increase to a mean peak value of approximately 11 nmol/L at term. [95] Pituitary PRL content increases progressively from 12 to 15 weeks, and in vitro fetal pituitary cells from midgestation fetsuses show limited autonomous PRL secretion, although PRL release increases in response to TRH and decreases in response to dopamine. [95] Brain and hypothalamic control of PRL matures late in gestation and during the first months of extrauterine life. [95] Estrogen stimulates PRL synthesis and release by pituitary cells, and the marked increase in fetal plasma PRL concentration in the last trimester parallels the increase in fetal plasma estrogen levels, although lagging by several weeks. [95] Anencephalic fetuses have plasma PRL concentrations in the normal or low-normal range. [95] These data support a role for estrogen in stimulating fetal PRL release. The fetal sheep exhibits a similar pattern of fetal plasma PRL levels, indicating that maturation and integration of brain and hypothalamic mechanisms modulating PRL release develop late in gestation and in the postnatal period, accounting for the delayed postnatal
fall in plasma PRL level in the neonate of this species. [12]

The somatotropins IGF-I and IGF-II are important factors in fetal growth. The mRNA and protein for both factors are present early in gestation in essentially all fetal tissues. [13] IGF-II transcripts are more abundant than those of IGF-I and are predominant in fibroblasts and mesenchymal tissues. [14] Receptors for the IGFs are also widespread in fetal tissues. Studies of transgenic mice with null mutations of the genes encoding IGF-I, IGF-II, or the IGF-I receptor have defined the role of the somatotropins; the birth weight of the embryos lacking IGF-I or IGF-II was 60% of that of the control mice. [15] When both genes were inactive birth weight was reduced another 30%, and mice lacking IGF-I receptor had birth weights averaging 45% of control values. [16]

Postnatally, GH acts through receptors in liver and other tissues to stimulate production of IGF-I and, to a lesser degree, IGF-II. Prenatally, in contrast, GH receptor mRNA levels and receptor binding are low in fetal liver, although receptor mRNA is present in other fetal tissues. [17] The growth of adenocystic fetuses is nearly normal, however, suggesting that factors other than GH stimulate fetal somatomedin production. Nutritional factors are known to play a role. [18] PRL receptors are present in most fetal tissues during the first trimester of gestation, and it is likely that lactogenic hormones have a significant role in organ and tissue development early in gestation. [19] The coordinate increase in fetal adipose tissue and adipose tissue PRL receptors PRL1 and PRL2 suggests that PRL may play a role in growth and maturation of fetal adipose tissue later in gestation. [20] PRL also plays a role in fetal skeletal maturation. [21] Ovine placental lactogen stimulates glycogen synthesis in fetal ovine liver, and hPL stimulates amino acid transport, DNA synthesis, and IGF-I production in human fetal fibroblasts and muscle cells. GH and PRL have little activity in these tissues.

Fetal Pituitary-Adrenal System

The primordium of the adrenal gland can be recognized just cephalad of the developing mesonephros by 3 to 4 weeks of gestation. [22] [23] The fetal adrenal is composed of three functional zones. The zona glomerulosa begins to develop around 8 weeks of gestation, with the zona fasciculata and zona reticularis developing later. [24] Near term the fetal cortisol production rate in blood, per unit body weight, is similar to that in the adult. [25] Ovine placental lactogen stimulates glycogen synthesis in fetal ovine liver, and hPL stimulates amino acid transport, DNA synthesis, and IGF-I production in human fetal fibroblasts and muscle cells. GH and PRL have little activity in these tissues.

Development of the fetal adrenal cortex is under control of several genes and growth factors. The genes include those coding for the orphan nuclear receptors SF-1 (steroidogenic factor-1) and DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X-chromosome factor). [26] [27] These genes show coordinate expression in adrenal cortex, testis, ovary, hypothalamus, and pituitary tissues. SF-1 gene knockout mice manifest adrenal and gonadal agenesis, gonadotropin deficiency, and absence of the hypothalamic ventromedial nucleus. [28] Inactivating DAX-1 gene mutations are associated with adrenal hypoplasia and gonadotropin deficiency. [29] The steroidogenic acute regulatory protein (STAR) is a rate-limiting factor in adrenal steroidogenesis. STAR knockout mice manifest glucocorticoid and mineralocorticoid deficiency and female genitalia in XY animals. [30] [31] In humans, inactivating STAR mutations cause adrenal hyperplasia and adrenal hormone insufficiency. [32]

Fetal adrenal transitional zone development is ACTH-dependent. [33] Proliferation of both the fetal and definitive zones is stimulated by fibroblast growth factor and EGf, and the fetal adrenal expresses high levels of IGF-II mRNA and protein, which are responsive to ACTH. [34] Moreover, IGF-II augments ACTH-stimulated expression of CYP11A1 (p450sc), CYP17, and 3HSD and stimulates cortisol and DHEA-S production in fetal adrenal cortical cells, suggesting a role in adrenal regulation during fetal and postnatal life. [35] The pattern of enzyme maturation in the fetal adrenal suggests that cortisol production does not occur de novo from cholesterol until 30 weeks of gestation. [36]

The major control of fetal adrenal function is mediated by fetal pituitary ACTH. Maternal levels of CRH are elevated during the last trimester of gestation and reach peak values of 0.5 to 1 mU/mL; at term; normal values in nonpregnant women are less than 0.01 mU/mL. [37] This CRH is bioactive and levels correlate with maternal cortisol concentrations, suggesting that CRH plays a role in stimulating maternal corticotropin release. Fetal plasma CRH levels at term, however, are approximately 0.03 mU/mL, and, relative to the presumably high levels in pituitary portal blood, probably have little role in modulating fetal corticotropin release. Midgestation fetal plasma corticotropin concentrations average about 35 pmol/L (250 pg/mL), levels that maximally stimulate fetal adrenal steroidogenesis, and concentrations are higher throughout gestation than in postnatal life, although they fall near term. [38] [39] [40]

Thus, the fetal adrenal cortex is maximally stimulated by pituitary corticotropin and produces large quantities of DHEA and pregnenolone and their sulfate conjugates. Much of the DHEA is converted to 16-Hydrox-DHEAS by the fetal adrenal and fetal liver. As already discussed, DHEA serves as a substrate for placental estrone and estradiol production; 16-Hydroxy-DHEA undergoes metabolism to estradiol in the placenta. In the anencephalic fetus, placental estrogen production is reduced to about 10% of normal. [41] An important factor in fetal adrenal function appears to be substrate inhibition of 3HSD activity by placental estrogens and intracellular adrenal steroids. [42] Near term the fetal cortisol production rate in blood, per unit body weight, is similar to that in the adult. [43] About two thirds of fetal cortisol is derived from the fetal adrenal glands, and one third is derived from placental transfer. [44] Both fetal adrenal cortisol and placental estradiol regulate hepatic synthesis of cholesterol in the fetus.
The corticotropin feedback control system matures progressively during the second half of gestation and the early neonatal period. Dexamethasone can suppress the human fetal parathyroid-adenal axis at term but not at 18 to 20 weeks of gestation. In the fetal sheep, hypothalamic and pituitary glucocorticoid receptors are present at midgestation and corticotropin suppressibility can be demonstrated by the midpoint of the third trimester of gestation. The number of glucocorticoid receptors in the pituitary gland increases at term at the time of increasing glucocorticoid levels, suggesting that some process in the fetus allows the normal autoregulation of glucocorticoid receptors to be overridden at term.

Adrenal hormone receptors, including glucocorticoid receptors (GRs) and mineralocorticoid receptors (MRs), are members of the nuclear receptor superfamily of steroid hormone, thyroid hormone, vitamin D, and retinoid receptors. GRs are present in most body tissues by the second trimester and play an important role in fetal development. Mice lacking GR receptor function manifest enlarged and disorganized adrenal cortices, adrenal medullary atrophy, lung hypoplasia, and defective gluconeogenesis. They appear normal at birth but do not survive without treatment.

Fetal cortisol is converted to cortisone through an 11βHSD in fetal tissues, and levels of circulating cortisone in the fetus at midgestation are fourfold to fivefold higher than cortisol concentrations. Cortisone is a relatively inactive glucocorticoid, and this metabolism protects the anabolic milieu of the fetus because cortisol can retard both placental and fetal growth. GRs are present at birth and are probably present at midgestation in most tissues, including placenta, lung, brain, liver, and gut. As term approaches, selected fetal tissues including liver and lung express 11β-hydroxysteroid dehydrogenase activity that promotes local conversion of cortisone to cortisol. Cortisol serves as an important stimulus to prepare the fetus for extraterine survival. The increase in fetal cortisol conversion occurs during the last 10 weeks of gestation and is the result of increased cortisol secretion and decreased conversion of cortisol to cortisone. This increase in fetal cortisol production has an important role in the maturation of several fetal systems or functions that are critical to extraterine survival (see "Transition to Extraterine Life").

The human fetal adrenal gland is capable of aldosterone secretion near term, and fetal plasma aldosterone concentrations in infants who are born by cesarean section are threefold to fourfold higher than maternal levels. Vaginal delivery and maternal salt restriction increase levels in both mother and infant. The increased aldosterone levels in the fetus are due to increased fetal adrenal secretion and persist during the first year of extraterine life. However, there is a poor correlation between plasma renin activity (PRA) and aldosterone levels in cord blood. Aldosterone secretion is low in the midgestation human fetal adrenal and is unresponsive to the secretagogues that are known to modulate aldosterone production in the adult. In sheep, fetal aldosterone becomes responsive to PRA and angiotensin II in the neonatal period. In this species, in which late fetal aldosterone levels are also high compared with adult levels, furosemide stimulates PRA but not aldosterone during the third trimester; the aldosterone response to furosemide (and PRA) is delayed until the neonatal period. This situation also appears to be the case in the human fetus and neonate.

MRs are present in fetal tissues from 12 to 16 weeks of gestation. MR immunoreactivity is detectable in fetal kidney, skin, hair follicles, trachea and bronchioles, esophagus, stomach, small intestine, colon, and pancreatic exocrine ducts. The role of MRs in these fetal tissues remains unclear. MR knockout mice appear normal at birth but demonstrate defects in mineralocorticoid and renin-angiotensin system functions in the postnatal period.

Angiotensin II levels in the sheep fetus are similar to maternal values, and blockade of fetal production with angiotensin-converting enzyme inhibitors decreases the fetal glomerular filtration rate. Two subtypes of angiotensin receptors, AT1 and AT2, are detectable in various tissues early in fetal development. AT1 receptor mRNA expression in the fetal sheep kidney is low early in gestation, increases in the latter third of pregnancy, and decreases postnatally; AT2 mRNA levels, in contrast, are high at midgestation and decrease during the third trimester. These changes are believed to reflect growth factor-mediated changes in cells that contain AT2 in various tissues. Hormonal factors modulate fetal renal AT1 gene expression in sheep; angiotensin II suppresses both AT1 and AT2, and cortisol increases AT1 gene expression.

The role of the fetal renin-angiotensin system is not clear; rather than modulating renal sodium excretion through aldosterone, it may maintain renal excretion of salt and water into amniotic fluid to prevent oligohydramnios. This renal effect is presumably mediated by modulation of arterial pressure. The mechanism for the high aldosterone levels in the fetal and neonatal periods remains unclear. Because plasma arial natriuretic factor concentrations are high in the fetus, the increased PRA and aldosterone levels are not due to relative arial natriuretic factor deficiency.

Aldosterone affects renal sodium excretion and in premature infants. Despite the fact that the newborn human kidney is relatively unresponsive to exogenous aldosterone, manifestations of mineralocorticoid deficiency in the newborn term infant can occur as a result of aldosterone deficiency or competition for binding to renal MRs by other steroids such as 17-hydroxyprogesterone. Relatively reduced glomerular filtration in the newborn limits sodium loss initially, but by 1 week of age aldosterone deficiency produces the characteristic manifestations of hyponatremia, hyperkalemia, and volume depletion.

**Fetal Pituitary Thyroid System**

The thyroid gland is a derivative of the primitive buccopharyngeal cavity and develops from contributions of two anlagen; a midline thickening of the pharyngeal floor (median anlage) and paired caudal extensions of the fourth pharygobranchial pouches (lateral anlagen). These structures are discernible by 16 to 17 days of gestation, and by 24 days the median anlage develops a thin, flaslike diverticulum extending from the floor of the buccal cavity to the fourth branchial arch. By 50 days of gestation, the median and lateral anlagen have fused and the buccal stalk has ruptured. During this period the thyroid gland migrates caudally to its definitive location in the anterior neck. By 70 days of gestation, colloid is visible histologically and thyroglobulin synthesis and iodide accumulation can be demonstrated within the gland. During the final follicular phase of development, colloid spaces increase in size and there is progressive cell growth and accumulation of thyroid hormones. At 12 weeks of gestation the fetal thyroid gland weighs about 80 mg, and at term it weighs 1 to 1.5 g.

![Figure 21-7](https://example.com/figure21-7.png) **Figure 21-7** Cartoon showing the homeobox genes programming development of the thyroid and parathyroid glands. HOXB3 may be responsible for activation of thyroid transcription factor 1 (TTF1) during early embryogenesis, with TTF2 and PAX8 involved in a synergetic cascade programming thyroid gland embryogenesis. These factors are also involved in thyroid follicul cell function, promoting thyroglobulin (TG), thyroid peroxidase (TPO), and thyroid-stimulating hormone receptor (TSHR) gene transcription. HOX15 gene knockout in mice causes parathyroid gland aplasia. See text for details.

The parathyroid glands develop between 5 and 12 weeks of gestation from the third and fourth pharyngeal pouches. The third pouches encounter the migrating thyroid anlage, and the parathyroid anlagen are carried caudally with the thyroid gland, finally coming to rest at the lower poles of the thyroid lobes as the inferior parathyroid glands. The fourth pouches encounter the thyroid anlage later and come to rest at the upper poles of the thyroid lobes as the superior parathyroid glands. The individual parathyroid glands increase in diameter from less than 0.1 mm at 14 weeks of gestation to 1 mm at birth. The fifth pouches contribute paired ultimobranchial bodies that are incorporated into the developing thyroid gland as the parafollicular or C cells that secrete calcitonin.

Four or more homeobox genes are involved in thyroid and parathyroid gland embryogenesis. These include the genes for thyroid transcription factors 1 and 2 (TTF1, TTF2) and PAX8. TTF2 gene knockout in mice results in thyroid dysgenesis and cleft palate. TTF1 knockout produces pulmonary hypoplasia and thyroid agenesis. Inactivating PAX8 mutations produce thyroid hypoplasia and renal anomalies. TTF1 knockout also produces parafollicular C-cell aplasia. The HOX genes appear to be important in the expression of TTF1 and PAX8. HOX15 gene disruption in mice results in parathyroid gland aplasia. TTF2 and PAX8 gene mutations have been identified in 2% of patients with familial thyroid dysgenesis and congenital hypothyroidism. However, most cases of congenital...
Hypothyroidism occurs sporadically, and the pathogenesis in these cases remains unclear.

During the first half of gestation, before the onset of significant fetal thyroid hormone production, fetal T₄ is derived from maternal-fetal-placental transfer. T₃ is detectable in human coelomic fluid at levels of 0.5 to 2 nmol/L between 6 and 11 weeks of gestation, before the onset of fetal thyroid function. At term, serum T₃ levels in the athyroid fetus range from 30 to 70 nmol/L (2.3 to 5.4 µg/dL). Isotopic equilibrium studies with pregnant rats at term suggest that 15% to 20% of the T₃ in fetal tissues is of maternal origin.

Pituitary and plasma thyrotropin (TSH) concentrations begin to increase during the second trimester in the human fetus, about the time that pituitary portal vascular continuity develops progressively during the last trimester. Metabolites in the fetus are iodothyronine sulfates. After birth indicates that significant amounts of circulating rT₃ are produced by fetal tissues rather than by the placenta.

The type III enzyme is expressed in most fetal tissues and in the placenta early in gestation and is responsible for production of the high levels of fetal plasma rT₃. Type II monodeiodinase activity is present in the brain, pituitary, and brown adipose tissue is a low-Kₗ enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Type III monodeiodinase in brain, pituitary, and brown adipose tissue is a low-Kₗ enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Type III monodeiodinase in liver, heart, skin, and placenta is responsible for inner-ring deiodination of T₃ to rT₃ and of T₄ to diiodothyronine. The type I monodeiodinase is largely responsible for production of T₂ that escapes from the cells into the circulation, whereas the type II enzyme is responsible for production of local T₃ in brain, pituitary, and brown adipose tissue. rT₃ also diffuses out of most tissues to appear in plasma.

The metabolism of thyroid hormones occurs through a progressive series of monodeiodinations. Several enzymes act on the iodines in the outer (phenolic) ring or the inner (tyrosyl) ring of the diiodothyronine molecule. Most of the circulating, biologically active T₃ in adults is derived by outer-ring monodeiodination of T₄ in liver and other nonthyroidal tissues; biologically inactive rT₃ derives from inner-ring deiodination of T₄ in peripheral tissues. Three iodothyronine monodeiodinase subtypes have been characterized. Type I, an outer-ring monodeiodinase in liver and kidney, is a high-Michaelis-constant (Kₘ) enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. This enzyme also has innerning deiodinating activity and catalyzes the conversion of T₃ to 3,3,5'-triiodothyronine. Type II outer-ring monodeiodinase in brain, pituitary, and brown adipose tissue is a low-Kₗ enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Type III monodeiodinase in liver, heart, skin, and placenta is responsible for inner-ring deiodination of T₄ to rT₃, and of T₃ to diiodothyronine. The type I monodeiodinase is largely responsible for production of T₂ that escapes from the cells into the circulation, whereas the type II enzyme is responsible for production of local T₃ in brain, pituitary, and brown adipose tissue. rT₃ also diffuses out of most tissues to appear in plasma.

The type III enzyme is expressed in most fetal tissues and in the placenta early in gestation and is responsible for production of the high levels of fetal plasma rT₃, which peak at midgestation in the range of 3 to 4 nmol/L (200 to 300 ng/dL). The persistence of elevated plasma levels of rT₃ in the neonate for several weeks after birth indicates that significant amounts of circulating rT₃ are produced by fetal tissues rather than by the placenta.

There is little conversion of T₄ to circulating T₂ in the midgestation human fetus; plasma T₂ levels are low (<0.2 nmol/L, <15 ng/dL) until 30 weeks of gestation, after which the mean value increases to 0.7 nmol/L (50 ng/dL) at term (Fig. 21-9). Sulfation is active in fetal tissues, and the predominant thyroid hormone metabolites in the fetus are iodothyronine sulfates. In the last third of gestation in fetal sheep, the mean plasma production rates for T₄ and metabolites are T₄ = 40, T₄ sulfate (T₄-S) = 10, rT₃ = 5, rT₃-S = 12, T₂ = 2, and T₃-S = 2 µg/kg body weight per day. All are biologically inactive except for T₂, and perhaps T₂-S so that 90% of the T₃ metabolites in the fetus are biologically inactive. The sulfated metabolites accumulate in fetal serum as a result of the low type I monodeiodinase activity in fetal tissues and because the sulfated sulfates are not substrates for type III monodeiodinase.

The production rate of T₂ increases progressively between 30 weeks of gestation and term because of maturation of type I monodeiodinase activity in the liver and other tissues and because of decreasing type III monodeiodinase activity in placenta. In the fetal sheep, hepatic type I monodeiodinase activity increases progressively during the last trimester. Type II monodeiodinase activity is present in the brain at

Figure 21-8 Patterns of change of fetal plasma thyroid-stimulating hormone (TSH), thyroid hormone (T₄), triiodothyronine (T₃), and iodothyronine sulfates (T₄-S, rT₃-S, and T₃-S) during gestation and in the neonatal period. The patterns for T₄-S and rT₃-S are based on limited 35-week data. (Data from Fisher DA, Klein AH. N Engl J Med 1991; 324:72712; Santini P, Chiocchio L, Ghieri P, et al. J Clin Endocrinol Metab 1989; 84:493498; Burrow GN, Fisher DA, Larsen PR. N Engl J Med 1994; 331:10721078.)

Figure 21-9 Patterns of change of plasma levels of human chorionic gonadotropin (HCG), luteinizing hormone (LH), testosterone (T₃), and estradiol (E₂) in a male fetus during gestation and in the neonatal period. (Data from Reyes FI, Boroditsky RS, Winter JS, et al. J Clin Endocrinol Metab 1974; 38:612167; Kaplan SL, Grumbach MM, Aubert ML. Recent Prog Horm Res 1995; 51:181206.)
midgestation and helps guarantee adequate brain T<sub>2</sub> in the sheep, a species in which brain maturation depends on thyroid hormone during the second half of gestation.  

Two genes code for the thyroid hormone receptors TR and TR, members of the steroid, retinoid, vitamin D family of nuclear transcription factors. Alternative splicing of expressed mRNA species leads to production of several TR isoforms. The major isoforms, TR<sub>1</sub>, TR<sub>2</sub>, TR<sub>1</sub>, and TR<sub>2</sub>, are developmentally regulated and are present in characteristic concentration ratios in various adult tissues. In human fetal brain, low levels of receptor binding have been detected at 10 weeks of gestation, with higher levels at 16 to 18 weeks. Liver, heart, and lung receptor binding has also been identified at 16 to 18 weeks.  

Human fetal growth is the net result of a complex interplay of genetic, hormonal, and growth factor effects, which are independent of thyroid hormone. Bone maturation levels of the hypothalamic infant, however, is delayed in 50% to 60% of cases and fontanelle closure is often delayed. Serum TSH concentrations are characterized by high levels of variation. Congenitally hypothyroid infants with marked hypothyroxinemia may manifest prolonged jaundice, lethargy, feeding difficulties, umbilical hernia, or macroGLOSSIA, but the classical signs and symptoms of congenital hypothyroidism, including myxedema, metabolic derangements, growth retardation, and irreversible mental and neurologic dysfunction, accrue progressively during the early months and years of life. The relative lack of signs and symptoms in the athyroid fetus and infant is probably related to the effects of transplacentally acquired maternal T<sub>2</sub>, which at term provides an estimated 20% of fetal thyroid hormone turnover. Developmental regulation of T<sub>2</sub> mediated transcriptional events in various organs and tissues and tissue-specific regulation of deiodinase activity are additional mechanisms.  

However, thyroid hormone is essential for normal central nervous system maturation. It regulates a diverse array of processes, including neurogenesis and neural cell migration, neuronal differentiation, dendritic and axonal growth, synaptogenesis, gliogenesis, myelination, and neurotransmitter enzyme synthesis. The most subtle effect of thyroid hormone on fetal brain development is observed in pregnancies associated with maternal hypothyroxinemia. Even subclinical maternal hypothyroidism has been associated with 5- to 10-point I.Q. deficits in the offspring.  

The molecular mechanisms by which thyroid hormone mediates these central nervous system effects remain unclear. Aside from a hearing impairment, TR knockout mice exhibited neither morphologic or functional abnormalities of brain development nor significant differences in mRNA levels of a number of T<sub>2</sub>-dependent cerebellar genes. No gross defects in behavior or in myelin have been reported to date in TR knockout mice. Thus, the major thyroid hormone effects on brain maturation are probably mediated by pathways common to both TR genes.  

Fetal Pituitary-Gonadal Axis  

The mammalian gonad is derived from two tissue anlagen, the primordial germ cells of the yolk sac wall and somatic, stromal cells that migrate from the primitive mesonephros. By 4 to 5 weeks of gestation, the germ cells have begun their migration from the yolk sac and the gonadal ridge has appeared as a derivative of the mesonephros. The germ cells are incorporated into the developing gonadal ridge during the sixth week, when the primitive gonad is composed of a surface epithelium, primitive gonadal cords continuous with the epithelium, and a dense cellular mass referred to as the gonadal blastema.  

Embryogenesis of the gonads is programmed by genes coding for the male sexual determinant SRY as well as SF-1 and DAX-1. SRY is the single critical regulator of male gonadal differentiation (see Fig. 21-5). SF-1 is also required for testicular and ovarian development and mediates müllerian-inhibiting hormone gene expression and gonadotropin production. SF-1 and DAX-1 are orphan receptors of the steroid-thyroid hormone family of nuclear receptors and appear to interact as heterodimers coordinately involved in the regulation of target genes in the adrenal glands and in hypothalamic gonadotropin cells and the ventromedial hypothalamic nucleus. The hierarchical pathway or pathways for these genes' programming events and the full menu of downstream gene targets remain to be defined. The net result, however, is the highly organized pattern of gonadal development and phenotypic sexual differentiation. Fetal pituitary gonadotropins are not required for gonadal development or sexual differentiation; LH or FSH receptor knockout mice are born phenotypically normal.  

Male gonadal differentiation begins at 7 weeks of gestation with organization of the gonadal blastema into interstitium and germ cell-containing testicular cords. The primitive cords lose their connections with the epithelium, primitive Sertoli cells and spermatogonia become visible within the cords, and the epithelium differentiates to form the tunica albuginea. Leydig cells derived from the undifferentiated interstitium are visible by the end of the eighth week of gestation and are capable of androgen synthesis at this time. By 14 weeks of gestation these cells make up as much as 50% of the cell mass, but as the tubules develop they account for a smaller percentage of the tissue. The fetal testes grow from approximately 20 mg at 14 weeks of gestation to 800 mg at birth; at 5 to 6 months they descend into the inguinal canal in association with the epididymis and the ductus deferens. Targeted disruption of the INS13 gene in mice impairs gubernaculum development and leads to bilateral cryptorchidism.  

In females, differentiation of ovaries begins during the seventh week of gestation. The gonadal blastema differentiates into interstitium and medullary cords containing the primitive germ cells now referred to as oogonia. The cords degenerate and cortical layers of surface epithelium, containing individual small oogonia, appear. By 11 to 12 weeks of gestation clusters of dividing oogonia are surrounded by cord cells within the cortex; the medulla at this time consists largely of connective tissue. At 12 weeks of gestation, primitive granulosa cells begin to replicate and many of the large oogonia in the deepest layers of the cortex enter their first meiotic division; other oogonia degenerate and their cords undergo the first meiotic division to become primary oocytes. Primordial follicles are present by 5 months of gestation, and during the seventh month stroma-derived thecal cells develop around the primordial follicles as they mature to primary follicles. This process continues after birth, again progressing toward the superficial layers. Each fetal ovary weighs about 15 mg at 14 weeks of gestation and 300 to 350 mg at birth.  

In the male, the development of Leydig cells leads to an increase in fetal testosterone production between gestational weeks 10 and 20. In vivo studies in the rat have shown that GC binding to fetal testis cells does not down-regulate LH receptors. If this is true in vivo, continuous exposure of the Leydig cell to HCG would not desensitize the fetal testis and would allow the maintenance of augmented testosterone production during development. Fetal LH may contribute to fetal Leydig cell function, but quantitatively HCG is the predominant gonadotropin. Testosterone itself, acting through the androgen receptor, stimulates differentiation of the primitive mesonephric ducts into bilateral ductus deferens, epididymides, seminal vesicles, and ejaculatory ducts. Dihydrotestosterone stimulates male differentiation of the urogenital sinus and external genitalia, including differentiation of the prostate, growth of the genital tubercle to form a phallus, and fusion of the urogenital folds to form the external genitalia. As opposed to the phallus, the urogenital tubercle is masculinized by the 5-reductase-dependent pathway within the urogenital sinus and urogenital tubercle and acts through the same androgen receptor that mediates the action of testosterone in the Wolffian ducts.  

The fetal testes also produces antimüllerian hormone (AMH), which causes dedifferentiation of the müllerian duct system in the male fetus. AMH is a glycoprotein with a monomer molecular size of approximately 72 kd and multimer sizes ranging from 145 to 235 kd. It is produced by testosterone Sertoli cells and reaches the müllerian ducts largely by diffusion; duct regression in vitro requires a 24- to 36-hour exposure to AMH, which is synthesized early in gestation.
most other tissues. The significance of estrogen receptors in fetal development remains unclear. Knockout of the ER gene in mice did not impair fetal development, but adult females were infertile with hypoplastic uteri and polycystic ovaries and adult males manifested decreased fertility. ER knockout mice also developed normally and female adults were fertile with normal sexual behavior; adult males reproduced normally but had prostate and bladder hyperplasia. It is known that estrogens regulate DHEA production in the baboon and human fetal adrenal. Studies of mice with knockout of both ER and ER functions should further clarify the role of these receptors in fetal development.

Gonadal hormones also control gonadotropin production in the brain that results in cyclic ovarian function and normal function of the testes. Testosterone administration to neonatal female rats produces permanent inhibition of cyclic hypothalamic control through local aromatization to estradiol and estrogen receptor binding. In primates and humans, estrogens seem to be more effective in this regard. However, there is no evidence for permanent programming in the primate, and there appear to be no major tissue biochemical differences between the sexes in utero to account for sexual dimorphic behavioral or gonadotropic programming. Thus, the mechanisms for these effects are not yet clear in the primate and human fetus.
Intermediate Lobe of the Pituitary

The intermediate lobe of the pituitary gland is prominent in both the human and the sheep fetus. Intermediate lobe cells begin to disappear near term and are virtually absent in the adult human pituitary, although the intermediate lobe in the adult of some lower species is anatomically and functionally distinct. The major secretory products of the intermediate lobe are -MSH and -endorphin derived from cleavage of the POMC molecule. Cleavage of POMC in the anterior lobe results predominately in corticotropin and -lipotropin formation.

In rhesus monkeys and humans, the fetal pituitary contains high concentrations of compounds resembling -MSH and corticotropin-like intermediate lobe peptide. -MSH levels in the human fetus decrease with increasing fetal age. The circulating levels of both -endorphin and -lipotropin are high in the fetal lamb, and the ratio of -endorphin to -lipotropin increases during hypoxic stimulation of the anterior pituitary. Because hypoxia provokes corticotropin release and -lipotropin production from the anterior pituitary, these data have been interpreted to suggest that basal -endorphin levels in the fetus originate in the intermediate lobe. -MSH and corticotropin-like intermediate lobe peptide may play a role in fetal adrenal activation, and -MSH may play a role in fetal growth. However, these effects are probably minor; the processing of pituitary POMC in the human fetus by the end of the second trimester is similar to that in the adult, but the role of these intermediate lobe peptides in the fetus remains obscure.
Posterior Pituitary

The fetal neurohypophysis is well developed by 10 to 12 weeks of gestation and contains both arginine vasopressin (AVP, also called antidiuretic hormone) and OT. In addition, arginine vasotocin (AVT), the parent neurohypophyseal hormone in submammalian vertebrates, is present in the fetal pituitary and pineal glands and in adult pineal glands from several mammalian species, including humans. AVT is present in the pituitary during fetal life and disappears in the neonatal period. In adult mammals, instillation of AVT into cerebrospinal fluid inhibits gonadotropin and corticotropin release, stimulates PRL release by the anterior pituitary, and induces sleep; however, its physiologic importance in these regards remains unclear. The role of AVT in the fetal pineal gland is unknown.

In the fetal sheep, the baseline fetal plasma AVP concentrations are similar to maternal levels after midgestation. During the last trimester of gestation, fetal hypothalamic and pituitary responsiveness to both volume and osmolar stimuli for AVP secretion are well developed and AVP exerts antidiuretic effects on the fetal kidney. Baseline plasma levels of AVT in fetal sheep during the last trimester approximate values for AVP and OT. Presumably this AVT is derived from the posterior pituitary, but the stimuli for AVT secretion in the fetus are not defined. The neurohypophysial peptides are synthesized as large precursor molecules (neurophysins) and processed to bioactive amidated peptides. Enzymatic processing involves progressive cleavage of carboxyl terminal extended peptides producing sequentially (for OT) OT-glycine-lysine-arginine (OTGKR), OTGK, OTG, and OT. Similar progressive processing yields AVPG and AVP from the AVP neurophysin. Enzymatic processing of neurophysins matures progressively in the fetus so that early in gestation fetal plasma contains relatively large concentrations of the extended peptides. For OT, the ratio of OT extended peptides to OT in fetal sheep serum is approximately 35:1 early in gestation and 3:1 late in gestation.

In the fetus, AVP appears to function as a stress-responsive hormone. Perhaps the major potential stress for the fetus is hypoxia, and the response of AVP to hypoxia is increased compared with the maternal response and with the fetal AVP responses to osmolar stimuli. Plasma AVP concentrations in human cord blood are elevated in association with intrauterine bradycardia and meconium passage. The vasopressor action of AVP may be important in the maintenance of fetal circulatory homeostasis during hemorrhage and hypoxia. AVP has a limited effect on fetoplacental blood flow. Fetal hypoxia is also a major stimulus for catecholamine release. There is little information on interaction between AVP and catecholamines during fetal hypoxia, but both fetal hypoxia and AVP stimulate anterior pituitary function. A role for AVP as a CRH is established in the adult, and the ovine fetal pituitary responds separately and synergistically to AVP and CRH early in the third trimester. The role of AVP in controlling fetal corticotropin release seems to decrease with gestational age. It is not known whether AVT functions as a fetal CRH.

OT receptors have been demonstrated in human fetal membranes at term, and AVP receptors have been found in renal medullary membranes of newborn sheep. Both AVP and AVT evoke antidiuretic actions in the sheep fetus during the last third of gestation, and both hormones act to conserve water for the fetus by inhibiting fluid loss into amniotic fluid through the lungs and kidneys. Aquaporin-1, aquaporin-2, and aquaporin-3 water channel receptors are present in the human fetal and newborn kidney, and the ability of the newborn infant to regulate free water clearance in response to volume and osmolar stimuli has been demonstrated. Whether AVT exerts its effects through AVP receptors or separate fetal AVT receptors is not clear. Maximal concentrating capacity by the fetal kidney is limited to about 600 mmol/L. This limitation is due not to inadequate AVP stimulation but rather to inherent immaturity of the renal tubules.
Fetal Autonomic Nervous System

The primordia of the sympathetic trunk ganglia are visible in the human fetus by 6 to 7 weeks of gestation. The preaortic sympathetic primordia at this time are composed of primitive sympathetic neurons and chromaffin cells, which condense into chains of cell masses along the abdominal aorta. By 10 to 12 weeks of gestation the paired adrenal masses are well developed. In addition, numerous extramedullary paraganglia (derived from preaortic condensations of sympathetic neurons and chromaffin cells) are scattered throughout the abdominal and pelvic sympathetic plexuses. Each of these extramedullary paraganglia may reach a maximal diameter of 2 to 3 mm by 28 to 30 weeks of gestation. The largest of the paraganglia, the organs of Zuckerkandl near the origin of the inferior mesenteric arteries, enlarge to 10 to 15 mm in length at term. After birth, the paraganglia gradually atrophy and disappear by 2 to 3 years of age. With increasing gestational age there is progressive growth of the adrenal medullae, increasing catecholamine content of the adrenal medullae, and progressive maturation of medullary functional capacity. Histologically, the adrenal medullae are somewhat immature at birth, but by the age of 1 they resemble the adult glands.

Both chromaffin and sympathetic nerve cells are derived from common neuroectodermal stem cells, and both respond to NGF. Sympathetic nervous system development is NGF-dependent, and injections of NGF antiserum into neonatal rats lead to degeneration of immature chromaffin cells, sympathetic cells, and pheochromoblasts. Whether NGF and other growth factors are involved in the transient life span and function of the paraganglia in the human fetus and neonate remains to be clarified. The role of placental NGF in maturation of the fetal autonomic nervous system is also unclear.

Catecholamines are present in the para-aortic chromaffin tissue by 10 to 15 weeks of gestation, and concentrations increase until term. The predominant catecholamine is norepinephrine (NE), presumably because of low activity of phenylethanolamine N-methyltransferase in para-aortic chromaffin tissue. This enzyme, which catalyzes the methylation of NE to epinephrine, appears to be activated by the high levels of cortisol that diffuse into the adrenal medulla from the adrenal cortex; in contrast, cortisol levels in extramedullary chromaffin tissue are low.

In fetal mammals, the chromaffin cells of the adrenal medulla can respond directly to asphyxia, long before splanchnic innervation develops, by secreting NE; the noninnervated para-aortic tissue responds similarly. In the fetal sheep, a similar developmental transition occurs between days 120 and 135 of the 150-day gestation. The central nervous system responds to stimuli that evoke sympathetic nervous system responses before the adrenomedullary splanchnic innervation, but the adrenal medulla is relatively unresponsive to such stimuli. The transition is heralded by an adrenomedullary response to hypoglycemia mediated by the central nervous system. This response is present in developing sheep, monkeys, and human fetuses during the third trimester of gestation. Central and adrenal enkephalins are also involved in fetal autonomic nervous system function, and pretreatment with naloxone potentiates and methadone inhibits the catecholamine response to hypoxia.

Basal plasma epinephrine, NE, and dopamine levels during the last third of gestation decrease as term approaches. The metabolic clearance rate of epinephrine increases with gestational age, whereas the production rate remains unchanged, indicating that the decreasing basal catecholamine levels that occur with fetal age are due to maturation of clearance mechanisms. The fetal sheep responds to maternal exercise or hypoxia with increased catecholamine levels. The human neonate responds to parturition with an increase in plasma epinephrine and NE concentrations, and these responses are augmented by hypoxia and acidosis.

Catecholamines are critical for fetal cardiovascular function and fetal survival. Gene knockout studies in mice targeting either tyrosine hydroxylase or dopamine -hydroxylase produced fetal catecholamine deficiency and midgestation fetal death in 90% of the mutant embryos. In addition, fetal catecholamines are the major stress hormones in the fetus. The fetal adrenal and the para-aortic chromaffin masses discharge large amounts of catecholamines directly into the circulation in response to fetal hypoxia. Moreover, the defense against fetal hypoxia involves catecholamine actions mediated through cardiac -receptors that are unique to immature animals. -Adrenergic receptors predominate in immature cardiac tissue and gradually decline in number as -adrenergic receptors increase with maturation. Chromaffin tissue in the fetus is also innervated by opiate receptors and contains relatively large amounts of opiate peptides that appear to be co-secreted with the catecholamines. The extent to which these peptides or pituitary endorphins are involved in modulating fetal catecholamine secretion remains unclear.
Parathyroid Hormone/Calcitonin System

Parathyroid gland development from the third and fourth pharyngeal pouches proceeds in synchrony with thyroid embryogenesis. Disruption of the HOX15 gene in mice resulted in parathyroid gland aplasia, indicating that this gene functions as part of the gene cascade programming normal thyroid-parathyroid gland development. Both endocrine systems are functional during the second and third trimesters.

Studies in fetal sheep and monkey and measurements in human preterm and term infants indicate that high concentrations of fetal calcium (averaging 2.75 to 3 mmol/L in the last trimester) are maintained by active placental transport from maternal blood. The transport of calcium occurs across the syncytiotrophoblast, which contains a calcium-binding protein that buffers intracellular calcium ions as they are transported across the syncytiotrophoblast. Adenosine triphosphatedependent calcium pump transports the calcium across the cell membrane to the fetal circulation. The placental calcium pump is stimulated by a midmolecule portion of the PTH/PTHrP secreted by the fetal parathyroid gland and by the placenta, where it may exert a paracrine effect. The placenta is impermeable to PTH, PTHrP, and calcitonin, but 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D are transported across the placenta and free vitamin D levels in fetal blood are similar to or higher than maternal values.

Thyroparathyroidectomy in the sheep fetus caused a rapid decrease in fetal plasma calcium concentration and a loss of the placental calcium gradient. In mice, knockout of the gene for PTH/PTHrP abolished the maternal-fetal calcium gradient and placental transport of calcium was reduced. Placental calcium transport in these models was restored by the midmolecule fragment of PTH/PTHrP (amino acids 67 to 86) but not by PTH or PTHrP fragments 1 to 34, which activate the PTH/PTHrP receptor.

Other factors are also involved in maintenance of fetal serum calcium levels because knockout of the mouse gene for PTH-PTHrP also results in hypocalcemia in the presence of normal or increased placental calcium transport. PTH and PTHrP, through the PTH-PTHrP receptor, presumably modulate fetal skeletal calcium flux, calcium excretion through the fetal kidney, and perhaps reabsorption of calcium from amniotic fluid. PTHrP has a major role in fetal bone development and metabolism as well as fetal calcium homeostasis. PTHrP knockout mice displayed increased ossification of the basal portion of the skull, long bones, vertebral bodies, and pelvic bones and mineralization of the normally cartilaginous portions of the ribs and sternum; as a result of the cartilaginous mineralization, the animals died of asphyxiation in the early neonatal period.

Fetal nephrectomy also reduces fetal calcium concentrations, and the hypocalcemia can be prevented by administration of 1,25-dihydroxyvitamin D. Moreover, infusion into the sheep fetus of antibody to 1,25(OH)₂D reduced the placental calcium gradient. Thus, fetal PTHrP and PTH appear to stimulate fetal renal 1,25(OH)₂D production, which acts to enhance maternal-fetal transport of calcium by the placenta. The fetal kidney can synthesize 1,25(OH)₂D via 1-hydroxylation of 25-hydroxycholecalciferol, and the placenta contains both 1,25(OH)₂D receptors and a vitamin D-dependent calcium-binding protein. In the sheep fetus, the endogenous production rate of 1,25(OH)₂D during the last third of gestation was six times greater than that in the mother. The metabolic clearance of 1,25(OH)₂D was also higher in the fetus than in the mother.

The fetal parathyroid-placental axis promotes maternal-fetal transfer of bone mineral and accretion of fetal bone mineral. The high blood levels of calcitonin in the fetus, probably resulting from the chronic stimulation by fetal hypercalcemia, are thought to contribute to the fetal bone mineral accreration. A prominent effect of calcitonin is to inhibit bone resorption, and the high fetal serum calcium concentrations coupled with high circulating calcitonin promote bone mineral anabolism. Calcitonin has been called a vestigial hormone because of its limited role in postnatal calcium regulation, but it may have an important role in the fetus. Placental calcitonin production may contribute to the calcitonin in fetal plasma, but the persistence of high plasma levels in neonatal plasma argues for predominant fetal production. Also, 1,25(OH)₂D or 24,25(OH)₂D may play a role in fetal cartilage growth and bone mineral accreration. These concepts are summarized in Figure 21-10.
Endocrine Pancreas: Insulin and Glucagon

Embryogenesis of the pancreas is mediated by a series of homeobox genes, including IDX1, ISL1, PAX4, and PAX6. IDX1 gene knockout in the mouse results in pancreatic agenesis. ISL1 knockout leads to islet cell agenesis, and PAX4 or PAX6 knockout results in beta cell or alpha cell agenesis or hypogenesis, respectively. The 2neuroD gene knockout in the mouse leads to marked beta cell dysplasia and hypoplasia and early death from diabetes. These factors and perhaps others farther downstream program the orderly maturation of pancreatic development and function (Fig. 21-11). The fetal pancreas is identifiable by 4 weeks of gestation, and alpha and beta cells can be recognized by 8 to 9 weeks. Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks of gestation. Alpha cells are more numerous than beta cells in the early fetal pancreas and reach a peak at midgestation; beta cells increase throughout the second half of gestation so that by term the ratio of alpha cells to beta cells is approximately 1.1. The insulin content of the pancreas increases from less than 3.6 pmol/g (0.5 U/g) at 7 to 10 weeks to 30 pmol/g (4 U/g) at 16 to 25 weeks of gestation and 93 pmol/g (13 U/g) near term; the concentration in the adult pancreas is approximately 14 pmol/g (2 U/g). Although the fetal beta cell is functional by 14 to 24 weeks of gestation, secretion of insulin by the fetal pancreas is low. Insulin release from the fetal rat pancreas in vitro in response to glucose or pyruvate is minimal but can be stimulated by leucine, arginine, tolbutamide, or potassium chloride, indicating that parts of the secretory mechanism are functional in the fetus. Insulin secretion in adult islets is mediated by two or more mechanisms, including stimulation of the adenylate cyclase system with production of cAMP and inhibition of potassium efflux, which leads to depolarization of the cell membrane and opening of voltage-dependent calcium channels. The former mechanism, although suppressed in the fetal islets, can be augmented by theophylline, but calcium channel activation does not occur in fetal islets in response to inhibitors of insulin release that cause depolarization of adult islet cells. The infusion of glucose or arginine in pregnant women before hysterotomy fails to provoke fetal insulin secretion at midgestation or near term, and plasma insulin levels in the late human fetus are relatively unresponsive to high glucose concentrations before the onset of labor. Similar observations have been made in the monkey. In this species, neither glucose nor arginine stimulated fetal insulin release near term but glucagon evoked prompt insulin secretion. Late in gestation in the ovine fetus, epinephrine inhibited insulin release through a receptor pathway. In the anencephalic human fetus, the endocrine pancreas develops normally if maternal carbohydrate metabolism is not impaired, but beta cell hypertrophy and hyperplasia do not occur in the anencephalic fetus or in decapitated fetal rabbits exposed to chronic hyperglycemia. This lack of beta cell response to hyperglycemia may be the result of GH deficiency because GH stimulates insulin gene expression and may play a permissive role in beta cell hyperplasia and hypertyrophy. Pancreatic glucagon concentrations are relatively high in fetal plasma and increase progressively with fetal age. The fetal pancreatic glucagon content at midgestation is approximately 6 µg/g, compared with an adult level of 2 µg/g. As is true for insulin, the capacity for glucagon secretion is blunted in the fetus. Hypoglycemia does not suppress fetal plasma glucagon levels in rats, monkeys, or sheep, and acute hypoglycemia does not evoke glucagon secretion in the rat fetus. Amino acids, which are important secretagogues for insulin and glucagon in the adult, probably have little role in modulating insulin and glucagon secretion in the preterm fetus. However, infusion of alanine into women before hysterotomy fails to provoke fetal insulin secretion at midgestation or near term, and plasma insulin levels in the late human fetus are relatively unresponsive to high glucose concentrations before the onset of labor. Thus, the fetal pancreatic islet cells, although histologically mature and capable of hormone synthesis and hyperplasia, are relatively immature functionally at birth with regard to the capacity to secrete both insulin and glucagon. The rapid maturation of responsiveness to glucose in the neonatal period in both premature and mature infants suggests that this blunted state may be a secondary result of the relatively stable fetal serum glucose levels maintained by placental transfer of maternal glucose rather than a primary, temporally fixed maturation process. The blunted capacity for insulin and glucagon secretion has been related to a deficient capacity of the fetal pancreatic islet cells to generate cAMP or a rapid destruction of cAMP by phosphodiesterase, or both. Insulin and glucagon are normally not necessary for substrate metabolism in the fetus. Glucose is obtained by placental transfer through facilitated diffusion. The fetal respiratory quotient is approximately 1, which suggests that glucose is the primary energy substrate for the fetus. Other substrates such as amino acids and lactate may also be utilized in the human as in the sheep fetus. However, at least early in gestation, hepatic metabolism and substrate utilization appear to be independent of insulin and to be modulated in an autoregulatory fashion by glucose. In addition, the constant supply of glucose normally precludes the necessity for endogenous gluconeogenesis, and gluconeogenic enzyme activities are low in the fetal liver. Glycogen storage in the fetus is modulated by fetal glucocorticoids and probably by placental hPL. Fetal insulin plays a role near term, when insulin also has the capacity to increase fetal glucose uptake and lipogenesis. Insulin receptors are present on most fetal cells in higher numbers than on adult cells; moreover, hyperinsulinemia fails to down-regulate fetal insulin receptors. Fetal hepatic glucagon receptors, in contrast, are reduced in number, and fetal liver is relatively resistant to the glycemic effect of glucagon. These conditions tend to potentiate the fetal anabolic milieu during the period of rapid growth in the last trimester of gestation.
NEUTRALIZATION OF HORMONE ACTIONS IN THE FETUS

After the period of embryogenesis, the fetal milieu is programmed to optimize body growth and organ development through an array of generalized and specialized growth factors (see "Fetal Growth"). These function in a stable metabolic environment with substrate supply maintained by the placenta. The endocrine-metabolic systems characterizing the extraterine environment are programmed to maintain metabolic stability in a changing external environment with intermittent substrate provision. Hormonal systems in the fetus are programmed to maintain anabolism with minimal hormonal perturbation. Thus, production of catabolic and thermogenic hormones is limited and the effects of the hormones altering metabolic substrate supply and distribution pathways are muted.

Limitation of Hormone Secretion

The human fetal pancreas is functional during the second trimester, but secretion of insulin in response to glucose or pyruvate is minimal until the neonatal period. Glucagon secretion is also blunted, although fetal blood glucagon levels are relatively high. Fetal islet hyperplasia and increased insulin secretion occur in response to chronic hyperglycemia as in the infant of the diabetic mother, and insulin release can be stimulated by acute fetal infusions of leucine, arginine, or tolbutamide. Moreover, responsiveness of both insulin and glucagon secretion to glucose develops rapidly in the neonatal period. It is not clear whether the limited fetal islet cell responsiveness is due to the relatively stable fetal serum glucose levels or a temporally fixed maturation process (for details, see "Endocrine Pancreas: Insulin and Glucagon").
Production of Inactive Metabolites

Throughout the latter part of gestation, cortisol is metabolized in fetal tissues to inactive cortisone through an 11HSD. The placenta is permeable to steroid hormones including cortisol. During midgestation, placental 11HSD activity is low and cortisol is transferred to the fetus. Placental 11HSD activity increases during the second half of pregnancy under the control of placental estrogens, and enzyme activity near term is high. Thus, maternal-fetal cortisol transfer decreases progressively. In addition, although many adult tissues can convert cortisone to cortisol, conversion is limited during most of fetal life. Consequently, most of the cortisol that crosses the placenta or is produced by the fetus is inactivated to cortisone by the placenta or by fetal tissues.

*See text for details.

Levels of cortisone in fetal plasma exceed those of cortisol by threefold to fourfold until after 30 weeks of gestation (see Fig. 21-5). Teleologically, this would help preserve the anabolic and growth-promoting milieu of the fetus and minimize premature maturational and parturitional effects of cortisol. After 30 weeks, the ratio of cortisol to cortisone in fetal tissues and plasma increases as a result of increased fetal secretion and decreased conversion of cortisol to cortisone within the placenta and fetal tissues. Cortisol has important maturational action on several fetal tissues near term (see later under "Transition to Extrauterine Life").

Fetal thyroid hormone metabolism is characterized by conversion of active thyroid hormones to inactive rT₃ and inactive sulfated iodothyronines and by limited receptor and postreceptor responsiveness to thyroid hormone in selected tissues. The placenta contains an iodothyronine inner-ring monodeiodinase that catalyzes conversion of maternal T₄ to rT₃. In addition, the fetal sheep liver and kidney, in contrast to the adult liver and kidney, manifest low levels of iodothyronine type I outer-ring monodeiodinase activity so that conversion of T₃ to active T₁ is limited and large amounts of inactive iodothyronine sulfon conjugates accumulate. As a consequence, plasma T₃ levels in the fetus remain low until the last few weeks of gestation (see Fig. 21-9). Selected fetal tissues (brain, brown adipose tissue) have active iodothyronine, type II, outer-ring monodeiodinase activities that contribute to local tissue T₃ concentrations; local T₃ is important in development, particularly in the hypothyroid fetus. Near term and in the neonatal period in the human fetus, the dramatic increase in plasma T₃ levels, and presumably T₃ production, heralds the onset of thyroid hormone actions on growth and development and on metabolism (Table 21-4).
Neutralization of Receptor Response

Selected ovine fetal tissues seem relatively unresponsive to thyroid hormones. Fetal ovine liver and kidney thermogenesis (as evidenced by oxygen consumption, Na⁺,K⁺-adenosine triphosphatase activity, and mitochondrial-glycerophosphate activity) is unresponsive to exogenous T₃ during the third trimester, and thyroid hormone responsiveness in a number of tissues (cardiac, hepatic, renal, and skin) develops only during the perinatal period. In Adrenergic receptor binding in heart

and lung of the ovine fetus is unresponsive to T₃ late in the third trimester but increases in response to T₃ in the neonatal period. In rodent species, in which development at birth is comparable to human fetal development at midgestation, pituitary GH concentrations become responsive to thyroid hormone only during the first weeks of extrauterine life. Mouse submandibular gland EGF and NGF levels become responsive to thyroid hormone during the second week of life, as do urine and kidney EGF concentrations and hepatic EGF receptor levels. Mouse skin EGF levels and EGF receptors are responsive during the first neonatal week.

Thus, despite the presence of nuclear T₃ receptors in significant concentrations in developing rat and sheep, many thyroid hormone actions in these species are delayed. The mechanism of this delayed thyroid hormone responsiveness is not clear; suppressor nuclear proteins may block gene expression in response to thyroid hormones during fetal development, and the levels of these suppressor proteins may determine the onset and degree of action of thyroid hormones during development.

The effect of the high circulating concentrations of GH in the fetus is also limited. Fetal somatic growth is only partially GH-dependent; indeed, the GH-deficient fetus has little or no growth retardation. The paucity of fetal GH effects is probably due to delayed maturation of GH receptors or postreceptor mechanisms. In animals such as sheep, hepatic GH receptor binding appears only during the neonatal period. Receptor deficiency may also be a factor in the limited PRL bioactivity in the fetus near term.

There is less information on fetal hormone responsiveness in other systems. Adrenergic receptor binding in heart and lung of the sheep fetus is relatively low near term and increases in the neonatal period in response to thyroid hormones. Moreover, premature lambs have an augmented plasma catecholamine surge at birth but have a relatively mild increase in plasma free fatty acid levels, which suggests reduced catecholamine responsiveness. The high levels of progesterone and estrogens in fetal blood also seem to have limited effects in the fetus. Progesterone receptors are present in low concentration in fetal guinea pig kidney, lung, and uterus at midgestation and increase progressively until term. Estrogen receptors appear in neonatal rat uterus, oviduct, cervix, and vagina during the first 10 days of extrauterine life, and both ER and ER mRNAs are present in human fetal tissues during the second trimester. The human neonate often manifests mild breast enlargement at birth, and vaginal estrogenation may be evident in female infants at birth. Estrogen effects otherwise appear limited (see Table 21-4).
FETAL GROWTH

Insulin-like Growth Factors

The somatomedins are involved in regulation of uterine and placental growth during pregnancy and in early embryonic and fetal development. IGF-I, EGF, and estrogens are mitogens for endometrial stromal cells, and the endometrial contents of IGF-I and IGF-I mRNA are high at implantation and during early embryogenesis in the sow. Uterine IGF-I and IGF-I mRNA levels decrease progressively with advancing gestation. Placental tissue also contains IGF-I and IGF-II mRNAs, significant concentrations of the respective proteins, and IGF-I receptors. Autocrine and paracrine roles for the IGFs in uterine and placental tissues are postulated. IGF-I and insulin are produced by embryonic tissues during the prepancreatic stage of mouse development, and both factors stimulate growth of embryonic mouse cells.

Immunoreactive IGF-I is present in most fetal tissues including brain, and fetal growth is regulated by the somatomedins. Transgenic mice with inactivating mutations of IGF-I, IGF-II, or IGF-I receptor have reduced birth weights, organ hypoplasia, and delayed bone development. Animals deficient in IGF-I receptor and some mice deficient in IGF-I die at birth; mice deficient in IGF-II survive and have near-normal postnatal growth, whereas surviving IGF-II-deficient animals have deficient postnatal growth. IGF-I and IGF-II mRNAs are localized in mesenchymal and fibroblast-like cells in interstitial and perivascular connective tissues and surrounding capsular tissues. In addition, immunoreactive IGF-I is produced by in vitro explant cultures of fetal mouse tissues, and fibroblasts cultured from fetal rat lung and skin synthesize both IGFs. These findings are consistent with a predominantly paracrine mode of action for these growth factors in the fetus.

Somatomedin-binding proteins are present as early as 5 weeks of gestation, and prenatally, as postnatally, somatomedins circulate associated with binding proteins. Thus, during fetal and postnatal life, plasma concentrations of somatomedins are relatively high compared with tissue concentrations. In the fetus, IGF-II levels are higher than those of IGF-I, in contrast to these levels in children and adults. Fetal levels of both peptides at term are 30% to 50% of adult levels. In most studies, cord blood IGF-I concentrations correlate with birth size. In spite of the fetal growth-enhancing effects of IGF-II, IGF-II levels are only weakly related to size at birth, largely because of the inhibiting effect of soluble IGF-II receptor (IGF2R). Soluble IGF2R is derived through proteolytic cleavage of the transmembrane region of the receptor in many tissues. Somatomedin receptors have been identified as early as 5 weeks of gestation and are widespread in fetal tissues. IGF-I stimulates glycogenesis in cultured fetal rat hepatocytes and induces formation of myotubes in cultured myoblasts. IGF-II is active in cultured muscle and neonatal rat astroglial cells. Insulin receptors are increased in fetal cells and are resistant to down-regulation; no similar data are available for the IGF-I receptor.

As discussed earlier, GH receptors are relatively deficient and receptors for hPL predominate in fetal tissues. Moreover, hPL stimulates IGF-I production and augments amino acid transport and DNA synthesis in human fetal fibroblasts and muscle cells. In addition, nutrition influences somatomedins in developing mammals. IGF-I levels fell in suckling rats deprived of milk, and IGF-I and IGF-II levels were reduced in fetuses of protein-starved pregnant rats and placently restricted sheep. The low IGF-II levels in the protein-starved rats were reversed by hPL. There is no evidence that thyroid hormones modulate GH or somatomedin levels in the mammalian fetus but, as mentioned earlier, glucocorticoids can inhibit fetal growth, presumably by inhibiting somatomedin action.

These data support the view that the somatomedins are important in embryonic and fetal growth and that in the fetus they are regulated, at least in part, by hPL and by nutritional substrate derived transplacentally. The high levels of IGF-II in fetal rat serum, the high levels of IGF-II mRNA in fetal tissues, and the presence of a truncated form of IGF-I in human fetal brain tissue suggest unique developmental actions of these peptides (Table 21-5).
Insulin

Insulin has been proposed to act as a fetal growth factor. Infants born to women with diabetes mellitus may have hyperinsulinemia associated with increased birth weight. Most of this increased weight is accounted for by body fat; there is little increase in body length, but some organomegaly may occur. Infants with hyperinsulinemia caused by nesidioblastosis or the Beckwith-Wiedemann syndrome may also have increased somatic growth in utero. Conversely, the human fetus with pancreatic agenesis is small and has decreased muscle bulk and little or no adipose tissue. Homozygosity for a null mutation of the insulin receptor gene in fetal mice led to early neonatal death with hyperglycemia and ketonemia; the pups, however, had a normal birth weight. These and other studies suggest that insulin may act as a fetal growth factor by promoting growth or hypertrophy of selected tissues. In clinical conditions associated with fetal hyperinsulinemia, insulin may act through insulin receptors (in adipose and liver tissues) or through type I IGF-I receptors. Insulin may also have a role in regulating IGF-I release.

*This listing will be expanded and more detailed as knockout and other information develops.*
Epidermal Growth Factor-Transforming Growth Factor System

The EGF/TGF- system has been characterized in considerable detail. EGF is a 6-kd peptide product of a large 1207-amino-acid precursor molecule and acts through a 170-kd membrane receptor glycoprotein. This receptor, like the somatodemin receptor, has intrinsic tyrosine kinase activity, and tyrosine kinasesmediated autophosphorylation is a critical event in EGF signal transduction. TGF-, which has 35% amino acid homology with murine EGF and 44% homology with human EGF, also acts through the EGF receptor system. Several additional family members have been characterized, including amphiregulin, heparin-binding EGF, betacellulin, and neuregulins. Three additional receptors are referred to as ErbB2, ErbB3, and ErbB4 in animals; the human receptors are referred to as human EGF receptor (HER) 2, 3, and 4. All were characterized in malignant tissues, where they function as oncogenes, and all are widely distributed in normal mammalian tissues.

EGF is a potent mitogen for ectodermal and mesodermal cells in tissue and organ culture. These cells include keratinocytes derived from skin and conjunctival and pharyngeal tissues, corneal endothelial cells, vascular smooth muscle cells, chondrocytes, fibroblasts, liver cells, thyroid follicular cells, granulosa cells, and mammalian gland cells. In adult humans, EGF is present in highest concentrations in sweat glands, salivary glands, Brunner's (duodenal) glands, stomach, pancreas, bone marrow, prostate, kidney, and endocrine glands (pituitary, adrenal, and thyroid). High concentrations of EGF are also present in urine.

The roles of EGF and TGF- in humans are incompletely understood. In rodents and sheep, EGF provokes precocious eyelid opening and tooth eruption in neonatal animals; stimulates lung maturation; promotes palatal development in organ culture; stimulates gastrointestinal maturation; evokes secretion of pituitary hormones including GH, PRL, and corticotropin; and stimulates secretion of chorionic gonadotropin and placental lactogen by the placenta. Both EGF and TGF- compete for binding to the EGF receptor, and both factors accelerate eye opening and tooth eruption in the neonatal rodent, presumably through interaction with the same "EGF" receptor.

EGF and pre-pro-EGF mRNA are present in most tissues in the postnatal rodent and most adult mouse tissues, but mRNA levels are highest in salivary glands and kidneys. EGF and pre-pro-EGF mRNA levels are absent or low in the fetal rodent, and levels remain low in mouse tissues during the early neonatal period. Nonetheless, the EGF receptor knockout mouse exhibits epithelial immaturity and multilogn failure with early death. Tissue concentrations of both EGF and EGF mRNA increase in the mouse during the first 2 months of postnatal life; indeed, levels of EGF in the salivary glands increase several thousandfold between 3 weeks and 3 months of age. Mouse urinary levels increase 200-fold, and kidney concentrations increase 10-fold between 1 week and 2 months of age. EGF concentrations in mouse ocular tissues increase 100-fold during the first week of life. Liver EGF concentrations increase more slowly, as do serum levels, and there is a high degree of correlation between serum and liver EGF levels in the developing mouse. Thus, the production of EGF in the rodent is accelerated during the early neonatal period, and it is during this time that most hormone-stimulated growth and development occur.

There are few data on tissue TGF- concentrations in developing mammals. Immunoactive TGF- concentrations are measurable at relatively high levels in lung and brain tissues at 20 days of gestation in the rat and show minimal changes through day 50 postnatally. Liver, which also has high TGF- levels at 20 days of gestation, shows a progressive reduction in concentrations postnatally to nadir values in the young adult. Kidney tissue has low concentrations of TGF- in late gestation, and levels increase progressively during the first 2 months of postnatal life. Thus, the ontogenic pattern of TGF- is tissue specific; most late fetal tissues studied contain TGF-, and levels persist or increase in most tissues through the period of growth and development.

EGF plays an important role in pregnancy and fetal development. Maternal salivary gland and plasma EGF concentrations in the mouse increase fourfold to fivefold during pregnancy. Removal of the salivary glands prevents the increase in plasma EGF; moreover, salivary gland removal reduces the number of mice completing term pregnancy (by 50%), decreases the percentage of live pups, and decreases the crownrump length of fetuses delivered. Administration of EGF antiserum to pregnant mice without salivary glands further increases the abortion rate, whereas administration of EGF improves pregnancy outcome. These observations suggest an important role of EGF in pregnancy in the mouse. Because maternal EGF is too large a molecule to traverse the placental barrier, an effect on maternal metabolism and an effect on the placenta are likely. The placenta is richly endowed with EGF receptors, and placental tissue binds and degrades EGF to constituent amino acids.

EGF receptors are present in embryonal and fetal tissues, and EGF stimulates protein synthesis during the morula-blastocyst transition and in postimplantation mouse embryo tissue. In vitro, EGF stimulates differentiation of the inner cell mass during early embryonic development. However, EGF and EGF precursor mRNA levels are absent or present at low levels in selected fetal mouse tissues. Low levels are also present in submandibular gland and kidney during the early neonatal period. Fetal mouse and human tissues have high levels of TGF-, suggesting that this factor may be the ligand for the fetal EGF receptor. TGF- is produced by the maternal decidua during the first half of gestation in rodents, and proTGF- mRNA is present in decidua. Decidual proTGF- mRNA levels peak at 8 days of gestation (term = 21 days) and decline through day 15, when the decidua is being absorbed. EGF receptors are present in decidua, and TGF- may stimulate proliferation of decidual tissue and enhance decidual PRL production.

Inactivation of the gene encoding the EGF receptor in mice led to fetal or neonatal death of homozygous fetuses. The receptor-deficient animals manifested impaired epithelial development in several organs, including skin, lungs, and gastrointestinal tract. Further evidence for a role of EGF in early mammalian development has come from studies of the effect of the administration of EGF antiserum to neonatal mice. EGF antiserum delayed eye and ear opening, delayed tooth eruption, accelerated hair growth, and reduced weight gain during the first 30 days of life.

The factors that control EGF and TGF- production are incompletely understood. The increases in EGF concentration in tissues, blood, and urine of the neonatal rodent correlate with and may be conditioned by the increases in thyroidal and gonadal hormone levels. EGF concentrations in the mouse submandibular gland are increased by thyroid hormones and testosterone. Thyroid hormones increase EGF concentrations in skin, ocular tissue, kidney, and urine in the developing mouse and up-regulate EGF gene expression and the production of pro-EGF in rat kidney; thyroid hormones also increase EGF receptor levels in developing mouse skin and liver. Urinary EGF excretion is highly correlated with serum thyroid hormone concentrations in premature and term human infants. GH increases urinary EGF concentrations in the neonatal mouse, and estrogens increase EGF and EGF mRNA levels in mouse uterus. Testosterone stimulates EGF and EGF mRNA levels in submandibular gland and increases EGF receptor levels in prostatic tissue. Thus, EGF may mediate growth and developmental actions of a variety of hormones in selected tissues (see Table 21-5). There is little information about the regulation of TGF- production postnatally or prenatally. Amphiregulin binds to and stimulates EGF receptor and HER2 in human epithelial cells and has been localized to breast and colonic epithelium.

Considerable evidence suggests a role for the EGF family of growth factors in mammalian central nervous system development. EGF, TGF-, neuregulins, and the EGF receptors are widely distributed in the nervous system. EGF promotes proliferation of astroglial cells, acts as an astroglial differentiation factor, and enhances survival and outgrowth of selected neuronal cells. Transgenic mice with a deficiency of neuregulin, ErbB2, ErbB3, or ErbB4 die in utero with cardiac anomalies and developmental anomalies of the hindbrain, midbrain, and ventral forebrain (see Table 21-5).
Nerve Growth Factor

NGF is a 13-kd protein that is present at high concentrations in mouse salivary gland and at low concentrations in many adult tissues. It is also produced by human placental tissue. It is the original member of an expanding family of neurotropic growth factors that now include brain-derived neurotropic factor, neurotropin 3, and two less well characterized factors and involving two receptors, NGF and NGF2 (or Trk). NGF binds to high-affinity plasma membrane receptors and is internalized and transported to subcellular organelles, including the nucleus, in neurons of the peripheral nervous system. It promotes neurite outgrowth and enhances tyrosine hydroxylase and dopamine-hydroxylase activities in developing sympathetic neurons. NGF acts on undifferentiated sympathetic cell precursors to elicit both hyperplastic and hypertrophic effects and plays a permissive role in stimulating the development of immature autonomic neurons along either a sympathetic or a cholinergic pathway.

The injection of NGF in neonatal mice causes a marked increase in the volume of the superior cervical ganglia and increases in RNA polymerase, ornithine decarboxylase, and tyrosine hydroxylase activities. This growth factor also increases the nerve supply of body organs. Likewise, injection of NGF antiserum during early neonatal life results in a decrease in the size of the superior cervical ganglia, reduction in tyrosine hydroxylase activity, and permanent sympatheticotomy. Maternal NGF autoantibodies in rats and rabbits impair autonomic nervous system development in utero. This impairment affects sympathetic and dorsal root ganglia and autonomic innervation of peripheral organs. NGF is produced by neonatal mouse astroglial cells in tissue culture, is present in developing mouse brain tissue, and, with brain-derived neurotropic factor and neurotropin 3, plays an important role in brain development.

Thyroid hormones and testosterone modulate postnatal NGF levels in the submandibular gland of the mouse. Thyroid hormones increase NGF, neurotropin 3, and brain-derived neurotropic factor mRNA levels in adult rat brain.
Other Factors

Additional growth factors are involved in fetal growth and development, including hematopoietic growth factors, platelet-derived growth factors, fibroblast growth factors, vascular endothelial growth factor, and members of the TGF- family. Hematopoietic growth factors are also active in the fetus during development; erythropoietin in the fetal sheep is produced by the liver rather than the kidney and erythropoietin gene expression in fetal sheep is regulated by glucocorticoids. A switch to kidney production occurs after parturition. Postnatally, thyroid hormones, testosterone, and hypoxia modulate erythropoietin production.

Platelet-derived growth factor (PDGF) represents a family of homodimers and heterodimers of PDGF-A and PDGF-B chains derived from two gene loci. Two PDGF receptors have been characterized, PDGF and PDGF. The genes for PDGF and its receptors are expressed in many tissues. PDGF-A gene inactivation in mice led to defects in lung, skin, intestine, testes, and brain resulting in early postnatal death. PDGF-B gene inactivation led to microvessel disruption and leakage with hemorrhage and edema and intrauterine death.

The fibroblast growth factor (FGF) family of heparin-binding growth factors now includes 17 members with diverse effects on development, angiogenesis, wound healing, and other biologic systems. These effects are mediated by ligand-activated tyrosine protein kinase receptors (FGFRs) transcribed from four related genes. Several receptor isoforms are products of alternative RNA splicing.

Targeted disruptions of FGF and FGFR genes in mice have defined critical roles in development. FGF3-deficient mice show tail and inner ear defects. Knockout of the FGF4 gene is lethal, leading to early death. Knockout of the FGFR1 gene also leads to early fetal death. FGF10 knockout mice die at birth because of pulmonary agenesis. FGF4, FGF8, FGF9, FGF10, or FGF17 deficiency is associated with limb deformities. FGF8 deficiency leads to abnormal left-right axis patterning. In mice, FGFR3 knockout results in chondrocyte hypertrophy and increased bone length.

In humans, a variety of gain-of-function FGFR mutations are associated with chondrodysplasias and craniosynostosis syndromes. FGF, like EGF, stimulates the production of hCG from a choriocarcinoma cell line. These observations and the fact that the placenta contains FGF, NGF, TGF-, TGF-, IGF-I, and IGF-II suggest that the placenta may play an important role in modulating fetal growth.
TRANSITION TO EXTRAUTERINE LIFE

The transition to extrauterine life involves abrupt delivery from the protected intrauterine environment and succor by the placenta to the relatively hostile extrauterine environment. The neonate must initiate air breathing and defend against hypothermia, hypoglycemia, and hypocalcemia as the placental supply of energy and nutritional substrate is removed. Both the adrenal cortex and the autonomic nervous system, including the para-aortic chromaffin system, are essential for extrauterine adaptation. Longer term transition requires adaptation to an environment of intermittent nutrient supply and transient substrate deficiency and requires maturation of the secretory control mechanisms for the PTH-calcitonin system and the endocrine pancreas.

Cortisol Surge

In most mammals, a cortisol surge occurs near term and is mediated by increased cortisol production by the fetal adrenal and a decreased rate of conversion of cortisol to cortisone. Pepe and Albrecht have proposed that the preterm fetal cortisol surge is due to the progressive stimulation by estrogens of placental 11HSD activity and the subsequent increase in placental conversion of cortisol to cortisone. The resulting decrease in maternal-to-fetal cortisol transfer results in stimulation of fetal CRH and corticotropin secretion through the negative-feedback control loop. The concomitant estrogen-stimulated increase in 11HSD activity in fetal tissues potentiates the relative fetal cortisol deficiency and the CRH-corticotropin response. Placental CRH may also potentiate the fetal adrenal activation.

The cortisol surge augments surfactant synthesis in lung tissue; increases lung liquid reabsorption; increases adrenomedullary phenylethanolamine N-methyltransferase activity, which in turn increases methylation of NE to epinephrine; increases hepatic iodothyronine outer-ring monodeiodinase activity and hence increases conversion of T4 to T3; decreases sensitivity of the ductus arteriosus to prostaglandins, which facilitates ductus closure; induces maturation of several enzymes and transport processes of the small intestine; and stimulates maturation of hepatic enzymes (Fig. 21-12). In some cases, these events involve increased synthesis of specific proteins or enzymes. In other instances, such as the action on the ductus arteriosus, the mechanism remains obscure.

Secondary effects of cortisol also promote extrauterine adaptations. The increased T3 levels stimulate -adrenergic receptor binding, potentiate surfactant synthesis in lung tissue, and increase the sensitivity of brown adipose tissue to NE. The significance of prenatal cortisol is demonstrated by the effects of gene-targeted CRH or glucocorticoid receptor deficiency in mice; the progeny of homozygous CRH-deficient or glucocorticoid receptor-deficient animals die in the first 12 hours with lung dysplasia and surfactant deficiency.
Catecholamine Surge

Parurition also evokes a dramatic catecholamine surge in the newborn, resulting in extraordinarily high levels of NE, epinephrine, and dopamine in cord blood. As indicated earlier, plasma NE concentrations exceed epinephrine levels because of peripheral and adrenomedullary and para-aortic catecholamine release. Cord blood NE levels of 15 nmol/L (2500 pg/mL) and epinephrine levels of 2 nmol/L (370 pg/mL) are common after spontaneous delivery of term infants. Levels of 25 nmol/L (4200 pg/mL) of NE and 35 nmol/L (640 pg/mL) of epinephrine are common in cord blood of premature infants. These changes evoke critical cardiovascular adaptations, including increased blood pressure and increased cardiac inotropic effects; increased glucagon secretion; decreased insulin secretion; increased thermogenesis in brown adipose tissue and increased plasma free fatty acid levels; and pulmonary adaptation, including mobilization of pulmonary fluid and increased surfactant release.
Thermogenesis in Neonatal Brown Adipose Tissue

Brown adipose tissue is the major site of thermogenesis in the newborn and is especially prominent in the mammalian fetus. The largest accumulations of brown adipose tissue envelop the kidneys and adrenal glands, and smaller amounts surround the blood vessels of the mediastinum and neck. The mass of brown adipose tissue peaks at the time of birth and gradually decreases during the early weeks of life. Surgical removal of this tissue leads to neonatal hypothermia. NE, through -adrenergic receptors, stimulates thermogenesis by brown adipose tissue, and optimal responsiveness of this tissue to NE is dependent on thyroid hormone.

Brown adipose tissue is rich in mitochondria containing a unique 32-kd protein (thermogenin) that uncouples oxidation and phosphorylation of adenosine diphosphate, reduces adenosine triphosphate production, and consequently enhances thermogenesis. Thermogenin is T3-dependent, and brown adipose tissue contains a 5'-monoiodothyronine deiodinase that synthesizes T3 locally from T4.

Full maturation of catecholamine-stimulated cellular respiration in brown adipose tissue occurs before delivery in the ovine fetus and requires thyroid hormone. Fetal thyroidectomy in this species leads to marked hypothermia, with low plasma free fatty acid levels and increased plasma epinephrine concentrations. In vitro, basal brown adipose tissue thermogenesis and NE-stimulated and dibutyryl cAMP-stimulated thermogenesis are decreased by fetal thyroidectomy.

The rapid onset of thermogenesis in brown adipose tissue is essential for survival in newborn infants. Catecholamine release is the stimulus for brown adipose tissue thermogenesis in the early neonatal period, and responsiveness to catecholamines is markedly increased by cutting of the umbilical cord. Fetal hypoxia and placental inhibitors, including prostaglandin E2 and adenosine, appear to inhibit brown adipose tissue thermogenesis in utero. Cord cutting, neonatal cooling, catecholamine stimulation, and augmented conversion of T4 to T3 in brown adipose tissue in the neonatal period are the essential features that mediate and condition newborn thermogenesis.
Calcium Homeostasis

The neonate must adjust rapidly from a high-calcium environment regulated by PTHrP and calcitonin to a low-calcium environment that requires regulation by PTH and vitamin D. With removal of the placenta in term infants, plasma total calcium concentration falls and reaches a nadir of approximately 2.3 mmol/L (9 mg/dL), and the ionized calcium concentration reaches a low level of about 1.2 mmol/L (4.8 mg/dL) by 24 hours of life. Plasma PTH levels are relatively low in the neonatal period and are minimally responsive to hypocalcemia during the first 2 to 3 days of life.

Calcitonin concentrations are high in cord blood (2000 ng/L), increase further during the early neonatal period, and remain high for several days after birth. The relatively obtunded PTH response and the high calcitonin levels lead to a 2- to 3-day period of transient neonatal hypocalcemia. Inhibition of calcitonin secretion and stimulation of PTH secretion gradually result in increased serum calcium levels in the neonate. The disappearance of PTHrP in the neonatal lamb is approximately coincident with the time of restoration of calcium levels to the adult range. The mechanism of transition from PTHrP to PTH secretion by the neonatal parathyroid glands is not clear.

Calcium homeostasis is also affected in the human newborn period by the low level of glomerular filtration that persists for several days. In addition, renal responsiveness to PTH is reduced in the first few days of life. These factors limit phosphate excretion and predispose the neonate to hyperphosphatemia, particularly if the diet includes high-phosphate milk such as unmodified cow's milk. Premature infants tend to have lower PTH and higher calcitonin levels and more immature kidney function; in these infants, neonatal hypocalcemia may be more marked and prolonged and the incidence of symptomatic hypocalcemia is higher. Birth asphyxia also predisposes the neonate to hypocalcemia. Infants born to mothers with hypercalcemia related to hyperparathyroidism have a high incidence of symptomatic hypocalcemia. These infants have a more marked suppression of parathyroid function and a longer period of transient hypoparathyroidism in the neonatal period. PTH secretion and calcium homeostasis usually return to normal in 1 to 2 weeks in full-term infants and within 2 to 3 weeks in the small premature infant.
Glucose Homeostasis

The abrupt withdrawal of the placental glucose supply leads to a prompt fall in plasma glucose in the term neonate. The low glucose and high catecholamine levels stimulate glucagon secretion, and the plasma glucagon level peaks within 2 hours after birth. Plasma insulin levels are low at birth and tend to fall further with hypoglycemia. The early glucagon response is short-lived; however, levels remain at about 100 ng/L for the first 12 to 24 hours, and the glucagon/insulin ratio is high enough to stabilize glucose levels in the range 2.8 to 4 mmol/L (50 to 70 mg/dL) during this period.

The early glucagon and catecholamine surges deplete hepatic glycogen stores so that the return of plasma glucose levels to normal after 12 to 18 hours requires maturation of hepatic gluconeogenesis under the stimulus of a high plasma glucagon/insulin ratio. Glucagon secretion gradually increases during the early hours after birth, especially with protein feeding, which stimulates gut glucagon release and pancreatic glucagon secretion. Premature infants have more severe and prolonged hypoglycemia because of reduced glycogen stores and impaired hepatic gluconeogenesis. Infants born to diabetic mothers have more severe neonatal hypoglycemia because of relative hyperinsulinism. In the healthy term infant, glucose homeostasis is achieved within 5 to 7 days of life; in premature infants, 1 to 2 weeks may be required.
Other Hormonal Adaptations

Delivery of the placenta results in decreases in fetal blood levels of estrogens, progesterone, hCG, and hPL. The fall in estrogen levels presumably removes the major stimulus to fetal PRL release, and PRL levels decrease within several weeks. The relatively delayed fall may be due to lactotrope hyperplasia in the fetal pituitary or to delayed maturation of hypothalamic dopamine secretion. The gradual fall of hGH levels during the early weeks of life is due to delayed maturation of hypothalamic-pituitary and feedback control of hGH release.\[95\] In the neonatal primate are concomitant decreases in plasma GH levels and GH responsiveness to exogenous GHRH.\[293\] The mechanisms remain unclear. Changes in secretion or in pituitary sensitivity to GHRH or somatostatin, or both, may be involved. Somatomedin levels fall to infantile values within a few days, presumably because of the removal of placental hPL and placental somatomedin production (see Fig. 21-5).\[295\]

In male infants (see Fig. 21-11), after a transient fall in testosterone levels as the hCG stimulus abates, pituitary LH secretion rebounds and there is a secondary surge of plasma testosterone that persists at significant levels for several weeks.\[95\] This surge is mediated by hypothalamic LHRH, and blockade of neonatal activation of the pituitary-testicular axis with an LHRH agonist in neonatal monkeys ablated the neonatal increments in LH and testosterone.\[295\] Such a blockade also resulted in subnormal increments in plasma LH and testosterone levels and subnormal testicular enlargement at puberty in these animals, which suggests that neonatal LHRH release with pituitary-testicular activation may be critical for normal sexual maturation of male primates.\[295\] In females, a transient, secondary surge in FSH may transiently elevate estrogen levels.

Delivery results in a reversal of the high fetal cortisol/cortisol ratio, and plasma cortisol concentrations are higher in the neonate despite relatively lower plasma corticotropin concentrations (see Fig. 21-7). Presumably, this increase is due to decreased inhibition of adrenal 3HSD by estrogen and perhaps to removal of a placental CRH action on fetal pituitary corticotropin release. Plasma DHEAS and DHEA levels fall as the fetal adrenal atrophies.

The increase in serum thyrotropin levels during the early minutes after birth is due to cooling of the neonate in the extrauterine environment.\[136\] The thyrotropin surge peaks at 30 minutes at a concentration of about 70 mU/L (see Fig. 21-9). This peak evokes increased secretion of T4 and T3 by the thyroid gland. In addition, increased conversion of T4 to T3 by liver and other tissues maintains the T3 level in the extrauterine range of 1.6 to 3.4 nmol/L (105 to 220 ng/dL). The reequilibration of thyrotropin levels to the normal extrauterine range is probably due to the readjustment of prevailing serum T3 levels and to maturation of feedback control of thyrotropin by thyroid hormones during the early weeks of life.\[147\] Production of rT3 by fetal and neonatal tissues abates by 3 to 4 weeks of age, at which time serum rT3 reaches adult levels.
IMPRINTING OF DEVELOPING ENDOCRINE SYSTEMS

Data for several mammalian species indicate that hormonal imprinting or programming occurs during a critical fetal or perinatal period of development. In the female rodent, transient neonatal androgen administration masculinized the pattern of hypothalamic control of LHRH secretion and pituitary gonadotropin secretion. Masculinized behavior and adult sexual activity, permanently altered the pattern of GH secretion, increased longitudinal bone growth and body weight, and masculinized the pattern of hepatic steroid metabolism. Prenatal androgens program the timing of neuroendocrine puberty in sheep; the higher the dose of prenatal testosterone, the earlier the initiation of the pubertal LH rise. Estrogen administration to pregnant rats during the last third of gestation produced cryptorchid male offspring and may permanently suppress spermatogenesis in adult males.

Perinatal estrogen administration to the developing female rodent led to growth retardation, delayed puberty, decreased adult pituitary weight, decreased pituitary TRH concentrations, low serum thyrotropin levels, and decreased thyrotropin responsiveness to propylthiouracil challenge. Chronic hyperprolactinemia also occurred, presumably secondary to the low-level continuous estrogen secretion in these anovulatory animals. Prenatal or neonatal diethylstilbestrol in the hamster predisposed to hypoplastic and neoplastic uterine lesions. In these exposed animals uterine levels of c-Jun, c-Fos, c-Myc, BAX, and Bcl-x were markedly increased in luminal and glandular epithelial cells, whereas Bcl-2 levels were decreased. Glucocorticoids are essential for many aspects of normal brain development. Rodents and primates exposed to excess levels of glucocorticoid in utero exhibited hyperactivity of the hypothalamic-pituitary-adrenal axis. Behavioral alterations after glucocorticoid exposure have also been documented in rodent species.

Transient levothyroxine administration to neonatal rodents led to growth retardation, delayed puberty, decreased adult pituitary weight, decreased pituitary TRH concentrations, low serum thyrotropin levels, and decreased thyrotropin responsiveness to propylthiouracil challenge. Adult adrenal function and EGF metabolism were also altered. Administration of insulin or alloxan to neonatal rats produced permanent alteration of glucose tolerance, and a single dose of vasopressin to the neonatal rat permanently enhanced the adult response to vasopressin. Neonatal catecholamine administration altered the response of adult rat vascular tissue to NE. Fetal exposure to high maternal glucocorticoid levels in the rat inhibited fetal growth and led to subsequent hypertension in the offspring.

There is less information about hormonal imprinting in primates and humans. Blockade of LHRH in neonatal monkeys with an LHRH agonist resulted in obtundation of gonadal function and normal with treatment. Congenital hypothyroidism in human infants may be associated with alteration of the set-point for feedback control of thyrotropin release so that serum thyrotropin levels remain inappropriately elevated after return of serum T4 levels to normal with treatment.

A growing literature now supports the concept of fetal programming of cardiovascular disease. It is now clear that intrauterine growth retardation with low birth weight for gestational age is associated with an increased risk of hypertension, insulin resistance and diabetes, and coronary heart disease. The mechanisms are not yet clear, but permanent prenatal changes of fetal endocrine and growth factor homeostasis seem to be involved. These include IGF metabolism, insulin secretion and action, kidney growth and structure, the renin-angiotensin system, and the hypothalamic-pituitary-adrenal axis. There are also permanent changes in the brain. The mechanisms for imprinting remain obscure. Neonatal administration of testosterone or glucocorticoid can have permanent effects on brain structure.

The mechanisms for imprinting remain obscure. Neonatal administration of testosterone or glucocorticoid can have permanent effects on brain structure. The effects in some instances may be transmitted to subsequent generations. A functional overlap of hormone-mediated imprinting may also occur; the administration of both thyrotropin and FSH to the rodent neonate altered the adult response to thyrotropin, and neonatal OT or vasopressin exposure can alter the adult response to vasopressin. Hormonal imprinting is also demonstrable in cell lines and in unicellular organisms, in which a single exposure to a hormone can produce persistent alteration of the hormonal response characteristics.

These observations suggest that hormone imprinting or programming may be due to plasticity of the hormone system during a critical period of maturation. Gene expression and nuclear receptors or plasma membrane receptors, or both, may be involved. Prohormone processing may also be involved in newborn rat intermediate pituitary lobe cells, in vitro treatment with dexamethasone decreased production of -MSH and increased production of corticotropin-related peptides. Whatever the mechanisms, the developing endocrine systems have significant plasticity, and the maturation of endocrine control systems can be influenced by alterations in the prevailing hormone concentrations.
Summary

The foregoing review summarizes current understanding of the intrauterine endocrine milieu and highlights progress in this challenging frontier of medicine. This progress has set the stage for fetal endocrine disease diagnosis, therapy of fetal endocrine and metabolic disorders, management of disorders of fetal growth, and diagnosis and management of perinatal or neonatal endocrine dysfunction. In addition, understanding of developmental endocrinology is increasingly relevant to management strategies for premature infants and infants and children with fetal growth retardation and for our understanding of the pathogenesis of adult endocrine and metabolic diseases.

We are now entering the era of direct access to and management of the intrauterine environment with provision of medical and surgical fetal therapy, entailing both potential advantages and risks. With expansion of the application and scope of amniotic fluid and fetal cell sampling and the advent of fetal visualization and intrauterine fetal blood sampling, direct access for fetal diagnosis is now possible. Women are treated with glucocorticoids to stimulate fetal lung maturation. Intrauterine diagnosis and treatment of fetal adrenal and thyroid disorders have become the standard of care. Intravenous nutritional supplementation of fetal sheep can prevent some forms of growth retardation, and chronic fetal therapy through indwelling pumps is feasible in animal fetuses. These approaches, coupled with increasing availability of synthetic hormones and growth factor agonists and antagonists, facilitate direct fetal endocrine therapy. In addition, intrauterine stem cell transplantation has been successful in the correction of congenital hematologic disease; the fetus in early gestation is a favorable recipient of cellular therapy, and fetal cell transplantation may be applicable to therapy for selected endocrine and metabolic diseases.

Chapter 22 - Disorders of Sex Differentiation

Melvin M. Grumbach
Ieuan A. Hughes
Felix A. Conte

Under most circumstances the distinction between male and female is considered absolute, and these terms are often used to epitomize opposites. Usually, the components of an individual's sexual makeup are indeed dominantly of one gender and conform to the chromosomal pattern established in the zygote at the time of fertilization. Most sexual characteristics, however, emerge from identical bipotential precursors in the embryo, and a spectrum of differentiation is possible at each level of sexual organization.

The remarkable accumulation of knowledge over the past five decades and new and continuing insights in the field of sex determination and differentiation represent major landmarks in biomedical science. No aspect of prenatal development is better understood. Advances in embryology, steroid biochemistry, molecular and cell biology, cytogenetics and genetics, endocrinology, immunology and transplantation biology, and the behavioral sciences all have contributed to the understanding of sexual anomalies in humans and to the improved clinical management of these disorders. Major contributions to this understanding have stemmed from studies of patients with abnormalities of sex differentiation. Noteworthy are the advances that have resulted from application of the techniques of molecular genetics.

Failure at any of the sequential stages of sexual development, whether the cause is genetic or environmental, can have a profound effect on the phenotype and lead to complete sex reversal, various degrees of ambisexual development, or less overt abnormalities in sexual function that first become apparent after sexual maturity. For general works on sex determination and differentiation see references. The diversity of sex-determining mechanisms in multicellular organisms is extraordinary and varies from a repertoire of genetic sex-determining models, including the X chromosome/autosome ratio in fruit flies and worms and the evolution of the highly conserved, dominant, testis-determining, Y-linked gene in mammals, to the temperature-dependent sex determination model in many egg-laying reptiles. Of interest is the commonality of sex-specific regulation of transcription factors and cell signaling molecules.
NORMAL SEX DETERMINATION AND SEX DIFFERENTIATION

Sex determination and differentiation are sequential processes that involve successive establishment of chromosomal (and genetic) sex in the zygote at the moment of conception, determination of gonadal (primary) sex by the genetic sex, and regulation by the gonadal sex of the differentiation of the genital apparatus and, hence, the phenotypic sex. At puberty, the development of sex-specific secondary sexual characteristics reinforces and provides more visible phenotypic manifestations of this sexual dimorphism. Sex determination is concerned with control of the development of the primary or gonadal sex, and sex differentiation encompasses the events subsequent to gonadal organogenesis. These processes are regulated by a myriad of different genes located on sex chromosomes and autosomes that act through a variety of mechanisms, including organizing factors, gonadal steroid and peptide hormones, and tissue receptors. Early embryos of both sexes possess indifferent, common primordia that have an inherent tendency to feminize unless there is active interference by masculinizing factors. The indifferent embryonic gonad develops into an ovary unless it is diverted by a testis-organizing gene on the Y chromosome; female differentiation of the somatic sex structures (the internal and external genital tract) is independent of gonadal hormones and takes place in the absence of fetal testes.

</table>
whether ovaries are present or not. Thus, the sexual dimorphism in phenotype in placental mammals is mediated by the fetal testis and its dual hormonal secretions and not by the ovary (Table 22-1). When luteal secretions are present, male differentiation takes place despite a fetal environment in which the concentration of circulating estrogens and progesterone is high.

Abnormalities of sexual development can be classified into two broad categories: (1) disorders of sex determination, which most often are caused by sex chromosome or gene abnormalities that affect gonadogenesis, and (2) disorders of sex differentiation, which usually are caused by a genetic defect and less often by adverse factors in the intrauterine environment. Before the genetic control of sex determination and gonadogenesis are discussed, a description of aspects of cytogenetics that are important to understanding abnormalities of sex determination is presented.

**Chromosomal Sex and X and Y Chromosomes**

A systematized array of metaphase chromosomes from a single cell is known as a karyotype. The meaning of this term is usually extended to imply that the chromosomal pattern in that cell typifies all the diploid cells of that individual or even of that species, although this is by no means always true. The 22 autosomes and two sex chromosomes (i.e., two X chromosomes or an X and a Y) are arranged and serially numbered according to size. The X chromosomes resemble the larger autosomes in the medium-sized group with submedian centromeres (group 6 to 12). The Y chromosome resembles the short acrocentric autosomes in chromosomes 21 and 22 (Fig. 22-1). Each of the pairs of chromosomes can be identified with chromosome banding and painting techniques. The pattern of DNA replication in human chromosomes can be studied by pulse labeling cell cultures with tritiated thymidine and preparing autoradiographs of the chromosomal spreads or by using the bromodeoxyuridine dye technique. One of the two X chromosomes in the female replicates late during DNA synthesis in the cell cycle, and this X chromosome gives rise to the distinctive X chromatin or Barr body seen in female somatic cells (see later discussion).

Chromosome banding techniques differentially stain chromosome segments. Caspersson and associates introduced a fluorescent staining method referred to as the Q staining method, in which substances such as quinacrine mustard or quinacrine hydrochloride are used to give a distinctive banding pattern (Q bands) for each chromosome (Fig. 22-2). The distal portion of the Y chromosome fluoresces intensely. Pardue and Galt subsequently reported a Giemsa staining technique that preferentially stains the centromeric regions of the chromosome; the areas of constitutive (centromeric) heterochromatin are known as C bands. The Giemsa staining technique has been modified by use of a multitude of pretreatment procedures on fixed metaphase chromosomes (e.g., hypertonic saline, sodium hydroxide, variation of pH, temperature, cation concentration, proteolytic enzymes), which produce Giemsa-stained bands that are identical (with minor exceptions) to the Q bands described by Caspersson and associates; this method yields preparations for conventional light microscopy (see Fig. 22-2), and the resulting bands are designated G bands. Reverse (R) banding is a Giemsa staining method that produces a pattern of chromosome banding that is the reverse of either the Q or G bands. The structural components of the chromosome that give rise to the banding patterns are uncertain, but the differential distribution of base composition and the state of condensation of the chromatin appear to be involved. The Q bands result from binding of quinacrine stains to adenine- and thymine-rich (AT-rich) regions of DNA, whereas guanine- and cytosine-rich (G-C-rich) regions of the chromosome quench the fluorescence. The G bands appear to be a consequence of differential binding of dye to nonhistone protein overlaying the AT-rich regions.

High-resolution chromosome banding and painting techniques provide precise methods for identification of each chromosome and analysis of chromosome abnormalities, including chromosome rearrangements. A standard nomenclature for identification and designation of individual chromosomes, chromosome regions and bands, and structurally altered chromosomes is embodied in the report of the 1995 International System for Human Cytogenetics Nomenclature. Table 22-2 summarizes the nomenclature applied to sex chromosome anomalies.

The identification of normal and structurally abnormal chromosomes, of supernumerary chromosomes, and of specific DNA sequences and genes (chromosome microdissection) has been revolutionized by the development of fluorescence in situ hybridization (FISH), the labeling of normal or abnormal DNA with fluorescent dyes, so-called chromosome painting. With the use of special cameras (multiplex FISH) or Fourier spectroscopy (spectral karyotyping), a variety of fluorophores, and computer programs, the karyotype of normal and complex chromosome spreads can be determined rapidly (Fig. 22-3).

### Mechanisms of Chromosome Anomalies

**Aneuploidy**

Aneuploids cells contain a total number of chromosomes different from that characteristic of the species. One mechanism producing aneuploidy is nondisjunction, which can occur during either mitotic or meiotic division. Nondisjunction is characterized by failure of either of a pair of sister chromatids or members of a pair of homologous chromosomes to separate during anaphase. As a result, one daughter cell receives an extra chromosome and the other is one short (Fig. 22-4). Aneuploidy can also be caused by anaphase lag, in which there is a simple loss of a chromosome from one or both of the two daughter cells, presumably because of failure of one chromosome to become properly oriented at the equatorial plate during metaphase. If both chromatids are lost, both daughter cell lines lack this chromosome. If only one member of the chromatid pair is lost, the descendants of one daughter cell are normal, and those of the other are one chromosome short (Fig. 22-4).

**Nondisjunction in the oocyte increases with advanced maternal age**: an abnormality in reciprocal recombination in the fetus manifested as a compromised exchange configuration predisposes to missegregation during the completion of meiosis I (less frequently of meiosis II) immediately before ovulation 10 to 40 years later.
Mosaicism

Mosaicism is the presence in an individual of two or more cell lines that differ in chromosomal constitution but originate from a single zygote. This condition can arise only from errors in mitosis after fertilization has occurred, but embryos with abnormal chromosomal makeup are prone to further errors of replication. Mosaicism is more common than first supposed, and many of the seeming paradoxes between genotype and phenotype are attributable to studies in which mosaicism was not rigorously excluded. 14 The difficulty in detecting or, especially, in excluding sex chromosome mosaicism cytogenetically was formidable in the past, but recombinant DNA techniques provide more specific and more accurate detection. 15 The use of X and Y DNA probes and chromosome- and locus-specific FISH analysis together with the polymerase chain reaction

*Chimerism*

Chimerism is the existence in an individual of two or more cell lines, each of which has a different genetic origin. In the freemartin, a common form of intersex in cattle, chimerism is derived by admixture of hematopoietic and primordial germ cells between biovular twins of opposite sex through anastomotic placental channels. Although in humans it may be difficult to recognize the presence of chimerism if the separate cell lines have the same sex, the presence of cell lines of different sex is marked by a 46,XX/46,XY karyotype. Chimerism can occur by (1) double fertilization (dispermy) of a binoocyte

![Figure 22-3](https://example.com/figure22-3.png)

*Figure 22-3* FISH for SRY analysis in metaphase and interphase 46,XY cells. Chimerism is derived by admixture of hematopoietic and primordial germ cells between biovular twins of opposite sex through anastomotic placental channels. Although in humans it may be difficult to recognize the presence of chimerism if the separate cell lines have the same sex, the presence of cell lines of different sex is marked by a 46,XX/46,XY karyotype. Chimerism can occur by (1) double fertilization (dispermy) of a binoocyte

*Structural Errors*

With the increased ability to characterize the morphology of human chromosomes by banding, FISH, and molecular biologic techniques, subtle as well as more obvious abnormalities of structure can be recognized. Structural errors result from chromosome breakage or partial deletion, often followed by improper reunion of the fragments (Fig. 22-5). Most structural abnormalities are of sufficient size to be visible by light microscopy are characterized by an abnormally long or short chromosome. Chromosome fragments lacking a centromere or containing an additional functional centromere are usually eliminated from the cell. The following are the more common structural abnormalities (see Table 22-2). 16

Isochromosomes are chromosomes with almost identical arms. They

![Figure 22-4](https://example.com/figure22-4.png)

*Figure 22-4* Daughter cell lines can arise from mitotic nondisjunction or anaphase lag during first mitotic division in the zygote. More complex mosaicism can result if the zygote is aneuploid or if replication errors arise beyond the one cell stage. In females, nondisjunction or anaphase lag may involve either the maternal or paternal X chromosome. Deductions regarding the origin of X chromosomes in aneuploid patients can be made by correlating sex-linked traits with those in parents and by using specific DNA probes for analysis.

were thought to arise by transverse rather than longitudinal division of the chromosome (termed centric fission) (Fig. 22-6). This error involves primarily the X and Y chromosomes and usually results in a chromosome consisting of two long arms (e.g., Xq1 or Yq1). Isochromosomes may have either one or two centromeric bands, and some isochromosomes have subtle differences in banding patterns and size of the two arms. These features and the limited evidence that centric fission can occur in human cells led to the hypothesis that most Xq isochromosomes arise from breaks in the short arm close to the centromere (not by centromeric misdivision), with fusion of the sister chromatids, followed by normal division of the centromere and duplication of the entire chromatid to form an
isochromosome; this view was supported by detailed molecular studies (see Fig. 22-6).

Deletion is characterized by detachment and loss of a portion of a chromosome. The notation q refers to deletion of a portion of the long arm, and p refers to deletion of a portion of the short arm.

Duplication occurs when a deleted segment is incorporated into another chromosome, usually the other member of a homologous pair.

Translocations are characterized by exchanges of chromosome segments between two chromosomes.

Ring chromosomes (e.g., a ring X [Xr]) arise by deletions from the ends (telomeres) of a chromosome, with reunion of the new distal portions to form a ring (see Fig. 22-5).

Biologic Functions of the Y Chromosome

Until the advent of human chromosome analysis, it was widely believed that the Y chromosome (Fig. 22-7) was inert and that male determinants were carried on the autosomes. The finding of a 47,XXY sex chromosome constitution in men with Klinefelter's syndrome and only a single X chromosome in women with the syndrome of gonadal dysgenesis (Turner's syndrome) provided convincing evidence that the Y chromosome carries a male-determining gene that can induce testicular development even in the presence of two or more X chromosomes. The presence of a Y chromosome drives testicular differentiation even in individuals with a 49,XXXXY sex chromosome constitution, whereas testicular differentiation does not occur in 45,X individuals. In addition, the Y chromosome is essential to spermatogenesis. In subsequent work the testis-determining gene, SRY, was localized to the short arm of the Y chromosome.

The human Y chromosome, which is composed of the remnants of a conserved region and, predominantly, of a single autosomal region addition estimated to have occurred 80 to 130 million years ago, represents about 2% of the human genome DNA and is approximately 60 Mb in length. A total of 33 genes on the Y chromosome are known, including 10 genes in pseudoautosomal region 1 (PAR1) and 4 genes in PAR2; the Y chromosome is unique because it contains few active genes and a large heterochromatic segment on the distal long arm. It contains genes that influence stature (GCY, growth controlling gene(s) on Yp) in addition to a gene affecting growth located in the PAR1 of the Y and X chromosomes. XY boys have a mean final height of about 188 cm, more than 13 cm taller than their fathers. Phenotypic females with a 46.X derivative karyotype having three doses of SHOX/PHOG are tall, as are XXY patients. Whether the increased stature in XXY patients is related solely to the extra dose of the pseudoautosomal SHOX/PHOG gene or to additional Y-borne genes is not known.

The length of the human Y chromosome varies as much as threefold in normal men. The length and morphology of the Y are heritable, are relatively constant in first-degree male relatives, and exhibit ethnic variation. Most of this variation is in the length of the long arm and in particular in the length of its distal, heterochromatic, brilliantly fluorescent segment in Q-stained preparations (see Fig. 22-8; see also Fig. 22-7). This polymorphism in the size of the fluorescent portion and even loss of part of the distal nonfluorescent portion of the long arm are consistent with normal male sex differentiation and are not associated with known phenotypic effects; consequently, it is likely that a large segment of the long arm of the Y chromosome is not engaged in gene transcription. The long arm of the Y chromosome contains highly repetitive Y chromosome-specific and non-Y chromosome-specific sequences of DNA. The euchromatic short arm and the proximal portion of the long arm of the human Y chromosome make up about 0.5% of the diploid genome (XY + 44 autosomes).

The euchromatic portion of the Y chromosome contains two regions, a Y-specific segment and regions at the distal ends of the short and long arms that are so-called pseudoautosomal regions (PARs) that are homologous to the distal ends of the short and the long arms, respectively, of the X chromosome. The X and Y chromosomes pair and recombine obligately only along these small segments at the distal ends during meiosis. They form chiasmata, thereby maintaining sequence homology and allowing for the proper distribution of sex chromosomes to the daughter cells. This process is critical to sex determination. Genes on the distal short and long arms of the X and Y chromosomes are paired and are not subject to dosage compensation (i.e., gene inactivation); hence, they are expressed as autosomal genes rather than X-linked genes, leading to the PAR designation (see Fig. 22-7).

At least 10 genes are located on the PAR1 of the short arm of the X and Y chromosomes. The short arm PAR (PAR1) is about 2.6 Mb in length, the boundaries being demarcated distally by the telomeres of the X and Y chromosomes and proximally by the Alu repeat sequence on the Y chromosome. The PARs of the X and Y chromosomes are 99% homologous distal to the Alu sequence. Distally on the short arm PAR is PGFL, which encodes a putative quanosome triphosphosphate (GTP) binding protein; next is SHOX/PHOG, then CSP2RA, which encodes the subunit of the granulocyte colony-stimulating factor receptor. Proximal to CSP2RA is IL3RA (encoding the subunit for the IL3 receptor, followed by ANT3 (adenine nucleotide translocase), ASMTL (ASMT-like), and ASMT (acetyl serotonin methyl transferase), XET (X-escape inactivation, function unknown), TRAMP (sequence homology with transposases suggests involvement in transposition), and MIC2 at the PAR boundary. PBDX is the XG blood group gene, and its homologue on the Y chromosome is an expressed pseudogene of XH.

The congruence between short stature and deletions of either Xp or Yp suggested that a gene for stature was present in the distal 700 kb of the PAR1 because patients with only a single copy of this region have short stature. A gene from this 700-kb distal PAR region of Xp and Yp (PAR1), called PHOG (pseudoautosomal homeobox-containing osteogenic gene), is expressed.
mainly in osteogenic cells and bone marrow stromal fibroblasts and encodes a transcription regulatory factor. Its location in the distal PAR, the nature of its predicted protein, and its expression in developing limbs and the first and second pharyngeal pouches suggested that it is involved in mesomelic short stature as well as the skeletal anomalies of Turner's syndrome. Analysis of 32 Leri-Weill patients from 18 families revealed SHOX/PHOG deletions in only 10 of the 18 families, suggesting multiple genetic causes of Leri-Weill syndrome. The phenotypic variation in patients with SHOX/PHOG heterozygous deletions or mutations (i.e., short normal male Turner syndrome stigmata Leri-Weill syndrome) is not understood.

A second PAR is found on the distal long arms of the X and Y chromosomes. This region is 330 kb long and recombines during meiosis at a 2% rate, much slower than the XpYp pseudoautosomal region combines but six times greater than average for X-specific DNA.

forms by the Y chromosome and its homologue on the long arm of the X chromosome (RS54X). On the short arm of the Y chromosome proximal to RS54Y is a gene that encodes for a protein that has 13 CysCys/HisHis zinc fingers and both an acidic and a basic domain and that has been termed ZFY (zinc finger Y).

The fluorescent end of the human Y chromosome in metaphase, when stained with the fluorochrome quinacrine hydrochloride or its mustard derivative, is visualized by using FISH for Y chromosome and X chromosome satellite DNA analysis the sex chromosomes can be identified in interphase cells.

The association of short stature with SHOX/PHOG haplinsufficiency in patients with Xp-, Yp-, in short otherwise "normal" males, and in patients with Leri-Weill syndrome and its expression in developing limbs and the first and second pharyngeal pouches suggested that it is involved in mesomelic short stature as well as the skeletal anomalies of Turner's syndrome. Analysis of 32 Leri-Weill patients from 18 families revealed SHOX/PHOG deletions in only 10 of the 18 families, suggesting multiple genetic causes of Leri-Weill syndrome. The phenotypic variation in patients with SHOX/PHOG heterozygous deletions or mutations (i.e., short normal male Turner syndrome stigmata Leri-Weill syndrome) is not understood.

A second PAR is found on the distal long arms of the X and Y chromosomes. This region is 330 kb long and recombines during meiosis at a 2% rate, much slower than the XpYp pseudoautosomal region combines but six times greater than average for X-specific DNA. The proximal 295 kb contain two genes SYBLL (synaptobrevin-like 1), a gene that may be involved in synaptic signaling, and HSPRY3 (human sprouty 3), a putative intracellular modulator of fibroblast growth factor (FGF) and FGF receptor tyrosine activity, which antagonizes Fas-dependent mitogen-activated protein (MAP) kinase signaling. Unlike genes on PAR1, these genes are inactivated on both the inactive X and the Y chromosome. The distal 35 kb of PAR2 contains two genes that are not inactivated: IL9R, the interleukin-9 receptor, and CXYorf7, a gene of unknown function, located 5 kb from the Xq telomere.

The euochromatic portion of the Y chromosome, the so-called sex-specific region present only in the male, extends from the proximal boundary of the PAR to the heterochromatic portion of the long arm of the chromosome. Deletion analyses of the Y chromosome in 46.XX males and 46.YX females indicate that the segment just proximal to the PAR on the short arm of the Y chromosome carries a gene or genes critical to testicular organogenesis and subsequent male sex differentiation. A 35-kb region immediately adjacent to the PAR boundary contains a gene termed SRY (sex-determining region Y). This gene encodes a testis-specific transcript that exhibits structural homology to two DNA-binding proteins: Mc, a mating-type protein of the fission yeast Schizosaccharomyces pombe, and HMG1 and HMG2, so-called nuclear high-mobility-group proteins. Proximal to SRY is a gene for ribosomal protein subunit-4 (RPS4Y), one of many housekeeping proteins that are encoded in slightly different

forms by the Y chromosome and its homologue on the long arm of the X chromosome (RS54X). On the short arm of the Y chromosome proximal to RS54Y is a gene that encodes for a protein that has 13 CysCys/HisHis zinc fingers and both an acidic and a basic domain and that has been termed ZFY (zinc finger Y). By analogy to similar zinc finger proteins, such as Xenopus transcription factor IIIA, the protein is thought to bind to DNA in a sequence-specific manner and to regulate transcription. Among other genes on the short arm of the Y chromosome are PRKY (protein kinase Y), TSPY (testis-specific protein Y), and AMELY (amelogenin), the gene that encodes the major extracellular matrix enamel protein in the developing tooth bud.

PRKY has a homologous site on the X chromosome (PRKX), which allows for illegitimate recombination between the X and Y chromosomes and hence the production of XX SRY-positive males. TSPY is present as a multicopy locus on the Y chromosome. TSPY may function as an oncogene responsible for gonadoblastoma formation in dysgenetic gonads. Its repetitive units map to the GSY (gonadalblastoma) critical regions on the Y chromosome.

The euchromatic portion of the long arm of the Y chromosome can be divided into three regions: AZFa, AZFb, and AZFc for azoospermic factors a, b, and c. These three nonoverlapping regions contain genes that when deleted result in infertility. AZFa is the region proximal to the centromere of the Y chromosome and it encompasses four genes: USP9Y, a ubiquitin-specific protease that encodes an H-Y antigen epitope, DBY (dead box Y), UTB (ubiquitous leucineproleopeptide repeat motif Y), and TB4Y (thymosin B4, A isoform). AZFb contains five genes, prominent among which are SMCY (selected mouse CDNA, Y), which encodes two H-Y antigen epitopes and RBMY (RNA-binding motif Y), a gene with a putative role in spermatogenesis. AZFc at the distal end of the euchromatic region has a five-gene cluster at its boundary, the most prominent of which is DAZ (deleted in azoospermia), an RNA-binding protein. Deletions of DAZ and one or more members of the RBMY family as well as USP9Y and DBY are a common cause of spermatogenetic failure. Other genes postulated to reside on the Y chromosome but not yet cloned include genes affecting height, on the long arm pericentromeric region GCY, as well as genes preventing the stigmata of the syndrome of gonadal dysgenesis, on the short arm, and genes affecting spermatogenesis.

Q-stained X chromatin bodies have been observed in cultured
female fibroblasts and certain other female tissues, but the intensity of fluorescence of the X body is less, and the size is three to five times larger than that of the Y body (see Fig. 22-8). In sum, more than 30 genes and gene families are currently identified on the Y chromosome.38 40

They are subclassified as follows:

1. Pseudoautosomal genes with identical sequences on X and Y (e.g., IR and MIC2).
2. Those located on the X-Y homologous regions of the nonrecombining region of Y (NRY); these genes are ubiquitously expressed and include DBY and UTY.
3. Genes that are Y specific and expressed only in the testis (e.g., SRY).

Although SRY is Y specific, it does not fit this classification in view of its different pattern of expression and its single copy nature. Surprisingly, nearly half of all genes involved in early stages of spermatogenesis are X linked, a specialty role of the X chromosome in sperm production that emerged as it evolved from an ancestral autosomal.38 39

Biologic Functions of the X Chromosome

The biologic functions of the X chromosome are more complex than those of the Y chromosome. The X chromosome consists of about 160 Mb; landmark DNA sequences (sequence-tagged sites) have been determined over the entire X chromosome. A large number of genes on one of the two X chromosomes of the female undergo X inactivation, a genesilencing mechanism activated in early embryonic development, to balance the expression of X-linked genes between males and females (see later). Genes on the X chromosome have a critical influence on sex determination in both the female and the male and on the differentiation of the somatic sex structures in the male. More than 300 gene loci unrelated to sex development are known to be X linked.38 39

The organization of the X chromosome resembles that of the Y chromosome in that it has both a pseudoautosomal region (PAR) on its distal short arm (PAR1), homologous to that on the Y chromosome (Xp22.3pter), an X-specific region, and a PAR on the long arm (PAR2) (Fig. 22-9). PAR1 of the Xp is the locus for at least 11 genes (PGFL, C5orf26, SHOX/PHOG, IL3Rα, AN73, ASMT, XE7, TRAMP, MIC2, and PBDX), and a gene deletion results in the neurocognitive defects seen in Turner's syndrome. The locus of the PBDX gene (the XG blood group gene) is unusual in that it appears to span the PAR boundary on the X chromosome.47 Immediately proximal to the boundary of the PAR are the loci for many genes, including those for chorondroplasia punctata and steroid sulfatase (STS), the gene encoding the amelogenin enamel protein in the developing tooth bud, and the locus for the zinc finger gene X (ZF5), which cross-hybridizes with DNA probes of the ZFY gene. Because the ZFX protein has 13 zinc fingers with 97% amino acid sequence homology to ZFY, it appears that both these zinc finger proteins may bind to the same nucleic acid sequences. Genes in the area of the X chromosome immediately proximal to the PAR (i.e., Xg [PBDX], STS, KAL1, ZFX) escape X inactivation. Other genes are postulated to reside in this region, including a gene or genes that prevent many of the somatic abnormalities found in the syndrome of gonadal dysgenesis.47 48 Proximal to this region are genes that are not homologous to sequences on the Y chromosome and are subject to dosage compensation by X inactivation on all X chromosomes in excess of one.47

Several genes that play a role in sex determination and differentiation are present on the short arm of the X chromosome. These include the Kallmann syndrome gene, KAL1, deletion or mutation of which results in anosmia and hypogonadotropic hypogonadism.49 KAL1 maps about 1.5 Mb proximal to STS on Xp22.3 and encodes a protein, anosin, that is critical for the migration of the luteinizing hormonereleasing hormone (LHRH) neurosecretory neurons from the olfactory placode to the hypothalamus.49 Proximal to the genes for Duchenne muscular dystrophy (DMD) and glycerol kinase (GK) in the Xp21 region is a locus that contains two overlapping regions, AHC (adrenal hypoplasia congenital) and DSS (dosage-sensitive sex reversal). A gene, DAX1 (DSS/MHC critical region on the X chromosome), has been cloned from this region.47 Deletions and mutations in the DAX1 gene are associated in the male with adrenal hypoplasia and hypogonadotropic hypogonadism.47 Duplication of the DAX1 gene in the XY human (and rodent) results in testicular dysgenesis and lack of or incomplete masculinization of the internal and external genitalia.47 48 Duplications in 46,XX females, however, do not affect ovarian function.47 48 In contrast, deletions of the DAX1 gene have no effect on testicular determination and differentiation and subsequent in utero masculinization of 46,XY' individuals. More proximal on the short arm, a lymphedema critical region has been proposed to reside in Xp11.4.47 48

Two X chromosomes are required in humans for normal ovarian differentiation and follicular maturation: 45,X individuals have bilateral streak gonads. Studies of patients with deletions of the X chromosome indicate that loci on both the short and long arms of the X chromosome are involved in ovarian differentiation and maturation.47 48

The long arm of the X chromosome contains a large number of genes that are subject to X inactivation and are responsible for a wide variety of X-linked traits. The gene for the androgen receptor protein is located in the paracentromeric region of the long arm of the X.47 The RPS4x gene is also located in this region and is subject to X inactivation. This region also contains the X-inactivation center, XIC, the site around which the X chromosome condenses to form the sex chromatin body and from which X inactivation spreads. (See X Chromatin and Gene Expression.)

X Chromatin (X or Barr Body)

Whereas the Y chromosome is one of the smallest human chromosomes and is mainly concerned with testis organogenesis, the X chromosome is the eighth longest
and contains about 5% of the total DNA content of the haploid genome (X + 22 autosomes). Furthermore, the X chromosome contains genes that encode functions involving every system in the body. Because females have twice as much of this genetic material in their cells as males, the biologic differences between the sexes should be far greater than is the case. Theories proposed to explain this paradox are an outgrowth of Barr's pioneering observations of the X chromatin body in somatic cells of females.

In 1949 Barr and Bertram described the presence of a stainable chromatin mass at the periphery of the nucleus in resting ganglion cells of female but not of male cats. This distinguishing characteristic of the female sex is present in most mammalian cells and can be used as a cytologic means of assessing the number of X chromosomes in humans (reviewed in reference 109, Fig. 22-10; see Table 22-3).

The X chromatin body is usually planarconvex, with the flattened side in apposition to the inner surface of the nuclear membrane; in some nuclei it has a bipartite structure. It is about 1 µm in diameter and stains positively for DNA. In certain tissues, such as amniotic membrane, almost every interphase nucleus is chromatin positive. In buccal mucosal smears (the most commonly used preparation for determining the X chromatin pattern), the proportion of X chromosome-positive nuclei in females may be lower than in other somatic tissues, but in most studies these nuclei are detected in no less than 20% of all nuclei.

In polymorphonuclear leukocytes in females, 1% to 15% of neutrophils (mean, 2.5%) have a drumstick-shaped, dense chromatin accessory nuclear appendage not found in normal males (see Fig. 22-10D). These appendages have the same significance as X chromatin in other somatic tissues.

In patients with more than one X chromosome, the maximal number of X chromatin bodies in any diploid nucleus is one less than the total number of X chromosomes. In 47,XXY females or 48,XXY, males, for example, at most two Barr bodies are present in diploid nuclei, whereas 46,XY and 45,X individuals are X chromatin negative (see Table 22-3). Abnormalities in shape and size of the X chromatin body can often be correlated with structural abnormalities of the X chromosome. The X chromatin body is small in females and one deleted X chromosome (46,XXp) and in those with one ring X chromosome (46,Xp). A large X body is associated with a long arm isochromosome (Xq) of a large X chromosome that gives rise to X chromatin bodies (Fig. 22-11). When an X is structurally abnormal, the aberrant X chromosome replicates late and gives rise to the X chromatin (except when the structurally abnormal X is an X-autosome translocation).

X Chromatin and Gene Expression

In 1959 Ohno and co-workers reported the first evidence that X chromatin (the Barr body) arises from only one of the two X chromosomes in the interphase nuclei of female somatic cells. The staining characteristics of such nuclei arise from the fact that a portion of one X chromosome is highly condensed (heteropyknotic); the other X, like the autosomes, is extended and filamentous.280 This difference in staining quality betokens a striking difference in the functional roles of the two X chromosomes. By studying the sequence of incorporation of tritiated thymidine into replicating chromosomes, Grumbach and colleagues281,282 showed that the X chromosome that gives rise to X chromatin completes DNA synthesis later than any other chromosome and that the maximal number of X chromatin bodies in a single diploid nucleus is equal to the number of late-replicating X chromosomes (Fig. 22-11). These observations and the incisive genetic studies of Lyon, Beutler, and others led to the concept that only one X chromosome in each cell is genetically active during interphase, the other X chromosome being heterochromatinized and genetically inactive for most functions.281,282,283 We do not refer here to constitutive heterochromatin but rather to facultative heterochromatin-euchromatic (active) chromosome regions silenced by transformation into a heterochromatin (or inactive) form.284,285

The change in state (inactivation)286,287 of one X chromosome in each female cell occurs during the late blastocyst stage, between the 12th and the 18th day in the human embryo. X inactivation is a multistep process that leads to stable and epigenetic silencing of genes on all X chromosomes in excess of one X. It involves (1) counting (ascertainment of X-autosome location and inactivation of all X chromosomes in excess of 1); (2) random selection of which X chromosome, either the maternal or paternal X, will inactivate; and (3) silencing of initiation, establishment, and maintenance of X-inactivation.286,287,288 The female germ cells beyond the stage of oogonia are the only cell lines known to be exempted from heterochromatinization and inactivation,289 which is seen as a finding in keeping with the requirement for a second X chromosome for normal ovarian differentiation. Both X chromosomes in mouse oocytes are active and code for the X-linked genes for glucose-6-phosphate dehydrogenase and hypoxanthine-guanine phosphoribosyltransferase.290 This observation has been confirmed in human fetal and postnatal oocytes.289 In each somatic cell, however, either the maternally or the paternally derived X chromosome is usually randomly inactivated. Once this transformation is accomplished, the inactive state of that particular X chromosome is transmitted to all descendants of that cell. This control system functions as an epigenetic mechanism of dosage compensation by which each female somatic cell functions virtually as if it had only one active X chromosome.286,287,289,290 The female, in effect, has only a little more active genetic material than does the male. This hypothesis is commonly referred to as the "Lyon hypothesis" (or the "inactivating X theory," or the "fixed differentiation hypothesis of X chromosome behavior") (Fig. 22-12). Although inactivation of structurally normal X chromosomes in individuals with more than one X chromosome in their genome is usually random, instances of skewed inactivation are well documented289,290 XX individuals heterozygous for X-linked immunodeficiencies and mental retardation disorders, Lesch-Nyhan syndrome, or adrenoleukodystrophy may appear to have nonrandom activation of their X chromosomes owing to post-inactivation selection (i.e., in vivo selection against those cells in which the normal allele is inactivated in tissues where the gene product is required).289,291,292 Skewed inactivation of the X chromosome has been reported in families with X-linked diseases and in monozoic twins discordant for an X-linked disease.293,294 If inactivation occurs normally as a random event in a small number of cells, 10% of "normal females" may show an 80:20 proportion of inactivated X chromosomes from one parent and even manifest symptoms of an X-linked mutant allele. Skewed inactivation also occurs in patients with a structurally abnormal X chromosome: the structurally abnormal X chromosome is inactivated, unless it is a part of an X-autosome translocation, in which case the X-autosome translocation will always be active, probably as the result of cell selection. A skewed pattern of X inactivation also has been described in a multigenerational study, suggesting that this character is controlled in some families by one or more X-linked genes.295,296

The fact that normal females function as genetic mosaics is one of X-linked traits is concerned has been documented in the mouse and in humans. For example, Davidson and associates295 demonstrated two populations of cells in females heterozygous for a mutant form of the X-linked gene for glucose-6-phosphate dehydrogenase (see Fig. 22-12). Inactivation of all X chromosomes in excess of one also explains the relatively minor phenotypic changes in women with more than
two X chromosomes (Fig. 22-13). By contrast, trisomy for an autosome as small as chromosome 21, as in Down's syndrome, is usually associated with profound effects. Biochemical analysis of DNA methylation of active and inactive X chromosomes and studies with 5-azacytidine (which impairs methylation of cytosine) suggest that DNA methylation plays an important role in the maintenance of X chromosome inactivation, late replication, and sex chromatin formation. DNA methylation differs in the two X chromosomes. The double-stranded palindromic cytosome-guanine dinucleotide clusters, the so-called CpG islands, commonly found at the 5' end of genes, are methylated mainly on the inactive X chromosome. The methylated cytosome residues serve to maintain the suppressed transcriptional activity and relative resistance to nuclelease. The chromatin of the inactive X contains more unacyetylated histones (histones H3 and H4) than the chromatin of the active X chromosome does. Histones function as DNA-packaging proteins; the DNA helix is wrapped around core

Figure 22-12 Diagram of the fixed differentiation or Lyon hypothesis of X chromosome behavior in somatic cells of the human female. At the late blastocyst stage (the time when X chromatin can first be identified), one of the two X chromosomes becomes heterochromatinized in each cell and gives rise to an X chromatin body; it is by chance in each cell whether this differentiation involves a maternally derived X (M) or a paternally derived X (P). Once differentiation has occurred, this characteristic is fixed in succeeding generations of somatic cells. Most of the genes on the heterochromatic portion of an X chromosome are suppressed or inactivated, thus serving as a means of "dosage compensation" for the greater number of X-linked genes in the female than in the male. This mechanism has an important bearing on expressivity and penetrance of an X-linked mutant gene in a heterozygous female. In the diagram, the maternally derived X carries a mutant gene (a) that is expressed only in cells in which this X is the Lyon-silenced, euchromatic active X (white X). Although the heterochromatinized X (black X) in this diagram is represented as wholly inactive, some loci on the heterochromatinized X do remain active and exert genetic effects. The female germ cell line beyond the oogonia stage is exempted from heterochromatinization.

Figure 22-13 Diploid somatic cells from a girl with a 49,XXXX karyotype. A. Four X chromatin bodies (arrows) in an interphase nucleus from a culture of skin fibroblasts. B, Autoradiogram of metaphase chromosomes, illustrating four areas of high grain density overlying four of the five X chromosomes. C, An autoradiogram of an interphase nucleus in a culture of skin fibroblasts; four peripheral "hot" areas (arrows) of high grain density overlie four X chromatin bodies and provide direct evidence that each X chromatin body is derived from one late-labeling X chromosome. (Modified from Gribanbach MM, Morishima A, Taylor JA. Human sex chromosome abnormalities in relation to DNA replication and heterochromatinization. Proc Nat Acad Sci USA 1963; 49:581589; and Gribanbach MM. On the significance of sex chromatin. In Second International Congress on Congenital Malformations. New York: International Medical Congress, 1964, pp. 62-67.)

a common requisite for the activation of gene expression, is mediated by histone acetyltransferase A, encoded by the HATA gene.

In contrast to the mouse, human X chromosome inactivation does not involve the entire chromosome. The heteropyknotic X in the human female is only segmentally inactive in terms of transcriptional activity, early studies of the heteropyknotized

X chromosome suggest that about 21% of genes on Xp escape inactivation in contrast to about 3% of genes on Xq. Genes on the PAR of the short and long arm as well as genes scattered along the short and long arms of the heteropyknotic X chromosome escape inactivation. Individuals with a 45.X or 47.XXY constitution, for example, have abnormalities both in gonadal development and in somatic features unrelated to sex. Furthermore, as noted previously, the gene for the red blood cell antigen Xg (PBDXX), the ST3 gene, and the ZFX genes escape inactivation and are active on both X chromosomes in the female; these genes have been mapped to the distal part of the short arm of the X, outside the PAR. Two genes, XIST (X-specific transcripts) and RPS4, which are located on the proximal long arm of the X chromosome, escape inactivation on the heteropyknotic X chromosome. Inactivation of the X chromosome is mediated by a cis-acting region of the X chromosome, the XIC (X-inactivating center), from which inactivation spreads along the X. The XIST gene, discovered by Willard and his colleagues, is an essential component of the XIC, at Xq13.6-14.1 (Fig. 22-13).

XIST is a unique gene in that its product, a noncoding RNA, is expressed in high levels only on the inactive X chromosome. Its expression correlates with the inactivation of the X chromosome in female somatic cells and with meiosis in spermatogonia. The XIST allele is turned off on the active X; hence, its lack of expression on an X chromosome indicates that the gene is transcriptionally active. Human and mouse XIST genes encode a long noncoding RNA transcript that is retained in the nucleus "coating" the inactive X chromosome and initiating the gene silencing process. Knockout of the XIST gene in embryonic stem cells prevents X inactivation in cis, whereas deletions of 65 kb of DNA at the 3' end of Xist (mouse homologue) result in that chromosome always being inactivated. In the mouse the gene-silencing function of Xist is lost with deletion of a conserved repeat sequence at the 5' end, but this mutant Xist continued to exhibit chromatin association and spreading. Additionally, the insertion of ectopic copies of Xist into autosomes of murine stem cells results in the molecular and heterochromatic features of X inactivation, including Xist RNA association in cis, gene inactivation, late replication, and a decrease in histone H4 acetylation. XIST apparently is not required for maintenance of X inactivation. The silent Xist gene on the active X chromosome is fully methylated at its 5' end. In the mouse placenta, X inactivation is imprinted the paternal X chromosome is inactivated. A mouse Xist antisense gene, Tsa, is located 15 kb downstream of Xist and extends across the Xist locus on the opposite strand. Tsa is thought to play a role in the repression of the maternal Xist allele in the mouse. However, the suppression of Xist by cis-acting Tsa, which prevents the initiation of X inactivation, does not account for random selection of the X.

Lee and co-workers searched for a trans-acting factor involved in X-chromosome choice in the mouse. They found a candidate, trans-acting molecule, the ubiquitous chromatin insulator and transcription regulator CTCF, which has 11 zinc fingers. However, Pericic and associates using chemical mutagenesis detected two genetically different autosomal dominant mutations (not involving CTCF) that affect X chromosome choice in the early embryo. They designated these mutations X-inactivation autosomal factors 1 and 2.

Migeon and co-workers have identified the human homologue of Tsa, TSIX on the X chromosome. However, unlike Tsa, TSIX RNA is truncated at the 5' end, does not cover the XIST promoter, and does not have a CpG island, which is critical for the function of Tsa. These differences have led Migeon to question the function of TSIX in X chromosome inactivation in humans. Its apparent lack of functionality may explain the discrepancy in X-chromosome imprinting in the human placenta between the humanc and rodent and creates uncertainty about the role of the human TSIX gene in X chromosome choice. The progress over the past decade in illuminating the epigenetic mechanism of X inactivation is remarkable.

Some patients with a 45,X/46,X "tiny" ring X chromosome karyotype differ in phenotype from other patients with gonadal dysgenesis with a ring X chromosome in their genome. These tiny ring X chromosomes do not express XIST, have histone H4 acetylation at a level consistent with that found on an active X chromosome, and contain genes that are active. These tiny ring X chromosomes that lack the XIST gene do not undergo X inactivation; as a consequence, the phenotype in affected patients results from functional disomy caused by lack of dosage compensation. In general, patients with small ring X chromosomes have a greater incidence of mental retardation than those with other forms of Turner's syndrome. Other congenital malformations such as syndactyly and abnormal facies are common.
Genes and Testicular Organogenesis

The genetic sex of the zygote is established by fertilization of a normal ovum by an X- or Y-bearing sperm, and the mechanisms involved in the translation of genetic sex into a testis or an ovary are understood in broad terms. From the early days of human chromosome analysis, compelling evidence was obtained for the regulation of testicular gonadogenesis by a gene (or genes) on the Y chromosome. Indeed, sex determination is essentially testis determination. The short arm of the Y chromosome contains a gene (SRY) that controls testis differentiation and, hence, maleness. The gene acts in a dominant fashion and leads to differentiation of the bipotential gonad as a testis. Several hypotheses were proposed to explain testicular morphogenesis (Fig. 22-14). H-Y antigen and ZFY were proposed as the sex determinators, but that proposal was discarded.\(^\text{144}\)\(^\text{145}\) Reports beginning in 1988 have provided compelling evidence that the SRY gene is the master gene that controls male sex determination.

H-Y Antigen

In 1955 Eichwald and Stilms discovered in males of a highly inbred strain of mice the H-Y antigen, a male-specific cell membrane component encoded by the Y chromosome that causes rejection by female mice of skin grafts from males of the same strain. Antibodies to H-Y antigen (now identified serologically) in male-grafted female mice by Goldberg and associates in 1971 and were utilized for measurement of H-Y antigen. Initial reports suggested that H-Y antigen was a good candidate for the testicular determining factor (TDF) on the Y chromosome, but the lack of reproducibility of the H-Y antigen assay led to increasing skepticism about its role in testicular determination. Finally, it was demonstrated that the gene for H-Y antigen is located on the long arm of the Y chromosome, separate and distinct from the gene for male sex determination.\(^\text{146}\)

ZFY Gene

In 1987 Page and associates proposed that the sex-determining function of the Y chromosome is located within a 140-kb segment of the short arm of the Y chromosome (see Fig. 22-14). A gene in this region encodes a protein with 13 CytoCysHisHis zinc fingers at the carboxyl terminus (and a basic and acidic region at the amino terminus).\(^\text{147}\) By analogy to Xenopus transcription factor II A, it was suggested that this protein binds to DNA and/or RNA in a sequence-specific manner and regulates transcription and that this zinc finger protein, ZFY, is the primary sex-determining signal on the Y chromosome. A sequence homologous to ZFY is present on the X chromosome (ZFX) in the Xp21.2-p22.1 region.\(^\text{148}\) The latter finding initially suggested that X inactivation (dosage compensation) might play a role in sex determination, but ZFX escapes inactivation, so X-chromosome inactivation cannot play a role in this process.\(^\text{149}\) Convincing evidence has shown that ZFY is not the testis-determining gene. Furthermore, in metatherian species (marsupials), sex determination is dependent even though ZFY-related sequences are not located on the X and Y chromosomes of these animals but rather on autosomes.\(^\text{150}\)

SRY Gene

The long quest for the testes-determining factor (TDF) finally met with success with the identification of the SRY gene. In 1989, Palmer and co-workers described three 46,XX males and one true hermaphrodite, the sibling of one of the 46,XX males.\(^\text{151}\) They were all ZFY negative, in spite of evidence for a Y-to-X chromosome exchange as the mechanism of their XX karyotype in the presence of testes with male sex differentiation.\(^\text{152}\) The fragment of Y chromosome translocated to the X chromosome in these patients involved sequences that were distal to the ZFY locus on the short arm of the Y chromosome. This demonstration of testes in patients with a Y fragment but no ZFY sequences, along with studies in marsupials\(^\text{153}\) and mice, doomed the hypothesis that ZFY was the TDF on the Y chromosome.\(^\text{154}\) The Y-to-X exchange in these four patients involved Y-specific sequences located within 35 kb of the boundary of the PAR on the short arm of the Y chromosome (Fig. 22-15).\(^\text{155}\) A 21-krb clone, pY53.3, was identified in this region within 8 kb of the PAR boundary.\(^\text{156}\) This probe detected male sequences in a wide variety of eutherian mammals.\(^\text{157}\)

Studies in mice established that Sry (the mouse homologue of the human SRY gene) is the TDF. Sry is present in the Sxr,XX mouse, a "male" mouse that has the smallest piece of Y chromosome known to code for testicular determination and differentiation translocated to the X chromosome.\(^\text{158}\) Sry is absent in the XY fertile "female" mouse, which has an 11q deletion involving the testes-determining region.\(^\text{159}\) Further studies in the mouse model demonstrated that Sry is expressed in the embryonic genital ridge for only a brief period, from 10.5 to 12.5 days after coitus and 24 hours before the genital ridge differentiates into a testis.\(^\text{160}\) Sry expression is limited to pre-Sertoli cells in the genital ridge, in contrast, Sry in the adult testes is expressed in the germ cells.\(^\text{161}\) The function of Sry transcripts in the adult mouse testis is unknown, because the transcripts are circular and are not associated with polysomes; they appear not to be translated into a protein.\(^\text{162}\)

Definitive proof that Sry was the TDF came from the demonstration that 46,XX mice with a transgene that contains a 14-kb piece of the Y chromosome including Sry differentiate as males with testes.\(^\text{163}\) In the first series of animals, one 46,XX progeny that expressed the transfact ed Sry gene was a well-differentiated 46,XX male that exhibited appropriate male sexual mating behavior.\(^\text{164}\) Histologic examination of the testes revealed normal somatic elements, absent spermatogenesis, and degenerating germ cells.\(^\text{165}\) The other two mice were 46,XX females; one was able to transmit the Sry transgene to her progeny, resulting in the generation of 46,XX males; 46,XX hermaphrodites; and 46,XX females.\(^\text{166}\) That the Sry transgene produced sex reversal in only 25% of transfected embryos may be attributable to the incorporation of the transgene into a region of the genome where it is either not expressed, expressed at a low level, or expressed late in relation to gonadal determination and differentiation.\(^\text{167}\) Nevertheless, this critical transgene experiment proved conclusively that Sry is the only gene on the Y chromosome necessary for testes determination and differentiation and that Sry is the TDF gene. In addition, these studies indicated that Y-borne genes other than Sry are involved in the regulation of spermatogenesis.

Evidence in the human from sex-reversed 46,XX males and 46,XY females confirms the conclusion that SRY is the TDF. In humans, an aberrant Y-to-X interchange during paternal spermatogenesis can transfer Y-specific loci to the X chromosome, and 80% of 46,XX males have a variable amount of the Y chromosome translocated to the X.\(^\text{168}\) All these patients are SRY positive.\(^\text{169}\) Between 30% to 40% of Xp/Yp interchanges occur between Xp22.3 (PRKX gene) and a region on the Y chromosome (PRKY gene) proximal to the SRY gene.\(^\text{170}\) The PRKX/PRKY genes are 94% homologus, are oriented in the same direction, and encode proteins with an adenosine triphosphate (ATP)-binding domain and a catalytic domain.\(^\text{171}\) The reciprocal translocation (i.e., Xp22.3 Yp31) results in 46,XY females who are SRY negative.\(^\text{172}\) In general, SRY-negative 46,XX males have an increased prevalence of ambiguity of the external genitalia and siblings with true hermaphroditism.\(^\text{173}\) The familial occurrence of 46,XX males and 46,XX true hermaphrodites who are SRY negative suggests the constitutive activation or inactivation of an X-linked or autosomal downstream gene (or genes) in the sex determination and differentiation cascade that is normally regulated by SRY.

Fifteen to 20 percent of females with the complete form of 46,XY gonadal dysgenesis have inactivating mutations in the
single exon SRY gene, an architectural transcription factor. Most of the mutations occur in the DNA-binding domain of the SRY protein (Fig. 22-16), the high-mobility-group (HMG) box that appears to act as a transcription factor and has the capacity of binding to and binding DNA. Rare mutations in the S and Z \( \sigma \) and \( \epsilon \) flanking regions in patients have led to complete and partial gonadal dysgenesis, respectively. The HMG box contains two nuclear localization signals (NLS) that bind calmodulin and importin B. Mutations in these nuclear localization signal domains in the HMG box of SRY result in failure to transport the SRY protein into the nucleus and result in consequent XY gonadal dysgenesis. The evidence in the mouse and in humans with sex reversal strongly support the critical role of SRY in sex determination and male sex differentiation.

The human SRY gene contains no introns and produces a 900-base-pair transcript that encodes a protein of 204 residues with three domains: an amino-terminal domain, a central DNA-binding domain consisting of a single HMG box, and a carboxy-terminal domain. In humans it is expressed in 46,XY gonads coincident with sex cord formation and it persists (unlike the brief expression of Sry in the embryonic mouse Sertoli cell) until at least 18 weeks of gestation in fetal Sertoli cells as well as adult Sertoli and germ cells. Comparison of nucleotide sequences of the SRY gene from different species indicates that only the HMG box is conserved. The HMG box is about an 80-amino acid residue domain that is similar to the DNA-binding domain of over 100 genes. A family of genes referred to as SOX (SRY-like HMG box) genes, exists in which the HMG region exhibits more than 60% sequence homology with that of SRY. The SRY protein binds specifically to the linear consensus DNA sequence 5'-ATGAACT(A/T)-3' and nonspecifically to cruciform (four-way junction) DNA. The SRY/HMG protein is made up of three helices and an extended loop-like domain that encodes a horseshoe shape and presents a concave surface to the DNA for sequence-specific binding. DNA binding occurs in the minor groove of the DNA and results in a bend of 40 to 70 degrees from linearity in the DNA, conforming to the shape of the HMG box. Additional conformational changes in the DNA include helix unwinding and minor groove expansion. The carboxyl terminus of SRY contains a 7-amino acid that can bind PDZ (P, Q, disc large, Zn\(_2\)) domains in the nuclear protein SIP1 (SRY-interacting protein 1). A 41-residue deletion in the carboxyl terminus of SRY resulted in XY gonadal dysgenesis. Furthermore, phosphorylation

SRY has no recognizable trans-activation domain. The control of gene expression by SRY may be mediated by the conformational changes in DNA that result in the approximation of distant regulatory elements of the transcriptional apparatus, thereby allowing them to interact with one another. Analysis of mutations in the HMG box in women with 46,XY gonadal dysgenesis suggests that the spatial rearrangements (bending) in DNA produced by the HMG-domain protein are critical to its activity, as is its bending. Induction of a structural bend in the DNA helix may allow the interaction of other spatially dependent proteins with the DNA. Mutations in the SRY HMG box that affect binding, bending, or nuclear transport of SRY and yet undefined mechanisms can result in the loss of transcriptional activity. The transcriptional activity of SRY has been demonstrated in vitro with the use of FOS-related antigen-1 promoter constructs. However, neither the upstream regulatory genes nor the downstream targets of SRY have been ascertained. The consensus sequence (ATGAACT(A/T)) is ubiquitous in the human genome, occurring at more than 105 sites, which makes it difficult to ascribe specificity to the interaction of SRY with a specific gene based solely on the presence of the consensus sequence in its promoter. The target gene is expressed in pre-Sertoli cells in temporal relationship to SRY protein and is directly transactivated by it. Because of the lack of an apparent strict relation between the absence of SRY and testicular development in some 46,XX males and 46,XX true hermaphrodites, McEreavy and associates proposed that the main function of SRY is to repress a putative gene termed “Z” that itself represses differentiation of the testis. At least four cellular roles for SRY protein have been defined. They include (1) the induction of Sertoli cell differentiation, (2) the migration of mesonephric cells into the genital ridge, (3) the proliferation of cells in the genital ridge, and (4) male-specific vasculature with recruitment of a large number of endothelial cells from the mesonephros. However, as noted previously, in spite of more than 10 years of research on the SRY gene as yet we remain uncertain of its upstream regulators or downstream target genes. The strongest contenders are the downstream autosomal gene SOX9 (see later) and upstream WTX (KTSW) isoform.

In sum, the evolutionary conserved HMG domain of SRY protein seems the only component essential for function. The only candidate downstream gene for SRY, at present, is the activation of SOX9. Finally, Graves has challenged the conventional wisdom that the SRY is the ultimate and all-powerful male determiner. She points out that Sry is an “ephemeral gene” recruited recently from a transcription factor possibly involved in brain development, is younger than the Y chromosome, and whose structure and function in evolutionary terms has evolved relatively rapidly. Graves estimates that the human Y chromosome and its SRY gene might only last another 5 to 10 million years.

Autosomal and X Chromosomal Genes

Other genes on autosomes and the X chromosome participate in the testis determination dosage-sensitive combinatorial network of complex interactions. (Table 22-4). These still incompletely understood, regulatory interactions are more than a linear cascade.

SOX9

Campomelic dysplasia is a severe skeletal malformation syndrome associated with an increased prevalence (75%) of 46,XY gonadal dysgenesis and consequent male to female sex reversal. The campomelic dysplasia and sex reversal locus has been mapped to 17q24.3-25.1, and a gene designated as SOX9 (SOX9-like HMG box) has been cloned from this locus. SOX9 belongs to a family of HMG domain protein transcription factors related to the “testis determining factor” SRY that share very similar HMG box DNA-binding attributes. SOX9, in contrast to SRY, has an intron and a well-defined transcriptional trans-activation domain. The human SOX9 gene from different species indicates that only the HMG box is conserved. Similar to SRY, SOX9 has nuclear localization signal sequences at either end of the HMG box that when mutated can reduce nuclear transport or result in campomelic dysplasia and XY sex reversal. SOX9 is expressed in the kidney, central nervous system, cartilage, chondrogenic precursor cells, and Sertoli cells of the testes. The SOX9 protein HMG box, about 70% homologous to the SRY HMG box, binds to a specific sequence, 5'-AGAACATG-3', in the minor groove of DNA, resulting in unwinding and bending of the DNA in a manner similar to other SOX proteins. Furthermore, SOX9 binds to the 6-base-pair DNA sequences ATGAAT and CACAAT found in the chondrocyte specific enhancer of the first intron of the human type II collagen gene (COL2A1), activating this gene and inducing chondrogenesis. SOX9 is a heterozygous mutation in the SOX9 gene can result in campomelic dysplasia in the absence of sex reversal in 46,XY individuals; chondrogenesis seems more sensitive to SOX9 gene dosage than sex determination. A mouse with haploinsufficiency of SOX9 had defective cartilage development and premature mineralization of cartilage, a phenoctype of the severe skeletal malformations seen in campomelic dysplasia. SOX9 haploinsufficient male mice did not result in XY sex reversal. Notably, lethality in mice with the SOX9 haploinsufficient males were normal. Other features such as micrognathia, cleft palate, respiratory distress, and neonatal death are similar to those in the affected human.

Whereas mutations in the SRY gene occur predominantly in the Y chromosome, they occur throughout the SOX9 gene (see Fig. 22-17). Mutations resulting in campomelic dysplasia and/or XY sex reversal include splice acceptor/donor changes, missense, nonsense, translocation, and frameshift mutations. Two of the major classes of mutations causing campomelic dysplasia and/or XY sex reversal are amino acid substitutions in the SOX9 gene and truncations or frameshifts that affect the carboxy-terminal (trans-activation) domain of SOX9.

SOX9 plays a critical role in the sex-determination pathway in all eutherian vertebrates. It is sexually dimorphically expressed; SOX9 is up-regulated in the testis-determining pathway shortly after SRY is expressed in the mouse as well as human. SOX9 and SRY are both expressed in Sertoli cell precursors and Sertoli cells. Expression of SOX9 is restricted to the nuclei of Sertoli cells after 6.5 weeks of gestation in the human male embryo, whereas its expression remains cytosolic in the XX embryonic gonad. In the XX embryo, SOX9 is not expressed in the mouse ovary; in the human a low level of expression is described...

copies of the DAX1 gene at this dosage-sensitive sex reversal locus (DSS) impairs testicular differentiation despite a normal-functioning SRY gene. The smallest Xp21 duplication found in an XY sex-reversed patient is a 160-kb region of Xp21 that contains the DAX1 gene. Deletions or intragenic mutations in the DAX1 gene cause X-linked cytomegalic congenital adrenal hypoplasia and hypogonadotropic hypogonadism. SOX9 encodes a transcriptional regulator. The gene consists of two exons separated by an intron. The encoded protein has 410 amino acids and is composed of a

46,XY individuals with duplications of the Xp21 region of the short arm of the X chromosome have dysgenetic gonads and male-to-female sex reversal. The presence of two active
SRY, binds to heat shock protein 70 (Hsp70) and has a trans-activation domain at the carboxy-terminal end. Selected mutations causing sex reversal and campomelic dysplasia are indicated by the solid circles, those causing only campomelia are indicated by the open triangles, whereas SRY mutations occur primarily on the HMG box. SOX9 mutations appear to occur throughout the gene.

carboxy-terminal half that is similar to the ligand-binding region of other nuclear receptors. A ligand for this orphan nuclear receptor has not been identified. The DAX1 protein has a unique DNA-binding domain that consists of three repeats of a novel amino acid sequence between amino acids 1 and 199 with another partial repeat extending into the ligand-binding region. Evidence indicates that DAX1 participates in a highly complex transcriptional network; DAX1 appears to act primarily as a transcriptional repressor either by binding to DNA hairpins in promoters through a direct effect on transcription targets or by the recruitment of co-repressor proteins. DAX1 is expressed in temporal conjuction with steroidogenic factor 1 (SF1) in the developing hypothalamus, pituitary, adrenal, and gonads. The evidence that DAX1/SF1 (lower case = mouse homologue) is the DSS gene has been demonstrated by studies in mice. DAX1/SF1 is expressed in Sertoli cells of the developing gonad along with other important testsis-determining factors such as WT1/Wt1, Sf1/Sf1, Sox9/Sox9, and Sry/Sry. A high dosage of Dax1 in transgenic mice retards the development of the embryonic tests in the mouse strain Postivusinus, which has a weak Sry allele, and causes complete female development in the mouse strain Tuxedo. These observations support the hypothesis that (1) the normally developing ovary in normal DAX1 mutation in a human female and in the XX Dax1 knockout mouse, (2) the normal testis determines in males with WT1 mutation, and (3) the XXY sex reversal in patients with a double dose of DAX1 indicate that the DAX1 gene is not critical for either ovarian or testicular differentiation but a double dose of DAX1 acts as an anti-testsis gene and leads to dosage-sensitive sex reversal in the affected genetic XY individual and female external genitalia.

WT1

The Wilms tumor suppressor gene (WT1) was first isolated from chromosome 11p13 because of its association with the contiguous gene deletion syndrome WAGR (Wilms tumor, Aniridia, Genitourinary anomalies, and mental Retardation). The gene WT1 encodes a transcription factor with four carboxy-terminal zinc finger DNA-binding domains and an amino-terminal proline/glutamine-rich regulatory region. WT1 contains 10 exons, including two alternative splice sites in exons 5 and 7 that can give rise to as many as 24 isoforms by means of alternative splicing, alternative translation start sites, and RNA editing. The major isoforms produced exist in a constant ratio; they are the result of alternative splicing of exon 5, with the insertion of a 17-amino acid segment encoded by exon 5 in the middle of the protein and the use of an alternative splice donor site at the end of exon 5, resulting in the insertion of three amino acids, lysine-threonine-serine (+KTS), between zinc finger 3 and 4. This +KTS isoforms affect DNA binding and RNA processing, whereas -KTS isoforms appear to act mainly as regulators of transcription. In vivo and in vitro studies suggest that WT1 acts as both a transcriptional activator and repressor. WT1 (+KTS) up-regulates SRY; two consensus sites for the binding of WT1 are present in the SRY promoter. In addition, there is temporal overlapping in the expression of WT1 and SRY in the human fetal XY gonad. WT1/WT1 is expressed in fetal renal mesenchyme, in the primordial gonads (i.e., the mouse genital ridge at 9 days post coitus), in the Sertoli cells of the developing seminiferous tubules, and in adult Sertoli and granulosa cells. Its critical role in sex determination and differentiation can be seen from studies in mice as well as humans. Knockout of the WT1 gene in mice results in the absence of gonads and kidneys in both male and female mice.

Only 10% to 15% of Wilms' tumors have a WT1 mutation, but two syndromes the Denys-Drash and Frasier are associated with a dysfunctional WT1 gene. The Denys-Drash syndrome, characterized by Wilms tumor, severe renal disease due to mesangial sclerosis, and dysgenetic gonads, which in the affected male leads to ambiguous genitalia. is caused most commonly by a heterozygous point mutation in the exons that encode the zinc finger motifs resulting in the expression of a dominant-negative protein that inhibits the function of the WT1 protein encoded by the normal gene on the opposite allele. The Frasier syndrome, a variant characterized by the XY complete gonadal dysgenesis resulting in sex reversal, late-onset glomerulopathy, foot deformities, and prenatal growth retardation, is also associated with the expression of a dominant-negative WT1. WT1 is a mediator of the testicular differentiation at the donor splice site of intron 9 of the WT1 gene, which results in a decrease in the ratio of +KTS/−KTS isoforms. The observations suggest that Denys-Drash and Frasier syndromes are part of a continuous spectrum rather than separate entities. Patients with isolated genital anomalies alone rarely have WT1 mutations.

SF1

Steroidogenic factor 1 (SF1), an orphan nuclear receptor, was first identified as a transcriptional regulatory element that interacted with the promoter elements in the proximal regions of several steroid (cytochrome P450) hydroxylases. Because it was initially discovered in steroidogenic cells, it was named steroidogenic factor 1 (SF1) or adrenal 4-binding protein (Ad4BP). SF1 is a homologue of the Drosophila fushi tarazu factor 1 (FTZ-F1). The SF1 gene is located on chromosome 9p33. SF1 has two zinc finger motifs with a DNA-binding domain in its amino-terminal region and a lig-and-binding domain at its carboxy-terminal end (Fig. 1-18). At the carboxy-terminal end of the DNA-binding domain an 8-amino acid residues (the A box) recognizes specific nucleotides 5' to the DNA response element AGGTCA of the target gene. SF1 has a carboxy-terminal AF-2 trans-activation domain similar to other ligand-inducible nuclear receptors. SF1 is expressed early in the development of the adrenals, gonads, hypothalamus, and pituitary gonadotropes. Its critical role in gonadal and adrenal development was assessed from the SF1 "knockout" mouse, which is born without gonads, resulting in female differentiation in XY males and adrenal aplasia. SF1 "knockout" mice also have impaired pituitary expression of gonadotropins and agenesis of the ventromedial hypothalamic nuclei. SF1 regulates gonadal and adrenal gonadotropinogenesis and the genes encoding the adrenocorticotropic hormone (ACTH) receptor, the steroidogenic acute regulatory protein ( STAR), the luteinizing hormone (LH)-subunit, the -subunit of glycoproteins, the high-density lipoprotein receptor SR-B1, and AMH. Furthermore, SF1/SF1 is a mediator of the development of the adrenals and gonads as well as male sexual differentiation (fetal testicular androgens and AMH) and steroid synthesis in the ovary.

SF1 is expressed at 32 days post ovulation in the gonadal ridge of the human embryo and by 26 days in the embryo. At this stage of the indifferent gonad, expression of SF1 is not sexually dimorphic. After differentiation of the definitive gonad, SF1 expression remains diffusely distributed in the human ovary (in contrast to its striking down-regulation in the mouse ovary). Similar to the mouse, SF1 is widely expressed in the human developing testis and is localized mainly to the Sertoli cells of the developing sex cords of the gonad. During embryonic gestation, SF1 expression is greater over the testis than the sex cord. In the human as well as the mouse, SF1 plays a critical role in gonadal development and function.

SF1 regulates the transcription of a variety of target genes, but unlike many nuclear receptors that bind to DNA as homodimers or heterodimers, SF1 binds specific gene promoters as a monomer. For example, WT1 and SF1 can associate to increase the expression of genes driven by SF1. SF1 bound to a consensus-binding site on Dax1 appears to be necessary for Dax1 expression in the mouse embryonic gonad. Several factors have been identified that regulate SF1 expression, including ubiquitously expressed E-box proteins (upstream regulatory factors 1 and 2) and Sox9. A specific Sox-binding site (AAGACG) is present in the proximal SF1 promoter. Mutations of this site resulted in down-regulation of SF1 promoter activity in embryonic and postnatal Sertoli cells. The interaction of SOX9 and SF1 appears to have a role in the greater expression of SF1 in the fetal testes than in the ovaries in the human and mouse. The complex interactions of these genes proteins, co-localized in Sertoli cells and temporally expressed in relationship to one another, have an important but incompletely understood role in the sex determination and differentiation cascade.

SF1 mutations are rare; three examples are known. The first SF1 mutation was reported in an XY sex-reversed "female" who had primary adrenal insufficiency, persistent müllerian structures, and streak gonads owing to a heterozygous loss of function missense mutation (Gly35Glu) in an amino acid in the first zinc finger of the DNA-binding domain of SF1 (see Fig. 23-18). The features of this patient as predicted in the ninth edition of this chapter, were similar to those of the SF1 "knockout" mouse. A prepubertal XX female with adrenal insufficiency and "putatively" normal ovarian differentiation had a heterozygous mutation, a GT transversion in exon 4 that resulted in Arg255Leu substitution in the ligand-binding region of SF1 and a transcriptionally inactive SF1 protein. A third patient, an infant, had XY sex reversal and adrenal insufficiency owing to a homozygous missense mutation (Arg52Gln) in the A-box of SF1, a region that functions as a secondary response element. In contrast to the other two patients, family members heterozygous for the mutation were asymptomatic. Functional assay expression of this mutation showed partial loss of binding and trans-activation, a less severe than first described heterozygous mutation. This case suggests that,
as with other genes in the sex determination and differentiation cascade, gonadal differentiation and function is highly gene dosage dependent.

**Chromosome 9p and DMRT1**

The human 9p- syndrome is characterized by varying degrees of XY sex reversal, mental retardation, and craniofacial abnormalities. Quite likely it is a contiguous gene syndrome because small terminal deletions of 9p are associated only with XY sex reversal. The proximal boundary of the sex reversal region is 9p24.3, 30 kb upstream from the start of a testis-specific gene DMRT1 (double sex, mab3, related transcription factor 1). DMRT1 encodes a protein homologous to the double sex gene in *Drosophila* and the mab3 gene of *Caenorhabditis elegans*; the latter genes are involved in the sex determination cascade in these organisms. Two other DMRT genes, DMRT3 and DMRT2, have been found proximal to DMRT1 on the short arm of chromosome 9.

DMRT1, 120 kb long, has five exons and encodes a protein of 373 amino acids that is expressed in the human embryonic gonad at 5 to 8 weeks' gestation. A male-specific pattern of expression is present in the genital ridge and the developing Sertoli cells by 7 weeks' gestation. The fact that DMRT1 is conserved across the phylogeny in sex-determining cascades, that it has a male-specific expression in the mouse and human sex determination, and that it is in close proximity to the minimal deleted 9p region, which causes XY sex reversal, make it a strong candidate gene in the human sex determination cascade. Gene dosage appears to be critical: haploinsufficiency of DMRT1 results in sex reversal. No point mutations in this gene have been described as yet in the human. It is of note that gene disruption in the mouse results in normal male development with absent testes postnatally similar to the vanishing testes syndrome in the human, but it had no effect on ovarian development and function. Nonetheless, the role of DMRT1 in ovarian development and function in the human is uncertain. In two 46,XX females with a distal deletion of 9p, Ogata and co-workers found evidence of mild gonadal dysgenesis. Accordingly, DMRT1 has a role in the formation of the indifferent gonad and haploinsufficiency can result in a spectrum of gonadal dysfunction in both males and females.

**Chromosome 10q**

Terminal deletions of chromosome 10q distal to 10q25 are frequently associated with urogenital anomalies, including renal hypoplasia, cryptorchidism, micropenis, hypospadias, hypoplastic labia major, and, rarely, complete XY sex reversal. A candidate gene on distal 10q involved in gonadogenesis, although suspected clinically, has not been identified.

**ATRX**

The -thalassemia mental retardation syndrome is an X-linked disorder characterized by the association of -thalassemia, severe mental retardation, and a variety of developmental anomalies, including genital abnormalities in 80% of affected 46,XY individuals. The ATRX gene (synonyms: XH2, XNF) is located at Xq13.3, spans about 300 kb, contains 35 exons, and undergoes X inactivation. It encodes a calcium-binding protein that is expressed in the early fetal mouse testes. The amino-terminal domain of the ATRX protein contains a zinc finger motif, the central portion has the ATPase and helicase motifs, and in the carboxyl-terminal domain a "P" box involved in transcriptional regulation and a "Q" box is thought to be involved in protein interaction. The spectrum of genital anomalies ranges from undescended testes to hypospadias, micropenis, and varying degrees of XY sex reversal. Mutations in affected males that lead to truncation of ATRX with loss of the carboxyl terminal region (the helicase domain) usually result in genital abnormalities. The spectrum of genital anomalies ranges from undescended testes to hypospadias, micropenis, and varying degrees of XY sex reversal. Mutations in affected males that lead to truncation of ATRX with loss of the carboxyl terminal region (the helicase domain) usually result in genital abnormalities. A mutation in ATRX is associated with XY gonadal dysgenesis, dysmorphic features, and mental retardation similar to those seen in the -thalassemia mental retardation syndrome but with no evidence of -thalassemia.

**Other Genes Involved in Gonadal Determination and Differentiation**

Lhx (LIM1) and 9 are members of a subfamily of homeobox genes involved in developmental processes. Lim homeobox proteins are characterized by two specialized zinc fingers located in the amino-terminal region of the protein followed by a DNA-binding homeobox domain. Lim1, the mouse homologue of human LIM1, is involved in the early stages of gonadal development. It is initially expressed in the intermediate mesoderm and nephrogenic cords. Mice homozygous for targeted deletions of Lim1 fail to develop kidneys, gonads, and anterior head structures. LIM1 mutations have not yet been described in humans but may represent a cause of gonadal agenesis or dysgenesis associated with cranial abnormalities.

Targeted disruption of the Lhx9 gene, which is expressed in the brain, limb buds, and urogenital ridge, leads to gonadal agenesis and no other abnormalities. Because SRY expression is reduced in the sex determination cascade of Lhx9-deficient mice, it has been suggested that Lhx9 may function upstream of SRY in the cascade. The human homologue of Lhx9, maps to chromosome region 1q25-q31 and is expressed at the time of gonad formation. A mutation in LHX9 was not detected in 41 patients with gonadal dysgenesis or dysgenesis including two "sisters." 

Emx2 is a mouse gene homologous to the *Drosophila* empty spiracles (*Em's*) gene involved in head morphogenesis. It is expressed early in the developing urogenital system and sex determination cascade of the mouse. Emx2 null mice have developmental abnormalities of the brain as well as absent kidneys, ureters, gonads, and genital tracts. Emx2 maps to chromosome region 10q26.1, and de novo heterozygous mutations have been found in humans with schizophrenia. However, no genital abnormalities have been observed.

m33, a mouse homologue of the polycomb genes in *Drosophila* may act by modifying higher-order chromatin structure to repress developmentally regulated genes. XY mice with null mutations of this gene exhibit male-to-female sex reversal. Abnormalities in the gonads of m33 mutant XY and XX mice were noted, suggesting that this gene functions early in the sex determination network upstream of SRY.

Desert hedgehog (DHH), a member of the hedgehog family of signaling proteins, which includes sonic hedgehog and Indian hedgehog, is the only known mammalian hedgehog protein expressed in the mouse embryonic gonad in Sertoli cells and the interstitium. DHH and Patched 1, the receptor for DHH, signaling have a critical role in the differentiation of Leydig cells by up-regulating SFR1, which in turn activates cholesterol side-chain cleavage. In mice, in which mutations in mice resulted in feminized 46,XY mice with decreased spermatogenesis. The human homologue, DHH, maps to human chromosome bands 12q12-q13.1. A homoygous mutation in DHH is reported in a 46,XY patient with partial gonadal dysgenesis and a polynuropathy; his "normal" father was heterozygous for this mutation.

Multiple developmental processes are regulated by fibroblast growth factors. The wide expression of Fgf9 prompted targeted deletion experiments in mice. An unexpected finding was sex reversal in homozygous Fgf9 null males, which usually but not always was complete. Fgf9 acts downstream of Sry and is involved in migration of the mesonephric cells into the embryonic testis and in Sertoli cell development. The mutation is lethal owing to severe pulmonary hypoplasia. A defect in Fgf9 signaling in the human is a potential cause of XY gonadal dysgenesis and sex reversal.

The felsalinC gene encodes a calcium-binding protein that is expressed in the early fetal mouse testes. Testatin, a cystatin-related gene, is expressed in fetal gonads and adult testes in a pattern similar to Sox9. A role, if any, of these two genes in human gonadogenesis is not known.
Genes and Ovarian Organogenesis

As early as 1958, it was suggested that two intact X chromosomes are required in the human for differentiation of the indifferent gonad into a normal functional ovary, in contrast to the mouse and some other mammals, in which an XO sex chromosome constitution does not prevent the development of a fertile ovary (although it leads to accelerated atresia of ovarian follicles). In 45,X individuals and in those with deletions of the short (Xp) or long (Xq) arm of the X chromosome, ovarian development commences in utero; however, oocytes usually do not survive meiosis, and folliculogenesis fails to occur or is defective. This results in loss of germ cells, oocyte degeneration, and, secondarily, gonadal dysgenesis (streak gonads). Both X chromosomes appear to be active in the primordial germ cell and oocyte from the onset of meiosis to oulation. In the human the functional integrity of genes on both X chromosomes is necessary for maintenance but not organogenesis of the ovary. The occurrence of familial 46,XX gonadal dysgenesis, which is transmitted as an autosomal recessive trait, suggests that autosomal genes, expressed through direct or indirect actions on the germ cell, are essential for ovarian organogenesis. A homozygous inactivating mutation in the gene encoding the follicle-stimulating hormone (FSH) receptor leads to ovarian dysgenesis and hypergonadotropic hypogonadism in family cohorts, as reported in Finland [see Chap. 24]. Other possible causes of familial 46,XX gonadal dysgenesis include a mutant autosomal gene that leads to a defect in development of the rete ovarii or in the synthesis or action of the putative meiosis stimulating factor.

In contrast to testis determination, there is a paucity of knowledge about confirmed and candidate genes involved in ovarian determination. Whereas DAX1 is an anti-testes gene, it does not have a critical role in ovarian differentiation. The WNT7A family of genes has been implicated in the development of ovaries. Wnt4, Wnt7a, and Wnt5a

Wnt4 is a member of a large family of WNT signaling glycoprotein molecules (WNT stands for wingless-type mouse mammary tumor virus integration site); their expression pattern during embryogenesis suggests that they are involved in determination of cell fates, cell-cell communication, and cellular proliferation. Wnt4 expression is maintained in the ovary, whereas Wnt7a is expressed in the genital primordium of the mouse from 10.5 to 14.5 days post conception and thereafter in the mesenchyme of the genital tract. Wnt5a is expressed in the genital primordium of the mouse from 10.5 to 14.5 days post conception and thereafter in the mesenchyme of the genital tract. Wnt5a mutant mice have a defective genital tubercle and lack external genitalia. Humans with mutations in WNT7A or WNT5A have not been described as yet. However, these genes play an important role in müllerian duct and clitoral/penile development in the mouse. Another candidate gene for ovarian determination and function, FOXL2, the winged helix/forkhead transcription factor maps to chromosome 3q23. Patients with blepharophimosis/ptosis/epicanthus inversus (BPE) syndrome have ovarian failure, which varies from streak gonads with no function to premature ovarian failure, and have a mutation that results in haploinsufficiency of FOXL2 expression. The polled intersex syndrome (PIS) in goats consists of a null mutant of Sry which leads to testis development in an XY female. In both sexes mutants fail to develop müllerian ducts and this occurs before AMH is active in regression of müllerian ducts in the male. The Wolffian ducts are stabilized in the female null mutant because of differentiation of Leydig-like interstitial cells in the ovary; the external genitalia, however, are not masculinized. Wnt4 is required for initial müllerian duct development in both sexes, and in the female to suppress Leydig cell differentiation in the ovary.

Another member of the WNT family, Wnt7a is required for complete differentiation of the müllerian ducts into the uterus, fallopian tubes, and upper part of the vagina, possibly by signaling through epithelial-mesenchymal interactions. Mutant male mice have persistent müllerian ducts and are infertile; mutant female mice develop functional ovaries but are sterile because of abnormal development of the oviducts and uterus. The abnormal development of the müllerian structures has similarities to that observed in the offspring of women treated with diethylstilbestrol during pregnancy.

Wnt5a is expressed in the genital primordium of the mouse from 10.5 to 14.5 days post conception and thereafter in the mesenchyme of the genital tract. Wnt5a mutant mice have a defective genital tubercle and lack external genitalia. Humans with mutations in WNT7A or WNT5A have not been described as yet. However, these genes play an important role in müllerian duct and clitoral/penile development in the mouse. Another candidate gene for ovarian determination and function, FOXL2, the winged helix/forkhead transcription factor maps to chromosome 3q23. Patients with blepharophimosis/ptosis/epicanthus inversus (BPE) syndrome have ovarian failure, which varies from streak gonads with no function to premature ovarian failure, and have a mutation that results in haploinsufficiency of FOXL2 expression. The polled intersex syndrome (PIS) in goats consists of a null mutant of Sry which leads to testis development in an XY female. In both sexes mutants fail to develop müllerian ducts and this occurs before AMH is active in regression of müllerian ducts in the male. The Wolffian ducts are stabilized in the female null mutant because of differentiation of Leydig-like interstitial cells in the ovary; the external genitalia, however, are not masculinized. Wnt4 is required for initial müllerian duct development in both sexes, and in the female to suppress Leydig cell differentiation in the ovary.

Wnt4 is an essential signal in ovarian development and function.

Another member of the WNT family, Wnt7a is required for complete differentiation of the müllerian ducts into the uterus, fallopian tubes, and upper part of the vagina, possibly by signaling through epithelial-mesenchymal interactions. Mutant male mice have persistent müllerian ducts and are infertile; mutant female mice develop functional ovaries but are sterile because of abnormal development of the oviducts and uterus. The abnormal development of the müllerian structures has similarities to that observed in the offspring of women treated with diethylstilbestrol during pregnancy.

Wnt5a is expressed in the genital primordium of the mouse from 10.5 to 14.5 days post conception and thereafter in the mesenchyme of the genital tract. Wnt5a mutant mice have a defective genital tubercle and lack external genitalia. Humans with mutations in WNT7A or WNT5A have not been described as yet. However, these genes play an important role in müllerian duct and clitoral/penile development in the mouse. Another candidate gene for ovarian determination and function, FOXL2, the winged helix/forkhead transcription factor maps to chromosome 3q23. Patients with blepharophimosis/ptosis/epicanthus inversus (BPE) syndrome have ovarian failure, which varies from streak gonads with no function to premature ovarian failure, and have a mutation that results in haploinsufficiency of FOXL2 expression. The polled intersex syndrome (PIS) in goats consists of a null mutant of Sry which leads to testis development in an XY female. In both sexes mutants fail to develop müllerian ducts and this occurs before AMH is active in regression of müllerian ducts in the male. The Wolffian ducts are stabilized in the female null mutant because of differentiation of Leydig-like interstitial cells in the ovary; the external genitalia, however, are not masculinized. Wnt4 is required for initial müllerian duct development in both sexes, and in the female to suppress Leydig cell differentiation in the ovary.

The expression of Wnt4 is similar to Dax1, both persisting in the ovary during fetal development. Overexpression of Dax1 in some human sex-reversed XY females with a Xp21 duplication suggests that Wnt4 may function in a similar manner as an anti-testis gene. The human WNT4 gene is in chromosome 1p35. An XY female had duplication of 1p31-p35 and over-expression of WNT7A. The mechanism of sex reversal due, at least in part, to WNT4 induced up-regulation of DAX1. The sexually dimorphic expression of WNT7A in the human, as well as the occurrence in the Wnt4 null mice of structurally and functionally masculinized ovaries, suggests that WNT4 is an essential signal in ovarian development and function.

Another member of the WNT family, Wnt7a is required for complete differentiation of the müllerian ducts into the uterus, fallopian tubes, and upper part of the vagina, possibly by signaling through epithelial-mesenchymal interactions. Mutant male mice have persistent müllerian ducts and are infertile; mutant female mice develop functional ovaries but are sterile because of abnormal development of the oviducts and uterus. The abnormal development of the müllerian structures has similarities to that observed in the offspring of women treated with diethylstilbestrol during pregnancy.

Wnt5a is expressed in the genital primordium of the mouse from 10.5 to 14.5 days post conception and thereafter in the mesenchyme of the genital tract. Wnt5a mutant mice have a defective genital tubercle and lack external genitalia. Humans with mutations in WNT7A or WNT5A have not been described as yet. However, these genes play an important role in müllerian duct and clitoral/penile development in the mouse. Another candidate gene for ovarian determination and function, FOXL2, the winged helix/forkhead transcription factor maps to chromosome 3q23. Patients with blepharophimosis/ptosis/epicanthus inversus (BPE) syndrome have ovarian failure, which varies from streak gonads with no function to premature ovarian failure, and have a mutation that results in haploinsufficiency of FOXL2 expression. The polled intersex syndrome (PIS) in goats consists of a null mutant of Sry which leads to testis development in an XY female. In both sexes mutants fail to develop müllerian ducts and this occurs before AMH is active in regression of müllerian ducts in the male. The Wolffian ducts are stabilized in the female null mutant because of differentiation of Leydig-like interstitial cells in the ovary; the external genitalia, however, are not masculinized. Wnt4 is required for initial müllerian duct development in both sexes, and in the female to suppress Leydig cell differentiation in the ovary.

Wnt4 is an essential signal in ovarian development and function.
Gametogenesis

Origin of Primordial Germ Cells

In humans as well as mice, primordial germ cells, the progenitors of the male and female gametes, originate from pluripotential cells in the epiblast. The specification of mammalian germ cells from proximal epiblast cells involves the action of at least three "bone morphogenetic factors": Bmp2, Bmp4, and Bmp8b and Oct4 and Cdx2. These "bone morphogenetic factors" are members of the transforming growth factor- superfamily, which act through the transcription factors Smad-a and Smad-b, whose targets are not yet known. In the 24-day-old human embryo, the differentiated germ cells recognized by their histologic appearance and the presence of alkaline phosphatase are located in the dorsal endoderm of the yolk sac close to the allantoic evagination. From this site, the cells increasing in number by mitosis, migrate during the fourth and fifth weeks of gestation in contact with each other through cell-cell and cell-matrix adhesive molecules to the hindgut and then through the dorsal mesentery to the genital ridge. In the absence of primordial germ cells, the gonad ridges in the female remain undeveloped. In contrast, germ cells are not required for the differentiation of a testis. Germ cells that fail to reach the gonads by the time of sex differentiation usually disappear, although they may persist outside the gonad and give rise to germ cell neoplasms.

Spermatogenesis

During early testicular differentiation the primordial germ cells become distributed throughout the primitive seminiferous tubules as progenitors of spermatagonia. A series of mitotic divisions occurs, followed thereafter by inhibition of entry into meiotic prophase presumably by a putative local factor secreted by Sertoli cells until the transient postnatal increase in mitosis, and later the initiation of full spermatogenesis late in the prepubescent period. Furthermore, it appears that both male and female germ cells are programmed to enter meiosis unless they are inhibited by a putative signal from the testicular somatic cells. With the onset of puberty, the basement membrane of the spermatogenic tubule becomes lined by proliferating spermatogonia that arise by the mitotic division of the spermatogonia. A glial cell line neutrophilic factor (GDNF) secreted by Sertoli cells appears to play a role in the proliferation and differentiation of spermatogonia.

Figure 22-20 Types of cell division. A female somatic cell undergoing mitosis is represented. At the metaphase plate are two X chromosomes and two homologous autosomes of group 21 to 22. Division occurs through the centromere, giving rise to two daughter cells of identical chromosomal composition. Replication of each arm into two chromatids takes place while the chromosomes are extended and before the next metaphase. The first meiotic division involves pairing of homologous chromosomes. The centromere does not divide in this cell division. It is by chance whether the maternal (X0) or paternal (X0) member of each pair goes to the respective daughter cells. During the complex prophase of first meiotic division, multiple exchanges are formed between the chromosomes of each pair, facilitating exchanges of chromosomal segments (crossing-over) between them. During the second meiotic division, the centromere again divides, giving rise to daughter cells identical to the parent cell. This division more nearly resembles mitosis than the first meiotic division. Nondisjunction can take place in mitosis or in the first or second meiotic division; representative examples are illustrated.

adult male are continually being renewed and undergoing maturation. Heller and Clermont estimated that the complete cycle in adult males from spermatagonium to mature sperm requires 74 ± 5 days.

The X chromosome undergoes inactivation in pachytene spermatocytes during meiosis. The condensed sex chromosomes form a sex vesicle or XY body. XY pairing must occur during normal meiosis. X inactivation may be involved in the heterochromatinization of those regions of the X chromosome that are similar to but not homologous to regions on the Y chromosome.

Oogenesis

Female germ cells pursue a different course. During ovarian differentiation, the primary germ cells undergo vigorous mitotic replication and successive differentiation
into oogonia. When mitotic division ceases and the cells enter meiosis, they are then termed oocytes. Meiotic oocytes are critical for differentiation of pre-follicular cells into follicular cells. The absence or loss of meiotic oocytes leads to degeneration of the prefollicular cells. The period of oogonial proliferation results in a peak population of about 6 million to 7 million germ cells in the two ovaries at 5 months' gestational age, including oogonia, oocytes in various stages of prophase, and degenerating oocytes. Oocytes degenerate at different stages of meiosis. Only 5% of the peak number of germ cells in the fetal ovary reach the diplotene stage. Formation of oogonia from primary germ cells ceases by the seventh month of gestation. Some oocytes remain in undifferentiated nests, whereas others form primordial follicles. A primordial follicle is formed when presumptive granulosa cells surround the diplotene (meiotic) oocyte and an intact basal lamina encloses this unit. If the oocyte is not enclosed in a follicle, it degenerates. The number of primordial follicles in the ovary is maximal at birth, and the number thereafter diminishes. In the germ cells that survive, the oocyte is arrested at late prophase of the first meiotic division (diplotene state). Oocytes remain in the prophase of the first meiotic division from fetal life until puberty when some unknown stimulus allows them to progress and eventually ovulation occurs. Before ovulation, the first polar body is extruded, thus completing the first meiotic division. The haploid secondary oocyte immediately begins a second meiotic division but remains in metaphase and does not extrude the second polar body until the ovum is penetrated by a sperm. The triploidy that is common in spontaneously aborted fetuses may be caused either by failure of extrusion of the second polar body (polygyny) or by double fertilization (polyspermy). The long life span of female germ cells, in contrast to those of the male, may explain the increased prevalence of certain chromosomal anomalies with advanced maternal age (see section on aneuploidy).
The gonads of both sexes develop from anlagen located on the mesodermal border of the urogenital ridge, adjacent to the kidney and the primitive adrenal. Until the 12-mm stage (approximately 42 days of gestation), the gonads of the male and female are indistinguishable on morphologic grounds and could potentially differentiate either as testes or as ovaries. The close ontogenic and anatomic relation between gonadal and adrenal cells at this early stage is noteworthy, because, as differentiation proceeds, nests of adrenal cells frequently separate with the gonad and are found as adrenal rests in the hilum of the mature ovary or testis. Such rests may become a problem in patients with long-standing untreated congenital adrenal hyperplasia (CAH). Adrenal cell rests in testes, for example, may enlarge under persistent corticotropin (ACTH, adrenocorticotropic) stimulation and be mistaken for testicular tumors or true testicular enlargement (see Chap. 24).

The primitive undifferentiated gonad is made up of four cell lineages, germ cells, connective tissue cells, steroid-producing cells, and supporting cells. They are derived from proliferation of the mesodermal coelomic epithelium, the mesenchymal cell mass in the urogenital ridge, mesonephric elements, and the large alkanine phosphatase-containing primordial germ cells that have migrated from the posterior endoderm of the yolk sac through the mesenchyme of the mesentery to the gonad. According to Witschi and co-workers, the number of migrating germ cells in the human embryo is 700 to 1300, and by the eighth week of embryogenesis about 600,000 germ cells are present, which later become either oogonia or spermatogonia. Lack of germ cells is incompatible with ovarian differentiation but does not prevent testicular morphogenesis. However, in the mouse, genes such as the (S1) gene, which encodes a peptide growth factor (SCF, stem cell factor), the proto-oncogene c-kit (also known as white spotting [W]), which encodes a tyrosine kinase receptor in the plasma cell membrane (a receptor for S1), and caderins affect the proliferation, mobility, and migration of primordial germ cells to the urogenital ridge. SCF, in its transmembrane second form, is expressed in human Sertoli cells and acts as an adhesion protein, binding germ cells. The precursor of the Sertoli cell of the testis and its counterpart in the ovary, the granulosa cell, originate from the coelomic epithelium.

There is a striking sexual dimorphism in the timing of gonadal differentiation. Under the influence of the testis-determining genes, testis organization begins at about 45 days of gestation (6 to 7 wk); the testis develops more rapidly than the ovary. The ovary does not emerge from the indifferent stage until 3 months of gestation, when the earliest sign appears: the beginning of meiosis, as evidenced by the maturation of oogonia into oocytes.

In the past it was believed that the testis is derived primarily from the medullary portion of the primitive gonad and the ovary from the cortical portion. According to this concept, the testis and ovary are not strictly homologous. Witschi and co-workers suggested that in genetic males the medullary portion secretes an inductor substance that stimulates development of seminiferous tubules and inhibits cortical development; conversely, the cortex of genetic females, the coelomic epithelium, was thought to secrete an inductor substance that inhibits testicular development and results in ovarian dominance. The proposal was that the differentiation of the primordial gonad was regionalized. Jost and co-workers, among others, called into question the histologic descriptions of gonadal differentiation that served as the basis for these theories. After careful examination of early embryos, Jost and Jirasek concluded that it is not possible to identify primary sex cords as such before the 15-mm stage and that the primitive gonad is truly bipotential. At about 45 days morphologic sex dimorphism is evident in the intermediate mesoderm of the genital ridge when epithelial cords derived from the coelomic epithelium, the gonadal blastema including stromal cells of mesonephric origin, and the primordial germ cells, antecedents of the seminiferous tubules, are apparent in the male. The onset of testicular differentiation is marked by the EN/dependent differentiation of the Sertoli cell, the first cell type to differentiate, and by the subsequent incorporation of the germ cells into the primitive seminiferous cords, when the germ cells of the gonad are suppressed and differentiation is arrested at the primitive spermatogenital stage. The XY gonadal somatic cells essentially block the development of primordial germ cell (pre-spermatogonia) from advancing to meiotic prophase (a cardinal feature of oocyte differentiation) and promote their spermatogonial differentiation.

While the somatic cells of the primordial gonad are bipotential, SRY expression directs the delaminated and proliferating somatic cells derived from the coelomic epithelium to differentiate into Sertoli cells that first cell to differentiate (whether Sertoli cells are derived as well from other progenitors) is not yet resolved. The differentiation of Sertoli cells drives development of the testis. This directed process includes proliferation of the somatic cells, which is more rapid and extensive in the XY gonad than the XX gonad; migration of stromal mesonephric cells and endothelial cells from the adjacent mesonephros into the gonad, which occurs only in XY gonads and is dependent on the expression of SRY; testis cord development and Sertoli cell differentiation, the initiation of which in the mouse, appears to be dependent on the migration of mesonephric cells. The latter include the progenitors of Leydig cells and peritubular myoid cells; and the differentiation of a testis-specific vasculature. The stromal cells migrating from the mesonephros have the capacity to differentiate into peritubular myoid cells and surround the developing testis cords to contribute along with the coelomic epithelium to the differentiation of Leydig cells and the testis-specific architecture. In sum, the developing testis is composed of (1) germ cells, the progenitors of future spermatagonia that migrated into the genital ridge from an extragonadal source; (2) Sertoli cells derived from the coelomic epithelium, which with their envelopment of the primordial germ cells leads to the formation of testicular cords containing (3) peritubular myoid cells of mesonephric origin that surround the testicular cords; and (4) the interstitial Leydig cells, which originate from the mesonephros and coelomic epithelium. This construct is largely derived from lineage tracing, studies in the mouse embryo by Capel and associates that included the use of differentiation and proliferation markers, and in the human, from ultrastructural studies of the early fetal gonad.

Burgoyne and associates proposed from studies of XX:XY chimeric mice that the Sry gene acts autonomously to induce Sertoli cell differentiation, which then mediates further testicular differentiation. After testicular differentiation occurs (at 43 to 50 days' gestational age), the male fetus can also be recognized by beginning regression of the primordial müllerian ducts (30-mm stage, about 60 days' gestation) and by differentiation of male external genitalia (45-mm stage, 65 to 77 days' gestation). An early endocrine function of the testis is the secretion by the Sertoli cells of AMH, a homodimeric glycoprotein that functions as a paracrine secretion; it passes by diffusion to the paired müllerian ducts and induces their dissolution by apoptosis. The versatile Sertoli cell also secretes inhibin, nurtures the germ cells, expresses stem cell factor, synthesizes an androgen-binding protein, and prevents meiosis. Both fetal Sertoli and germ cells exhibit apoptosis as well as proliferation during gestation.

Leydig cells are first found in 32- to 35-mm fetuses (about 60 days' gestation). After differentiation of the primitive testicular cords, they rapidly proliferate during the third month and the first half of the fourth month; during this period the interstitial spaces between the seminiferous tubules are crowded with Leydig cells. The onset of testosterone biosynthesis occurs at about 9 weeks. Human chorionic gonadotropin/luteinizing hormone (hCG/LH) receptors are present.
critical period of male sex differentiation, but whether testosterone synthesis at its onset is HCG dependent is unclear. The question of whether HCG is required to initiate testosterone secretion in the human is complicated further by the presence of HCG-like material in the fetal testis. The pattern of testosterone secretion early in gestation follows that of HCG. The number of Leydig cells decreases after 18 weeks, by apoptosis and by dedifferentiation, and few cells show Leydig cell characteristics in the interstitium of the testis at birth. However, a low level of testosterone secretion is maintained after 15 weeks of gestation under the control of fetal pituitary LH and HCG. Fetal pituitary LH is necessary for the normal growth of the differentiated penis and scrotum during the latter half of gestation and for the descent of the testes. The male fetus with anencephaly or congenital hypopituitarism often has hypoplastic male external genitalia and undescended testes containing a decreased number of Leydig cells. Fetal Leydig cells differ from adult Leydig cells in their morphology, their regulatory mechanisms, and their lack of desensitization to high doses of HCG and LH.

Figure 22-22 correlates the pattern of testosterone, HCG, and fetal pituitary FSH and LH concentrations during gestation with the histologic changes in the fetal testis. In surm, organogenesis of the testis involves successive differentiation of the Sertoli cell and the seminiferous cords with envelopment of the extragonadally derived germ cells by Sertoli cells, development of the tunica albuginea, appearance of Leydig cells, and differentiation of the mesonephric tubules into the ductuli efferentes, which connect the seminiferous tubules and rete network with the epididymis to provide the pathway for sperm transport into the ejaculatory duct system.

Ovary

In the absence of testis-determining genes, the gonadal primordium has an inherent tendency to develop as an ovary, provided that germ cells are present and survive. The indifferent stage persists in the female fetus weeks after testis organogenesis begins. There is, however, continued proliferation of the coelomic epithelium and primordial germ cells, which gradually enlarge and become oogonia. Despite the discordance in the histologic appearance of the primordial testis and ovary, George and Wilson noted the simultaneous development at 8 weeks of gestation of the capacity of the fetal testis to synthesize testosterone and of the fetal “ovary” to synthesize estradiol when incubated with C19-steroid precursors. In contrast to the fetal adrenal gland, the gonads of both male and female fetuses have 3-hydroxysteroid dehydrogenase 2 (3-HSD) activity at this stage; however, the activity of this enzyme is more than 50-fold greater in the fetal testis. Testosterone is synthesized by the fetal Leydig cell, but the site of the meager synthesis of estradiol in the primordial ovary is not known. Gongos and Hobet identified interstitial cells in the ovarian primordium at about 12 weeks of gestation that have the ultrastructural characteristics of steroidogenic cells and that may be a site of estrogen synthesis. The human fetus is bathed in estrogens of placental origin, but the fetal ovary does not contribute significantly to circulating estrogens, which in the fetus are almost exclusively of placental origin. The ovary has no documented role in differentiation of the female genital tract.

During the ninth week the rete ovarii arise from the hilar mesonephric tubules and infract the gonad as a syncytium of tubules and cords. At about the 11th to 12th week (80-mm stage), long after differentiation of the testis in the male fetus, germ cells in the ovary begin to enter meiotic prophase, which characterizes the transition of oogonia into oocytes and marks the onset of ovarian differentiation. The oogonia in the central part of the ovary are the first to come in contact with the rete ovarii and the first to enter meiosis but not beyond the diplotene phase. According to Byuskov, the rete secretes a meiosis-inducing substance; meiosis activity steroid (MAS), a precursor of cholesterol, is suggested as the factor initiating meiosis in the fetal ovary. The initial stages of ovarian organogenesis and the formation of primordial follicles do not involve placental or fetal pituitary gonadotropins or their receptors (see reference ). After the diplotene stage, the first meiotic division stops and the chromosomes enter a resting stage until meiosis is completed just before ovulation in the adult. The formation of primordial follicles (in which the oocyte is enveloped by a single layer of flat granulosa cells that share a common lineage with Sertoli cells) reaches a maximum during the 20th to the 25th week of gestation. In contrast to the fetal testis, FSH and LH/HCG receptors are not detected in the human fetal ovary between 8 and 16 weeks’ gestation; the fetal ovary becomes responsive to FSH stimulation later in gestation (see reference ).

The growth, development, and maintenance of follicles appear to be regulated in late gestation by fetal pituitary gonadotropins, mainly FSH. The sequence and timing of events in gonadal organogenesis and their relation to the differentiation of male and female somatic sexual characteristics are shown in Figure 22-24.
Differentiation of the Genital Ducts

At the seventh week of intrauterine life, the fetus is equipped with both male and female genital ducts derived from the mesonephros. The müllerian ducts serve as the analog of the uterus and fallopian tubes, whereas the mesonephric or wolffian ducts have the potential to differentiate further into the epididymis, vas deferens (ejaculatory ducts of the male), and seminal vesicles. During the third fetal month, either the müllerian or wolffian ducts complete their development, and involution occurs simultaneously in the opposite structures (Fig. 22-25).

Jost and Josso and associates demonstrated that secretions from the fetal testis play a decisive role in determining the direction of genital duct development. In the presence of functional testes, the müllerian structures involute and undergo programmed cell death and the wolffian ducts complete their development; in the absence of testes, the wolffian ducts do not develop and the müllerian structures differentiate (Fig. 22-26). The regression of the müllerian ducts and the stabilization and differentiation of the wolffian ducts are mediated by different secretions of the fetal testes: the glycoprotein AMH secreted by the fetal Sertoli cells, and the steroid testosterone synthesized by the fetal Leydig cells.

Female development is not contingent on the presence of an ovary, because development of the uterus and tubes occurs if no gonad is present. However, the müllerian duct (paramesonephric duct) fails to differentiate in the absence of the mesonephric ducts, which serve as the anlage for both the male urogenital tract and the metanephros (primordial kidney); and therefore renal aplasia is commonly associated with hypoplasia of the fallopian tubes and uterus and vaginal agenesis.

The influence of the fetal testis on duct development is exerted locally and unilaterally; if one testis is removed at an early stage of development, the oviduct develops normally on that side but müllerian regression occurs on the side of the intact testis.

Systemic administration of androgen to an early embryo does not cause regression of müllerian structures. Even when large amounts of androgen are implanted locally in the gonadal region of female fetuses, the müllerian ducts do not atrophy, although the differentiation of the wolffian ducts is stimulated. On the other hand, if a testis is grafted onto an ovary, müllerian regression and wolffian stimulation occur on that side (see Fig. 22-26). For these reasons, Jost proposed that the fetal testis secretes a müllerian duct inhibiting substance that is distinct from ordinary androgens.

Jost and co-workers and Josso and associates studied the influence of the fetal testis on müllerian duct inhibition in organ culture. Direct contact between the testis and the müllerian anlage was not necessary to bring about this inhibition. By separating the testis from the müllerian ducts with dialysis membranes, they concluded that the material secreted from the testis was a protein and not a steroid. They also demonstrated that the human fetal testis, regardless of age, inhibits the müllerian ducts of 14.5-day-old fetal rats in similar organ culture studies and that AMH activity is present in human testes until 8 to 10 years of age.

Using bovine fetal testes in which tubules and interstitial tissue were isolated and assayed separately, they showed that AMH activity is derived from the Sertoli cell, with peak levels occurring at the time of müllerian duct regression (9 to 12 weeks). Thereafter, the levels remain high until birth, after which a steady decline occurs until the pubertal period.

The decline (but not disappearance) in AMH levels observed at puberty in males has been attributed to various factors that include testosterone secretion, meiotic entry, and terminal maturation of the Sertoli cells. AMH is present in the ovarian follicle and is synthesized and secreted by the granulosa cells, but only after birth; whereas plasma concentrations are low in childhood, they increase at puberty. Elevated serum levels of AMH occur in patients with granulosa cell tumors.

AMH secretion by the postnatal ovary does not affect the fallopian tubes and the uterus, because they are apparently insensitive to AMH after 9 to 12 weeks of gestation, the period during which müllerian duct regression usually occurs.

In the freemartin the fetal ovary and the müllerian structures are exposed to AMH before the refractory period. AMH secreted by the fetal Sertoli cells of the male twin passes by means of placental vascular anastomoses to the female twin and results in müllerian regression, ovarian inhibition with loss of germ cells, tunica albuginea formation, and development of seminiferous tubule-like cords.

Studies show that transgenic female mice that persistently express the human AMH gene resemble the bovine freemartin. The AMH transgenic female mice lack müllerian derivatives, and at birth the ovaries have fewer germ cells than normal. During the first 2 weeks of life germ cells are lost, and the somatic cells become organized into seminiferous tubule-like structures that do not persist to adulthood.

In the transgenic male mice, sex differentiation is usually normal, although some males, those that express the highest AMH levels, have incomplete virilization of the external genitalia, incomplete wolffian duct development, and undescended testes secondary to the effect of AMH on Leydig cell maturation and steroid synthesis.

The relevance of these studies to normal sex differentiation is unclear, because the levels of AMH and its continuous secretion are different from those in the normal mouse fetus. Gene knockout of Amh produced normal male mice with normal müllerian duct derivatives that were fertile, indicating that AMH is not required for normal ovarian function, at least in mice.
In Amh-deficient males, as expected, had persistence of the müllerian derivatives. Ninety percent of the Amh-deficient mice were infertile because of interference by the müllerian duct derivatives with the passage of sperm from the epididymis and vas deferens to the urethra. The testes showed normal spermatogenesis but marked Leydig cell hypoplasia, suggesting that AMH may affect Leydig cell proliferation.

The mechanism of action of AMH includes proteinase activated programmed cell death. It causes a gradient of cranial...
During differentiation of the Wolffian ducts to form the epididymides, vasa deferentia, and seminal vesicles, the Wolffian ducts lack the enzyme 5-reductase, which converts testosterone to dihydrotestosterone (DHT). Experimental data and studies in humans with steroid 5-reductase type-2 deficiency provide additional evidence that testosterone (not DHT) mediates the differentiation of the Wolffian ducts. This is in striking contrast to the urogenital sinus and genital tubercle, which express steroid 5-reductase-2 even before the testis has developed the capacity to synthesize testosterone. DHT mediates the masculinization of the urogenital sinus (including formation of the prostate) and external genitalia. Despite this difference in the action of testosterone and DHT on the primordia of the genital tract, the androgen receptor, at least in the rabbit fetus, is the same in the Wolffian duct and in the anlage of the urogenital sinus and external genitalia.

In patients with ambiguous genitalia, male genital ducts are well differentiated only in those who have functional testes and androgen receptors. Females with CAH do not display Wolffian duct differentiation even though their external genitalia may be highly virilized in utero. Patients with asymmetric gonadal differentiation likewise have asymmetric male duct development that correlates with the degree of testicular differentiation on that side.

If the critical role of the testis in male duct development is to provide a high local concentration of testosterone, male duct development would be expected to be deficient, even though testes are present, in patients with severe defects in steroid biosynthesis (e.g., deficiency of steroidogenic acute regulatory protein [STARD]) and in XY patients whose tissues are unresponsive to testosterone (complete androgen resistance syndrome). The epididymides and vasa deferentia of these patients are generally underdeveloped. However, Wolffian duct remnants (and sometimes fully developed duct derivatives) are observed with 17-hydroxysteroid dehydrogenase 3 deficiency, Leydig cell hypoplasia (hCG/LH unresponsiveness) and, indeed, in some patients with complete androgen resistance. During sex differentiation, testosterone and AMH effect their morphogenetic actions on the underlying mesenchymal cells rather than directly affecting the epithelial cells. Action of the hormone-stimulated mesenchyme on the epithelial cells mediates the morphogenesis of the male ducts and regression of the müllerian ducts.

Furthermore, from animal studies, EGF and GH may also play a role in stabilizing Wolffian duct development.
Differentiation of the External Genitalia and Urogenital Sinus

Origin of the External Genitalia

At the eighth fetal week the external genitalia of both sexes are identical and have the capacity to differentiate in either direction. They consist of a urogenital slit bounded by paired urethral folds and, more laterally, by labioscrotal swellings. The urogenital slit is surmounted by a genital tubercle consisting of corpora cavernosa and glans. The mucosa-lined urethral folds may remain separate, in which case they are called labia minora, or they may fuse to form a corpus spongiosum enclosing a phallic urethra. The fleshy labioscrotal swellings may remain separate to form labia majora or fuse in the midline to form a scrotum and the ventral epididymal covering of the penis. The distinction between a clitoris and a penis is based primarily on size and whether the labia minora fuse to form a corpus spongiosum. The clitoris has two corporeal bodies that are analogous to but smaller than those of the penis. Baskin and colleagues describe in detail the neural innervation and the extensive, pudendal nerve-derived neurovascular network of the fetal clitoris through three-dimensional computer reconstructions. This study has an important bearing on the preservation of sensation and function in the design of clitoral reconstructive surgery.

By the 50-mm crown-rump stage, male and female fetuses can be distinguished by inspection of the external genitalia; in the male, the urethral folds have fused completely in the mid-line to form the cavernous urethra and corpus spongiosum by 12 to 14 weeks of gestation. The penis in the male increases linearly, at about 0.7 mm/week, from 10 weeks to normal term; a 12-fold increase occurs from 0.3 cm at 10 weeks to 3.5 cm at term, a rate of growth about 3.5 times that of the clitoris. The mean stretched length of the penis in full-term infants is 3.5 ± 0.7 cm (SD) and the diameter is 1.1 ± 0.2 cm (SD). The clitoral size in full-term infants is similar in several studies. The mean clitoral length is 0.40 ± 0.012 cm (SD), and the width is 0.033 ± 0.078 cm (SD).

 Origin of the Vagina

The urogenital sinus separates from a common cloaca in early fetal life. There is disagreement about the relative contribution of the müllerian duct and the urogenital sinus to the vagina, but the contact and interaction of the fused müllerian ducts with the urogenital sinus is essential for normal development of the vagina. In normal female development, proliferation of the vesicovaginal septum pushes the vaginal orifice posteriorly so that it acquires a separate external opening; thus no urogenital sinus, as such, is preserved. The lower vagina probably originates from the urogenital sinus. Uroplakins are membrane proteins specific to the urothelial plaque. Examination of human female fetuses of 9 to 18 weeks of gestation showed expression of uroplakins in the urothelium of the urogenital sinus, opening; thus no urogenital sinus, as such, is preserved. The lower vagina probably originates from the urogenital sinus. Uroplakins are membrane proteins specific to the urothelial plaque. Examination of human female fetuses of 9 to 18 weeks of gestation showed expression of uroplakins in the urothelium of the urogenital sinus, including the part that evaginates to form the sinovaginal bulbs. In male development, the vaginal pouch is usually obliterated when the müllerian ducts are resorbed, although a vestigial blind vaginal pouch known as the prostatic utricule can sometimes be demonstrated; it is the site of prostate formation later in development.

The prostate gland and bulbourethral glands of Cowper in the male are outgrowths of the urogenital sinus; their differentiation is mediated by DHT and requires the presence of androgen receptors. In the female, the paraurethral glands of Skene and the vestibular glands of Bartholin have homologous origins.

Mechanism of Androgen Action

The effects of testosterone are varied and tissue specific and reflect the sum of its action and the actions of its conversion products, DHT and estradiol.

It is thought that testosterone and DHT have different roles. The testosterone-receptor complex modulates the secretion of LH by the hypothalamic-pituitary unit and processing of the mRNA, the RNA moves to the cytoplasm, where it is translated by cytoplasmic ribosomes and results in synthesis of new proteins and hence and functional key roles for residues in the androgen receptor by the study of a range of mutations that cause androgen resistance (see later). After transcription and presence of ligand; thus the ligand is internalized and does not reside on the surface of the androgen receptor. Much information has been gained about structural ligand-binding domain that binds to receptor-interacting motifs, LXXLL, in co-regulators (L is leucine, X is any amino acid).

The mechanism of dimerization, nuclear localization signaling, and ligand binding.

In the absence of ligand, steroid hormone receptors (but not the thyroid hormone receptor) are complexed to chaperone proteins that are heat shock proteins and form large receptor complexes. Ligand binding causes a conformational change in the receptor, additional phosphorylation of serine residues located in the amino-terminal trans-activation domain, dissociation of the receptor from heat shock proteins, and "activation" of the receptor.

The monomeric activated steroid-receptor complex is smaller (<45S) than the unactivated complex (>85S). The steroid-receptor complex dimerizes and binds to palindromic steroid-responsive elements in genomic DNA that are upstream from CAAT and TATA boxes. The AF regions interact with an intermediary group of proteins termed co-regulators to form protein-protein interactions in a ligand-dependent manner to either increase (co-activator) or decrease (co-repressor) gene transcription. The multiprotein complex includes co-regulators such as CBP, SRC-1, and ARA70, the last one believed to be a protein more specifically associated with the androgen receptor. Co-regulators appear to act as a physical bridge to link nuclear receptor transcription factors to the general transcriptional machinery, such as RNA polymerases.

RNA polymerase and other transcription factors and co-activators are recruited to initiate transcription of the steroid response gene at a point 19 to 27 kb downstream of the TATA box. The mechanism of trans-activational transcription is ill understood but the ligand-dependent AF-2 region is located within one of the -helices (H12) of the ligand-binding domain that binds to receptor-interacting motifs, LXXLL, in co-regulators (L is leucine, X is any amino acid). The crystal structures of several nuclear receptor ligand-binding domains, including most recently the androgen receptor, have been characterized. They have in common 12 -helices in the form of a sandwich fold. The most carboxyl terminus is helix 12, which becomes realigned by closing like a lid to form a hydrophobic pocket in the presence of ligand; thus the ligand is internalized and does not reside on the surface of the androgen receptor. Much information has been gained about structural and functional key roles for residues in the androgen receptor by the study of a range of mutations that cause androgen resistance (see later). After transcription and processing of the mRNA, the RNA moves to the cytoplasm, where it is translated by cytoplasmic ribosomes and results in synthesis of new proteins and hence androgenic effects. Despite an abundance of biologic actions of androgens ranging from male sex differentiation to muscle growth, erythropoiesis and skeletal development, little is known about the target genes that mediate these effects. Known androgen-responsive genes are the prostate-specific proteins, probasin and prostate-specific antigen. However, the myriad of androgen-responsive genes that must be developmentally regulated during male fetal sex differentiation remain to be identified and characterized.

It is thought that testosterone and DHT have different roles. The testosterone-receptor complex modulates the secretion of LH by the hypothalamic-pituitary unit and affects the stabilization of the Wolffian ducts, whereas the DHT-receptor complex acts in the fetus to promote masculinization of the urogenital sinus and external genitalia of the fetus and acts puberty to induce maturation of secondary sex characteristics. A defect in any of the essential steps in the action of...
androgen in a male fetus impairs masculinization of the urogenital sinus and external genitalia (Fig. 22-32).

**Role of Androgens in the Differentiation of the External Genitalia and Urogenital Sinus**

The induction of male differentiation of the external genitalia and urogenital sinus is affected by DHT, the 5-reduced metabolite of testosterone. Testosterone is the prohormone that is delivered through the blood stream to these target tissues, which are rich in the enzyme 5-reductase and can readily convert testosterone to DHT, even before the fetal testis acquires the capacity to secrete testosterone. DHT binds to the androgen receptor and initiates the events that lead to androgen action. As in the case of the genital ducts, there is an inherent tendency for the external genitalia and urogenital sinus to feminize in the absence of fetal gonadal androgen secretions. Complete male differentiation of the external genitalia and urogenital sinus occurs only if the androgenic stimulus is received during the critical period of development (8 to 12 weeks) in fetal life. DHT stimulates growth of the genital tubercle and induces fusion of the urethral folds and labioscrotal swellings. It also induces differentiation of the prostate and inhibits growth of the vesicovaginal septum, thereby preventing the development of the vagina. These morphogenetic effects of androgen seem to be mediated by the mesenchyme of these tissues and not by the overlying epithelium.

After about the 12th week, when the vagina has separated from the urogenital sinus, fusion of the labioscrotal folds and urethral groove cannot occur, even with an intense androgenic stimulus. The pattern of expression of the androgen receptor explicates, at least in part, why androgen exposure that begins after about the 12th to 13th week of gestation in the female fetus no longer has the capacity to masculinize the urogenital sinus and its derivatives. Androgen receptors, which are expressed as early as the 9th week of gestation, are absent or greatly diminished by the 14th week in the urothelium of the urogenital sinus and the lower vaginal epithelium as well as in the surrounding stroma. However, androgen receptors persist in the clitoris; androgenic stimulation can cause clitoral hypertrophy at any time during fetal life or after birth.

The male fetus with steroid 5-reductase-2 deficiency and impaired conversion of testosterone to DHT has defective masculinization of the external genitalia and urogenital sinus, including absence or hypoplasia of the prostate. The failure of testosterone to masculinize the fetal external genitalia has been ascribed primarily to inability of the target tissues to form DHT. The growth of the external genitalia at puberty in patients with steroid 5-reductase-2 deficiency is attributed to the postnatal expression of the isozyme 5-reductase-1.

Whereas in some species fetal pituitary gonadotropins are required to sustain the secretion of testosterone by the fetal testes, in humans, placental hCG stimulates fetal Leydig cell development and function; human fetal pituitary LH plays a role only after differentiation of the external genitalia is already advanced. This probably explains why the external genitalia of male infants with anencephaly or fetal hypopituitarism and pituitary gonadotropin deficiency usually differentiate normally but remain small. Incomplete fusion of the labial folds and retention of the vaginal pouch in male infants may therefore be caused by deficient androgen secretion or by failure of the target tissues to respond to androgenic stimulation. Conversely, if female infants are subjected in utero to androgenic stimulation from some gonadal or extragonadal source, the external genitalia can masculinize, ranging from clitoral hypertrophy to the formation of a normal-appearing penis. Thus, similar external abnormalities can be produced in the male by androgen deficiency (or failure of the target tissues to respond) and in the female by exposure to androgen from some pathologic source in the fetus or mother.
Endocrine and Paracrine Control Mechanisms in Sex Differentiation

The regulation of sex differentiation by chemical messengers involves two types of control mechanisms. One is the classic endocrine mechanism: a cell, usually in a discrete endocrine gland, secretes a hormone into the blood stream, where it is transported to a distant target tissue to regulate or induce differentiation. Testosterone is a striking example of an endocrine secretion; testosterone secreted by the fetal Leydig cell is delivered through the circulation to the anlagen of the external genitalia and urogenital sinus. Similarly, hCG synthesized by the syncytiotrophoblast acts on the Leydig cell to stimulate testosterone secretion.

The second type of regulation in sex differentiation is paracrine control. This local and more primitive regulatory mechanism involves the dissemination of a hormone from its site of synthesis to its target cells by local diffusion through the extracellular space. Examples of this delivery system for chemical messengers are the action of AMH on the müllerian duct and the action of testosterone on the wolffian duct (in this instance testosterone is a paracrine secretion).
Hormonal Sex Differentiation

Sex differentiation is not complete until the secondary sexual characteristics have matured, fertility is attained, and the ultimate goal, reproduction, becomes possible (Fig. 22-33) (Figure Not Available). These developments occur during puberty. In the past, puberty was regarded as a de novo event because of the dramatic changes brought about by the maturation of the gonads and the increased secretion of gonadal steroids. However, the development of gonadal function is actually a continuum extending from the differentiation of the gonad and the ontogeny of the hypothalamic- pituitary-gonadal system in the fetus, through puberty, to the attainment of full sexual maturation and fertility. Puberty is not an isolated event but rather a critical stage in a sequence of complex maturational changes. The hypothalamic-pituitary unit (including the pulsatile secretion of hypothalamic LHRH and FSH and LH) functions in the fetus, is suppressed to a low level of activity for about a decade during childhood, and is reactivated at the onset of puberty. The hormonal changes and the neuroendocrinology of puberty, including adrenarche and gonadarche, are reviewed in Chapter 24.

Sex Differentiation in the Hypothalamus

Although the control of gonadal function in both sexes is mediated by both FSH and LH, the secretory patterns of the gonadotropins differ in males and females. The male pituitary characteristically secretes both FSH and LH in a pulsatile but relatively constant and sustained manner, whereas in the mature female the pulsatile secretion of FSH and LH is cyclic and is characterized by a preovulatory gonadotropin surge that leads to ovulation.

In 1936, Pfeiffer reported that the rat pituitary becomes differentiated during the early postnatal period according to the nature of the gonads, but the cyclic secretory pattern characteristic of the female pituitary is not an innate property of the pituitary itself. The pituitary of a male animal, when grafted under the hypothalamus of an adult female, is fully able to sustain the rhythm of repeated estrous cycles. When the male pituitary is grafted elsewhere in the recipient, ovulation fails to occur. Therefore, the hypothalamus or higher neural centers function differently in the two sexes.

In addressing the issue of whether genes encoded by the sex chromosomes cause sex differences in development, it is essential to consider the sex chromosomes themselves. ZFY is expressed in the hypothalamus and frontal and temporal cortex of the human adult male brain, as well as fetal brain, but its function is unknown. SRY is expressed in the hypothalamus and frontal and temporal cortex of the human adult male brain, as well as fetal brain, but its function is unknown.
PSYCHOSEXUAL DIFFERENTIATION

A counterpart to Jost's radical and seminal contribution to our understanding of the developmental effects of androgens and AMH in male sex differentiation was the discovery in the laboratory of W. C. Young by Phoenix, Goy, Gerall, and Young in 1963 more than a decade later of the "organizing action" of prenatal administration of testosterone to the pregnant guinea pig, a long gestation species (compared with the rat and mouse), on the mating behavior of the affected female offspring. Their study, similar to earlier, but less definitive, work by Dantchakoff, described male mounting behavior and "defeminization" of the female pseudohermaphrodite guinea pig and emphasized a critical period (30 to 65 days of gestation) for the exposure to the testosterone. This was the first study to demonstrate unambiguously the fact that prenatal exposure to androgen could irreversibly masculinize the fetal brain and lead to male-type behavior postnatally. It extended to the central nervous system the developmental actions of the fetal tests and its androgenic secretions.

Sexually dimorphic behavior may be classified into four broad categories (Table 22-6): (1) core gender identity, which is defined as the fundamental sense of self as being male or female; (2) gender role behavior, which refers to participation in stereotypical masculine and feminine activities; (3) gender or sexual orientation, which refers to preference for sexual partners of the same or other sex; and (4) cognitive differences.

Studies in lower species suggest that the sexual role adopted at maturity is determined by the hormonal environment in early life. As with other aspects of sex differentiation, there appears to be an innate tendency to develop female sexual postures. Development of male patterns of sexual behavior in lower species is influenced to a large extent by exposure to androgens, in particular testosterone, and their aromatization to estrogens during the prenatal and perinatal period. This organizing capacity of testosterone administered at a critical stage of development has been localized to specific areas of the brain. The sex hormones act through specific nuclear receptors in the nervous system as well as by nongenomic actions. There is a difference between the sexes in the volume of the sexually dimorphic nucleus in the preoptic area of the rat brain, and structural differences of the brains of the two sexes are now recognized in many species, including humans. However, in humans, aromatase does not contain the transport of estradiol to the central nervous system, and testosterone-binding globulin (TβG), also called sex hormone-binding globulin (SHBG), has a greater affinity for testosterone than for estradiol. Therefore, the protection hypothesis does not apply to be applicable in humans. The human, masculinization of the brain does not result from estrogen aromatized from testosterone but from testosterone and related C11 steroids. Further, XY women with the complete androgen resistance syndrome do not have a "masculinized" brain; androgen action is ineffective and fetal estrogen synthesized in the central nervous system by aromatization does not induce masculine behavior. Apparently.

fetal estrogens do not have a critical effect on the human on either feminization or masculinization of the brain; the human fetus is bathed in circulating estrogens that do not exhibit a sex dimorphism. Human males are more frequently left handed than are females, a difference that has been ascribed, at least in part, to the prenatal effect of testosterone on the brain.
Sexual identity is usually established by 18 to 30 months of age. If at puberty discordant secondary sexual characteristics are allowed to mature, some individuals may develop doubts about their true gender identity. This has been described in some patients with 5-reductase-2 deficiency, 17-hydroxysteroid dehydrogenase 3 (17-HSD 3) deficiency, or 45,XX/46,XY mosaicism. About half to two thirds of these XY individuals assigned a female sex changed their gender role to male consequent to virilization by the retained testes at puberty. Imperato-McGinley and associates reported on a geographic and cultural isolate of male pseudohermaphrodites with 5-reductase deficiency who masculinized at puberty. In these patients, a change in gender behavior was common but not invariable. Furthermore, differentiation of the sexually dimorphic nucleus of the preoptic area of the human hypothalamus is detectable between about 5 years of age and puberty, although its role in gender identity is unknown. These clinical studies have cast increasing doubt on the hypothesis that gender identity is irreversibly fixed by environmental factors by 2 to 3 years of age. They also emphasize the effect of gonadal steroids at puberty on gender identity and behavior and attest to the plasticity of gender identity in the cultural-genetic isolates studied. In another genetic isolate of patients with 5-reductase deficiency in the Eastern Highlands Province of Papua New Guinea, gender role appeared to be affected primarily by social-experiential and cultural factors rather than by hormonal mechanisms.

Stronger credence is now given to the role of early hormonal influences on sexually dimorphic behavior in humans, and in, for example, the rhesus monkey. As noted studies of women and girls with prenatal virilization caused by virilizing CAH or maternal ingestion of progestagens demonstrate no effect on gender identity in well-managed patients. However, gender-related behavior can be affected and result in general, but not always, in a variable degree of masculine sex-dimorphic behavior as compared with unaffected girls. Prenatally androgenized girls have more interest in outdoor play and competitive sports and are more "tomboystyle" than are unaffected girls. As a group, they are more career oriented and tend to lack a strong interest in doll play and mothering. The pattern is persistent and is not abnormal for female behavior in our culture. According to some studies, a higher proportion of young women with virilizing CAH rated themselves as bisexual or homosexual; another study did not support this contention. The interpretation and implications of psychosexual studies in CAH women have been critically assessed.

We have discussed our present, and far from complete, knowledge of the sex dimorphism in brain structure, the effect of androgens on sex differentiation of the brain, and sex differences in the expression in brain of certain genes on the sex chromosomes, which can be considered important components of the intrinsic or nature component of gender identity. The evidence related to hypothalamic males, patients with the complete form of androgen resistance, and prenatally virilized girls supports the thesis that exposure to androgens before birth can contribute to the programming of sexually dimorphic behavior. Even in XY individuals who had normal testicular function and androgen responsiveness in fetal life and had either a severe malformation of the penis or traumatic loss in the neonatal period, androgens have a "facilitative," not a deterministic, preordained role in gender identity. These hormonal factors are not predictably decisive in patients with classic abnormalities of sex differentiation. More important elements in the development of gender identity are the assigned sex of rearing, the reinforcement that this assignment receives during infancy and early childhood by the parents and siblings, and reinforcement by appropriate gonadal steroid secretion or replacement therapy at the normal age of puberty. If this reinforcement is weak because of ambiguous attitudes of the parents and the community setting, the outlook for attaining a normal gender identity in adult life is diminished.

In sum, the gender neutrality at birth dogma is no longer tenable. There is also no convincing support for the hypothesis that fetal androgens, through their action on the organization and function of the developing central nervous system, are the sole determining factor in the evolution of male gender identity. We do not know if there is a critical period for masculinization of the fetal brain as is the case in the guinea pig. And quantitative, even grossly qualitative, aspects of the magnitude of androgen exposure and the variation in the central nervous system response leading to masculinization of the brain are not known. Rather, the complex, still poorly understood interaction of nature (androgens and genes) and nurture (primarily socialization, parental interaction and reinforcement, and self experience) results in genetic identity. That no one factor has proven to be an invariant determinant is a manifestation of the plasticity and complexity of the process and of the variation of biologic and psychosocial factors, even the dominance of one over the other in a given individual. For example, SRY and ZFY are expressed in the male brain, but yet XY individuals with complete androgen resistance (well represented by those with a deletion or null mutation of the X-linked gene encoding the androgen receptor) exhibit female gender identity. Female pseudohermaphrodites with virilizing CAH exhibit varying degrees of fetal androgen effects on the brain, but the vast majority express female gender identity, especially those in whom glucocorticoid treatment has suppressed the postnatal androgen excess. The few studies of ablation penis discussed earlier, and the studies of Reiner and associates in XY patients with cloacal exstrophy orchidectomized in the neonatal period and assigned a female sex of rearing, support the critical role of the secretion of testosterone by the normal fetal testes in masculinizing the brain. However, even in these rare disorders some affected XY individuals had a female gender identity whereas others had a strong male gender identity. In addition, the outcomes of genital surgical techniques, once quite discouraging, have greatly advanced, including the repair of severe hypospadias often at a single stage and feminizing genioplasty of the masculinized external genitalia of female pseudohermaphrodites.

Our understanding of the complexity of determinants of gender identity and gender role behavior has advanced remarkably in recent years. But there are large gaps in our knowledge and understanding; particularly limiting is the lack of long-term follow-up into adulthood of intersex individuals treated in the past two to three decades, which leaves little room for dogma.
CLASSIFICATION OF ERRORS IN SEX DIFFERENTIATION

In the past, individuals with hermaphroditism were classified according to their gonadal morphology. In the terminology of Klebs, a true hermaphrodite is a person who possesses both ovarian and testicular tissue. A male pseudohermaphrodite is one whose gonads are exclusively testes but whose genital ducts or external genitalia, or both, exhibit the phenotype of a female or incompletely differentiated male. A female pseudohermaphrodite is a person with ovaries whose external genitalia exhibit some masculine characteristics. We have classified errors in sex differentiation by a modification and expansion of this broad framework and have attempted to blend etiologic mechanisms and clinical entities into a simplified rational classification (Table 22-7). The clinical and etiologic heterogeneity of syndromes with similar anatomic findings merits emphasis. The format of this edition thus maintains the traditional pseudohermaphroditism terminology, which is useful clinically for diagnostic algorithms. In discussing intersexuality with patients and parents it is important to refer to the masculinized female and the undermasculinized male.

TABLE 22-7 -- Classification of Anomalous Sexual Development

I. Disorders of Gonadal Differentiation
   A. Seminiferous tubule dysgenesis (Klinefelter syndrome)
   B. Syndrome of gonadal dysgenesis and its variants (Turner syndrome)
   C. Complete and incomplete forms of XX and XY gonadal dysgenesis
   D. True hermaphroditism

II. Female Pseudohermaphroditism
   A. Androgen-induced
      1. Congenital virilizing adrenal hyperplasia
      2. CYP19 (P450arom) aromatase deficiency
      3. Glucocorticoid receptor gene mutation
      4. Androgens and synthetic progestagens transferred from maternal circulation
   B. Other teratologic factors (nonandrogen-induced) associated with malformations of intestine and urinary tract

III. Male Pseudohermaphroditism
   A. Testicular unresponsiveness to hCG and LH (Leydig cell agenesis or hypoplasia due to hCG/LH receptor defect)
   B. Inborn errors of testosterone biosynthesis
      1. Enzyme deficits affecting synthesis of both corticosteroids and testosterone (variants of congenital adrenal hyperplasia)
         a. STAR deficiency (congenital lipoid adrenal hyperplasia)
         b. Side-chain (P450sc) cleavage deficiency heterozygote
         c. 3-Hydroxysteroid dehydrogenase/4,5-isomerase type 2 (3-HSD-2) deficiency
         d. CYP17 (P450c17[17,20 lyase]) deficiency
         e. Smith-Lemli-Opitz syndrome: 7-dehydrocholesterol reductase deficiency
      2. Enzyme defects primarily affecting testosterone biosynthesis by the testes
         a. CYP17 (P450c17[17,20 lyase]) deficiency
         b. 17-Hydroxysteroid dehydrogenase type 3 (17-HSD 3) deficiency
   C. Defects in androgen-dependent target tissues
      1. End-organ resistance to androgenic hormones
         a. Syndrome of complete androgen resistance and its variants (testicular feminization and its variant forms)
         b. Syndrome of incomplete androgen resistance and its variants (Reifenstein's syndrome)
         c. Androgen resistance in phenotypically normal males (infertile and fertile)
      2. Defects in testosterone metabolism by peripheral tissues; 5-reductase-2 (SRD5A2) deficiency (pseudovaginal perineoscrotal hypospadias)
   D. Dysgenetic male pseudohermaphroditism
      1. XY gonadal dysgenesis (incomplete)
      2. XO/XY mosaicism, structurally abnormal Y chromosome, SRY mutation
      3. Deryns-Drash syndrome (WT1 mutation)
      4. Fraiser syndrome (mutation of WT1 splice site junction mutation-deleting KTS)
      5. WAGR syndrome (WT1 deletion)
      6. Campomelic dysplasia (SOX9 mutation)
      7. SFI mutation
      8. DAX1 (duplication)
      9. WNT4 (duplication)
      10. 9p (DMRT1 deletion)
      11. 10q
      12. ATRX syndrome (XN2 mutation)
      13. Testicular regression syndrome
   E. Defects in synthesis, secretion, or response to antimüllerian hormone: persistent müllerian duct syndrome (female genital ducts in otherwise normal men; herniae uteri inguinale)
   F. Maternal ingestion of progestagens
   G. Environmental chemicals (endocrine disrupters)

IV. Unclassified Forms of Abnormal Sexual Development
   A. In males
Disorders of Gonadal Differentiation and Sex Chromosome Anomalies

Not all patients with anomalies of sex chromosomes have abnormal gonads; conversely, congenital defects in gonadal differentiation are not always caused by chromosomal errors. The association is so frequent, however, that these topics are inseparable. Exceptions to this association are of special importance in defining the genetic and chromosomal determinants of gonadogenesis. (see Table 22-4).

Seminiferous Tubule Dysgenesis: Klinefelter's Syndrome and Its Variants

47,XXY Seminiferous Tubule Dysgenesis (Typical Klinefelter's Syndrome)

Seminiferous tubule dysgenesis is a common cause of primary hypogonadism and male infertility (Table 22-8). This syndrome, as defined by Klinefelter and associates, usually becomes manifest first during adolescence as gynecomastia, a variable degree of androgen deficiency, small atrophic testes with hyalinization of the seminiferous tubules, aggregation of Leydig cells, aspermatogenesis, and increased plasma gonadotropins, especially plasma FSH.

In 1956, several groups found that a high proportion of patients with this syndrome are X chromatin positive despite their phenotypic male appearance. In 1959, Jacobs and Strong and Ford and co-workers first reported a 47,XXY sex chromosome constitution in patients with this disorder, explaining the positive sex chromatin pattern. Various other sex chromosome compositions, including mosaicism, were described subsequently. Virtually all these variants have in common the presence of at least two X chromosomes and a Y chromosome, except for the rare group that has a 46,XX sex chromosome complement by karyotype analysis of multiple tissues.

The differentiation of testes and lack of ovarian differentiation in patients with 47,XXY and, more strikingly, in those with 49,XXXXY complements indicate that a single Y chromosome and the expression of the testis-determining gene (SRY) are sufficient to bring about testis organogenesis and male sex differentiation in the presence of as many as four X chromosomes.

Clinical Features

In the postpubertal patient, the only constant clinical features are a male phenotype, small testes, firm testes; seminiferous tubule dysgenesis; azoospermia; Leydig cell hyperplasia; and blunted in adulthood. Impairment in verbal I.Q. is slight (10 to 20 points), and the mean I.Q. falls between 85 and 90, with a wide range of variation. Most boys with Klinefelter's syndrome require help in reading and spelling. Severe retardation is uncommon. One study of 13 47,XXY males monitored from birth through adolescence noted a mean I.Q. 21 points lower than that of a matched control group. Despite neurocognitive difficulties including reading and writing, 12 of 13 graduated from high school and 4 attended college. In general, lack of motor skills hindered participation in competitive sports; 3 of 13 were successful in achieving personal goals and in their family relationships. The families of these 3 boys were among the most stable and supportive of the study group. Most patients with Klinefelter's syndrome do not have behavioral disorders, and, in spite of verbal deficits, adult men with Klinefelter's syndrome are not significantly different as a group from other hypogonadal males or even normal controls as far as education, employment, socioeconomic status, social adjustment, and criminal behavior are concerned.

Patients with a 47,XXY karyotype tend to be taller (mean height 180 cm compared with 174 cm for their normal adult brothers) than average because of disproportionate length of the legs. This finding is present before clinical signs of puberty are evident and may not be accompanied by a proportional increase in arm span. The prepubertal onset suggests that disproportionate leg length is not related to androgen deficiency or delayed epiphyseal closure. Androgen deficiency after the age of puberty augments the prepubertal deviation in skeletal proportions. XXXY individuals have three pseudoautosomal SHOX genes (one in each X chromosome and one on the Y chromosome).

Prepubertally, the basal plasma concentration of FSH and LH and the response to LH-RH are within the normal range for age. The timing and onset of secondary sexual characteristics and puberty were reported as normal in one study and as delayed in another. With the onset of puberty, testicular histology becomes abnormal and testosterone synthesis is impaired. In postpubertal patients the plasma concentrations of testosterone tend to be low, the levels of plasma estradiol are normal or increased, and the gonadotropin levels are elevated. Testosterone responses to hCG appear to be normal in childhood and early adolescence and blunted in adulthood. Potency is usually diminished in the adult, and Leydig cell reserve is impaired, as reflected by a subnormal increase in the concentration of serum testosterone after administration of hCG and an increased concentration of LH in plasma. The testosterone production rate, levels of total and free testosterone, and rates of metabolic clearance of testosterone and estradiol tend to be low, whereas plasma estradiol levels are normal or elevated.

Gynecomastia and signs of androgen deficiency, such as diminished facial and body hair, a female escutcheon, a small phallus, poor muscular development, and a further increase in the disproportion between leg and body length, usually become evident during or after puberty. The testicular failure in Klinefelter's syndrome appears to progress with age. Gynecomastia, which occurs in about 90% of patients, is considered to be secondary to an increased ratio of serum estradiol to testosterone (see also Chapter 18).

Associated Abnormalities

Abnormalities in thyroid function include a diminished thyroid response to thyrotropin, decreased
The frequency of diabetes mellitus is increased. Nielsen reported that 19% had impaired glucose tolerance and that 8% had overt diabetes. The prevalence of diabetes mellitus was also increased in the parents. The patients with diabetes mellitus were usually younger than 50 years of age, and the type II diabetes was usually mild. Insulin resistance with secondary hyperinsulinemia may be the cause of glucose intolerance.

47,XXY patients with gynecomastia have an increased predisposition to cancer of the breast. In a survey of 187 males with breast cancer, 8 patients with chromatin-positive seminiferous tubule dysgenesis were detected, about 18 times the expected prevalence. Whether this increased incidence is solely the consequence of the gynecomastia is unclear (see Chapter 17). Further, whereas male breast cancer is rare, a Swedish study of Klinefelter patients concluded that there is a 50-fold increased risk of developing breast cancer relative to normal males. Infiltrating ductal carcinoma is the most common histologic type. Even though a study of 696 men with Klinefelter’s syndrome did not report an overall increase in cancer incidence, the prevalence of germ cell tumors (particularly in the mediastinum) that secrete hCG and cause LHRH-independent sexual precocity is increased. Twenty to 50 percent of boys 8 years of age or older with primary mediastinal germ cell tumors have Klinefelter’s syndrome. The latter diagnosis is suggested by the association of prepubertal-size testes with sexual precocity. Routine screening is not indicated, given an estimated incidence of germ cell tumors of 1.5 per 1000 persons with Klinefelter’s syndrome but the diagnosis of Kleinfelter’s syndrome should be considered in all boys with a gynecomastia at any site (see Chap. 24).

A British study of mortality and cancer incidence in 646 patients with Klinefelter’s syndrome showed that mortality was increased from diabetes, cardiovascular and respiratory disease, as well as lung and breast cancer.

About 25% of adults with Klinefelter’s syndrome have osteoporosis, but it is uncommon in patients on testosterone replacement. Chronic pulmonary disease and varicose veins with stasis ulcers may also be more prevalent in adults. Patients with both androgen resistance and a 47,XXY karyotype have been reported. These patients had female or ambiguous male genitalia and some clinical features of the 47,XXY karyotype. This combined defect is probably caused by fertilization of an oocyte containing two X chromosomes, each bearing a defect in the X-linked gene coding for the androgen receptor (e.g., uniparental disomy for the X chromosome), by a normal sperm containing a Y chromosome. Similarly, a null mutation, which causes intrauterine death in males usually with X-linked dominant incontinentia pigmenti, is associated with survival in affected XXY patients.

Several males with 46,XY plus a marker chromosome have been reported. In these patients, the marker found was a small ring X chromosome that did not express XIST and hence was not inactivated. The abnormal dosage of X-active chromosome genes caused developmental delay and dysmorphic features.

Surveys of the prevalence of 47,XXY fetuses by karyotype analysis of unselected newborns indicate an incidence of about 1 per 800 to 1000 males, the most common human chromosomal abnormality. No racial or geographic predilection has been observed.

Testicular Lesions.

Klinefelter’s syndrome accounts for 10% to 20% of men attending a male infertility clinic. Changes in the histologic structure of the testis become more marked with age in 47,XXY individuals. A limited number of studies of fetal testes have been reported, and the findings are variable. Grumbach and associates reported normal histology for the testes of a 1700-g chromatin-positive premature infant, as was similarly reported in a 49,XXXXY 21-week fetus, but examination of several other affected fetuses suggested that the germinal epithelium was deficient and that germ cells were heterotopic; these observations indicate that the histology of the fetal testes varies. In three infants aged 3 to 12 months with a 47,XXY karyotype, spermatogonia were decreased. In later childhood, testicular biopsies have revealed small tubules with progressive reduction in spermatogonia. In considering the testicular lesion, it seems that a normal or near-normal complement of germ cells is present early in fetal life. During late gestation and early infancy, a drastic loss of spermatogonia ensues, possibly because of an exaggeration of the normal apoptosis of spermatogonia in the neonatal period. In addition, excessive germ cell loss could result from defective maturation or failure of the germ cells to migrate to the periphery of the tubule and align in opposition to the basement membrane. An experimental XXY mouse model has been established. The histology of the testes in adult mice is consistent with the human syndrome. Progressive loss of germ cells in XXXY mice was observed by 10 days after birth.

With the approach of adolescence, even before pubertal signs are well advanced, the actions of pituitary gonadotropins on the intrinsically defective testis induce progressive hyalinization of the seminiferous tubules and pseudoadenomatous clumping of Leydig cells. Despite this clumping, the mean volume of Leydig cells usually is normal. After pubescence, the testes are characterized by small dysgenetic tubules with arrested development, fibrosis, and hyalinization. The result is testes that are small in size and firm in consistency. Peritubular elastic tissue is usually absent or diminished. That gonadotropin secretion plays a direct or indirect role in the progressive degeneration of the testes was suggested in a 7-year-old 48,XXXY boy with true precocious puberty and elevated urinary gonadotropin levels. Unlike the relatively normal testicular architecture in most boys of this age with Klinefelter’s syndrome, the testes of this boy exhibited extensive hyalinization and fibrosis of the tubules and clumping of Leydig cells.

Hyalinization of the tubules is usually extensive but varies in degree from patient to patient and even between the testes of the same patient. The fibrosis tends to progress with age, and in some older patients few tubules can be identified. Conversely, in some patients the tubules are lined by Sertoli cells, tubular fibrosis is relatively slight, and the histologic appearance resembles that of germinal cell aplasia. Rarely, spermatogenesis is found in isolated tubules. This finding could represent hidden mosaicism in the gonad or possibly mitotic nondisjunction or anaphase lag in germ cells giving rise to 46,XY cells that would then go on to spermatogenesis. There have been sporadic reports of paternity; most fertile individuals proved to have sex chromosome mosaicism, and in others acceptable
distinguish them from patients with typical Klinefelter's syndrome. Analyses of sperm chromosomes from a 46,XY/47,XXY male showed that 1% of sperm had a 24,XY haplotype, which suggests that some 47,XXY cells can undergo meiosis and form XY-bearing spermatooza. The technique of intracytoplasmic sperm injection (ICSI) has been used with some success for achieving fertility, including the birth of twins. However, there is a risk of trisomy 21 in offspring of patients with Klinefelter's syndrome.

47,XXY males may develop through nondisjunction of the sex chromosomes during either the first or second meiotic division in either parent or, less commonly, through mitotic nondisjunction in the zygote at the time of or after fertilization. Fertilization of a 46,XX ovum by a Y-bearing sperm or of an X ovum by a 46,XY-bearing sperm would yield a 47,XXY zygote. Mitotic nondisjunction of the sex chromosomes in a 46,XY zygote could yield a 47,XXY and a 45,Y daughter cell. Because the 45,Y cell line is nonviable, only the 47,XXY cell line would survive.

These abnormalities of meiosis almost always occur in patients with normal sex chromosome constitution. However, Rosenkrantz described two 47,XXY patients whose mothers were, respectively, 47,XXX and 46,XX/47,XXX mosaic. Whether a 47,XXY karyotype is derived more frequently than previously suspected from a polysomic X constitution in the mother remains to be determined.

In a study of 47,XXY males, Jacobs and colleagues found that the XXY constitution resulted from paternal nondisjunction in the first meiotic division in 53% of the patients, from maternal nondisjunction during the first meiotic division in 34%, and from maternal nondisjunction during the second meiotic division in 9%. Three percent of cases appeared to be related to postzygotic mitotic nondisjunction. Ferguson-Smith and colleagues and others reported a positive association with advanced maternal age in 47,XXY patients, although this association is less marked than in trisomy 21. The association with advanced maternal age correlates with first meiotic division errors. Some studies in X Y Y individuals indicate that paternal nondisjunction does not depend on age. A finding reminiscent of that in patients with autosomal trisomy. Nevertheless, the prevalence of XY, YY, and XX disomy in human sperm appears to be increased in older men.

Furthermore, in a study of the sperm of healthy men who were fathers of boys with Klinefelter's syndrome, the frequency of YY sperm (7.5 per 10,000) was 31% higher among fathers in their 40s and 100% higher for those in their 50s.

Rarely, Klinefelter's syndrome is associated with a supernumerary X chromosome that is structurally abnormal, for example, an X-autosome translocation or an isochromosome for the long arm of the X.

Among a small, rare group of phenotypic females with a 46,XXY karyotype, six (one set of monozygotic twins) had the complete androgen resistance syndrome. Both X chromosomes harbored a deleted or mutant gene encoding the androgen receptor. One 47,XXY fertile woman had a structurally abnormal Y chromosome devoid of the SRY gene attributable to an illegitimate X-Y interchange.

Etiologic Factors.

An important factor in the origin of the 47,XXY chromosome constitution is advanced maternal age and maternal nondisjunction. As discussed previously, an important effect in chromosome abnormalities may be a consequence of the long diplonete stage of human ova. Oocytes remain suspended in prophase of the first meiotic division from birth to ovulation, which may not occur for decades. The defective segregation of the two X chromosomes could be caused, at least in part, by reduction of the length of the chiasma as the length of the diplonete stage increases (see section on aneuploidy). As in the syndrome of gonadal dysgenesis, the prevalence of twinning in sibships of 47,XXY individuals may be increased.

 Genetic factors that predispose to nondisjunction have been demonstrated in lower species. Although chromosome abnormalities are usually sporadic, families have been reported in which leukemia and various chromosome abnormalities have occurred in siblings and relatives. In addition, patients with more than one form of trisomy seem to occur more frequently than expected by chance alone. A role for radiation, viruses, environmental toxins, folate deficiency, or autoimmune as a predisposing factor has not been established.

Diagnosis and Treatment.

The diagnosis of Klinefelter's syndrome in the postpubertal male is suggested by the typical phenotype and hormonal changes and confirmed by the finding of a 47,XXY karyotype or a variant sex chromosome complement in blood, skin, or gonads. Treatment should be directed toward androgen replacement therapy when there is evidence of androgen deficiency. In general, parenteral androgens are more effective in inducing virilization and are safer than oral preparations.

Hepatic tumors and abnormalities in liver function have been associated with chronic administration of oral androgens that have substitutions at the 17-position (e.g., a methyl group), but such abnormalities are not a problem with testosterone ester preparations such as propionate or enanthate or the testosterone dermal patch. Testosterone enanthate in oil, 200 mg intramuscularly every 2 to 3 weeks, is recommended for full replacement therapy, but it is wise to begin therapy at a lower dose (e.g., 50 mg intramuscularly every 4 weeks) to avoid rapid virilization and bone maturation, especially in adolescent males. The testosterone dermal patch is a useful, but more expensive, therapeutic approach. In general, conspicuous and long-standing gynecomastia does not diminish as a result of androgen replacement. However, in some patients, especially those with less striking gynecomastia, regression can occur with androgen replacement therapy. Severe or psychologically disturbing gynecomastia is corrected by reduction mammoplasty or by liposuction.

The diagnosis of Klinefelter's syndrome should be suspected in prepubertal patients with one or more of the following: (1) long legs, (2) smaller than normal penis, (3) learning disorders, and (4) developmental delay in speech and language. Similarly, based on the outcome of cytogenetic surveys of newborns, it is recommended that all boys with undescended testes or a micropenis or who have gynecomastia should have a karyotype performed. Many of these features are amenable to therapy, so early detection and intervention may be beneficial. Nielsen and Pels et al. suggested that prepubertally diagnosed patients with Klinefelter's syndrome should be offered therapy with testosterone at 11 to 12 years of age to initiate puberty and to prevent the physical and psychological complications of hypogonadism. We have employed a regimen that begins replacement therapy with 50 mg of testosterone enanthate in oil intramuscularly each month at a bone age of 12 years. When the bone age has advanced to 14 years, the dose may be increased to 100 mg intramuscularly monthly. After several years of treatment at these doses, a height is usually attained that is appropriate for genetic height potential of the individual and pubertal progression is usually adequate. When full masculinization is desired, an adult replacement dose of 200 mg every 2 weeks or 300 mg every 3 weeks may be given.
Approximately 20% of 46,XX males are SRY negative. These males have a much higher prevalence of genital ambiguity, such as micropenis, hypospadias, and peritubular and interstitial fibrosis occurs. In some patients the morphology of the testes is similar to that in 47,XXY patients. The diagnosis may be suspected from the clinical features. Male phenotype and psychosocial orientation and are similar clinical and endocrinologically to individuals with classic Klinefelter's syndrome except for minor differences. Postpubertally, as in Klinefelter's syndrome, they have decreased libido and potency may not appear until the fourth or fifth decade. The Leydig cells appear hyperplastic. In some patients the morphology of the testes is similar to that in 47,XXY males; they have small testes with azoospermia. A 46,XX karyotype is present in about 1 of every 20,000 phenotypic males. In general, the greater amount of Y material present, the more virilized the phenotype. Several theories have been advanced to explain this type of sex reversal: (1) loss of a Y chromosome early in embryogenesis, (2) cryptic sex determination. Several theories have been advanced to explain this type of sex reversal: (1) loss of a Y chromosome early in embryogenesis, (2) cryptic sex differentiation, (3) translocation between a Y chromosome and an X chromosome or autososome resulting in the presence of the testis-determining gene (or genes) on an X chromosome or autosome, (4) a mutation involving either an autosomal or X-linked gene in the pathway to testis differentiation. Such 46,XX patients have had three copies of the pseudoautosomal region in their constitution, most are mentally retarded, although this may in part relate to ascertainment bias, because a significant proportion of cases are detected in screening mental and psychiatric hospitals. The 48,XXXX karyotype is usually associated with tall stature (the mean height of 26 patients was 181 cm), disproportionately low extremities, gynecomastia, delinquent behavior, and unusual dermatoglyphic patterns. Peripheral vascular disease, especially varicose veins and stasis dermatitis, has been observed. Secondary sexual characteristics are poorly developed, and testicular histology is similar to that of 47,XXY patients. The sex chromatin pattern is indistinguishable from that of the 47,XXY groups; however, two fluorescent Y bodies are present in a high proportion of somatic nuclei. Further resolution of meiosis and nondisjunction must occur in paternal meiosis. In two informative matings the Xb blood groups indicated that the factor contributed an X as well as two Y chromosomes, suggesting that an X ovum was fertilized by an XY sperm (arising from successful nondisjunction in the first and second meiotic divisions). The 48,XXXX karyotype in a patient whose mother was 47,XXX could have arisen by the fertilization of an XX ovum by a YY sperm. The diagnosis of 46,XY/47,XXY mosaicism may result from nondisjunction or anaphase lag in 47,XXX zygote.

46,XX males.

A 46,XX karyotype is present in about 15% of all 20,000 phenotypic males. These patients have a male phenotype and psychosocial orientation and are similar clinically and endocrinologically to individuals with classic Klinefelter's syndrome except for minor differences. Postpubertally, as in Klinefelter's syndrome, they have decreased libido and potency. Increased androgen deficiency. With the increase in the number of X chromosomes, the severity and frequency of somatic anomalies such as short neck, epicanthal folds, radioulnar synostosis, and clindactyly increase. Mental retardation, somatic anomalies, and small testes also occur in 46,XXXXY patients.

46,XXX.

The 46,XXX karyotype has been reported in more than 100 patients since the first report by Fraccaro and colleagues in 1960. The diagnosis may be suspected from the clinical features. Male phenotype and psychosocial orientation are similar clinically and endocrinologically to individuals with classic Klinefelter's syndrome except for minor differences. Postpubertally, as in Klinefelter's syndrome, they have decreased libido and potency. Compared with males with a 47,XXY karyotype, 46,XXY males have a lower frequency of intellectual and psychosocial problems; they are shorter (mean height, 168 cm) than 47,XXY or normal males; they have varying degrees of testosterone deficiency, gynecomastia, and small testes with azoospermia. Testosterone production is usually decreased, as is the response to hCG. Both basal and LH-RH-induced FSH and LH levels are increased. There is a 10% incidence of hypospadias that is attributed to a deficiency of testosterone formation by the fetal Leydig cells. 46,XX males with genital abnormalities usually lack evidence of SRY DNA in their genome and manifest a greater prevalence and degree of gynecomastia than 46,XX men. In contrast to the morphology in Klinefelter's syndrome. In contrast to the morphology in Klinefelter's syndrome, the diagnosis may be suspected. The morphology of the testes is similar to that in 47,XXY males; they are older (mean age, 45 years) at the time of diagnosis than 47,XXY patients. Decreased libido and potency may not appear until the fourth or fifth decade. In general, the greater amount of Y material present, the more virilized the phenotype.

46,XY/47,XXY Mosaicism

46,XY/47,XXY mosaicism is the second most common karyotype in chromatin-positive men. The presence of a normal XY cell line in these patients can modify the clinical expression of the 47,XXY cell line. In general, these patients manifest a lesser degree of gynecomastia, androgen deficiency, and testicular pathology. As a group they are older (mean age, 45 years) at the time of diagnosis than 47,XXY patients. Decreased libido and potency may not appear until the fourth or fifth decade. These findings suggest that both anomalous Y-to-X exchange and maternal or paternal nondisjunction occurred in these patients. Approximately 20% of 46,XX males are SRY negative. These males have a much higher prevalence of genital ambiguity, such as micropenis, gynecomastia, and azoospermia. SRY sequence and the PAR.

Approximately 20% of 46,XX males are SRY negative. These males have a much higher prevalence of genital ambiguity, such as micropenis, gynecomastia, and azoospermia. SRY sequence and the PAR.
associated with true hermaphroditism. These observations are consistent with the origin of a small proportion of 46,XX males as a consequence of a mutation in a downstream autosome or X-linked gene (or genes) involved in the testis-determining cascade. They also suggest that 46,XX males and 46,XX true hermaphrodites may arise by similar pathogenic mechanisms. In sum, the 46,XX male syndrome arises mainly as a result of a Y-to-X translocation; other possible mechanisms include mutation in an X chromosomal or autosomal gene and cryptic mosaicism that involves a Y-bearing cell line in all at least the Sertoli cells.

### Syndrome of Gonadal Dysgenesis: Turner's Syndrome and Its Variants

In 1938 Turner described seven phenotypic women with short stature, sexual infantilism, webbing of the neck, and cubitus valgus. Studies of this syndrome and its variants have made a major contribution to the evolution of current concepts of sex differentiation. (For reviews, see references [18] and [19].)

In the early 1940s Albright and colleagues and Vamey and associates found that the excretion of urinary gonadotropin was increased in affected adolescents and adults. Wilkins and Fleischmann soon thereafter described the gonads as bilateral, pale *streaks* of connective tissue situated in the mesosalpinges and devoid of any germ cells. Wilkins proposed, in light of Jost's fetal castration experiments in the rabbit, that some of these functionally agonal patients might be genetic males, because fetal castration of either sex invariably leads to a female phenotype. The discovery in 1954 that many of these patients, contrary to their phenotype, were X chromatin negative seemed initially to confirm that hypothesis, but after techniques became available for analysis of the chromosome constitution Ford and co-workers reported that the sex chromosome constitution in a 14-year-old phenotypic female with this syndrome was 45,X rather than 46,XY. Work in many laboratories thereafter defined more precisely the chromosomal basis of this and related disorders.

The absence of a second sex chromosome (X chromosome monosomy with haploinsufficiency) is associated with five cardinal features: female phenotype, short stature, sexual infantilism owing to rudimentary gonads, a variety of associated somatic abnormalities, and embryonic lethality. These features may be modified by the presence of lesser degrees of sexual chromosome deficiency. It is therefore useful to consider the syndrome of gonadal dysgenesis and its variants as a continuum of features ranging from those of the typical 45,X phenotype to that of a normal female or male. The functional importance of chromosomal additions to the basic 45,X pattern can be deduced from the extent to which they modify normal, in at least some cases, the short stature, sexual infantilism, and somatic anomalies that typify the 45,X patient.

Partial sex chromosome monosomy (haploinsufficiency) may be attributed to a structurally abnormal second sex chromosome (X or Y), sex chromosome mosaicism involving a 45,X cell line, or both. Even though the modified clinical forms are almost invariably associated with partial sex chromosome monosomy, the contrary is not necessarily true; partial sex chromosome monosomies can cause the typical clinical picture found in 45,X patients.

**Typical 45,X Gonadal Dysgenesis (Turner's Syndrome)**

In patients with the cardinal features of sex chromosome monosomy, the X chromosome pattern is negative in about 60%; most of these patients have a 45,X sex chromosome constitution (Table 22-9). Significant variability occurs in expression of the somatic anomalies associated with sex chromosome monosomy ([Fig. 22-38](#)).

### Clinical Aspects

The typical patient (see [Fig. 22-38](#)) is often recognizable by the distinctive facies, in which micrognathia; epicantal folds; prominent, low-set, rotated and/or deformed ears; a fish-like mouth with a narrow, high-arched palate; piosis; and strabismus are present with varying degrees of frequency. The chest is usually square and shield-like with microthelia and inverted nipples. The areolae appear to be widely spaced. The neck is short and broad, and the hairline in back is low. Webbing of the neck is present in 25% to 40%, and

![Diagram of the short arms of the X and Y chromosomes during meiotic pairing. A: A crossover (dashed lines) usually occurs between the pseudoautosomal regions of the X and Y chromosomes. Anomalous but equal crossovers (solid lines) can occur that result in an X chromosome with the sex-determining region (SRY) and a Y chromosome deficient in the SRY. It is estimated to occur at the PRKX and PRKY locus in 40% of SRY XX males. Zygotides with these sex chromosomes will become XX males of XY females as indicated. B, Anomalous unequal crossovers (solid lines) during male meiosis can result in an X chromosome with an SRY gene as well as the pseudoautosomal regions of both the X and Y chromosomes. SRY, sex-determining region Y; ZFY, zinc finger Y.](#)

coarctation of the aorta occurs in 10% to 20%. Those with coarctation usually also have webbing of the neck. Additional anomalies include congenital lymphedema of the feet and hands (30%) ([Fig. 22-39](#)) or puffyiness of the dorsum of the fingers; short fourth metacarpals (50%); renal abnormalities (40%); high-arched palate; various skeletal anomalies; including cubitus valgus, Madelung's deformity of the wrist, genu valgum, and scoliosis; increased number of pigmented nevi; tendency to keloid formation; abnormal nails; recurrent otitis media, which may result in conductive hearing loss (as well as progressive sensorineural loss of hearing); unexplained hypertension; and, rarely, gastrointestinal bleeding secondary to intestinal telangiectasia, hemangiomatosis, or dilated veins. Money and others have reported that impairments of directional sense and space-form recognition, visual-motor coordination, and motor learning are common; this perceptual disability results in a lower mean performance I.Q. than in the general population and is evidence of diffuse or multifocal cerebral dysfunction, whereas verbal ability (including comprehension and vocabulary) is normal. In general, patients with gonadal dysgenesis do not tend to differ from siblings in overall intelligence; however, mental retardation (I.Q. < 70) may be more common than the 1% to 3% incidence reported in the general population. Gender identity and sexual attitudes are feminine. Girls with gonadal dysgenesis are generally more immature and distractable and have less self-esteem, poorer peer relations, and more difficulty at school than peers. Skuse and associates described poorer adjustment and "social cognition" in 45,X M(40), maternally derived X chromosome) individuals with Turner's syndrome. This difference was attributed to genomic imprinting, the silencing of some gene on the maternal X chromosome located in the pericentric region of the short arm or on the long arm of the X chromosome. This putative gene, which apparently escapes inactivation, is the first imprinted gene proposed for the human X chromosome. Further studies of parental origin of the X chromosome in Turner's syndrome are helping to elucidate behavioral phenotypes for a number of neurodevelopmental aspects.

As adults, women with gonadal dysgenesis exhibit more conservative sexual attitudes and a more negative body image. Lack of ovarian function (including infertility), rather than height, was the major concern of adult women with the syndrome of gonadal dysgenesis in one study. Severe psychopathological manifestations are uncommon. In general, most women with gonadal dysgenesis are independent, self-sufficient, and socially active. One study of 63 women with Turner's syndrome reported normal psychological well-being but more difficulties in establishing social and partner relationships compared with the general population.

Increased plasma LH and FSH concentrations; decreased plasma estradiol levels

The risk of anorexia nervosa and inflammatory bowel disease may be increased. The epiphysis Bonnie-Ullrich syndrome has been applied to phenotypic female infants with lymphedema of the distal extremities and loose folds of skin over the back of the neck in addition to the typical features of gonad dysgenesis (Fig. 22-40). In the neonate, pleural effusions and ascites that clear spontaneously are not uncommon and pericardial effusion has been reported. The serous effusions and the lymphedema are attributable to hypoplasia and other defects of the lymphatic system. 45, X abortuses commonly exhibit generalized edema and a large hygroma of the neck. Postnatally, the latter abnormality results in webbing of the neck. These findings can be detected by prenatal ultrasonography. Shephard and Fante suggested that the severe edema that occurs secondary to hypoplastic lymphatic and lymphatic duct hypoplasia in 45, X fetuses is responsible for many of the malformations involving the ears, hairline, neck, nipples, nails, and kidneys. The increased incidence of congenital heart disease associated with webbed neck, especially coarctation of the aorta (40%), has led to the suggestion that lymphatic obstruction is involved in the pathogenesis of both types of deformation.

The prevalence of cardiovascular abnormalities has varied from 20% to 50%. In a Danish study of 179 patients, 26% had cardiovascular malformations. Coarctation of the aorta was the most common, occurring in 10% of patients, primarily those with a 45, X karyotype. The prevalence of bicuspid aortic valves in Turner syndrome determined by echocardiography has ranged from 5% to 34%. Bicuspid aortic valves carry an increased risk for subacute bacterial endocarditis and tend to evolve with age into stenotic and/or insufficient aortic valves. An increased incidence of mitral valve prolapse has been reported in patients with gonadal dysgenesis. Other studies have reported an increased incidence of partial anomalous venous drainage and hypoplastic left heart syndrome. On echocardiography, 8% to 29% of patients with the syndrome of gonadal dysgenesis have aortic root dilation, and rupture from aortic dilation has been reported in more than 20 patients. Therefore, all patients with Turner's syndrome should have a thorough baseline cardiac evaluation, including an echocardiogram or magnetic resonance imaging study or both in infancy and again at adolescence. Patients with increased risk factors for dissection and rupture (e.g., those with coarctation, hypertension, and aortic root dilatation) require yearly follow-up and therapeutic measures to decrease the risk of dissection. Pregnancy (after in vitro fertilization) carries an increased risk of fatal aortic dissection. Patients with a bicuspid aortic valve should be given prophylactic antibiotic therapy before surgery or dental procedures, to prevent subacute bacterial endocarditis.

The most common renal abnormalities are rotation of the kidney, horseshoe kidney, duplication of the renal pelvis and ureter, and hydronephrosis secondary to ureteropelvic obstruction. Complete absence of the kidney and gross renal ectopia in 7 of 141 patients was reported by Lippe and associates. Malformation of the kidneys and upper collecting system including an abnormal vascular supply are so common that intravenous urography, a renal sonogram or renography should be obtained routinely at the time of diagnosis.

Skeletal maturation is normal or slightly delayed in childhood and lags further in adolescence as a result of gonadal steroid deficiency. In most cases, the skeleton exhibits localized areas of rarefaction (fish-net appearance), especially of the hands, feet, elbows, and upper femurs. Bicorporeal girls with gonadal dysgenesis have normal bone density for height and age but decreased density at the wrist for bone age and body mass index. The risk of wrist fractures is increased. Bechtold and colleagues, using quantitative computed tomography of the forearm and human growth hormone (hGH) in estrogen-treated adolescent and young adult patients, detected low total volumetric bone mineral density owing to decreased cortical thickness and suggested bone strength may be inadequate for the relatively high body weight. Patients not treated with estrogen often develop a severe form of the post-menopausal type of osteoporosis and may develop fractures and vertebral collapse. Lanes and associates reported in young women with Turner's syndrome the failure to obtain normal peak bone mass despite estrogen replacement therapy begun in adolescence. Osteochondrosis-like changes of the spine, vertebral hypoplasia, and scoliosis are common.

In addition to the metacarpal sign (shortening of the fourth metacarpal), Kosowicz described a carpal sign characterized by a more acute angular configuration of the proximal row of carpal bones. Madelung's or "bayonet" deformity of the wrist, a feature of the Leni-Weill syndrome caused by haploinsufficiency of the SHOX gene, is present in about 10% of patients. Cubitus valgus (an increased carrying angle) occurs in half, is a consequence of a developmental abnormality of the trochlear head, and develops after birth. The knee may show deformities of the medial tibial and femoral condyles with obliterated tibial epiphyses and medial projections of the tibial metaphyses that can result in genu valgum. The pelvis tends to have a male-type infer. Midface hypoplasia is common. The growth of the temporal bone, condylar cartilage, and sphenoid-occipital synchondrosis is abnormal. Scoliosis is present in approximately 10% of patients, secondary either to...

Hormone profile: Increased plasma LH and FSH concentrations; decreased plasma estradiol levels

| LH, luteinizing hormone; FSH, follicle-stimulating hormone |

**Figure 22-38** Variation in physical appearance in five patients with the typical form of the syndrome of gonadal dysgenesis. All of these patients had a 45,X karyotype, and all had differences between height age and chronologic age of 5 years or more. (Modified from Grumbach MM. Some considerations of the pathogenesis and classification of anomalies of sex in man. In Astwood EB [ed]. Clinical Endocrinology. New York, Grune & Stratton, 1960, pp 407-436.)

**Figure 22-39** A patient aged 14 years, 10 months with the typical form of the syndrome of gonadal dysgenesis. The X chromatin pattern was negative and the karyotype was 45,X. She was short (height, 134.5 cm; height age, 9 years, 5 months), was sexually infantile except for the appearance of sparse pubic hair, and exhibited characteristic stigmata of the syndrome: a short webbed neck. These findings can be detected by prenatal ultrasonography. Shephard and Fante suggested that the severe edema that occurs secondary to hypoplastic lymphatic and lymphatic duct hypoplasia in 45,X fetuses is responsible for many of the malformations involving the ears, hairline, neck, nipples, nails, and kidneys. The increased incidence of congenital heart disease associated with webbed neck, especially coarctation of the aorta (40%), has led to the suggestion that lymphatic obstruction is involved in the pathogenesis of both types of deformation.

The most common renal abnormalities are rotation of the kidney, horseshoe kidney, duplication of the renal pelvis and ureter, and hydronephrosis secondary to ureteropelvic obstruction. Complete absence of the kidney and gross renal ectopia in 7 of 141 patients was reported by Lippe and associates. Malformation of the kidneys and upper collecting system including an abnormal vascular supply are so common that intravenous urography, a renal sonogram or renography should be obtained routinely at the time of diagnosis.

Skeletal maturation is normal or slightly delayed in childhood and lags further in adolescence as a result of gonadal steroid deficiency. In most cases, the skeleton exhibits localized areas of rarefaction (fish-net appearance), especially of the hands, feet, elbows, and upper femurs. Bicorporeal girls with gonadal dysgenesis have normal bone density for height and age but decreased density at the wrist for bone age and body mass index. The risk of wrist fractures is increased. Bechtold and colleagues, using quantitative computed tomography of the forearm and human growth hormone (hGH) in estrogen-treated adolescent and young adult patients, detected low total volumetric bone mineral density owing to decreased cortical thickness and suggested bone strength may be inadequate for the relatively high body weight. Patients not treated with estrogen often develop a severe form of the post-menopausal type of osteoporosis and may develop fractures and vertebral collapse. Lanes and associates reported in young women with Turner's syndrome the failure to obtain normal peak bone mass despite estrogen replacement therapy begun in adolescence. Osteochondrosis-like changes of the spine, vertebral hypoplasia, and scoliosis are common.

In addition to the metacarpal sign (shortening of the fourth metacarpal), Kosowicz described a carpal sign characterized by a more acute angular configuration of the proximal row of carpal bones. Madelung's or "bayonet" deformity of the wrist, a feature of the Leni-Weill syndrome caused by haploinsufficiency of the SHOX gene, is present in about 10% of patients. Cubitus valgus (an increased carrying angle) occurs in half, is a consequence of a developmental abnormality of the trochlear head, and develops after birth. The knee may show deformities of the medial tibial and femoral condyles with obliterated tibial epiphyses and medial projections of the tibial metaphyses that can result in genu valgum. The pelvis tends to have a male-type infer. Midface hypoplasia is common. The growth of the temporal bone, condylar cartilage, and sphenoid-occipital synchondrosis is abnormal. Scoliosis is present in approximately 10% of patients, secondary either to...
Short stature is an invariable feature in 45,X individuals and may be evident in utero. Intrauterine growth retardation is common, and the average birth weight (2.83 ± 0.57 kg) and length (48.2 ± 3.2 cm) are 1 standard deviation (SD) below the mean value for normal infants of comparable gestational age. The growth retardation is evident by the middle of the second trimester of gestation and affects all long bones. The mean final height of patients in different series ranged from 142 to 147 cm. In a survey of 12 European countries, a total of 661 patients were found, 51% of whom were 45,X and had a mean final height of 144.3 ± 6.7 cm; none had received estrogen therapy before the age of 14 years. The ratio of sitting to standing height is frequently increased by late childhood and reflects the greater retardation in growth of the legs. Growth curves specific for Turner’s syndrome are available, including growth curves for some nationalities (Fig. 22-41).

Postnatal growth failure is evident from early infancy. By age 3 years, the mean deficit in height is 3.0 ± 1.5 SD. By a bone age of 9 years the difference in mean height between patients and normal individuals (16 cm) is close to the difference at maturity (20 cm). Hence, there is little additional loss of height relative to normal individuals after a bone age of 9 years despite the lack of a pubertal growth spurt (see Fig. 22-41). This may be a result of prolongation of growth as a consequence of the effect of estrogen deficiency on bone maturation. Although final height in untreated patients may not be achieved until late in the second decade of life, there is no major gain in height after the age of 16 years. Final height correlates with birth weight and target height.

The short stature is not attributable to a deficiency of growth hormone, insulin-like growth factor I (IGF-I, also called somatomedin-C), IGF-II, or adrenal or gonadal steroids (see Chapter 23). Decreased amplitude and frequency of growth hormone pulses have been reported after 8 years of age. Likewise, IGF-I levels that are normal up to 10 years of age are low thereafter; however, administration of either estrogen or growth hormone induces a rise in the concentration of plasma IGF-I. The changes in growth hormone secretory dynamics and IGF-I concentrations after 8 to 10 years of age are probably secondary to the lack of the estrogen-induced rise in plasma growth hormone concentration and IGF-I levels at puberty. The cause of the progressive growth failure is attributable, at least in part, to the missing PAR1.

Sexual Infanticilism.

The genital tract and external genitalia in this syndrome are female in character but immature. Located in the mesosalpinges parallel to the fallopian tubes are long, attenuated, pale, fibrous streaks of connective tissue. Typically, these streak-like or spindle-shaped structures consist of fibrous stroma arranged in whorls similar to those in ovarian stroma, but they lack primordial follicles. Vestigial mediulary elements and rudimentary mesonephric tubules like those found in the primitive genital ridge are common at the hilus. After puberty, aggregates of epithelioid cells resembling Leydig or hilus cells are present in variable quantity. Ultrasonography of the pelvis or MRI commonly detects the small uterus and streak gonads.

Singh and Carr studied the gonadal ridges of eight spontaneously aborted embryos and fetuses ranging in gestational age from 5 weeks to 4 months. Primordial germ cells were observed in all eight specimens. Until the third month of gestation, no appreciable differences were noted between these gonads and those from 46,XX fetuses; after that, connective tissue stroma increased and formation of follicles was impaired, suggesting that primordial germ cells seed the 45,X gonad, that many degenerate during oocyte formation and folliculogenesis, and that surviving oocytes undergo accelerated apoptosis. Jirasek noted that oocytes in patients with 45,X karyotype degenerate after formation of the primary follicle, possibly because the surrounding follicular cell layer is incomplete. Two active X chromosomes appear to be required for the normal development of human oogonia and oocytes. Follicles are common in the gonadal streaks of 45,X infants at birth but are uncommon by late childhood and adolescence. Nevertheless, spontaneous puberty, menarche, and fertility can occur in putative 45,X patients.

Longitudinal studies of both basal and LH-releasing hormone secretions demonstrate a lack of feedback inhibition of the hypothalamic-pituitary axis by the dysgenetic gonads in infants and young children with gonadal dysgenesis. In 58 patients aged 2 to 20 years, plasma FSH levels were elevated in those aged 2 days to 4 years and decreased to normal values between 5 and 10 years of age (Fig. 22-42). After 10 years, the plasma FSH level rose again into the castrate range. Therefore, the pattern of plasma FSH concentration followed a diphase curve similar to but higher than that in normal infants and children. The pattern of change in LH levels was comparable, but the concentrations were one third to one tenth those of FSH. LH-releasing hormone-induced LH and FSH responses exhibited a diphase pattern with age, similar to those of basal levels. In patients younger than 5 years of age, both the mean basal levels and the rise in gonadotropin levels induced by administration of LH-releasing hormone were increased. Between ages 5 and 10 years, basal levels of FSH and LH and LH-releasing-evoked responses were less than those of younger patients with gonadal dysgenesis (see Fig. 22-42). In some patients between ages 6 and 10 years, both FSH and LH concentrations and the LH-releasing-induced gonadotropin responses were comparable to those in normal children. After age 11 years a striking rise in basal and readily releasable LH and FSH levels was observed. Therefore, between the ages of 5 and 10 years, basal and LH-releasing-evoked gonadotropin responses may not reflect the functional status of the gonads in all patients with gonadal dysgenesis.

Astragalian strephos is the rule in 45,X gonadal dysgenesis, exceptions have been documented. Primary follicles have been described in the gonadal ridges of some 45,X individuals at adolescence, and this correlates with the rare occurrence of menarche and a variable but attenuated period of regular menses. In a large study of Turner’s syndrome patients older than 12 years, including, in addition to 45,X patients, those with X chromosome mosaicism and structural abnormalities, spontaneous pubertal development occurred in 16%, including menarche at a mean age of 13 years. Regular menses occurred 9 years post menarche in just over one third of this group. The presence of a second X chromosome was much more evident in those with spontaneous puberty. The figure for spontaneous pregnancy appears to be 3% to 5%. In addition to variability in the rate of follicular atresia, another possible explanation for the presence of
the section on clinical aspects. The deviation in parental origin of the retained X chromosome in 45,X individuals is a consequence of mitotic nondisjunction, which occurs in 15% to 30% of patients. The prevalence of thyroid antibodies and hypothyroidism (or hyperthyroidism) increases during childhood and adolescence and is the presence of a cryptic Y cell line. Males with a 45,X karyotype have a Y to X chromosome or a Y-autosome translocation involving variable segments of the euchromatic (sex-determining) region of the Y chromosome. Translocations have been reported involving the short arm of chromosomes 5, 14, 15, and 18 and the X chromosome. Most patients have had either minor or major anomalies not usually associated with the syndrome of gonadal dysgenesis, such as the cri-du-chat syndrome. These additional anomalies are no doubt related to the autosomal involvement in the translocation and to the degree of deletion involved.

Incidence in Abortuses, Newborns, and Twins.

The incidence of gonadal dysgenesis is approximately 1 per 2000 live female births, and approximately 50% of the patients have a 45,X karyotype. There is, in addition, a considerable loss of 45,X embryos and fetuses. About 7% of spontaneous abortuses have a 45,X constitution. It is estimated that the frequency of 45,X zygotes is 2%, probably the most common chromosome anomaly in humans but fewer than 1% of 45,X conceptuses survive to term. Hook and Warburton have analyzed chromosome karyotypes in embryonic and fetal deaths and demonstrated a significant disparity between the 45,X karyotype and those with mosaicism and/or an isochromosome for the long arm of the X chromosome (Xq;). They postulated a “fetoprotective” effect of more than one dose of some locus or loci on the long arm of the X chromosome.

Turner's syndrome carries a threefold increase in mortality and a reduction in life expectancy of 6 to 13 years; it is less in 45,X patients than in non-45,X Turner syndrome.

The incidence of autoimmune disorders is increased; the most prevalent is autoimmune thyroiditis and Graves' disease, which occurs in 15% to 30%. The prevalence of Crohn's disease and ulcerative colitis is increased and the inflammatory bowel disease is often severe.

As discussed earlier, congenital renal anomalies are common (about ninefold greater than the general population) and the risk of the obstructive uropathy and pyelonephritis is greatly increased. In addition, vascular malformations involving the kidney are more prevalent.

During childhood, problematic otitis media is common and may result in conductive hearing loss. Abnormalities in the growth of the temporal bone, condylar cartilage, and sphenoid synchondrosis result in an abnormality in the positioning of the external auditory meatus and the relation of the middle ear to the eustachian tube in patients with the syndrome of gonadal dysgenesis. These changes, along with abnormalities in the shape of the palate, are thought to be responsible for the increased incidence of otitis media. Sensorineural deafness is present in about two thirds of adult patients. The frequent episodes of otitis media and the sensorineural hearing loss are independent variables in gonadal dysgenesis; the sensorineural hearing loss may be related to loss of genes on the X chromosome responsible for the gonadal dysgenesis phenotype.

In a Danish study, Turner's syndrome women had a fivefold increased risk of developing cancer of the colon and rectum. As noted previously, the prevalence of anorexia nervosa is increased; its onset usually coincides with the initiation of estrogen treatment.

Origin of 45,X Constitution and Phenotype.

A 45,X chromosome constitution (see Fig. 22-1A and Fig. 22-4) may be a consequence of nondisjunction or chromosome loss during gametogenesis in either parent that results in a sex or ovum lacking a sex chromosome. Although errors of mitosis in a normal zygote often lead to mosaicism, a pure 45,X constitution may arise at the first cleavage division from anaphase lag with loss of a sex chromosome or, less likely, from mitotic nondisjunction with failure of the complementary 47,XXX or 47,XYY cell line to survive. However, the percentage of aborted fetuses with a 45,X karyotype is the same as in liveborn infants. Therefore, imprinting does not appear to affect fetal survival in 45,X individuals. Although some studies showed no effect of imprinting on phenotype, 45,X patients appear to have an increased prevalence of cardiovascular anomalies and webbed neck; furthermore, the height in 45,X correlates more strongly with maternal height than with midparental height. A putative imprinted gene on the maternal X chromosome, which affects social cognition, is discussed earlier in the section on clinical aspects.

The very high embryonic and fetal mortality of 45,X conceptuses, as opposed to those with 45,X/46,XX or 45,X/46,XY mosaicism or a structurally abnormal X
mosaic for all or part of the Y chromosome. The similar results obtained by Binder and colleagues indicate a low level of Y chromosome mosaicism in 45,X and chromatin-positive individuals with gonadal dysgenesis. The significance of low-percentage mosaicism for Y chromosome material and its relation to gonadal differentiation and the risk of malignancy are still to be determined. Cryptic Y chromosome identification by sensitive PCR techniques may, however, not show concordance between clinical signs of hyperandrogenism and molecular studies on gonadal tissue. In such Y-negative gonads there is hirsus cell hyperplasia. The routine screening of all Turner's syndrome patients for the presence of SRY is not recommended.

The classic gonadal dysgenesis phenotype is usually associated with absence of all or a proximal portion of the short arm of the X or Y chromosome. The haploinsufficiency of genes in these loci that are not inactivated is postulated to cause the phenotype. Page and co-workers suggested that the genes that encode ribosome protein S4X (RPS4X), and its homologue on the Y chromosome (RPS4Y), are candidate genes. However, the location of this gene on the long arm of the X chromosome and the fact that it is expressed in patients with 46,XXp and 46,XY karyotypes make it an unlikely candidate. Zimm and associates using both cytogenetic and molecular analyses found evidence of a critical region, Xp11.2p22.1, that included loci for short stature (in addition to the more distal SHOX gene), gonadal failure, high arched palate, and thyroid autoimmunity.

Ogata and Matsuo postulated that the gonadal dysgenesis phenotype is multifactorial in origin. According to their construct, the phenotype is related to (1) quantitative loss or alteration of euchromatic or noninactivated genes (haploinsufficiency), leading to global nonspecific developmental defects; (2) haploinsufficiency of pseudoautosomal and/or Y-specific growth genes and lymphogenic genes, resulting in short stature and the "deformative" stigmata; and (3) oocyte loss and gonadal dysgenesis from impaired or failed chromosome pairing during meiotic prophase.

The underlying cause of this sex chromosome abnormality is not known. An increased frequency of thyroid autoimmunity in patients with the syndrome of gonadal dysgenesis and in their parents suggests that the genetic predisposition to develop autoantibodies in one or both parents is associated with an increased prevalence of the 45,X constitution and other chromosome abnormalities in the offspring. Infants with the syndrome of gonadal dysgenesis have been born after artificial insemination and in vitro fertilization. Familial occurrence of 45,X gonadal dysgenesis is rare.

**Diagnosis and Treatment**

Phenotypic females with the following features should have a karyotype analysis: (1) short stature (>2.5 SD below the mean height value for age), (2) somatic stigmata associated with gonadal dysgenesis, and (3) delayed adolescence with increased plasma or urinary gonadotropin levels. Although determination of the X chromatin pattern (Barr body) is a rapid method of screening, karyotype analysis is the definitive procedure. The concentration of plasma FSH and inhibins is useful in assessing the functional status of the gonads.

Even though many severely affected 45,X individuals with prominent dysmorphic features (lymphedema, loose folds of skin over the back of the neck) or coarctation of the aorta are recognized at birth or early infancy, the diagnosis in the less severely affected may be delayed until childhood when short stature is evident or until the age of puberty when secondary sex characteristics fail to appear. It is important to obtain a karyotype on all girls with unexplained short stature especially those with even subtle dysmorphic features of the syndrome of gonadal dysgenesis. Saverständti and Davenport found that (excluding...}

those in whom the diagnosis was made in infancy) overall delay in diagnosis was 7.7 years. Early diagnosis is important for more optimal long-term management, treatment, and counseling, including, if appropriate and with informed parental consent, the use of recombinant hGH treatment before the child falls below -2.0 SD in height, to achieve better growth in childhood and potentially normal adult stature.

The following studies should be done in women when the diagnosis of the syndrome of gonadal dysgenesis is made: an intravenous pyelogram or ultrasonographic examination to exclude a renal anomaly; an echocardiogram or MRI study to assess cardiovascular function; periodic hearing examination and evaluation of thyroid function and thyroid antibodies; regular measurements of plasma glucose levels after adolescence; and monitoring for scoliosis and bone density in late adolescence and adulthood for evidence of osteopenia. Guidelines for the diagnosis and management for Turner's syndrome in childhood and adulthood have been updated following an international consensus workshop and reviewed by Elsheikh and co-workers. There is particular emphasis on long-term monitoring for cardiovascular disease (including hypertension, aortic dilatation and the risk of aortic dissection), regular screening for thyroid dysfunction, recognition of hearing impairment which worsens in adult life and early planning for any request for assisted conception. Table 22-10 presents the suggested follow-up of adults with Turner’s syndrome.

Therapy is directed toward augmenting stature, correcting somatic anomalies, inducing secondary sexual characteristics and menses, and counseling. As noted, the short stature in gonadal dysgenesis is not related to a deficiency of growth hormone, insulin-like growth factors, thyroid hormone, or adrenal or gonadal steroids. However, administration of pharmacologic doses of biosynthetic hGH increases growth rate and augments final height by a mean of 5 to 10 cm. The heterogeneity in response appears to be related to the chronologic age at the start of therapy, the duration of therapy, the dose and frequency of growth hormone administration, the use of oxandrolone and/or estradiol, the growth standards used, the height of the parents, and the growth hormone peak elicited by pharmacologic stimulation. Rosenfeld and co-workers have the longest and most extensive study. Starting in 1983, 70 patients between the ages of 4.7 and 12.4 years with normal growth hormone responses to provocative stimuli were studied. They were randomly assigned to (1) a control group for 1 year; (2) the anabolic steroid oxandrolone at a dose of 0.125 mg/kg by mouth daily; (3) growth hormone 0.125 mg/kg subcutaneously three times per week; or (4) a combination of oxandrolone and growth hormone. After 12 to 24 months, all groups except the growth hormone alone group were placed on combination therapy; however, the oxandrolone dose was lowered to 0.0625 mg/kg because of signs of virilization. After 3 years, most patients received daily growth hormone rather than thrice weekly; however, the dose of 0.375 mg/kg per week was unchanged. The mean height in patients who completed therapy was 151.7 cm, for a net mean gain of 9 cm over projected height and historical controls. Long-term studies now indicate that when growth hormone treatment alone is started early enough, most girls will benefit and some will achieve normal final height.
Attaining a final height of 150 cm is now a realistic target. 14 It is important to individualize the dose of growth hormone depending on the patient's growth response to the usual dose (0.375 mg/kg per week in six or seven divided doses). Growth hormone treatment should be considered when the patient's height falls below -2.0 SD on the growth curve for normal girls.

Growth hormone therapy is approved by the U.S. Food and Drug Administration for the treatment of patients with Turner's syndrome, and it was approved earlier in Japan and many Western European countries. It is prudent to discuss growth hormone therapy with the parents and patients, including its efficacy and side effects, in all patients with gonadal dysgenesis whose height is more than 2.0 SD below the mean value for age, especially those whose growth rate is less than 5 cm/year. Studies are in progress to evaluate the effects of initiating growth hormone therapy at 5 to 6 years of age before the growth deficit is severe. Growth hormone therapy is usually continued until the growth rate falls to less than 2 cm/year or the bone age exceeds 15 years. Supraphysiologic doses of growth hormone induced insulin resistance but not hypoglycemia; the increased insulin values returned to the normal range when growth hormone treatment was discontinued. 14

Estrogen therapy has commonly been deferred until age 15 or later on the assumption that treatment at an earlier age leads to rapid skeletal maturation and diminished height. This premise was based largely on the fact that pharmacologic doses of estrogens can accelerate bone maturation and lead to premature epiphyseal fusion without a proportionate increase in height. Studies in patients with aromatase deficiency and in a patient with a mutation in the estrogen receptor indicate that estrogen rather than androgen is the principal gonadal hormone involved in bone maturation and fusion and bone mineral accretion. 15 16 17 We examined the effect of early low dose, conjugated estrogen therapy on linear growth, bone age, and the development of secondary sexual characteristics in a group of patients with gonadal dysgenesis. 18 Low-dose conjugated estrogens (9 µg/kg body weight per day) or ethinyl estradiol (141 ng/kg body weight per day) was given to 21 patients with the syndrome of gonadal dysgenesis who had a mean age of 13 years and mean bone age of 10.7 years. Growth rate was transiently accelerated but declined to below the pretherapy rate after 12 months of therapy. The final height of the patients treated with low-dose estrogen was not different from that of control nontreated patients or that of a group of six girls with Turner's syndrome in whom normal ovarian function was present and spontaneous puberty ensued. Hence, no increase or decrease in mean final height was noted in our study. However, girls who received estrogen with a bone age of less than 11 years were shorter than the girls who began low-dose estrogen therapy after a bone age of 11 years. 19 Similar results have been obtained subsequently in other studies. 20 21 Initially it is important to use the lowest dose of an estrogen preparation (including an estradiol patch) 22 that gradually will induce pubertal development.

Serious psychological effects are frequently associated with a prolonged delay in the treatment of sexual infantilism. 23 The institution of low-dose, conjugated estrogen, synthetic estrogen therapy or transdermal estradiol patch 24 alone at approximately 13 years of age (bone age >11 years) elicits a brief growth spurt without inordinate advancement of skeletal maturation or reduction in final height and induces the development of secondary sexual characteristics at an age comparable to that of normal peers, thereby obviating the undesirable psychological consequences and deficient bone mineralization of a prolonged delay in sexual maturation. Studies in which growth hormone treatment was combined with early estrogen therapy (i.e., in patients younger than 12 years of age) indicate a shorter final height than those patients treated with the growth hormone alone. 25 26 The number of years of growth hormone therapy before estrogen therapy is a critical factor in predicting height gained, and hence the time of initiation of estrogen therapy in the growth hormonetreated patient has an important influence on final height. 27 Earlier introduction of growth hormone therapy or the use of higher doses of growth hormone or both to induce normal or near-normal height for age 28 29 permits the initiation of estrogen therapy by about 13 years of age, an important psychologic consideration. Therefore, in the treatment of girls with Turner's syndrome, the goal of increased adult height must be balanced against the desire for sexual maturation in each individual patient.

Estrogen replacement therapy may improve certain neuropsychologic deficits (nonverbal processing speed, motor function, and memory). 30 31 However, the neurocognitive deficits in adult women with Turner's syndrome were not altered significantly by estrogen replacement. 32 33 A number of instances of endometrial carcinoma have been reported in patients with gonadal dysgenesis. 34 The evidence suggests that estrogens, especially when unopposed by progesterone, can produce a progression of histologic changes from endometrial hyperplasia to invasive carcinoma (see also Chapter 16). To clarify the relation between estrogen therapy and endometrial pathology in gonadal dysgenesis, Rosenwaks and colleagues 35 36 studied 41 patients receiving estrogen replacement therapy. Increased risk of abnormal endometrial histology correlated with (1) a lifetime dosage of conjugated estrogens of more than 2500 mg, (2) more than 7 years of estrogen therapy, and (3) a daily dosage of conjugated estrogens greater than 1.25 mg. Progestagens can modify the effect of estrogens on endometrial histology. It is therefore prudent to treat patients with gonadal dysgenesis with low-dose cyclic estrogen replacement therapy, with progestagen added at the end of each cycle. Further studies are necessary to assess the optimal dose of estrogen that reduces the risk of endometrial carcinoma while concurrently preventing osteoporosis.

Rarely, patients with a 45,X karyotype and no cytogenetic evidence of Y chromosome material develop gonadoblastomas. 37 However, a study employing multiple Y-specific DNA probes indicates that 3.4% of apparent 45,X patients have Y chromosomal material present. 38 These 45,X patients may be at risk for gonadoblastoma formation. Most patients with a 45,X karyotype have little or no risk of neoplastic transformation of the streak gonads.

Replacement Therapy.

We routinely initiate therapy (depending on the height) at about 13 years of age with 0.3 mg of conjugated estrogen or 5 µg of ethinyl estradiol by mouth or very low dose transdermal 17-estradiol. 39 The oral dose is gradually increased over the next 2 to 3 years to 0.6 to 1.25 mg of conjugated estrogens or 10 µg of ethinyl estradiol daily for the first 21 days of the month. The patient is maintained on the minimal effective dose of estrogen needed to maintain secondary sexual characteristhaps, permit withdrawal bleeding, and prevent osteopenia. Medroxyprogesterone acetate, 5 to 10 mg/day, is given from the 10th through the 21st day of the month to ensure more physiologic menses and to reduce the risks of endometrial and breast cancer. There is only limited clinical experience on the use of transdermal estradiol patch in adolescent girls, but with this approach (while more expensive) the natural estradiol reaches the systemic circulation directly without first undergoing metabolism by the intestine and liver. 40 The common late adolescent and adult oral dose of estrogen replacement therapy often fails to increase to normal the size of the uterus (especially an adult fundal-cervical ratio as assessed by pelvic ultrasonography). The attainment of a mature heart-shaped uterine configuration is important only if the patient elects to become pregnant by oocyte donation and in vitro fertilization. 41

An important part of the management is the education of the patient and family. 42 A frank discussion with the parents of the pathophysiology of the condition is appropriate when the diagnosis is made and reinforced at later sessions. Thereafter, the child should be given as much information about her condition as she can comprehend to allay any false fears or anxieties. An honest assessment of reproductive function based on clinical findings as well as hormone levels should be given to the patient when appropriate. Advances in in vitro fertilization and embryo transplantation make pregnancy possible for these patients, but the miscarriage rate is high 43 and the risk of aortic rupture is increased during pregnancy. The importance of medical and psychosocial management throughout life in patients with the syndrome of gonadal dysgenesis must be emphasized. Social and psychosocial support from the parents and the physician usually results in a well-adjusted woman.

Partial Sex Chromosome Monosomy and Clinical Variants of the Syndrome of Gonadal Dysgenesis

Partial sex chromosome monosomy may or may not modify the expression of the classic 45,X phenotype. 44 45 Forty to 50 percent of patients with the typical syndrome of gonadal dysgenesis are X chromatin positive. This group usually has a structurally abnormal X chromosome or sex chromosome mosaicism involving a 45,X cell line. Chromatin-positive and chromatin-negative variants of gonadal dysgenesis are discussed here in relation to the more usual types of sex chromosome abnormalities to which they may be associated. The diagram in Figure 22-44 shows the variable effect of partial sex chromosome monosomy (haploinsufficiency) on the typical features of the syndrome.

In patients with sex chromosome mosaicism, the ratio in each gonad, 45,X primordial germ cells and blastemal components to those with a normal 46,XX or 46,XY constitution is probably the major determinant of whether the ultimate gonadal structure is a streak, a dysgenetic or hypoplastic ovary, or testis. 46 47 48 We believe the evidence supports the idea that, after X-ray, the primitive gonad, primordial germ cells that bear a 45,X constitution degenerate more rapidly, quite likely by apoptosis, than do 46,XX cells, resulting in a streak, hypoplastic, or normal ovary. 49 Similarly, if the gonadal blastemal components, in particular the Sertoli cells, do not contain an appropriate number of 46,XY cells, testicular development does not take place. 50 51

The quantitative relation between 45,X cells and those with a 46,XX or 46,XY pattern in peripheral tissues may also be responsible for the variable effect of mosaicism on stature and associated somatic stigmata. 52
In patients with a single cell line (euploid) containing a structurally abnormal sex chromosome, the somatic and gonadal consequences appear to be related to the nature and degree of the short or long arm deficiency of the second X or Y chromosome. Table 22-11 summarizes the correlation between structural abnormalities of the X and Y chromosomes and the clinical manifestations. The use of deletion mapping of the human sex chromosomes to clarify the relation of phenotype to karyotype has limitations. Structural abnormalities are often associated with mosaicism because of loss of the structurally abnormal sex chromosome from the stem cell line. Furthermore, structural rearrangements of chromosomes are complex. However, the advent of chromosome banding and molecular genetic techniques has facilitated the analysis of structurally abnormal sex chromosomes. At present, the data suggest that (1) ovarian determinants are located on both the long and short arms of the X chromosome and that patients with short arm deletions proximal to band Xp21 or long arm deletions proximal to band Xq25 usually have streak gonads and sexual infantilism; and (2) the short arm of the X chromosome (and to a lesser extent the long arm) contains loci that, if deleted, result in short stature and the somatic stigmata of the syndrome of gonadal dysgenesis (see section on biologic functions of the X chromosome and Y chromosome).

45,X/46,XX, 45,X/47,XXX, and 45,X/46,XX/47,XXX Mosaicism.

45,X/46,XX mosaicism is the most common finding in patients with chromatin-positive gonadal dysgenesis and is second in frequency only to 45,X; the mosaic karyotype arises through loss of one X chromosome in a 46,XX conceptus. Patients with this form of mosaicism usually exhibit fewer of the associated somatic anomalies, are not invariably short, may menstruate, and may even be fertile. One gonad may be of the streak type, and the contralateral gonad may be either a hypoplastic or a normal ovary; alternatively, both ovaries may be either normal or hypoplastic. During a family survey for a leucocyte anomaly, a normal grandmother with 45,X/46,XX/47,XXX mosaicism was discovered fortuitously. Some appreciation of the variable clinical features may be gleaned from nine patients with these forms of mosaicism studied by Morishima and Grumbach. All had normal female external genitalia. Of seven who attained pubertal age, four developed some female secondary sexual characteristics, and two were menstruating regularly. One of the two had had three pregnancies. In some, no important somatic abnormalities were detected, and two were of normal stature. One of the 45,XY/46,XX patients had a webbed neck, coarctation of the aorta, and other gonadal dysgenesis stigmata but was of normal stature and menstruated regularly. A 12-year-old 45,X/46,XX/47,XXX patient had primary hypothyroidism and autoimmune thyroiditis.

Patients with the Xqi structural abnormality (isochromosome for the long arm of the X) have an X chromosome that consists primarily of two long arms (Xq) and lacks a short arm (Xp); it arises mainly as a consequence of a break in sequence in the proximal short arm and not by centromere misdivision (Fig. 22-45) and occurs in about 15% of Turner's syndrome individuals (about 1 in 13,000 female live births). The Xqi chromosomes may be either monocentric or dicentric X. In a review of 89 cases, 29 were monocentric. Of these, only 5 of 17 were associated with mosaicism for a 45,X cell line. In contrast, 49 of 60 patients with a dicentric isochromosome had a 45,X cell line. Dicentric X isochromosomes are more unstable than monocentric forms and probably result more frequently in sex chromosome mosaicism through loss of the heteromorphic dicentric X chromosome. In 14 patients studied with molecular biologic techniques, Xp markers were found in three dicentric Xq chromosomes and in three monocentric Xq chromosomes. In five instances the Xqi was paternally derived. Isochromosome for the long arm of the X is the most common form of structural rearrangement of the X chromosome.

Patients with a long arm X isochromosome are invariably short and have streak gonads, although some menstruate spontaneously. In general, the somatic stigmata of gonadal dysgenesis are less severe than in 45,X patients. Coarctation of the aorta and severe lymphedema of the hands and feet are less common in 46,XXX patients. Webing of the neck, if present, is usually slight. The findings indicate that absence of the short arm on the second X, even in the presence of an X chromosome composed of two long arms, leads to short stature, failure of ovarian development, and some somatic stigmata of gonadal dysgenesis. The prevalence of autoimmune thyroiditis, decreased glucose tolerance, and inflammatory bowel disease may be higher in patients with structural abnormalities of the X chromosome, especially 46,X,qX, than in 45,X individuals.

Structurally abnormal X chromosomes are usually late replicating (except in balanced X-autosome translocations), and they give rise to the X chromatin body.

46,Xqpi.

There is controversy about the existence of an isochromosome for the short arm of the X chromosome. Of the 11 reported cases, 3 have been revised to long arm deletions, 4 were reported as presumptive, and 2 have been questioned on cytogenetic grounds. The controversy revolves around the difficulty in distinguishing Xp1 from deletions of the long arm.
of the X chromosome, because the banding pattern of Xp is quite similar to that of Xq from the centromere to Xq24. There have been no reports of either high-resolution chromosome banding or molecular genetic analysis in a patient with 46,XXpi.

46,XX or 45,XXI,XXii.

A ring X chromosome usually occurs as part of 45,XX/46,XX mosaicism or a more complex karyotype (see Fig. 22-45). Short stature is present in most patients, and most have minor stigmata of gonadal dysgenesis; some have a webbed neck or coarctation of the aorta. Approximately one third have spontaneous menses and develop secondary sexual characteristics. A mother and daughter with 45,XX/46,XX have been described. Although most patients with 45,XXI,XXI have the gonadal dysgenesis phenotype, patients with severe mental retardation, syndactyly, and abnormal facies have been reported. XIST, a gene that is transcribed only by the inactive X chromosome, is usually not expressed in these severely affected patients. All genes analyzed on the proximal short and long arms of the ring X were expressed, suggesting that the abnormal phenotype in these patients is caused by disomy for these genes on the X chromosome resulting from lack of dosage compensation. A ring X chromosome is associated with significant learning difficulties and some behavior problems. The degree of mental impairment is usually more severe in patients with a ring X chromosome than in those with active X chromosomes. The molecular phenotype associated with active or inactive ring X chromosomes confounds predicting prognosis in an affected fetus detected by prenatal diagnosis.

The proportion of X chromatin-positive cells is decreased in patients with a ring X chromosome, and the X chromatin bodies tend to be small. The ring X chromosome, with rare exceptions, exhibits late DNA replication.

The ring X chromosome arises by loss of both ends (telomeres) of the chromosome and union of the proximal breaks; as a consequence, a variable amount of chromosomal material is lost from each arm (see Fig. 22-45). Ring chromosomes are unstable, and the size of the ring varies in different cells of the same subject. In relation to gonadal dysgenesis, studies of patients with a ring X chromosome have established that loss of both telomeres of an X chromosome need not lead to the development of streak gonads.

It is sometimes difficult to be sure of the cytogenetic origin of the ring chromosome, a distinction that is critical in view of the increased risk of gonadal tumors associated with dysgenetic gonads and Y cell lines. Molecular cytogenetic analysis with specific X and Y chromosome probes has made identification easier.

Deletions of the short arm of the X chromosome (Xp) are rare and are frequently associated with 45,X mosaicism. Phenotypic-karyotypic analysis of 40 nonmosaic patients indicated considerable variation in somatic stigmata and gonadal function. Patients with a terminal deletion of the short arm of the X (distal to Xp22) can have normal ovarian function and no somatic stigmata of gonadal dysgenesis with the possible exception of a modest degree of short stature. Patients with deletions proximal to Xp22 usually have short stature, variable stigmata of gonadal dysgenesis, and gonadal dysfunction (Fig. 22-46). A lymphedema critical region is proposed at Xp11.4.

The abnormal X chromosome is usually the late DNA-replicating X and is responsible for the small X chromatin body in interphase nuclei in these patients. Of interest is the report of a familial group of seven patients with the syndrome of gonadal dysgenesis secondary to a deletion of the short arm of an X chromosome in which the disorder was transmitted by carriers of a balanced translocation between the X and chromosome 1.

X chromosome in which the disorder was transmitted by carriers of a balanced translocation between the X and chromosome 1. Familial Xp deletions have been detected in seven additional families with a variable phenotype and short stature as the only major phenotypic abnormality.

46,Xq and 45,XII,XX.

Patients have been reported with a deletion of the long arm of the X chromosome (Xq). In general, patients with only a 46,XXq cell line are normal in stature or have moderately short stature and exhibit few manifestations of gonadal dysgenesis but have primary amenorrhea, sexual infantilism, and streak gonads. We have studied two patients with 46,XXq karyotypes, and the findings in one are summarized in Figure 22-47. Exceptions to the rule that 46,XXq patients lack stigmata of gonadal dysgenesis and are of normal height were reported before chromosome banding techniques became available. Such cases may represent either hidden mosaicism or complex structural rearrangements of the X chromosome, including inversions and interstitial rather than terminal deletions. Studies with FISH and Southern blotting suggest that gonadal dysgenesis stigmata are absent when the break point is distal to Xq24 and that deletions distal to Xq25-q28 do not reduce stature. Most Xq patients sooner or later have ovarian failure or premature menopause irrespective of the size of the deletion.

Isodicentric X.

Isodicentric X chromosomes are large X chromosomes with two C bands. These chromosomes replicate

Figure 22-45 Structural abnormalities of the X chromosome. The normal X at the left is G banded. A dark band on the short arm and two major dark bands on the long arm are visible. The first Xq and the ring X chromosome (Xr) are not banded. They show late replication with tritiated thymidine. Note symmetry of the arms of the second Xq. Even with G banding, it is difficult to distinguish this chromosome from a possible short arm isochromosome. The long arm isochromosome (Xq) appears to be dicentric. The two chromosomes to the far right are isodicentric X chromosomes. Both have two C bands but only one functional centromere. There is a mirror-like band pattern on both sides of a point between the two C bands. The first isodicentric X chromosome presumably represents a break in the long arm of X at q22 with fusion of chromatids and duplication of the entire chromosome. The second isodicentric X chromosome appears to represent a terminal break in the short arm so that reduplication of the chromatids has produced what appears to be almost two X chromosomes.

late, form a large bipartite sex chromatin body, and apparently have one functionally suppressed centromere (see Fig. 22-45). The banding pattern of isodicentric X chromosomes reveals a mirror image about a point between the two centromeres (C bands). These chromosomes are usually associated with mosaicism for a 45,X cell line and presumably arise by chromatid break and fusion of sister chromatids. This event would produce an aneural fragment that would be lost during cell division and thereby result in a 45,X cell line. Phenotypic-karyotypic correlations in these patients are similar to those in Xp and Xq patients.
X-Autosome Translocations.

X-autosome translocations have been reviewed. In general, women with a break in the X chromosome between Xp13 and Xp26 manifest infertility, confirming the belief that this region contains genes critical to gonadal differentiation and function. Male carriers of a balanced X-autosome translocation with an X chromosome break in the "critical region," Xp13 to Xp26, are usually infertile.

X Chromatin-Negative Variants of Gonadal Dysgenesis

The pattern of sex chromosome mosaicism and structural abnormalities of the Y chromosome is similar to that for the X chromosome. Usually, as a consequence of its effect on gonadal differentiation, a Y-bearing cell line modifies the typical female phenotype of the syndrome by causing a variable degree of masculine differentiation of the genital tract.

A highly diverse phenotype is encountered in these forms of mosaicism, ranging from phenotypic females to individuals with ambiguous external genitalia to phenotypic males. As in 45,X/46,XX mosaicism, short stature and the associated somatic abnormalities, although frequently present, are inconsistent features and may vary independently of each other and of gonadal differentiation. In the review by Zah and co-workers of 60 patients with 45,X/46,XY mosaicism, two thirds were reared as females.

Of nine patients with 45,X/46,XY or 45,X/46,XY/47,XXY mosaicism studied by Morishima and Grumbach, one was a phenotypic female, one was a phenotypic male, and seven had ambiguous external genitalia (Table 22-13). The gonads varied from bilateral streaks in the phenotypic female to bilateral dysgenetic testes. In others the development was asymmetric: one patient had a streak in one mesosalpinx and a rudimentary testis on the contralateral side (so-called mixed gonadal dysgenesis); another had a normal testis in the scrotum and a streak in the hernia. The proportion of X chromatin bodies that were slightly small. Plasma gonadotropin levels were elevated: LH was 5.6 µg/L (LER-960), and follicle-stimulating hormone level was 36.5 µg/L (LER-869). The buccal smear showed a normal proportion of X chromatin bodies in interphase nuclei, which were conspicuously small. Karyotype analysis and autoradiography revealed a 46,X0p karyotype. The X chromosome that had been deleted close to the centromere, but a small segment of the short arm was visible distal to the centromere. C. A 20-year-old phenotypic female with a chief complaint of dysfunctional uterine bleeding. She had short stature, slight puffiness of hands and feet, and short fourth metacarpals. Female secondary sexual characteristics appeared at age 11, and menarche at age 13 was followed by regular menses, which later became irregular. The buccal smear contained nuclei with a normal proportion of small sex chromatin bodies. Bilateral ovaries were identified grossly and histologically during an appendectomy. Karyotype was 46,X0p. The extent of deletion of the short arms of the abnormal X chromosome in this patient is less than that seen in patients in A and B. A segment of the short arm is readily discernible above the centromere. It appears that, in these three patients with X0p karyotypes, somatic and gonadal manifestations of the syndrome of gonadal dysgenesis correlated with the magnitude of deletion of the short arm of the X chromosome.

45,X0,X, 45,XY, 45,X0XY, 45,X0XY/47,XXY, and Related Abnormalities (Table 22-12)

A brief review of the chromosome analyses of 58 patients in this category is presented. Presence of an 80% proportion of X chromatin in the buccal smear indicated a mosaicism with one cell line of greater than 20%. Habitus:

| Karyotype: | 45,X/46,XY |
| Genitalia: | Female ambiguous male with normal gonadal function |
| Wolffian duct derivatives: | Duct differentiation, contingent on functional integrity of homolateral fetal gonad (i.e., streak) |
| Müllerian duct derivatives: | Uterus, fallopian tubes, dysgenetic testes variable structures; testes wolffian duct derivatives |
| Gonad: | Streak gonads dysgenetic testes normal testes; Streak gonad + dysgenetic testis "mixed gonadal dysgenesis"; risk gonadal neoplasm (gonadoblastoma) |
| Habitus: | Short, stigmata of gonadal dysgenesis; genitalia: streak gonads female with sexual infantilism at puberty; dysgenetic testes ambiguous genitalia; if gonadoblastoma present gynecomasia secondary to estradiol production; testes normal male differentiation |
| Hormone profile: | Increased plasma FSH and LH; decreased testosterone concentrations |

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

During screening of a family for bone marrow transplantation donors, we discovered an adult with 45,X/46,XY mosaicism. Except for short stature, no stigmata of the syndrome of gonadal dysgenesis were present, and he had normal adult male genitalia (Fig. 22-49). Plasma gonadotropin and testosterone levels, both basally and in response to LH-RH, were within the normal range for adult men. On pelvic ultrasonography, müllerian duct derivatives were absent, and the testes appeared normal and homogeneous. The sperm count was 17 million/mL, and the patient demonstrated fertility, as evidenced by the fathering of a "normal" 46,XY fetus. The finding of a short, otherwise normal fertile male with 45,X/46,XY mosaicism extends the phenotypic spectrum of this disorder.

Ascertainment bias may be responsible for the lack of well-differentiated males in reports of this disorder. A review of the chromosome analyses of 58 patients in the literature who were ascertained because of ambiguous genitalia shows a preponderance of 45,X cells, suggesting that only individuals whose abnormality...

Because 45,X/46,XY mosaics not only may harbor gonadoblastomas, roughly 30% of which are associated with germ cell tumors, but also have an increased prevalence of CIS, gonadal biopsy is indicated in all individuals with a male phenotype and 45,X/46,XY mosaicism. If the testis is histologically normal and is in the scrotum or can be placed in the scrotum, it can be retained. However, careful close follow-up is mandatory. Müller, Skakkebaek, and associates recommend ultrasonography of the gonads and biopsy of the retained testis at the start of puberty. If biopsy and ultrasonography show lack of evidence of CIS, they suggest an annual ultrasonographic examination and a second biopsy at 20 years of age. The absence of CIS at age 20 suggests that the risk of a gonadal germ细胞 tumor is minimal. Page and his group proposed the location of a gonadoblastoma susceptibility locus on the Y chromosome detected Y chromosomal material in 12.2%; the occurrence of gonadoblastoma was estimated at 7% to 10% of those with Y chromosome DNA.

The restricted local or paracrine action of the testis on the development of genital ducts is well demonstrated in patients with asymmetric gonadal development. In such patients, development of male ducts and involution of the müllerian structures are also asymmetric and parallel the degree of testicular development on each side. As discussed previously, local action of the testis on müllerian duct regression is mediated through AMH, whereas unilateral differentiation of male ducts is mediated by high local levels of testosterone in the wolffian ducts and their derivatives. The presence of Sertoli cells in the ipsilateral gonad correlates with the absence of müllerian structures on the same side in patients with 45,X/46,XY mosaicism. This observation is consistent with the local secretion of AMH by embryonic and fetal Sertoli cells. Male differentiation of the external genitalia is, however, brought about by the systemic effects of testosterone secreted by a fetal testis and
Figure 22-49. The external genitalia of a normally differentiated male with 45,X/46,XY mosaicism. Karyotype analyses revealed 10% and 68% mosaicism for a 45,X cell line in blood and skin, respectively. Gonadotropin levels, both basal and LHRH-stimulated, and plasma testosterone levels were normal. Fertility was documented in vitro and by the conception of a normal male fetus.

Figure 22-49. 45,X/46,XY mosaicism with a feminizing gonadoblastoma. A. A 20-year-old female with many stigmata of the syndrome of gonadal dysgenesis, including short stature, multiple new, cubitus valgus, and hyperconvex, small nails. The buccal smear was X chromatin negative; on fluorescence microscopy, 30% of interphase nuclei had a single Y body. Karyotype was 45,X/46,XY. The patient had spontaneous development of pubic and axillary hair at age 12. At age 18, breast development was noted. Her height was 139 cm (-6.1 SD) and weight 39 kg (-2.5 SD). Bone age was 17 years; an intravenous pyelogram was normal. The concentration of plasma gonadotropins at 20 years of age was elevated; plasma luteinizing hormone was 8 μU/mL (LER-860) and follicle-stimulating hormone was 50 μU/L (LER-889). The concentration of plasma estradiol was 95 pmol/L (26 pg/mL), and that of estrone was 117 pmol/L (32 pg/mL); the plasma testosterone level was less than 0.7 nmol/L (0.2 ng/mL). On exploratory laparotomy, normal-appearing fallopian tubes and a uterus were found. The right gonad was a typical "streak," with whorls of fibrous connective tissue. B. The left gonad was replaced by a 1.3 × 1.1 × 1.0 cm tumor mass, which, on histologic section, revealed well-defined nests and islands of Sertoli-Leydig-like cells and germ cells, as well as calcification consistent with diagnosis of gonadoblastoma. C. Higher magnification illustrates aggregates of germ cells and small epithelial cells resembling immature Sertoli cells, as well as cells indistinguishable from Leydig cells. After gonadectomy the concentration of plasma estradiol was prepubertal (<18 pmol/L [<5 pg/mL]).

Diagnosis and Treatment.

The presence of functional testicular elements can be detected before puberty by the rise in the concentration of serum testosterone above prepubertal values after a course of hCG and the determination of serum AMH and inhibin B.

In some patients with 45,X/46,XY or 45,X/47,XXY mosaicism, the brightly fluorescent portion of the Y chromosome is absent. Caspersson and colleagues noted the absence of bright fluorescence of the Y chromosome in four of seven patients. In one patient, a Y-to-chromosome-2 translocation during gametogenesis was suspected. In other such patients there was no evidence of translocation or deletion of the Y chromosome. Fluorescence, C banding, and replication of the Y chromosome were altered compared with normal.

Magenis and Donlon studied 12 structurally altered Y chromosomes with a panel of banding techniques. They concluded that the nonfluorescent Y chromosome is an isodicentric chromosome that most likely arises from a chromatic break at the heterochromatic-euchromatic junction on the long arm of the Y chromosome with sister chromatid fusion and duplication of the Y. Subsequent studies with Y-specific DNA probes verified their interpretation but revealed variability in the break point on the Y. Isodicentric chromosomes are more prone to mitotic errors that result in a 45,X cell line. In patients bearing a Y cell line who have "dysgenetic gonads," gonadal extirpation is prudent. Some patients have mosaicism with a cell line containing a minute nonfluorescent chromosome fragment whose exact nature (i.e., either X or Y) is not apparent by standard chromosome banding techniques. Molecular DNA analyses or FISH should be performed in these cases to ascertain the origin of the fragment.

Mixed, asymmetric, or atypical gonadal dysgenesis is a term that has sometimes been used to describe patients with a streak gonad on one side and a testis on the other. Although this association is common in 45,X/46,XY mosaicism, these gonadal findings are not specific for this mosaicism and also occur with a 46,XY karyotype (e.g., in familial 46,XY gonadal dysgenesis).

45,X/46,XY mosaicism probably arises mainly through anaphase lag and is frequently associated with structurally abnormal Y chromosomes. Interchromosomal rearrangements with loss of the structurally abnormal Y may be a common mechanism for the production of 45,X/46,XY mosaicism. 45X/46,XY mosaicism in phenotype female patients with typical features of 45,X Turner's syndrome has been associated with a mutation in the 5' non-HMG box region of the SRY gene. In these patients the SRY mutation apart from the 45,X cell line would have prevented the differentiation of testicular tissue.

Diagnosis and Treatment.

The diagnosis is established by demonstration of 45,X/46,XY mosaicism in blood, skin, or gonadal tissue. A Y chromosome, even one lacking the distal fluorescent portion of its long arm, can be recognized by its size and morphologic appearance (parallel long arms and short, fuzzy short arms) and the presence of a segment of Giemsa 1 positive heterochromatin; it can also be identified by use of Y-specific DNA probes for the centromeric region as well as for the long and short arms. The decision as to the sex of rearing should be based on the potential for normal function of the external genitalia. In patients assigned a female gender role, the gonads should be removed, and the external genitalia should be repaired by clitoral recession, vaginoplasty, and labioscrotal reduction. Estrogen therapy should be initiated at the age of normal puberty to induce female secondary sexual characteristics. In affected infants for whom a male gender assignment is selected, all gonadal tissue except that which appears functionally and histologically normal and is in the scrotum should be removed, and prostatic tests should be placed in the reconstructed scrotal sac if appropriate. In these patients, removal of the müllerian duct remnants is indicated, as is repair of any hypospadias.

As discussed previously, most 45,X/46,XY mosaic males detected by amniocentesis are born with normal male genitalia. In these infants, it is prudent to perform MRI of the pelvis and testes to detect any müllerian structures and any inhomogeneity of the testes suggestive of dysgenesis or neoplasm. Hypothalamic-pituitary-gonadal integrity can be assessed by serial determinations of plasma gonadotropin and testosterone levels. Plasma AMH and inhibin B levels are markers of the functional integrity of the Sertoli cells. If there is hormonal or imaging evidence of testicular dysgenesis, testicular biopsy or gonadectomy (or both) is indicated in infancy. Even in the absence of evidence for testicular dysgenesis, close follow-up is indicated, including a testicular biopsy at puberty and at age 20 to ascertain malignant potential (e.g., carcinoma in situ). The need for androgen replacement therapy at adolescence depends on the capacity of the testis to secrete testosterone.

Structural Abnormalities of the Y Chromosome

Structural abnormalities of the Y chromosome that are of clinical significance are rarer than those of the X chromosome. This may be because the abnormal Y chromosome, being smaller than most structurally abnormal X chromosomes, is more readily lost from the cell during mitosis. The 45,X composition may therefore occur as a consequence of a structural abnormality of the Y chromosome that is lost at an early cleavage division. Deletions of both the long and short arms of the Y chromosome, as well as rings, isochromosomes of both arms, and dicentric chromosomes, have been described, and the PAR regions of the Y chromosome have
been defined. Proximal to the PAR region on the short arm of the Y chromosome are the sex-determining region and the sex-determining gene SRY. In general, males with deletions of the short arm of the Y chromosome do not differentiate as males and may manifest gonadal dysgenesis stigmata, especially lymphedema. They are not short. The findings in these patients support earlier evidence that genes responsible for the stigmata of gonadal dysgenesis are primarily on the short arms of the X and Y chromosomes, whereas a gene for stature (PHOG/SHOX on PAR1) and certain skeletal abnormalities resides on the proximal long arm of the Y chromosome. Deletions of the long arm of the Y chromosome and, to a lesser extent, the long arm of the X chromosome do not result in gonadal dysgenesis somatic stigmata.

The genes mapped to the long arm of the Y chromosome include a locus for H-Y antigen (SMCY) as assessed by the cytotoxic T cell assay, the pseudogene for STS, the YRBMI family of genes, and a putative locus that affects spermatogenesis.

A gene (GBY) that has a role in gonadoblastoma formation in patients with dysgenetic gonads is co-localized to a 1- to 2-Mb region (regions 3 and 4) near the centromere of the Y chromosome. A small number of patients with putative isochromosomes for the short and long arms of the Y chromosome are not mosaics. Three fourths of the patients reported with short arm isochromosomes, Ypi, were phenotypic males; the others had ambiguous genitalia. Seven patients with long arm isochromosomes, Yqi, were phenotypic females with gonadal dysgenesis. Gonadal dysgenesis stigmata and short stature were present in half the patients. In other words, the phenotype in 46,XYq11 individuals was that expected with the loss of Yp and thus SRY and the genes that prevent gonad dysgenesis stigmata, whereas patients with Ypi invariably had male differentiation. Patients with Yp Y chromosomes usually have an associated 45,XX cell line and hence are mosaics. The phenotypes vary from that of a normal male (depending on the presence of the SRY gene) through individuals with ambiguous genitalia and male pseudohermaphroditism to women with infanticile female external genitalia and bilateral streak gonads. The variation in phenotype is best explained by the effect of the 45,X cell line as well as the loss of genes on the Y chromosome.

Instances of apparently balanced Y-autosome translocations are known; usually the distal heterochromatic region of the long arm of the Y chromosome is translocated to either a D or G autosome. Other reciprocal balanced and unbalanced Y-autosome translocations have been reported in which male sex differentiation is normal.

As noted previously, Y-to-X translocations involving the sex-determining portion of the Y chromosome and a variable portion of the short arm of the X chromosome (usually the PAR) are found in more than 85% of XX males. There have also been reports of males with a 46,Y(Xp22:Yq11) karyotype who inherited the X(Y) from their mothers. These males have an intact Y chromosome and a variable deletion of the short arm of the X chromosome. The phenotypic features are variable and correlate with the extent of the deletion of the short arm of the X chromosome. Hence, short stature, mild mental retardation, chondrodysplasia punctata, STS deficiency with ichthyosis, anemia, and hypogonadotropic hypogonadism (Kallmann's syndrome) are variable features of this contiguous gene deletion syndrome. Phenotypically normal females with a 46,X(X;Y) karyotype have been reported. All females with Xp22:Yq11 translocations have been normal except for short stature and increased fetal wastage. In patients with Y-to-X translocation, careful cytogenetic and molecular DNA studies should be performed to define the exact breakpoints on the X and Y chromosomes. One can assess the functional integrity of the gonads by measuring the concentration of basal and LH/HRH-evoked plasma gonadotropins and plasma steroids. Pelvic MRI is helpful in defining the pelvic contents and gonads.

Y-autosome translocations have been reported in 45,X males. In general there appear to be two preferential locations, on chromosomes 5p and 18p, resulting in monosomy for 5p and 18p and multiple congenital anomalies. Three unrelated phenotypic males with an XQY karyotype had severe mental retardation, generalized hypotonia, and microcephaly with evidence of partial X chromosome disomy. Aberrant XY exchange involving the distal long arm of the X and the distal euchromatic region of the long arm of the Y chromosome results in functional disomy for X-linked genes, and the phenotype has been designated the XYq syndrome.

Pure Gonadal Dysgenesis

This term has been applied to phenotypic females with a 46,XX or 46,XY karyotype who have rudimentary streak gonads and remain sexually infantile but are of normal or tall stature and lack the somatic stigmata of gonadal dysgenesis. At puberty, they exhibit the usual effects of prepubertal castration, and plasma and urinary gonadotropin values are increased. The X chromatin pattern may be either positive or negative. Some X chromatin-negative patients have clitoral enlargement, which may be present at birth or first become manifest at puberty; clitoral enlargement is rarely present in X chromatin-positive patients. The designation pure gonadal dysgenesis was introduced by Hamrden and Stewart in 1959 in their report of a 19-year-old phenotypic female with the described phenotype and 46,XY karyotype. It is now known that a variety of etiologic factors may lead to the development of this clinical picture. We have chosen to restrict the term pure gonadal dysgenesis to patients with XX or XY gonadal dysgenesis (see later discussion). The latter is also referred to as complete XY sex reversal.

Familial and Sporadic Complete 46,XX Gonadal Dysgenesis and Its Incomplete Forms

46,XX gonadal dysgenesis is characterized by normal stature, sexual infantilism, bilateral streak gonads (similar in structure to those of 45, gonadal dysgenesis), normal female internal and external genitalia, primary or secondary amenorrhea, elevated gonadotropin levels, absence of the somatic stigmata of the syndrome of gonadal dysgenesis, and a 46,XX karyotype (Table 22-14).

The habitus is often eunuchoid. Rare patients have had a few somatic abnormalities, including cubitus valgus, but none has had the typical gonadal dysgenesis phenotype. McDonough and associates reviewed the phenotypic and cytogenetic findings in 82 phenotypic female patients with primary gonadal failure. Sex chromosome anomalies were found in association with ovarian failure in 52 of 82 patients, all of whom were less than 160 cm tall. Conversely, all patients taller than 160 cm with ovarian failure had either a 46,XX or a 46,XY karyotype.

Occasionally, women with clitoral enlargement, hirsutism, and other signs of virilization have serum testosterone levels above the range for normal women. The streak gonads secrete testosterone, presumably from nests of hilus cells. The high concentration of gonadotropins apparently leads to hilus cell hyperplasia and a modest increase in circulating androgen levels, which, in the presence of meager estrogen production, have potent biologic action.

Families may have multiple siblings affected, and within families the expression of the disease may vary in affected siblings. The gonads may range from bilateral streak gonads to hypoplastic ovaries with varying degrees of ovarian function resulting in secondary rather than primary amenorrhea. In the

FSH, follicle-stimulating hormone; LH, luteinizing hormone.
Familial cases transmission is consistent with an autosomal recessive trait. A locus for XX gonadal dysgenesis was mapped to the short arm of chromosome 2 in a large group of Finnish women. A homozygous missense mutation in the gene encoding the FSH receptor was detected; it resulted in a substitution of valine at residue 189 of the FSH receptor protein, and receptor activity was decreased but not absent in transfected cells. The affected women with XX gonadal dysgenesis had either primary or secondary amenorrhea, variable development of secondary sexual characteristics, and elevated gonadotropins. However, women with the FSH receptor mutation had primary follicles present in their ovaries, whereas women with primary ovarian failure of other causes had no or few ovarian follicles. Males homozygous for the same mutation of the FSH receptor had variable degrees of spermatogenetic failure but not azoosperma. Abnormal folliculogenesis in patients without the FSH receptor mutation may result from the effect of a mutant gene on germ cell migration, the gonadal blastema, or the rate of germ cell attrition, a defect in the putative ovary-organizing factor or its receptor, or accelerated atresia.

Familial 46,XX gonadal dysgenesis has been associated with sensorineural deafness. Genetic heterogeneity is suggested by concordance of the gonadal defect with deaf mutism in these families and by other families in which short stature, 46,XX gonadal dysgenesis, microcephaly, and arachnodyactyly occurred in affected siblings. Hamet and colleagues described three sisters with renal failure, adrenal hyperplasia, hypertension, sensorineural deafness, and primary hypogonadism. A kindred with cerebellar ataxia and hypergonadotropin hypogonadism and a family with mental retardation, streak gonads, myopathy, and various neurologic abnormalities have been described. The association of XX gonadal dysgenesis and eyelid dysplasia, ptosis, and epicanthus can occur in families. Haploinsufficiency of the FOXL2 gene on chromosome 3q23 (a member of the winged helix/forkhead family of transcription factor) causes autosomal dominant blepharophimosis/ptosis/epicanthus inversus syndrome (BPES type 1), which mainly involves a null mutation. In the mouse, Foxl2 is expressed in ovarian follicle cells and the developing eyelid.

Sporadic cases of 46,XX gonadal dysgenesis are heterogeneous. For example, ovarian hypoplasia has been associated with aneuplody, especially trisomy 13 and trisomy 18. Patients with 46,XX gonadal dysgenesis should be distinguished from those with ovarian failure caused by infection (e.g., mumps in childhood, autoimmune oophoritis) and from patients with antibodies to gonadotropin receptors, biologically inactive FSH, galactosemia, or biosynthetic errors that affect estrogen formation (e.g., deficiency of steroid 17-hydroxylase and/or 17,20-lyase [CYP17]).

Rare 46,XX patients with absent gonads, hypoplastic müllerian duct derivatives, and other congenital anomalies have been described in sibships with similarly affected 46,XY phenotypic females, suggesting an autosomal recessive mode of inheritance. The term 46,XX gonadal agenesis or agenadism has been applied to these patients because of the complete absence of gonads, even gonadal streaks, and the occurrence of müllerian duct abnormalities. In contrast to 46,XY gonadal dysgenesis, gonadal neoplasms are rare in 46,XX gonadal dysgenesis. The diagnosis of 46,XX gonadal dysgenesis is based on finding a normal karyotype in a sexually infantile phenotypic female with hypergonadotropin hypogonadism. In sporadic cases, it is important to confirm the presence of streak or hypogynadistic gonads by ultrasonography, pelvic MRI, or laparoscopy. Replacement therapy with estrogen is similar to that for patients with 45,X gonadal dysgenesis.

46,XY gonadal dysgenesis was first described by Swyer. This syndrome in its complete form is characterized by a female phenotype, normal to tall stature, bilateral diencephalic gonads, sexual infantilism with primary amenorrhea, eunuchoid habitus, and a 46,XY karyotype. Common features of gonadal dysgenesis are usually absent. The internal structures are female with bilateral fallopian tubes, a uterus, and a vagina. Clitoral enlargement is not uncommon, and gonadal neoplasms, especially gonadoblastoma and germinoma (seminoma, dysgerminoma), occur in 10% to 30%. In individuals with the incomplete or variant form, both the internal and external genitalia may be ambiguous. Breast development after the normal age of puberty suggests the presence of an estrogen-secreting gonadal tumor, especially a gonadoblastoma. Plasma and urinary gonadotropin levels are increased. In some patients the concentration of serum testosterone is higher than in adult women, presumably because of the secretion of androgens from the hilus cells of the streak gonads. A male proportion of single fluorescent Y bodies is present in interphase nuclei. Excluded from this syndrome are patients with variants of the syndrome of gonadal dysgenesis (e.g., 45,X/46,XY mosaicism) and those with microscopically visible structural abnormalities of the Y chromosome.

XY gonadal dysgenesis is a heterogeneous condition that can result from deletions of the short arm of the Y chromosome, mutations in the SRY gene, mutations in a variety of sex-determining genes, or duplications of the DAX1 gene on the X chromosome. As noted previously, patients with extensive contiguous deletions of the short arm of the Y chromosome can manifest gonadal dysgenesis stigmata as well as XY gonadal dysgenesis. Point mutations in the SRY gene have been found in 10% to 20% of patients with complete XY gonadal dysgenesis. Presumably,

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

most patients with XY gonadal dysgenesis who do not have a mutation in the SRY gene have mutations either in upstream or downstream genes in the testes determination and differentiation cascade. Almost all the mutations in the SRY gene in patients with the complete form of XY gonadal dysgenesis, except for example, one in the 3' region and a deletion in the 5' region of the gene, are in the DNA-binding (HMG) box domain of the SRY protein. These mutations are usually nonsense or missense single-amino-acid substitutions (15 of 23 mutations) and affect DNA binding or binding. Familial aggregates of 46,XY gonadal dysgenesis have been reported. The presence of complete 46,XY dysgenesis in "daughters" of fathers who have the same mutation in the SRY HMG box is perplexing. Possible explanations for this phenomenon include (1) another mutation in the father that allows for normal testicular determination and differentiation; (2) segregation of another polymorphic locus that interacts with SRY; (3) variations in the timing and the critical level of SRY expression achieved; and (4) mosaicism. Two novel SRY missense mutations causing reduced DNA binding have been identified in XY females and their fathers. Analyses of DNA from the fathers indicated that they were mosaic for both the wild-type and mutant SRY genes and quite likely are mosaic for the SRY mutation in their testes.

Familial 46,XY gonadal dysgenesis without an apparent mutation in the SRY may be transmitted as an X-linked, sex-limited
autosomal dominant or possibly as an autosomal recessive trait. Within a family, affected individuals may vary in the appearance of the external genitalia and the development of secondary sexual characteristics. Usually, the external genitalia and internal genital ducts are female, and the patient is sexually infantile (complete form). However, affected siblings may have ambiguous external genitalia, ambiguous genital ducts, and a urogenital sinus (incomplete or variant form). The spectrum of findings suggests heterogeneity in transmission or variable expression of the mutant gene in the same cohort. In a family reported by Chemke and colleagues, two siblings had 46,XY gonadal dysgenesis with bilateral streak gonads and another had the incomplete form with genital ambiguity, bilateral dysgenetic testes, and müllerian derivatives. We studied an infant born to the "normal" 46,XX sister in this family who had a 46,XY karyotype, ambiguous external genitalia, bilateral dysgenetic testes, and müllerian duct derivatives; inheritance in this family is consistent with an X-linked recessive or male-limited autosomal dominant trait.

46,XY gonadal dysgenesis can be caused by a duplication of the DAX1 locus on the short arm of the X chromosome (Xp21). This gene, which encodes congenital adrenal hypoplasia, is postulated to act as a suppressor of SRY. Duplication of DAX1 in 46,XY individual leads to sex reversal; deletion of the DAX1 gene has no effect on testicular development. A further example of gene duplication causing XY sex reversal has been reported for the WNT4 gene. The mechanism postulated for the sex reversal is WNT4-induced up-regulation of DAX1.

46,XY gonadal dysgenesis occurs in association with campomelic dysplasia, 844 which is caused by a mutation in the SOX9 gene on 17q21. Mutations in a single allele for this gene in males can result in both XY gonadal dysgenesis and campomelic dysplasia (see Fig. 22-17). 845,846 46,XX affected females have normal ovarian development. Homozygous mutations are probably lethal, owing to the critical function of SOX9 in chondrogenesis. No SOX9 mutations have been reported in patients with XY gonadal dysgenesis alone.

9p- and 10q- deletions also can cause 46,XY gonadal dysgenesis. 847,848 The DMRT1 at 9p24.3 is a candidate sex-determining gene that would be deleted in the 9p- patients; the gene(s) on 10q- affecting testsis determination is not known. 849,850 Mutations of WNT1 result in the Denys-Drash, Frasier, and WAGR syndromes (see later discussions). Various names have been applied to this syndrome. 840,841,842 46,XY gonadal dysgenesis has also been associated with multiple congenital anomalies (genito-palato-cardiac syndrome) as in the Smith-Lemli-Opitz syndrome (see later).

Like some 45,X individuals, some patients with 46,XY gonadal dysgenesis have ovarian follicles in the dysgenetic gonads. Cussen and MacMahon described germ cells and follicles in the underdeveloped gonads of a 3-month-old 46,XY female. Subsequent examination at age 3 years 10 months revealed bilateral streak gonads and a gonadoblastoma in one gonad. Some ovarian follicles persisted and functioned at puberty in 46,XY phenotypic females who underwent spontaneous puberty and experienced menarche. Examination of the gonads after development of secondary amenorrhea revealed only gonadal streaks with a few hilus cells. We recommend that these patients not be classified as true hermaphrodites.

There is a high prevalence of gonadal tumors, especially gonadoblastoma and germinoma, in 46,XY gonadal dysgenesis, and they can occur bilaterally in childhood. Bilateral prophylactic gonadectomy is indicated in all patients with 46,XY gonadal dysgenesis, even those who have deletions or mutations involving the SRY gene. The sex rearing of patients with the incomplete form of 46,XY gonadal dysgenesis is determined by the extent of genital ambiguity and the age at diagnosis. Patients raised as females should be placed on estrogen replacement therapy at age 12 to 13 years and should eventually be cycled monthly with estrogen and progestagen. In patients raised as males, testosterone replacement therapy should begin at the age of puberty.

"Male Turner's Syndrome"

Many phenotypic males have been reported with short stature, webbed neck, and other somatic abnormalities associated with the syndrome of gonadal dysgenesis in whom the testes were hypoplastic and frequently undescended. The resemblance of these males to females with 45,X gonadal dysgenesis suggested a pathogenetic parallelism or gonadal dysgenesis in the male. However, with rare exceptions, this relation is no longer tenable. A few patients with the phenotypic features of gonadal dysgenesis syndrome have a sex chromosome abnormality (e.g., 45,X/46,XY mosaicism) and represent a variant form of gonadal dysgenesis. The other patients have "Male Turner's Syndrome"

Among the group of phenotypic males previously classified as having male gonadal dysgenesis syndrome, a distinctive clinical entity was identified that led to the identification of its counterpart in the female and its designation as separate from the syndrome of gonadal dysgenesis. Various names have been applied to this new well-established syndrome (Noonan's syndrome, 46,XX and 46,XY Turner's phenotype, pseudo-Turner's syndrome, Ultich's syndrome), but we prefer to exclude Turner" from the designation. Table 22-16 lists the clinical features of 2 phenotypic males and 12 phenotypic females with this entity studied by us in 1962. These patients have a characteristic facies that includes hypertelorism, down-slanting palpebral tissues, epicanthal folds, ptosis, low-set anteriorly rotated ears, and, frequently, a webbed neck and short stature (Fig. 22-51); in 12 of the 14 cases, congenital heart disease was present. The most common cardiac malformation is pulmonary valvular stenosis (50% to 60%) often with dysplasia. Hypertrophic cardiomyopathy occurs in 20% to 30% of patients and can manifest in the neonatal period; the electrocardiogram is frequently abnormal. Atrial septal defects are found in 10% of patients. The echocardiogram is abnormal in 50% to 80% of individuals with Noonan's syndrome. Coarctation of the aorta and aortic stenosis, the most common cardiovascular anomalies in the syndrome of gonadal dysgenesis, are infrequent (10%). Pectus carinatum superiorly, pectus excavatum inferiorly, and cubitus valgus are often present. Feeding problems in infancy are common, including gastric dysmotility. Mental development is impaired in about 15% of patients. There are few reports of cognition and intelligence in individuals with Noonan's syndrome. Several reports have described the Noonan phenotype predicted a specific pattern of defects in cognitive functioning. Refractive errors and strabismus are common. Lymphedema occurs in 15% of patients. Sixty-five percent of patients have easy bruising or excessive postoperative bleeding as a result of a variety of coagulation defects; the most common is partial

factor XI deficiency. The chromosome constitution is normal, and gonadal differentiation is appropriate for the phenotypic and chromosomal sex. Cryptorchidism is common in males, and the testes may be hypoplastic and exhibit germinal aplasia. Puberty is delayed, and androgen deficiency is not uncommon. However, 50% of affected males have normal testicular function, including fertility in the absence of cryptorchidism. Affected females have functioning ovaries and, although the onset of puberty may be delayed, female secondary sexual characteristics eventually emerge.

Noonan’s syndrome has an incidence of 1 in 1000 to 1 in 2500 live births and about 50% of cases are sporadic. Familial clusters are usually consistent with autosomal dominant inheritance in this genetically heterogeneous disorder. Linkage analysis in a large Dutch kindred suggested location of a gene for Noonan’s syndrome on the long arm of chromosome 12 (12q24). Missense mutations in PTPN11, the gene encoding the nonreceptor protein tyrosine-2 phosphatase (SHP-2) that contains two Src homology-2 (SH2) domains, is a cause of Noonan’s syndrome, accounting for about 50% of affected individuals. A gain of function arising from excess SHP-2 activity is postulated as the disease mechanism. The abnormality of gonadal function and the higher incidence of congenital heart disease in males may play a part in the apparently higher maternal transmission of the mutant gene.

The diagnosis is based on the constellation of stigmata, the most prominent of which are short stature, webbed neck, pectus excavatum, ptosis, and right-sided congenital heart disease in a patient with a normal sex chromosome constitution. The differential diagnosis of this syndrome is extensive and includes structural abnormalities of the Y chromosome (especially those involving the short arm), 45,X/46,XY mosaicism, and dysmorphic syndromes secondary to hydantoin, primidone, or alcohol exposure during gestation. At puberty, affected males may require testosterone replacement therapy. Mean final height tends to follow the lower limits of the growth curve; mean adult height was 162.5 cm in men and 152.7 cm in women according to Ranke and co-workers.

True Hermaphroditism

The diagnosis of true hermaphroditism requires the presence of both ovarian (containing follicles) and testicular tissue in either the same or opposite gonads. Failure to adhere to this definition has led to considerable confusion. Gonadal stroma arranged in whorls, similar to those found in the ovary but lacking oocytes, should not be considered sufficient evidence to designate the rudimentary gonad as an ovary. Similarly, if testicular tissue is present in the contralateral gonad, we do not consider the presence of a few oocytes in a streak gonad to be adequate evidence for the diagnosis of true hermaphroditism. Because rare female-type germ cells may be found in patients with 45,X gonadal dysgenesis, it is of little value from the clinical, cytogenetic, embryologic, or nosologic standpoint to classify as true...
hermaphrodites the 45,X/46,XY mosaics or individuals with 46,XY complete gonadal dysgenesis in whom a dysgenetic gonad contains rare oocytes. Similarly, the status of the internal and external genitalia, which invariably exhibit some degree of ambisexual development, should not be used as a criterion for classification of an individual as a true hermaphrodite. This uncommon type of intersex is relatively more prevalent in South African blacks.

Classification

True hermaphroditism is uncommon but has been reported in more than 400 individuals. 

Patients with this syndrome may be subclassified according to the type and location of the gonads.

Lateral.

A testis is present on one side, and an ovary is present on the other in about 20% of patients. The ovary is frequently found on the left side. 

Bilateral.

Both testicular and ovarian tissue are present bilaterally, usually as ovotestes, in about 30% of patients. 

Unilateral.

Testicular and ovarian tissue is present on one side and a testis or ovary is found on the other side in slightly less than one half of cases. 

A testis or ovotestis may be

and incomplete fusion of the labioscrotal folds. The labioscrotal folds are asymmetric in half of the patients, with the right side more predominant. In rare cases a penile urethra is present. Cryptorchidism is common, but at least one gonad is usually palpable in the labioscrotal fold or in the inguinal region. An inguinal hernia, which may contain a gonad or uterus, is present in about one half of the cases, and a vagina and a uterus are present in most patients; the uterus may be underdeveloped (hemivagina), rudimentary, or absent. The differentiation of the genital ducts usually follows that of the gonads. The ovotestis is the most common gonad in true hermaphrodites, followed by the ovary and, least commonly, the testis. In patients with a testis on one side and an ovary on the other, the development of the homolateral duct is usually consistent with that of the gonad, despite the varied appearance of the external genitalia. Most patients with an ovotestis have predominantly female development of the genital ducts. The relation between gonadal structure and differentiation of the genital tract in true hermaphroditism provides additional evidence for the local action of AMH secreted by the Sertoli cells of the embryonic testes.

Breast development is common during puberty in true hermaphrodites, and menses occur in more than half of the patients. Periodic hematuria associated with menstruation is a late clue to the diagnosis. Spermagogenesis is rare; seminiferous tubules in an ovotestis or testes are abnormal in most cases, and interstitial fibrosis of the testes is common. Ovulation is not uncommon, and pregnancy and childbirth can occur in patients with a 46,XX karyotype, whereas only one 46,XY true hermaphrodite has been reported to have fathered a child.

Few studies of hypothalamic-pituitary-gonadal function have been carried out in true hermaphrodites. Whereas an ovary or
True hermaphroditism could result from sex chromosome mosaicism (apparent or cryptic), chimerism, Y-to-autosome or Y-to-X chromosome translocation, or mutation of either X-linked or autosomal genes involved in sex determination. Most 46,XX true hermaphrodites (85%) have SRY-negative in leukocyte DNA. However, by the use of molecular genetic and histochemical techniques for the SRY gene and the SRY protein, SRY gene expression and protein has been detected in the ovotestes of XX true hermaphrodites in whom leukocytes and ribosomal DNA were negative for SRY. In six XX hermaphrodites in whom the peripheral karyotype was SRY negative, all ovotestes exhibited low levels of expression of the SRY gene and SRY protein was detected mainly in Sertoli and germ cells. These observations suggest cryptic mosaicism or chimerism of a Y-bearing cell may be more common in XX 'true' hermaphrodites than previously thought.

The (genes or) responsible for XX (SRY) true hermaphroditism has not yet been identified; however, it is probably a downstream gene in the sex determination pathway that, when mutated, allows for testicular differentiation. That Y sequence generates 46,XX males and 46,XX true hermaphrodites can occur in the same pedigree is well documented. For example, studied a pedigree with two 46,XX true hermaphrodites and one 46,XX male who were first cousins. The three patients were negative for Y sequences, including PABY (pseudoautosomal boundary Y), SRY, and ZFY. The frequency of occurrence of 46,XX true hermaphrodites and 46,XX maleness was compatible with an autosomal dominant or an X-linked dominant mode of transmission with variable expression in the case of a putative X-linked gene mutation.

It has been postulated that random inactivation would result in true hermaphroditism and nonrandom inactivation would lead to an XX male. However, no evidence for a functional inactivation in the X chromosome has been reported. Reinforcement of the external genitalia has led to a general acceptance of the X chromosome as a testis determiner. In 1987, Spurle and colleagues carried out a detailed DNA analysis of the X chromosome in 66,XX SRY-negative true hermaphrodites and found no evidence of uniparental disomy of the X chromosome. Sarafoglou and Oster reviewed the familial cases of true hermaphroditism and pedigrees in which both true hermaphroditism and XX maleness have occurred. An SRY-X translocation was detected in one pedigree, but in the other affected families an X-linked gene, a sex-limited autosomal dominant gene, or an autosomal recessive gene that could have made the sex determination.

A small number of "Y-positive" 46,XX true hermaphrodites have been reported in kindreds with 46,XX males. It has been postulated that inactivation of the X chromosome would lead to a true hermaphroditism. The SRY gene by the spread of inactivation into the translocated segment. However, in one SRY-positive 46,XX true hermaphrodite, the translocated X was randomly inactivated; on the other hand, nonrandom inactivation of the X chromosome bearing the Y translocation was found in another SRY-positive 46,XX male. Accordingly, in some instances X inactivation may play a role in the gonadal phenotype of 46,XX SRY-positive males.

Sex chromosome mosaicism arises from mitotic or meiotic errors. In contrast, 46,XX/46,XY chimerism is usually a consequence of double fertilization or, possibly, fusion of two normally fertilized ova. Chimeric individuals have two distinct populations of cells, each of which has a different genetic origin (in contrast to mosaicism). Study of 46,XX/46,XY chimeras provides evidence for the fertilization of a binucleate ovum by two sperm, one bearing an X and the other a Y. Not all patients with whole-body chimerism have true hermaphroditism. One 46,XX/46,XY patient was a phenotypic male without true hermaphroditism; a likely mechanism for the chimerism in this case, based on the blood group studies and other findings, is fusion of two zygotes or fertilization of an ovum and its polar body. The experiments of Tarkowski with XX and XY mouse blastocysts demonstrated that random fusion of two blastocyst s seldom produces XXXY true hermaphrodites; fused mouse blastocysts usually develop testes rather than ovaries or ovotestes. A 46,XY true hermaphrodite, the least pattern of inactivation of the XX chromosome, has been reported. The normal expression of chimerism). Study of 46,XX/46,XY chimeras provides evidence for the fertilization of a binucleate ovum by two sperm, one bearing an X and the other a Y. Not all patients with whole-body chimerism have true hermaphroditism. One 46,XX/46,XY patient was a phenotypic male without true hermaphroditism; a likely mechanism for the chimerism in this case, based on the blood group studies and other findings, is fusion of two zygotes or fertilization of an ovum and its polar body. The prevalence of gonadal neoplasms is increased in patients with certain types of dysgenetic gonads, in particular all those with a Y-bearing cell line. Germinoma (dysgerminoma, seminoma), teratoma, and gonadoblastoma have been found. Cryptorchid testes, even when not associated with intersexuality, are also associated with an increased risk of malignancy. The probability that cryptorchid testes will undergo malignant degeneration is difficult to assess, but it is at least 10 times greater than the probability for normally descended testes. Approximately 7% of males with testicular neoplasms have been or are cryptorchid at the time of diagnosis. In addition, in one third of patients with cryptorchidism who develop carcinoma of the testis, the neoplasm occurs after orchiectomy; in patients with unilateral cryptorchidism, 25% of tumors were located in the contralateral descended testes. C I S is a premalignant lesion of the testes. It is characterized by germ cells that are larger than normal spermatogonia, have clumped chromatin, are highly aneuploid, and are positive for placent al alkaline phosphatase. C I S, also called intratubular germ cell neoplasm (IGCN), is commonly seen adjacent to germ cell tumors in adults. However, it is not found adjacent to tumors before puberty, and the cells differ morphologically from those in postpubertal males. The natural history of CIS in prepubertal patients remains to be determined. About 50% of postpubertal patients with CIS develop germ cell tumors within 5 years of diagnosis; it has been suggested that, with time, the incidence may approach 100%. C I S is thought to originate from primordial germ cells. It occurs in 2% to 4% of males with cryptorchidism, in 25% of XY individuals with ambiguous genitalia, in individuals with dysgenetic testes and an XY cell line (XY gonadal dysgenesis, XO/XY mosaicism), and in the syndrome of androgen resistance. Localized low-dose radiotherapy to the testis will eradicate CIS and germ cells but preserves Leydig cells. The progression from CIS to invasive germ cell tumors appears to correlate with expression of cyclins and cyclin-dependent kinase inhibitors.

Gonadal neoplasms are uncommon in patients with 47,XXY seminiferous tubule dysgenesis, but a small number of patients have gonadal or extragonadal germ cell tumors. Similar gonadoblastoma is rare in the streak gonads of 45,X patients and in 45,X mosaics with a normal or structurally abnormal X chromosome in the second cell line. Gonadoblastoma and dysgerminoma, mucinous cystadenoma and a hilus cell tumor with signs of utilization have been reported in gonadal dysgenesis. However, these patients have not been studied for a low percentage of Y chromosome mosaicism by molecular analyses.

Gonadoblastomas are usually composed of three elements; large germ cells, sex cord derivatives (Sertoli-granulosa cells), and stromal cells (theca cells, Leydig cells). They are found almost exclusively in patients who have a 46,XY cell line. They may be microscopic or large, especially if overgrown by other germ cell elements, and often calcified. A comprehensive review of gonadoblastoma was published by Scully (see Fig. 22-50). In 27 of 74 patients, a tumor was present in both gonads. Thirty patients were younger than 15 years of age when the tumors were diagnosed, and 10 were age 15 years or older. A few of these tumors were detected incidentally on histologic examination of dysgenetic gonads removed for other indications. In patients in whom chromosomal studies were carried out, the predominant karyotypes were 45,X/46,XY and 46,XY. Although 80% of 46,XY patients are reared as females, most display some degree of clitoromegaly or hirsutism; rarely, the tumors secrete enough estrogen to induce breast development (see Fig. 22-50). Pure gonadoblastomas can be regarded as germ cell tumors in situ and as such do not metastasize. In half the cases, however, the germ cells infiltrate the stroma of the tumor to form a seminoma. Gonadoblastomas are also associated with more highly malignant germ cell tumors such as endodermal sinus tumors, embryonal carcinoma, and choriocarcinoma (10%). There is an increased risk of gonadal tumors (gonadoblastoma and/or seminoma) in patients with 46,XY gonadal dysgenesis and particularly in familial cases. The strikingly disparate propensity for neoplastic transformation in the streak or dysgenetic gonads of patients with 46,XY gonadal dysgenesis in contrast to 46,XX gonadal dysgenesis must be emphasized. The gonadoblastoma locus (GBY) has been mapped to a critical interval on the short arm and adjacent centromeric region of the Y chromosome. Five functional genes have been identified in this region as possible candidates for the cancer-predisposing locus. TSPY, one of the encoded proteins, is preferentially expressed in the germ cells of gonadoblastoma specimens.

In view of the well-documented malignant potential of dysgenetic gonads, the question of prophylactic gonadectomy merits serious attention. The neoplasms are infrequent in childhood, but the risk rises appreciably in young adults. High gonadotropin levels may play a role in their growth, and substitution therapy with gonadotropins may afford some protection. A prudent course is to advise laparotomy or laparoscopy and removal of the dysgenetic gonads of all patients with 46,XY gonadal dysgenesis (complete and incomplete forms) and of all patients with the syndrome of gonadal dysgenesis who have a cell line with a normal or a structurally abnormal Y chromosome or who have Y chromosome material as determined by molecular genetic studies. Exceptions to this rule occur in patients who are 45,X/46,XY mosaics with normal male genitalia, histologically normal testes, and normal gonadotropin levels and in patients with 45,X/46,XY mosaicism with ambiguus genitalia who have been assigned a male gender role and in whom a histologically normal gonad is located in the scrotum. However, the fact that a gonad is located in the scrotum or labial folds and is palpable does not guarantee against a disastrous result, because seminomas can metastasize at an early stage, before a local mass is obvious. Hence, it is prudent to subject these testes postpubertally to ascertain the presence of CIS (a premalignant lesion). Patients with 45,X gonadal dysgenesis who have no suggestion of clitoromegaly are not at risk. The incidence of gonadal tumors in patients with other X chromosome abnormalities, such as 45,X/46,XX, 45,XX, 46,X(, and 46,XXp, is low; however, these patients should be examined at regular intervals and, if indicated, monitored by ultrasonography of the pelvis for signs of gonad or uterine neoplasia.

Sex Chromosome Abnormalities Unassociated with Gonadal Defects

The addition of one more sex chromosomes to the genome has a deleterious effect on cognitive function. The following five sex chromosome abnormalities are not accompanied by a typical gonadal defect but are frequently associated with mental retardation.

47,XXX

This common chromosome abnormality has the frequency of about 1 per 1000 female newborns. The prevalence of 47,XXX individuals in institutions for the mentally retarded is 4.3 per 1000, suggesting an increased risk for severe mental retardation. 47,XXX females have reduced general intelligence and low scores on tests of attention, concept formation, spatial thinking, verbal fluency, and academic skills. XXX individuals demonstrated less overall psychosocial adaptation and a greater degree of psychological disturbance, compared with patients with Klenefelter's syndrome or gonadal dysgenesis. Although some have delayed menarche or premature ovarian failure, most 47,XXXX females have normal ovarian function. 47,XXX females can rarely give birth to 47,XXX sons and the prevalence of congenital malformations is increased in the progeny of 47,XXX women. Subtle clinical features in infants ascertainment by karyotype analysis include the following: a tendency to low birth weight, decreased head circumference, advanced mean parental age, an increased incidence of clinodactyly, normal postnatal growth patterns, an increased risk of speech and language problems, and a lower mean I.Q. than the siblings or a control group. The extra X chromosome is of maternal origin in most instances, arising mainly from nondisjunction during the first or second meiotic divisions. The diagnosis of 47,XXX can be confirmed by the finding of two sex chromatin bodies in interphase cells and by the demonstration of a 47,XXX karyotype through the use of appropriate banding techniques. Because of the increased risk in the offspring of a sex chromosome abnormality (47,XXX and 47,XXY) and congenital malformations, prenatal counseling and amniocentesis should be considered in 47,XXX females who become pregnant.

48,XXX

This rare anomaly is associated with considerable phenotype heterogeneity, making identification by clinical means difficult. The most constant feature is a variable degree of mental retardation affecting speech. Ovarian function is usually normal. Average adult height is 169 cm; the prevalence of skeletal anomalies, such as clinodactyly and radioulnar synostosis, is increased. The diagnosis is suggested by finding three sex chromatin bodies in 6% to 9% of somatic nuclei and is confirmed by karyotype analysis.
The rare penta-X syndrome is invariably associated with severe prenatal and postnatal growth delay and mental retardation. Other stigmata include microcephaly, hypertelorism, epicanthal folds, up-slanted palpebral fissures, depressed nasal bridge, abnormal dentition, a short neck, congenital heart disease, clinodactyly, overlapping toes, and joint laxity. The external genitalia and gonadal function are usually normal; however, fertility is still to be documented. A proportion of interphase nuclei contain four X chromatin bodies and four late replicating X chromosomes (Fig. 22-13).

47,XXY

The first subject reported by Sandberg and associates was an essentially normal fertile man of average intelligence who was detected only because he had a daughter with Down's syndrome. However, surveys in penal institutions suggested an increase in prevalence of this anomaly, especially in tall prisoners, and gave rise to an undeserved stereotype that has been modified by later studies. Among 43 47,XXY boys 1 to 12 years of age, ascertained by routine karyotype analysis in the newborn period, no clear-cut 47,XXY syndrome emerged in childhood. No major deviations could be attributed to an extra Y chromosome, with the possible exception of a skew to the left in I.Q. scores, although full-scale I.Q. scores ranged from 80 to 140. In general, 47,XXY patients tend to be easily distractible and hyperactive and to have low tolerance of frustration. The prevalence of antisocial and other behavioral difficulties is increased. 47,XXY is a common sex chromosome abnormality, occurring in 1 per 1000 male births; it is the only aneuploidy not selected against before birth. Among the features are tall stature, nodulocystic acne, and skeletal anomalies such as radioulnar synostosis. Sexual development is usually normal, and the rare reports of hypospadias in 47,XXY patients may be coincidental. The diagnosis should be suspected in hyperactive tall men with nodulocystic acne and can be confirmed by demonstration of two fluorescent Y bodies in somatic interphase nuclei or by karyotype analysis. The additional Y chromosome most commonly arises by nondisjunction at meiosis II.

48,XXYY

The variable phenotypes associated with this rare karyotype include multiple somatic abnormalities and mental retardation. The diagnosis is confirmed by finding three fluorescent Y bodies in interphase nuclei or by karyotype analysis.

Sex Differentiation Genes

The genes known to be involved in sex differentiation are listed in Table 22-18.
### Classification of Errors in Sex Differentiation (Continued)

#### Female Pseudohermaphroditism

Female pseudohermaphroditism ([Table 22-19](#)) is the easiest of the sexual anomalies to comprehend, because the ovaries and Müllerian derivatives are normal and anatomic abnormality is limited to the external urogenital sinus and genitalia. Because in the absence of testes there is an inherent tendency for the external genitalia to feminize, a female fetus is masculinized only if exposed to androgens. The degree of fetal masculinization is determined by the stage of differentiation at the time of exposure. Once the vagina has separated from the urogenital sinus (at about the 12th fetal week), androgens cause only clitoral hypertrophy.

Even with severe masculinization of the external genitalia, the uterus and fallopian tubes are normal, because regression of the primordia for these structures, the Müllerian ducts, requires secretion of AMH by fetal testes, and this action cannot be mimicked by androgens. Although the presence of virilized genitalia usually provides prima facie evidence of an androgenic influence during gestation, ambiguous genitalia, superficially resembling those produced by androgen, are an occasional feature of other, more generalized teratologic malformations.

#### Congenital Adrenal Hyperplasia

CAH accounts for most of the cases of female pseudohermaphroditism and approximately half of all patients with ambiguous external genitalia.

#### Biochemical Variants of Congenital Adrenal Hyperplasia

Mutations in five genes, four that encode biosynthetic enzymes for steroid hormone synthesis (CYP21, CYP17, CYP11B1, CYP11A1, and HSD3B2) and one that encodes the intracellular cholesterol transport protein (StAR, steroid acute regulatory protein), can cause CAH, each resulting in distinctive biochemical consequences and clinical features ([Fig. 22-54](#) ; see Chapter 14). All (but the rare CYP11A1 heterozygous mutation) are transmitted as autosomal recessive traits. The common denominator in all six biochemical defects is impaired cortisol secretion, which results in hypersecretion of corticotropin-releasing hormone (CRH) and corticotropin and consequent hyperplasia of the adrenal cortex. Only deficiencies of 21-hydroxylase (CYP21) and 11-hydroxylase (CYP11B1), however, are predominantly virilizing disorders. In patients with "classic" forms of these two enzymatic defects, the most striking abnormality of the sexual phenotype is masculinization of the female fetus because of overproduction of adrenal androgens.

**TABLE 22-19 – Classification of Female Pseudohermaphroditism**

1. **Androgen-Induced**
   A. Fetal source
      1. Congenital adrenal hyperplasia
         a. Virilism only, defective adrenal 21-hydroxylation (CYP21)
         b. Virilism with salt-losing syndrome, defective adrenal 21-hydroxylation (CYP21)
         c. Virilism with hypertension, defective adrenal 11-hydroxylation (CYP11B1)
         d. Virilism with adrenal insufficiency, deficient 3-HSD 2 (HSD3B 2)
   2. P450 aromatase (CYP19) deficiency
   3. Glucocorticoid receptor gene mutation

B. Maternal source
   1. Iatrogenic
      a. Testosterone and related steroids
      b. Certain synthetic oral progestagens and rarely diethylstilbestrol
   2. Virilizing ovarian or adrenal tumor
   3. Virilizing luteoma of pregnancy
   4. Congenital virilizing adrenal hyperplasia in mother

C. Undetermined source
   1. Virilizing luteoma of pregnancy
and androgen precursors. Affected males have no abnormalities of the genitalia. These autosomal recessive disorders of steroid biosynthesis, of which more than 90% are caused by 21-hydroxylase deficiency, are discussed in this section as causes of female pseudohermaphroditism.

Patients with 3-HSD, CYP17, CYP1A1, or STAR deficiencies have defects that not only block cortisol synthesis but also impair the production of gonadal steroids by the gonads and by the adrenal glands. Affected males have varying degrees of male pseudohermaphroditism because of deficient testosterone production by the fetal Leydig cells, whereas affected females may or may not exhibit virilization. If present, virilization in females is much less severe than in CYP21 and CYP11B1 deficiencies. These forms of CAH in the male are discussed in the section on male pseudohermaphroditism. Administration to the pregnant rat of selective synthetic inhibitors of the enzymes involved in adrenal and testicular steroid biosynthesis produced abnormalities of sex differentiation in the offspring that are the counterparts of CAH in humans and

![Figure 22-53 Female pseudohermaphroditism induced by prenatal exposure to androgens. Exposure after 12th fetal week leads only to clitoral hypertrophy (diagram on left). Exposure at progressively earlier stages of differentiation (depicted from left to right in drawings) leads to retention of the urogenital sinus and labioscrotal fusion. If exposure occurs sufficiently early, the labia fuse to form a penile urethra. (From Grumbach MM, Ouchterlm JR. The effects of androgens on fetal sexual development: androgen-induced female pseudohermaphroditism. Front Pediatr 1965; 11:157-185. Reproduced with permission of the publisher. © The American Pediatric Society.)](image)

served to clarify the role of steroidogenic enzymes in the control of fetal sex differentiation. CYP21 (21-Hydroxylase) Deficiency

Simple Virilizing Form of CYP21 Deficiency.

Deficiency of CYP21 (CYP21A2; cytochrome P450C21), the most common cause of ambiguous genitalia in infants, is inherited (as are the other forms) as an autosomal recessive trait. The simple virilizing form of CYP21 deficiency has an incidence of about 1 per 50,000 persons and accounts for approximately 25% of subjects with CYP21 deficiency. Deficiency in the 21-hydroxylation of 11-deoxycorticosterone results in elevated circulating testosterone levels. Before the 12th week of gestation, high fetal androgen levels lead to a varying degree of labioscrotal fusion and clitoral enlargement in the affected female fetus; exposure to androgen after week 12 causes isolated clitoromegaly. (See Rule of Androgenic Dominance in the Differentiation of the External Genitalia and Urogenital Sinus.) Exposure to excess androgens in the male during gestation can result in subtle penile enlargement (e.g., testotoxicosis, virilizing adrenal hyperplasia).

The genitalia of females with the virilizing forms of CAH (CYP21 and CYP11B1) may exhibit a spectrum of masculinization from simple enlargement of the clitoris to complete labioscrotal fusion with a penile urethra (see Fig. 22-53). In severe cases the urogenital sinus is usually preserved and serves as a common outlet for both the urethra and vagina. The hypersecretion of androgens and androgen precursors begins weeks before the 12th week of gestation, especially in patients

![Figure 22-54 Diagram of the steroid biosynthetic pathways and the biosynthetic defects that result in congenital adrenal hyperplasia. The defect in patients with "lipoid adrenal hyperplasia" is not (except for one reported case) in the CYP11A1 (cholesterol side-chain cleavage) enzyme but in STAR, the sterolgenic acute regulatory protein. This protein is involved in the transport of cholesterol from the outer mitochondrial membrane to the inner membrane where the CYP11A1 enzyme is located. CYP11B1 (11-hydroxylase) catalyzes 11-hydroxylation of deoxycorticosterone and 11-deoxycorticisol primarily. CYP17 (17-hydroxylase/17,20-lyase) catalyzes both 17-hydroxylation and splitting of the 17,20 bond, but for the latter it has preferential \( ^{17} \)-17-hydroxylation activity (see text). CYP19 (aromatase) catalyzes the conversion of androstenedione to estrone and testosterone to estradiol. CYP11B2 (aldosterone synthetase) catalyzes the conversion of corticosterone to aldosterone. 3-HSD I and 3-HSD II, 3-hydroxysteroid dehydrogenase/isomerase types I and II; CYP21 (P450C21), 21-hydroxylase; 17-HSD 3, 17-hydroxysteroid dehydrogenase type 3. In the human, deletion or a homoygous null mutation of CYP11A1 (P450scs) is probably lethal in utero but a heterogeneous mutation caused congenital lipoid adrenal hyperplasia (see text).](image)

who manifest more than simple clitoromegaly. In addition to the traditional pathway, Auchs has raised the possibility that 5-reduced \( ^{5} \)-steroids such as 17-hydroxyloiprogrenin may be an important substrate for conversion to dihydrotestosterone by peripheral tissues. The uterus and fallopian tubes (mullerian structures) and the ovaries are normally formed, except in rare cases. Wolffian duct development is consistently absent regardless of the degree of virilization of the external genitalia in affected females. Thus, internal genital masculinization corresponds to gonadal sex in both affected females and males.

Postnatally, secretion of testosterone by the adrenal gland and conversion of androstenedione to testosterone in peripheral tissues result in continued virilization of the untreated patient. In the simple virilizing form of CYP21 deficiency, the 21-hydroxylation of \( ^{17} \)-deoxycorticosteroids and \( ^{17} \)-deoxycorticisol is primarily impaired. However, even in patients with "mild," late-onset CYP21 deficiency the 21-hydroxylation of mineralocorticoids is defective, as evidenced by elevated plasma 21-deoxycorticosterone levels after corticosteroid stimulation. Untreated patients with simple virilizing CYP21 deficiency usually, but not always, have normal plasma renin levels and normal aldosterone secretion rates. Untreated patients, increased androgen production leads to the early appearance of pubic hair, acne, clitoromegaly (or penile enlargement in the male), increased muscular development, other signs of virilization, rapid growth during childhood, and disproportionate increase in the rate of skeletal maturation, which results in premature closure of the epiphyses and short stature in adolescence and adulthood.

In patients with severe CYP21 deficiency, both virilization and salt loss can occur. This variant, which occurs in about 75% of patients with classic CYP21 deficiency (1 in 15,000 live births), is caused by a severe or complete defect in adrenal 21-hydroxylation that leads to impaired cortisol (adrenal fasciculata) and aldosterone (adrenal glomerulosa) secretion and increased plasma renin. Electrolyte and fluid losses due to aldosterone deficiency cause hyponatremia, hyperkalemia, acidosis, dehydration, vascular collapse, and, if untreated, death. About 50% of patients have the first salt-losing adrenal crisis at between 6 and 14 days of age; the"crisis" usually occurs as early as 6 to 12 weeks of age, usually in association with a concomitant stress. Masculinization of the external genitalia and urogenital sinuses in affected females tends to be more severe in complete CYP21 deficiency than in simple

CYP21. Without specific therapy, death can result from hyperkalemia, dehydration, hypoglycemia, and shock. In the affected male whose genitalia are normal, the differential diagnosis includes septal, pyloric stenosis, gastroenteritis, congenital heart disease, congenital adrenal hypoplasia, pseudohypopaldosteronism, and isolated defects in mineralocorticoid biosynthesis.

A newly identified abnormality in patients with classic 21-hydroxylase deficiency (especially the salt-losing form) or 11-hydroxylase deficiency is chronic adrenomedullary hypofunction as initially detected by subnormal plasma concentrations of epinephrine and free metanephrine. Adrenomedullary function correlates highly with the genotype in 21-hydroxylase deficiency. The concentration of plasma total metanephrine and especially free metanephrine was lowest in the salt-losing form, and it correlated with the expected 21-hydroxylase activity according to the genotype. It seems that determination of plasma free metanephrine is a useful indicator of the severity of 21-hydroxylase deficiency/cyan inexpensive biochemical marker that is available in commercial laboratories. More recently, children with these adrenal disorders and adrenomedullary hypofunction were reported to have increased serum leptin levels and evidence of insulin resistance. The adrenomedullary hypofunction is attributed to a low concentration of intra-adrenal cortisol and developmental defects in the formation of the adrenal medulla. Although the possibility of potential adverse effects of the adrenomedullary hypofunction and its documented biochemical consequences has been raised, these effects remain to be documented.

Nonclassic CYP21 Deficiency.

Studies of families affected with 21-hydroxylase deficiency have revealed heterogeneity in the biochemical and clinical manifestations of this condition, including asymptomatic as well as symptomatic “late-onset” disease. Affected females have no genital ambiguity at birth, in contrast to those with classic CYP21 deficiency, but can manifest symptoms of androgen excess, such as premature development of pubic hair in early childhood, accelerated linear growth, and bone maturation with resulting short stature, cystic acne, male-pattern baldness, hirsutism, menstrual abnormalities, and infertility. Symptoms and findings in women may be similar to those in women with polycystic ovary disease.

In affected males, premature development of pubic hair, beard growth, growth spurt, and phallic maturation can occur prepubertally as a result of the increased adrenal androgen production. Oligospermia and decreased fertility have also been attributed to late-onset CYP21 deficiency. Mostly, affected males are entirely asymptomatic, having been detected serendipitously as a result, for example, of family studies.

In studies of families with classic CYP21 deficiency, some individuals have hormonal criteria of this disease (i.e., elevated basal and/or corticotropin-stimulated 17-hydroxyprogesterone, androstenedione, and testosterone levels) but no clinical signs of androgen excess. These patients have been designated as having “cryptic” CYP21 deficiency. Symptoms of hyperandrogenism may wax and wane in these patients, who therefore may not be truly asymptomatic over a period of time.

New and co-workers, using corticotropin-induced rises in 17-hydroxyprogesterone, have defined hormone reference data in the form of a nomogram. Their studies provide a means of distinguishing patients with classic CYP21 deficiency from those with milder variant forms, heterozygotes, and normal individuals. These hormonal data in conjunction with linkage studies with human leukocyte antigen (HLA) typing, and in some instances, genotyping, indicated that all three variants classic CYP21 deficiency and the cryptic and late-onset variants resulted from a defect in the same gene. The features of the cryptic and late-onset forms can occur in families with the classic disease and can be present in the same patient at different times of life. The cryptic and late-onset forms arise from allelic variants of the gene that causes classic CYP21 deficiency. Genotypically, patients may be compound heterozygotes with a classic mutation and a variant allele, or they may have two variant alleles. Using hormonal data and linkage studies, Spelzer and co-workers estimated that nonclassic CYP21 deficiency is the most common autosomal recessive disorder in humans, the disease frequency being 0.1% to 0.2% in all ethnic groups. The gene frequency is higher in Ashkenazi Jews (3%-4%), and in Hispanics and Yugoslavs (1%-2%).

Molecular Genetics of CYP21 Deficiency.

CYP21, a member of the cytochrome P450 superfamily of mono-oxygenases, is a heme-containing enzyme that is bound to endoplasmic reticulum and receives electrons from NADPH by way of a flavoprotein, P450 reductase. The gene for this enzyme is located within the major HLA locus on the short arm of chromosome 6 (6p21.3). HLA types are co-dominantly inherited and can be used in informative families (those containing an affected child and the parents) to distinguish homozygotes, heterozygotes, and unaffected individuals. Although a wide variety of HLA antigens and haplotypes is found in affected patients, genetic disequilibrium has been found for certain specific types and haplotypes. In particular, HLA-Drw7 has a high degree of association with the salt-losing form of CYP21 deficiency, and HLA-DR14 occurs more frequently in patients with the nonclassic form of the disease.

Two CYP21 genes are located on each chromosome 6 between HLA-B and HLA-DR (Fig. 22-57) (Figure Not Available), a functional CYP21 gene and a nonfunctional CYP21P (CYP21A1P) pseudogene. The CYP21 gene, the gene for the fourth component of complement (C4), and a gene for a large extracellular matrix protein called tenasin are duplicated in tandem in the sequence C4A, CYP21P, XA, C4B, CYP21, and X8. This locus is one of the most complex and polymorphic in the human genome. The CYP21 genes and X genes overlap one another on opposite strands of DNA. The CYP21 and
In affected patients, plasma 17-hydroxyprogesterone values usually range from 90 to 1200 nmol/L (3000 to 40,000 ng/dL), depending on age and the severity of the disease. Infants who are sick, and especially premature infants, may have elevated androstenedione and 17-hydroxyprogesterone levels that can confound the diagnosis. Measurement of plasma 17-hydroxyprogesterone and androstenedione establishes the diagnosis in affected infants and children. The level of plasma 17-hydroxyprogesterone normally decreases within 2 to 3 weeks after birth and can be followed as a guide to the adequacy of the medical treatment. The karyotype should be obtained. Pelvic ultrasonography or MRI is useful to determine the nature of internal genital structures. An elevated concentration of plasma androstenedione also establishes the diagnosis in affected females. The level of plasma androstenedione normally decreases within 2 to 3 weeks after birth and can be followed as a guide to the adequacy of the medical treatment. The karyotype should be obtained. Pelvic ultrasonography or MRI is useful to determine the nature of internal genital structures.

Suspected CYP21 deficiency includes measurement of plasma electrolytes and glucose, 17-hydroxyprogesterone, androstenedione, and testosterone levels. An elevated concentration of plasma androstenedione and elevation of electrolytes and glucose establishes the diagnosis in affected females. The level of plasma androstenedione normally decreases within 2 to 3 weeks after birth and can be followed as a guide to the adequacy of the medical treatment. The karyotype should be obtained. Pelvic ultrasonography or MRI is useful to determine the nature of internal genital structures. An elevated concentration of plasma androstenedione also establishes the diagnosis in affected females. The level of plasma androstenedione normally decreases within 2 to 3 weeks after birth and can be followed as a guide to the adequacy of the medical treatment. The karyotype should be obtained. Pelvic ultrasonography or MRI is useful to determine the nature of internal genital structures.

Newborn screening programs for CYP21 deficiency have been instituted in a number of regions and countries by measurement of heel-blot 17-hydroxyprogesterone levels. A blood heel-blot specimen is obtained at 3 to 5 days of life in conjunction with screening for hypothyroidism and a variety of other inborn metabolic diseases. 17-hydroxyprogesterone (the “gold standard”), androstenedione, and 21-deoxycortisol levels identifies affected infants. 

In the past, diagnosis of CYP21 deficiency was based on assessment of the excretion of urinary 17-ketosteroids and pregnanetriol. The excretion of 17-ketosteroids varies with age, and in the first few days of life in unaffected infants it can be as high as 7 to 14 μmol/day (2 to 4 mg/24 hr). After 1 month of age, urinary 17-ketosteroid levels decrease to an upper limit of approximately 1.6 μmol/day (0.5 mg per year of age) until the onset of adrenarche. An elevated level of pregnanetriol, the metabolite of 17-hydroxyprogesterone, is a hallmark of 21-hydroxylase deficiency. However, in the neonatal period the excretion of urinary pregnanetriol may be within the normal range in affected infants. Thereafter, the levels rise and are useful diagnostically.

Infants with salt wasting usually have clinical evidence of frank or incipient adrenal insufficiency or crisis after the sixth day of life and especially during the second week. Early diagnosis of the salt-losing form of CAH is usually based on the clinical findings of poor feeding, weight loss, vomiting, hypotension, hyperkalemia, and often renal acidosis. The plasma concentration and excretion of aldosterone are low, and plasma renin activity is high. Mild salt losers may have normal electrolytes under basal conditions but exhibit elevated plasma renin activity and hypertension, hyperkalemia, and inappropriate natriuresis with salt restriction.

Prenatal Diagnosis and Therapy. 

The striking elevation in the level of plasma 17-hydroxyprogesterone is such a distinctive marker of 21-hydroxylase deficiency that prenatal diagnosis has been attempted by determining its concentration in amniotic fluid at risk. 

The success of prenatal diagnosis has led to attempts at prenatal treatment. Dexamethasone crosses the placenta and suppresses the fetal adrenal gland if given in sufficient doses; unlike cortisol or prednisolone, the placenta does not convert the 11-hydroxy group of dexamethasone to the inactive 11-keto group. Dexamethasone administration to pregnant women early in gestation (starting at 4 to 6 weeks) can decrease the virilization of the external genitalia in the majority of affected female infants.

The use of prenatal dexamethasone therapy in pregnancies with a fetus at risk for CYP21 deficiency is not without problems and remains controversial. 

Striking improvement in mortality and morbidity of patients with CAH has occurred over the past 50 years following the introduction of glucocorticoid and mineralocorticoid therapy. 

Treatment.
Steroid replacement treatment is usually initiated for 7 to 10 days with doses in excess of maintenance to suppress more rapidly elevated ACTH concentrations and consequent hyperandrogenism and to reduce the size of the hyperplastic adrenal glands. Lack of recognition of the true cortisol secretion rate in infants (estimated daily cortisol production about 8 mg/m² per day), and of the efficient absorption of orally administered hydrocortisone has also contributed to excess treatment. Consequently, for the initiation of glucocorticoid treatment (as opposed to maintenance therapy) we use high doses of hydrocortisone, 50 mg/m² daily (12.5 mg/day for the neonate) divided into an every-6-hour dose for five to seven days, together with fludrocortisone, 100 to 200 μg daily depending on the concentration of serum Na⁺ and the blood pressure. Salt is added to the feedings (17 to 34 mEq of sodium chloride to 2 g). Hydrocortisone is the preferred preparation in tablet form, which can be crushed or split before administration. The oral suspension of hydrocortisone is unstable and has been discontinued.

Ongoing treatment needs to be monitored using a combination of clinical indices such as growth velocity, signs of glucocorticoid excess, and skeletal maturation as determined by bone age measurements, but also biochemical indices to help modulate treatment on a shorter-term basis. Because 17-OH-progesterone is a sensitive index of 21-hydroxylase deficiency, the steroid has also been used as a monitor of control. However, it is subject to a profound diurnal variation in secretion, so that it is important to standardize the hour of sampling. The development of filter paper blood spot and saliva assays to measure 17OH-progesterone has led to the use of daily profiles to monitor treatment, the samples often conveniently collected at home by the family. However, the availability of blood spot and saliva assays for profiling and routine use is limited (e.g., it is not generally available in North America) and its cost effectiveness has not been established. Serial plasma androstenedione and testosterone measurements are also useful to monitor control in children and women, although testosterone cannot be used in boys from puberty onward in view of the predominance of testicular testosterone secretion. With careful monitoring, especially during growth and skeletal maturation, it is usually possible to maintain control during childhood with hydrocortisone doses in the range of 10 to 15 mg/m² per day divided into three equal doses and even less in the milder forms of CAH. The cortisol secretory rate in premature and term infants is 7 to 9 mg/m² per day and in normal children and adolescents is about 6 mg/m² per day. Longer-acting preparations of glucocorticoids such as prednisolone (2 to 4 mg/m² per day about 1/5 the dose of hydrocortisone) or dexamethasone (0.25 mg/m² per day as a single dose) are generally only used after linear growth has ceased because of the greater risk of complications of glucocorticoid excess such as suppressed growth velocity, obesity, and other cushingoid features. These preparations may be particularly useful in the postpubertal female with amenorrhea or irregular menses.

All salt-losers should be treated with fludrocortisone at the time of diagnosis in infancy because it decreases ACTH and vasopressin secretion and reduces the maintenance dose of hydrocortisone. The adequacy of mineralocorticoid replacement is best monitored by plasma renin determinations and blood pressure. Excess mineralocorticoid therapy can result in hypertension and congestive heart failure. Although there is a tendency for salt-losing to improve with age, this may only have occurred owing to the patient compensating by increasing dietary salt. Even though, by definition, aldosterone deficiency is not clinically apparent in the simple virilizing form of 21-hydroxylase deficiency, in a majority of patients it is useful to add fludrocortisone to the glucocorticoid regimen, especially in patients difficult to control on glucocorticoid therapy alone. The addition of mineralocorticoid often leads to a reduction in the dose of glucocorticoid. Increased circulating levels of progesterone and 17-hydroxyprogesterone are mineralocorticoid antagonists and their action on the renal mineralocorticoid receptor is blocked by the potent fludrocortisone.

Long-term follow-up studies on the effects of glucocorticoid and mineralocorticoid replacement in patients with CAH indicate that the mean adult height of both males and females was less than that of unaffected siblings and less than the normal mean adult height. More recent studies of final height indicate values more likely to be within the normal population range but still below target height. A meta-analysis of data from 561 patients with classic CAH (from 18 centers) found a mean final height of -1.4 SD less reduction in adult height than generally thought. Noteworthy, a randomized prospective crossover study showed that CAH patients treated with 15 mg/m² per day of hydrocortisone (in the lower dosage range) had a greater growth velocity compared with those given doses of 25 mg/m² per day, an observation that supports the use of the lower dose to avoid the effect of excessive glucocorticoid on growth, despite higher plasma concentrations of 17-hydroxyprogesterone. The aim is to reduce plasma 17-hydroxyprogesterone plasma levels to between 400 and 1000 ng/dL reductions to the normal range require excessive doses of glucocorticoid, especially because final height does not correlate well with the magnitude of suppression of adrenal androgens. It is likely that circulating bone and cartilage estradiol concentrations arise from conversion of adrenal androgens to estrogen by aromatase and have a role in the rate of skeletal maturation and growth. Early diagnosis with the avoidance of excessive glucocorticoid treatment and careful monitoring of compliance can lead to an adult height within the normal range for target height.

A retrospective study reported that the prevalence of learning disorders was increased in children with the salt-losing form, probably related to unrecognized hypoglycemia and to electrolyte derangements. Retrospective studies in adult women have described a high prevalence of an inadequate introitus, lack of or decreased interest in sexual activity, and a below-average proportion who were married or had sexual partners. More recent observational data suggest improvement in surgical outcome, but long-term outcome studies of the improved surgical techniques are not yet available.

The fertility rate among heterosexual sexually active women, especially those with the salt-losing form in one of these studies, was low. However, more recent studies of women who have had the advantage of improved medical, surgical, and psychological treatment and guidance report an improvement in fertility rate. An apparent increase in the frequency of homosexual and bisexual fantasies and an increased propensity for homosexual and bisexual behavior has been reported. Gender identity remains female. Although fertility can occur in untreated adult males with CAH, those who discontinue therapy or are noncompliant are at risk for tumors from adrenal rests (see Chapter 24). The testicular adrenal rest tumors are usually responsive to glucocorticoid treatment. Some rests contain LH receptors, which may be a cause of unresponsiveness to glucocorticoids.
adrenal rests can be reversed when glucocorticoid therapy is reinstituted. In some patients, surgical ablation of enlarged adrenal rests has been indicated.

Noncompliant patients are at increased risk for adrenal adenoma or carcinoma and adrenal incidentalomas, which may occur in more than 70% of affected adults, including those with the nonclassic form of CAH and even heterozygotes.

It is recommended that all patients receive treatment throughout life with a glucocorticoid and, if indicated, a mineralocorticoid (Fig. 22-60 : Table 22-21 ).

With the improved fertility rate with modern medical and surgical management of affected females, one can look forward to an increased number of successful pregnancies. When possible, these patients should be managed in a tertiary center with the facilities, personnel, and experience to care for high-risk pregnancies. It is important to use glucocorticoids that are metabolized by placental 11-hydroxysteroid dehydrogenase II (e.g., hydrocortisone, prednisone, prednisolone, not dexamethasone). Table 22-22 contains guidelines for the care of women with classic CAH during pregnancy and delivery.

Genital surgery should not be undertaken until the parents provide informed consent after discussion and thorough review of clinical status; issues surrounding the need for and the type of surgery, the experience and skill of the surgical team, and the surgery to be undertaken; and the options. Emerging clinical evidence suggests that the recommended time of genitoplasty is at age 2 to 6 months, especially for infants with a high proximal junction of the vagina and urethra. Citroplasty is the procedure of choice, not clitoridectomy, and it merits thorough consideration. If clitoridoplasty is undertaken, it is essential, as indicated by long-term outcome studies, to preserve the neurovascular bundle, the glans, and surrounding skin. In a retrospective study of cosmetic and anatomic outcomes in a selected group of women (which included those with CAH) who had feminizing genital surgery in childhood, nearly half had a poor cosmetic result and nearly all the patients needed further treatment for tampon use or intercourse. The time of revision of the vaginoplasty in adolescence is the decision of the patient and, if undertaken before 18 years of age, the patient and the family. The patient and parents must be reassured that with appropriate treatment and compliance the child will grow and develop into a normal, functional adult. Fertility in males and feminization, menstruation, and fertility in females can be expected in the adequately treated patient.

Labor and Delivery

Stress Dose Glucocorticoid Therapy

A soluble hydrocortisone ester (up to 50100 mg IV every 8 hr) should be given at the initiation of active labor and continued until after delivery, followed by a rapid taper to previous maintenance doses.

Cesarean versus Vaginal Delivery

Android pelvic characteristics may increase the risk for cephalopelvic disproportion.

Elective cesarean section should be considered in all patients, especially those who have had reconstructive genital surgery.

Evaluation of the Infant

Examine the infant for ambiguous genitalia. Female pseudohermaphroditism may be a consequence of either maternal hyperandrogenism or, if the father is a carrier, fetal 21-hydroxylase deficiency. (Male infants may have enlarged external genitalia.)

If the external genitalia are ambiguous, appropriate laboratory studies in the infant should be carried out to exclude 21-hydroxylase deficiency.

Suppression

Use a glucocorticoid that is metabolized by placental 11-hydroxysteroid dehydrogenase-II (e.g., hydrocortisone, cortisol acetate, prednisone, methylprednisolone).

Assess clinical status, serum electrolytes, and serum androgen levels regularly to determine the need for increased glucocorticoid and/or mineralocorticoid therapy. Excessive nausea, salt craving, and poor weight gain suggest adrenal steroid insufficiency. In select cases, measurement of plasma renin activity may be helpful.

Serum testosterone and free testosterone levels should be measured every 6 weeks in the first trimester and every 6 to 8 weeks thereafter. Target free testosterone levels to the high normal range for pregnancy; however, management must be individualized for each patient. Avoid inducing cushingoid effects from too high a dose of glucocorticoids.

Fetal gender determination by ultrasonography may be helpful in guiding treatment goals, because maternal androgen excess will have minimal effects on the male fetus.

**Cesarean versus Vaginal Delivery**

Android pelvic characteristics may increase the risk for cephalopelvic disproportion.

Elective cesarean section should be considered in all patients, especially those who have had reconstructive genital surgery.

**Evaluation of the Infant**

Examine the infant for ambiguous genitalia. Female pseudohermaphroditism may be a consequence of either maternal hyperandrogenism or, if the father is a carrier, fetal 21-hydroxylase deficiency. (Male infants may have enlarged external genitalia.)

If the external genitalia are ambiguous, appropriate laboratory studies in the infant should be carried out to exclude 21-hydroxylase deficiency.

*In an affected mother with 21-hydroxylase deficiency, we estimate the risk of having an affected female infant with fetal congenital adrenal hyperplasia to be approximately 1 in 240 based on an estimated 1 in 60 incidence for heterozygous individuals (see text for further details).
advancement in skeletal maturation with premature epiphyseal closure. An effective intermediate dose cannot consistently be achieved in some patients, especially those with the severest form of CAH associated with null mutations. Adolescents and adults with this disorder who have been treated from infancy are being assessed currently in many clinics, and despite the improvement in survival, the overall results, even with acceptable compliance with the treatment, are disappointing in terms of growth, obesity, bone mineral density, and, in women, fertility, especially in those with severe CYP21 deficiency. These considerations have led to a reassessment of therapy and the proposal to test and assess surgical and novel medical treatments.

Adrenoleukopenia by laparoscopy is increasingly being used in a small number of centers for females with null CYP21 gene mutations, on the basis that physiologic glucocorticoid and mineralocorticoid substitution therapy may be easier in the absence of ACTH-induced hypersecretion of abnormal amounts of androgens and estrogen. Histologically, adrenal tissue appears to be normal, and this controversial procedure is now safely undertaken by laparoscopy and normal menses, and body composition can be restored in poorly controlled adult females. Recurrence of virilization has been reported after adrenalec-tomy in females, the source of androgens being ovarian or ectopic adrenal tissue.

A second experimental approach involves the use of pharmacologic agents to improve skeletal growth. Trials are in progress to study the effects of third-generation aromatase inhibitors to reduce the conversion of androgens to estrogens in conjunction with an antiandrogen. The usefulness of aromatase inhibitors such as letrozole or anastrozole to block estrogen production in the periphery was suggested by the finding of delayed skeletal maturation in a man with estrogen resistance and men and women with severe generalized aromatase (CYP19) deficiency, indicating a critical role for estrogen in epiphyseal maturation and fusion. Pharmacologic blockade of estrogen production and androgen action may make it possible to reduce the dose of glucocorticoid to a physiologic level. A 2-year interim analysis of a study of children with CAH given testolactone (a weak aromatase inhibitor) and flutamide (an antiandrogen) showed a reduction in the dose of hydrocortisone (8.6 mg/m² per day versus 13.5 mg in treated and control groups, respectively) and improved short-term growth and skeletal maturation.

The long-term outcome of this approach and the safety of such polypharmacy for the treatment of CAH will require careful evaluation and monitoring. Experience with LHRH agonists in true precocious puberty has led to a trial in a small cohort of short CAH patients of treatment with hGH with or without an LHRH agonist; this approach improved growth velocity, and predicted final height and long-term data are awaited with interest.

Other potential future therapies may involve the application of corticotropin-releasing factor (CRF or CRH) receptor antagonists that already are showing promising results in the treatment of psychiatric disorders. Because receptors for CRF are widely expressed, the challenge will be to use antagonists selective for the role of CRF in pituitary-adrenal function.

The management of single gender disorders such as CAH can benefit from the advances in gene therapy. Restoration of normal adrenal steroidogenesis was reported in homozygous 21-hydroxylase-deficient mice given intra-adrenal injections of an adrenoviral vector encoding the genomic sequence of human CYP21. There are clearly issues to resolve not only about efficient, safe, stable, tissue-specific gene delivery systems but also about the practicalities of serial intraadrenal injections in patients with CAH. Nevertheless, the adrenal may be a "privileged site" for gene therapy.

CYP11B1 (11-hydroxylase) Deficiency: Virilization with Hypertension

Cytochrome P450 c11 is located in the mitochondrial inner membrane. It serves as a terminal oxidase of an electron transport chain that includes adrenodoxin reductase and adrenodoxin. There are two distinct 11-hydroxylase enzymes. CYP11B1 (P450 c11) and CYP11B2 (P450 c11a), encoded by two genes located in tandem at 8p22-22.1. The genes contain nine exons and are 93% identical. CYP11B1 encodes the 11-hydroxylase, which converts 11-deoxycorticosterone to corticosterone and 11-deoxycorticisol to cortisol. CYP11B2 encodes the enzyme aldosterone synthetase, which catalyzes the conversion of deoxycorticosterone to corticosterone and corticosterone to aldosterone. CYP11B1 has little 18-hydroxylation and 18-oxidation activity.

CAH resulting from CYP11B1 deficiency was first described by Eberlein and Bongiovanni and accounts for 5% to 8% of patients with CAH, occurring in about 1 of 10,000 births of European extraction. However, there is an increased incidence of 11-hydroxylase deficiency among Sephardic Jews from Morocco (1 in 5,000 to 1 in 7,000) and Arabs. In its classic form, CYP11B1 deficiency impairs conversion of 11-deoxycorticisol to cortisol and of deoxycorticosterone (DOC, a mineralocorticoid) to corticosterone in the zona fasciculata of the adrenal gland, resulting in accumulation of these steroid precursors. The cortisol deficiency results in increased corticotropin secretion and leads to increased secretion of 11-deoxycortisol, DOC, corticosterone, and androgen by the adrenal gland. Hypertension, a hallmark of 11-hydroxylase deficiency, occurs in approximately two thirds of patients, sometimes as early as the first few years of life. Hypertension is presumably a consequence of the excess DOC secretion, with resultant salt and water retention, and volume expansion. Classically, plasma renin activity levels are low (low renin hypertension); hypokalemia is uncommon. The presence of hypertension does not always correlate with the plasma concentration of DOC and, contrariwise, transient salt loss has been reported in rare infants with apparent classic 11-hydroxylase deficiency.

Excess androgen secretion in utero by the stimulated fetal adrenal gland masculinizes the external genitalia of the female fetus and causes female pseudohermaphroditism. Postnatally, untreated males and females experience progressive virilization and rapid somatic growth and skeletal maturation. Prepubertal gynecomastia can occur in untreated patients and regresses with glucocorticoid therapy.

Putative mild, late-onset, and even cryptic forms of 11-hydroxylase deficiency have been reported. These patients are born with normal genitalia and develop signs and symptoms of androgen excess in childhood, at adolescence, or as adults, but they usually do not manifest hypertension.

Over 31 mutations in the CYP11B1 gene have been reported associated with 11-hydroxylase deficiency. Most are substitutions with a small number of deletions or insertions. There appears to be some clustering in exons 6 to 8 of the gene mutations. In Moroccan Jews, all affected patients are homozygous for the same mutation, Arg448His, consistent with a founder effect. This mutation is also found in other ethnic groups. Another mutation, Arg448Cys, occurs in codon 448, suggesting that this codon is a "hot spot" for mutations. Although CYP11B1 and CYP11B2 are closely linked homologues, both genes are functional, and gene conversions are not a cause of impaired enzyme activity. As with 21-hydroxylase deficiency, the nonsense mutations (i.e., those resulting in less enzymatic activity) would be expected to result in the more severe phenotypic manifestations. However, as in 21-hydroxylase deficiency, heterogeneity in phenotypic manifestations with the same genotype can occur.

Mutations in the CYP11B2 gene impair the conversion of DOC to aldosterone and result in hyponatremia, hyperkalemia, and failure to thrive but do not impair sex differentiation or gonadal function. Two forms exist: so-called corticosterone methyl oxidase I (CMO1) deficiency, a defect in the 18-hydroxylation of corticosterone, and short corticosterone methyl oxidase II (CMO2) deficiency, a defect in the 18-oxidation of 18-hydroxycorticosterone to aldosterone. Neither of these mutations affects cortisol synthesis or results in excess androgen secretion. Glucocorticoid-suppressible hyperaldosteronism and hypertension result from the fusion of the 5' end of the CYP11B1 gene and the 3' end of the CYP11B2 gene; as a consequence of this mutation, synthesis of aldosterone in the zona fasciculata is mediated by corticopin. There is no defect in 11-hydroxylation of deoxycorticisol; hence, virilization does not occur.

Diagnosis.
DOC, and corticosterone levels in plasma or measurement of tetrahydrodemobolates in urine. The diagnosis should be suspected in patients who have levels of these steroids that are at least threefold higher than the 95th percentile for age. The increased secretion of the mineralocorticoid DOC produces salt and water retention and consequently results in the suppression of plasma renin activity and aldosterone. Steroidogenic enzymes for CYP11B1 activity do not differ from normal individuals in the response of 11-deoxycorticosteroids, DOC, or corticosterone to the administration of corticotropin. The disorder can be detected prenatally, and the masculinization of the external genitalia of affected female fetuses can be prevented by prenatal dexamethasone treatment.

The treatment of CYP11B1 deficiency is similar to that of the non-salt-losing form of CYP21 deficiency. Cortisol suppresses corticotropin secretion and, as a consequence, corrects the increased secretion of adrenal androgens and DOC. Replacement therapy usually arrests virilization and alleviates the hypertension. However, in patients with long-standing hypertension, adjunctive therapy with antihypertensive agents may be necessary to control the hypertension. The principles concerning surgical repair of the external genitalia are similar to those relating to CAH caused by 21-hydroxylase deficiency.

### 3-Hydroxysteroid Dehydrogenase-14,15-Dioxygenase Deficiency

3-Hydroxysteroid dehydrogenase type 1 and type 2 (HSD3B1 and HSD3B2) are enzymes that convert cholesterol to androgens and estrogens. Mutations in these genes can lead to a variety of clinical manifestations, including virilization in females and ambiguous genitalia in males. Inheritance is typically autosomal recessive. The diagnosis is made by detecting elevated basal or corticotropin-induced 11-deoxycortisol, DOC, or corticosterone across the age span. The most useful steroid synthesis from 5-17-hydroxypregnenolone is the 17-steroid synthesis from 5-17-hydroxypregnenolone. Aldosterone is synthesized from 11-deoxycortisol, which is converted to aldosterone by the enzyme aldosterone synthase. Aldosterone is a mineralocorticoid that regulates blood pressure and sodium and water balance. The increased secretion of aldosterone results in sodium and water retention, leading to hypertension. The diagnosis should be suspected in patients who have levels of aldosterone that are at least threefold higher than the 95th percentile for age. The increased secretion of aldosterone produces hypertension and is associated with the non-salt-losing phenotype.

Inheritance of HSD3B2 gene is expressed in the placenta, adrenals, testes, and ovaries. The diagnosis should be suspected in patients who have levels of aldosterone that are at least threefold higher than the 95th percentile for age. The increased secretion of aldosterone produces hypertension and is associated with the non-salt-losing phenotype.
stereoidogenesis. In contrast to the rat and the pig, the human and bovine P450{	extsubscript{C17}} enzymes preferentially convert 17-hydroxyprogrenenolon to DHEA (19, 21, 22). In contrast to the rat and the pig, the human and bovine P450{	extsubscript{C17}} enzymes preferentially convert 17-hydroxyprogrenenolon to DHEA (19, 21, 22). They have very poor 17,20-lyase activity (22). The human 17,20-lyase is about 50 times more efficient than the 17,20-lyase. This enzyme also has significant 16-hydroxylase activity. The enzyme is bound to the smooth endoplasmic reticulum where it accepts electrons from a specific flavoprotein, NADPH450 oxidoreductase. The gene CYP17, which encodes the enzyme, is approximately 13 kb long, contains eight exons, is located on chromosome 10 at 10q24.25, and is expressed in the adrenals and gonads, but not in the placenta or in ovarian granulosa cells.

Two types of enzymatic deficiency causing this rare form of 17-hydroxylase and 17,20-lyase deficiency. The combined form is most common (discussed in the section on male pseudohyperplasmosis). However, rare patients with putative isolated 17,20-lyase deficiency have been described. Women with 17,20-lyase deficiency would be expected to have sexual infantilism with lack of adrenarche and elevated gonadotropins at puberty resulting from an inability to synthesize both androgens and estrogens in the adrenals and gonads. In contrast to 17-hydroxylase deficiency, there should be no defect in cortisol synthesis and no mineralocorticoid (DOC) excess and hypertension. Studies on a patient with combined 17-hydroxylase and 17,20-lyase deficiency demonstrated another defect: the absence of 16-ene-synthetase activity, which resulted in impaired conversion of pregnenolone to C{	extsubscript{19}}-steroid sex pheromone precursor and suggests that CYP17 affects 16-ene-synthetase activity in the gonads.

17-Hydroxylase deficiency is a rare autosomal recessive disorder that occurs in approximately 1 in 50,000 individuals. More than 130 cases have been reported. It was initially reported by Biglieri and colleagues in 46,XX females who had low renin hypertension, hypokalemia, and sexual infantilism. Subsequently, this defect was described in 46,XY male infants, children, and adults with pseudohyperplasmosis. A defect in 17-hydroxylase in both the adrenal cortex and gonads results in impaired synthesis of 17-hydroxyprogestrone and 17-hydroxyprogrenenolone and thus of cortisol, androgens, and estrogens. Decreased cortisol synthesis causes increased corticotropin secretion, which results in excessive secretion of 17-deoxysteroids by the adrenal cortex, including the mineralocorticoid DOC, corticosterone, and 18-hydroxycorticosterone. Excess DOC secretion leads to hypertension, hypokalemia, suppression of the renin-angiotensin system, and, secondarily, diminished aldosterone synthesis and secretion in most reported patients. Corticosterone is a weak glucocorticoid, the high plasma concentrations in this disorder prevent the signs and symptoms of cortisol deficiency and modulate the secretion of corticotropin.

The phenotypic manifestations are a consequence of the biochemical defects in adrenal and gonadal steroid biosynthesis. 17-Hydroxylase deficiency is usually recognized at the time of expected puberty in the female because of the presence of hypertension and/or hypokalemia associated with hyperadrenocorticism. Affecte 46,XX females have normal female internal and external genitalia, but the ovaries cannot secrete estrogens at puberty, resulting in sexual infantilism and hypogonadism with elevated plasma FSH and LH levels. In addition, the lack of adrenal and ovarian androgens can result in little or no growth of pubic and axillary hair. In affected 46,XY individuals, the ovaries have a high proportion of atretic follicles and some ovaries contain an increased number of enlarged follicular cysts. (For manifestations in 46,XY males, see Figure 22-63).

In contrast to the rat and the pig, the human and bovine P450{	extsubscript{C17}} enzymes preferentially convert 17-hydroxyprogrenenolon to DHEA (19, 21, 22). In contrast to the rat and the pig, the human and bovine P450{	extsubscript{C17}} enzymes preferentially convert 17-hydroxyprogrenenolon to DHEA (19, 21, 22). They have very poor 17,20-lyase activity (22). The human 17,20-lyase is about 50 times more efficient than the 17,20-lyase. This enzyme also has significant 16-hydroxylase activity. The enzyme is bound to the smooth endoplasmic reticulum where it accepts electrons from a specific flavoprotein, NADPH450 oxidoreductase. The gene CYP17, which encodes the enzyme, is approximately 13 kb long, contains eight exons, is located on chromosome 10 at 10q24.25, and is expressed in the adrenals and gonads, but not in the placenta or in ovarian granulosa cells.

The CYP17 gene has been studied in many patients, and more than 22 different mutations have been identified in its coding region. Complete absence of 17-hydroxylase/17,20-lyase activity has resulted from a variety of mutations, including single base-pair changes resulting in missense mutations, duplications, deletions, and premature translational termination. These mutations, except for one reported in Mennonite kindreds and one in Micronesian patients, appear to be random. The most common mutation is the four base-pair duplication in exon 8, shared by Mennonites and individuals in the Friesland region of the Netherlands, which is attributed to a founder effect originating in Friesland. The mutations in the CYP17 gene that result in complete loss of 17-hydroxylase activity provide strong evidence that only one enzyme has 17-hydroxylase activity.

Patients with partial combined deficiencies of both activities have been analyzed. A 46,XX female with homozgyous deletions of the phenylalanine codon at amino acid 53 or 54 is a deletion of phenylalanine at codon 53 or 54. Subsequently, is a deletion of 518 nucleotides and an insertion of 469 nucleotides. His120 + 7nt is a seven-nucleotide duplication at codon 120 (histidine). +ILe112 is a duplication of isoleucine at codon 112. GC300,301 is a deletion of two nucleotides, guanine and cytosine, at codon 300 and 301. Leu480 + 4nt is a four-nucleotide duplication (cytosine-adenine-thymidine-cytosine) at codon 480. Asp487, Ser487, and Phe489 indicate a deletion of aspartic acid (codon 487), serine (codon 488), and phenylalanine (codon 489). All of these mutations cause 17-hydroxylase deficiency. Missense mutations at codons 347 and 358 (indicated by the box) have been associated with "isolated" 17,20-lyase deficiency.

The mutations in the CYP17 gene that result in complete loss of 17-hydroxylase activity provide strong evidence that only one enzyme has 17-hydroxylase activity.

Patients with partial combined deficiencies of both activities have been analyzed. Patients with partial combined deficiencies of both activities have been analyzed. A 46,XY male with the same mutation had only hypoplasdas and cryptorchidism. Another 46,XY male with ambiguous genitalia was a compound heterozygote with a stop codon (TGA) at amino acid position 239 in exon 4 (a null mutation) on one allele and a missense mutation on the other allele that changes a proline to threonine at amino acid 342 (Pro342Thr) in exon 6. This patient had 20% of 17-hydroxylase activity in transfected cells. Analysis of these mutations suggests that 5% of normal activity in a 46,XX female is necessary to allow estrogen production with normal secondary sexual characteristics and irregular menses, whereas more than 25% of normal activity appears to be necessary to achieve normal virilization of the external genitalia of affected 46,XY males.

Diagnosis.

17-Hydroxylase/17,20-lyase deficiency should be considered in all patients with ambiguous genitalia and hypergonadotropic hypogonadism and in all phenotypic females with or without sexual infantilism, including absent adrenarche, who have hypertension and hypokalemic alkalosis. Elevated levels of 17-deoxy-C{	extsubscript{19}}-steroids such as progesterone, pregnenolone, DOC, and corticosterone in plasma and increased urinary excretion of their metabolites establish the diagnosis. The basal plasma concentrations of DOC, corticosterone, 18-hydroxycorticosterone, and 18-hydroxy-DOC and their response to a corticotropin challenge can be used to discriminate among homogonadotrophic, heterogonadotrophic, and unaffected individuals.

Glucocorticoid therapy for 21-hydroxylase deficiency suppresses DOC and corticosterone secretion. With suppression of the excess circulating mineralocorticoids, the blood pressure and serum potassium level return to normal. At puberty, both affected males and affected females usually require gonadal steroid replacement.

This autosomal recessive form of CAH is associated with severe glucocorticoid and mineralocorticoid deficiency, in which no C{	extsubscript{19}}-C{	extsubscript{21}}, or C{	extsubscript{21}}-steroids are elaborated by the adrenal glands or gonads because of failure to convert cholesterol to pregnenolone. This disorder is the most severe genetic defect in steroidogenesis can result in little or no mineralocorticoid production and absent mineralocorticoid derivatives. Females with this disorder have normal internal and external genital development. Clinical manifestations of adrenal insufficiency, including hyponatremia, hypokalemia, acidosis, dehydrad, and hypoglycemia, usually become apparent in the first few weeks of life, but for survival for months without therapy has been described. Hypogonadism is common, and respiratory distress occurs in about one fourth of neonates. On ultrasonography, CT, or MRI, markedly enlarged, lipid-laden adrenals displace the kidneys downward.

Most of the more than 80 patients with SIAD deficiency are of Japanese and Korean origin; it is seen in 50% of patients with SIAD deficiency in prevalence in Japan and Korea. There is an unexpected 3:1 male/female sex ratio. Many affected individuals...
die in infancy (approximately one third survive with replacement therapy); we have cared for one patient for more than 30 years. In contrast to the severe fetal and postnatal testosterone deficiency in affected 46,XY individuals, surviving affected 46,XX females can enter puberty and menstruate; they later develop hirsutism and may develop gonadal tumors. The prolonged survival described in a few patients is the result of adrenal insufficiency and the puberty and menses described in females have been perplexing. As proposed by Bose, two separate events seem responsible for these phenomena: The first event is the loss of steroid hormone synthesis, which is dependent on StAR in steroid-producing cells. The second event is the accumulation of cholesterol, which cannot be converted to pregnenolone by the cell. Eventually this accumulation engorges the cell and results in disruption of the structural and functional integrity of the cell. It is assumed that the functional activity of the cell in question mediates the time course to functional and structural disruption. Hence, postnatal survival for a period of time may reflect the relatively low level of activity of the definitive adrenal glands prenatally. Postnatally, the zona glomerulosa and fasciculata can make a limited amount of steroids independent of StAR until they become engorged and dysfunctional. The ovaries, in contrast to the testes, remain relatively quiescent through fetal life and childhood. At puberty, estrogen synthesis independent of StAR can occur, leading to feminization and menses. Progressive gonadal failure due to cholesterol engorgement of steroidogenic cells then results (see Color Plates).

In support of the two-hit hypothesis, no surviving XY patient has had evidence of testicular function at the expected age of puberty. All patients are markedly pigmented. The SIAR knockout mouse has a similar phenotype to patients with congenital lipoid adrenal hyperplasia, consistent with the two-hit hypothesis model.

The transfer of cholesterol from the outer to the inner mitochondrial membrane is the rate-limiting step in acute or rapid steroid synthesis. A 30-kd mitochondrial protein in adrenal cells rapidly increases in response to corticotropin stimulation and is inhibited by cycloheximide; it is also present in the gonads.

The CDNA for this factor has been cloned, and the protein for this gene was named the steroidogenic acute regulatory (StAR) protein. As with other steroid hormone hydroxylases, the SIAR gene is transcriptionally regulated by SF1. The stimulation of SIAR by corticotropin and by LH is mediated through a cyclic adenosine monophosphate (AMP)/protein kinase A-dependent pathway and involves the phosphorylation of the SIAR protein.

The stimulation of cholesterol transport by SIAR from the outer to the inner mitochondrial membrane, the site of the cholesterol side-chain cleavage complex, apparently does not require the import of SIAR across the mitochondrial membrane. Human SIAR is encoded by a gene on chromosome 8p11.2 and is expressed in the adrenal gland and gonad, but not in the placenta or the cerebral nervous system. Fifty-seven patients with congenital lipoid adrenal hyperplasia (studied from 10 countries) had mutations in the gene encoding SIAR (Fig. 22-65). In 80% of affected alleles from affected Japanese and Korean individuals, a Gln285Stop mutation was detected, whereas an Arg182Leu mutation was present in 78% of alleles from affected Arabs. Study of congenital lipoid adrenal hyperplasia provided the decisive evidence of the critical role of SIAR in steroid hormone biosynthesis in humans. Unlike CYP11A1, the gene encoding the SIAR protein is not expressed in the human placenta, and mutations in SIAR do not impair progesterone synthesis by the placenta.

In patients with SIAR deficiency, little or no C19→C21 steroids are detectable in plasma or urine, even after corticotropin stimulation. In 46,XX females the differential diagnosis includes congenital adrenal hyperplasia. Demonstration of greatly enlarged adrenals in StAR deficiency by imaging techniques readily differentiates these two entities, even when affected with a frameshift mutation affecting small adrenal glands. Imaging. Affected males are raised as females, and their functionless testes are reduced to make the risk of malignant transformation and for cosmetic reasons. Therapy requires replacement with glucocorticoids and mineralocorticoids and the addition of estrogen when gonadal failure ensues.

In obligate heterozygotes with a SIAR mutation, unlike heterozygotes with other forms of CAH, steroid responses to corticotropin are normal. Prenatal diagnosis of SIAR deficiency was successfully demonstrated in a family in which two previously affected children. Amniotic fluid levels of progesterone and pregnenolone were 30% and 50% of normal, respectively, but the concentrations of steroids such as 17-hydroxypregesterone, cortisol, DHEA, androstenedione, and estradiol were low or undetectable; androstenedione and subsequent failure to synthesize fetal adrenal precursors for transformation to estrogens by the placenta result in low maternal plasma and urinary estradiol values.

The clinical manifestations of each form of CAH are summarized in Table 22-23.

AFFECTED FEMALES ARE BORN WITH CLITOROMEgALy, VARYING DEGREES OF POSTERIOR FUSION, SRCRALIZATION OF THE LABIOSCROTAL FOLDS, AND, IN SOME INFANTS WITH A UROGENITAL SINUS, A SINGLE
perineal orifice (Table 22-24). Müllerian structures are normal. 

During infancy, basal and LHRH-induced FSH and LH are elevated. The history of the ovary in infancy is normal, but under increased FSH stimulation in the absence of ovarian CYP19, multiple enlarged follicular cysts develop. All pubertal affected females have hypergonadotropin hypergonadism, fail to develop female secondary sexual characteristics, and exhibit progressive virilization. 

Plasma androstenedione and testosterone are elevated, and estrone and estradiol levels are low or unmeasurable. The ovaries enlarge and develop multiple cysts at puberty, in one affected female, polycystic ovaries were detected in infancy. The hypergonadotropism and the multiple ovarian cysts respond to estrogen replacement therapy.

The affected 2 adult men had normal sex differentiation and pubertal maturation with macro-orchidism (in one male) and elevated concentrations of FSH, LH, and testosterone in plasma. They also had osteoporosis, hyperinsulinemia, and abnormal plasma lipids, similar to the findings in a tall man with a null mutation in the estrogen receptor. These observations suggest that estrogens as well as testosterone and inhibin play a role in the regulation of gonadotropin secretion in males and females and that estrogen deficiency in males can be associated with insulin resistance and hyperinsulinemia and an abnormal plasma lipid profile.

The finding of apparently normal psychosexual development in the three aromatase-deficient adolescent or adult patients and in the man with an estrogen receptor defect suggests that estrogen does not play a critical role in sex differentiation of the human brain, as has been reported in nonprimate mammals. The detection of severe defects in critical regions of the gene encoding CYP19 that lead to generalized aromatase deficiency is strong evidence that survival of the conceptus can occur in the absence of estrogen synthesis by the implanting blastocyst, the fetus, and the fetal compartment of the placenta.

Analysis of the CYP19 gene in nine affected individuals has revealed 10 different mutations (Fig. 22-67) (Table 22-25). The patient of Shouz and colleagues was homozygous for a mutation (GT GC) in the consensus 5' splice acceptor sequence in the gene. This mutation resulted in a CYP19 protein with a 29-amino acid insert and less than 0.3% of normal enzyme activity. A second patient was a compound heterozygote with two missense mutations. Assay of the expressed mutated proteins showed that one allele had 1.1% of the activity of the wild-type CYP19, whereas the other had no activity. The male and female siblings reported by Morishima and associates resulted in a single base change that resulted in an amino acid substitution. Expression of this mutant cDNA showed that it had 0.2% of the wild-type aromatase activity. The patient of Mullis and co-workers had a cytosine deletion in one allele (codon 408, proline) that corresponds to the point mutation (GT GC) in the consensus 5' splice acceptor sequence in the gene. This mutation resulted in a CYP19 protein with a 29-amino acid insert and less than 0.3% of normal enzyme activity. A second patient was a compound heterozygote with two missense mutations. Assay of the expressed mutated proteins showed that one allele had 1.1% of the activity of the wild-type CYP19, whereas the other had no activity. The male and female siblings reported by Morishima and associates resulted in a single base change that resulted in an amino acid substitution. Expression of this mutant cDNA showed that it had 0.2% of the wild-type aromatase activity. The patient of Mullis and co-workers had a cytosine deletion in one allele (codon 408, proline) that corresponds to the

Glucocorticoid Receptor Gene Mutation

Autosomal dominant forms of glucocorticoid resistance, a rare disorder, are a consequence of a heterozygous mutation in the gene encoding the glucocorticoid receptor, usually in the ligand-binding domain of this transactivation factor. End-organ insensitivity to glucocorticoids in the heterozygote is heterogeneous in its manifestations but characteristically there is excess ACTH secretion, with elevated cortisol levels without Cushing syndrome and usually with few symptoms. Nevertheless, the hypersecretion of ACTH increases adrenal steroidogenesis and can lead not only to increased cortisol secretion but also to increased...
mineralocorticoids (as a consequence, hypertension and hypokalemia may occur) and androgen precursors. The latter steroids can produce acne, hirsutism, adolescent hyperandrogenism, menstrual abnormalities in the female, and sexual precocity in the male.

A Brazilian girl has been reported who had female pseudohemophrditism owing to a novel homozygous inactivating mutation in the glucocorticoid receptor gene. Born of consanguineous clinically unaffected parents, she had a large clitoris, posterior labioscrotal fusion, and a urogenital sinus. When she was 9 years of age, studies showed low renin hypertension and hypokalemia with increased plasma DOC and cortisosterone, high concentrations of plasma ACTH and cortisol, and impaired suppression of plasma cortisol during a dexamethasone test. Consistent with her advanced bone age and progressive virilization, the concentrations of plasma testosterone, androstenedione, and 17-Hydroxyprogesterone were elevated. Molecular analysis identified a homozygous Val571Ala mutation involving the ligand-binding region. Mutant receptors had less than one sixth the binding affinity and one tenth to one fifth of the trans-activation activity of the wild-type receptor. After repair of the hypokalemia, high-dose dexamethasone therapy (6 mg/day) led to impressive clinical improvement.

**Maternal Androgens and Pregestagens**

Masculinization of the external genitalia of female infants has been observed after maternal ingestion of testosterone or synthetic progestational agents during the first trimester of pregnancy. If the exposure occurs after the 12th week of gestation, the labioscrotal folds do not fuse, although the clitoris may enlarge. Severe masculinization of the external genitalia of a female fetus may be caused, for example, by methylnorchisosterone in dosages as low as 3 mg daily, even though androgenic effects are not noticeable in the mother. Placenta aromatase may be unable to efficiently aromatize synthetic androgens such as methyltestosterone.

Because progesterone itself is only slightly active when administered orally, various synthetic derivatives that may be taken orally were prescribed in the past for women with habitual or threatened abortion. Most of these progestagens are 19-nortestosterone derivatives; they are intrinsically androgenic to some degree and can cause virilization of female fetuses in experimental animals. Principal among the offenders have been norethindrone and ethisterone and, less commonly, norethynodrel and the C17-steroid medroxyprogesterone acetate. Ishizuka and co-workers reported some degree of masculinization of the external genitalia in 2.75% of female infants whose mothers received synthetic progestagens of various types during pregnancy. This consequence of synthetic progestagen administration to the pregnant female is dose and time dependent.

Danazol, the 2,3-disoxazole derivative of 17-ethinyltestosterone, a progestagen, is used for the treatment of endometriosis. Danazol crosses the placenta and can cause virilization of the external genitalia of the fetus in a manner similar to other androgenic compounds. Several instances of female pseudohemaphroditism are believed to be the consequence of maternal ingestion of danazol. The mechanism of masculinization is unknown but may be related to inhibition of 3-HSD by stilbestrol or its metabolites.

Masculinization of the female fetus occurs on occasion if the mother has a virilizing ovarian tumor (usually arrhenoblastoma or Krukenberg’s tumor) or adenral tumor, a virilizing form of CAH, or virilization of some other cause during pregnancy. An increasing number of women with CAH are becoming pregnant as a result of improved treatment and it is reassuring to note that female offspring of such pregnancies are not virilized (with a single exception), despite higher than usual maternal testosterone levels. Luteoma of pregnancy, an ovarian pseudotumor composed of hyperplastic luteinized thecal cells that regress after delivery, has been associated with masculinization of the external genitalia of female infants, especially in the presence of maternal virilization.

**Ovarian lutein cysts in pregnancy (hyperreactio luteinalis), considered by some to be a cystic form of luteoma, are less frequently associated with maternal virilization and only rarely with fetal masculinization.** Placental aromatization of androgens such as testosterone and androstenedione protects the mother and the female fetus from virilization unless the placental CYP19 (P450arom ) activity is insufficient for the androgen steroid load or unless the synthetic androgen is not a substrate for CYP19.

Some of the rare cases of female pseudohemaphroditism of undetermined origin may have resulted from a luteoma of pregnancy that regressed spontaneously after delivery or an undiagnosed placental aromatase deficiency. In these patients a history of maternal ingestion of androgenic steroids is lacking and the postpartum course of the mother is inconsistent with a virilizing neoplasm, but the clinical features are most compatible with fetal exposure to androgens. The absence of virilism in the mother does not exclude a maternal source of androgen in these children, because the amounts of androgen required to masculinize the external genitalia of a female fetus may be less than those required to cause overt manifestations in the mother.

Female pseudohemaphroditism caused by the transfer of androgenic steroids from the mother to the fetus is the most easily treated of all types of androgens in terms of successful development. No hormone therapy is necessary, postnatal virilism does not occur, and female secondary sexual characteristics can be expected to emerge at the usual age of adolescence. Surgical correction of the external genitalia in infancy or childhood is rarely indicated.

**Malformations of the Intestine and the Urinary Tract (NonAndrogen-Induced Female Pseudohemaphroditism)**

Genital abnormalities are frequently associated with imperforate anus, renal agenesis or dysplasia, and other congenital malformations of the lower intestine and urinary tract. Carpenter and Potter reviewed the findings in such infants and suggested the term "nonspecific female pseudohemaphroditism." Some of these anomalies are incompatible with life. Renal failure, often accompanied by pyelonephritis, is common and may confuse the clinical picture with that of adrenal insufficiency. In contrast to other forms of female pseudohemaphroditism, the female müllerian derivatives may also be malformed. The findings in these patients may be bizarre; persistence of a primitive cloaca, imperforate anus, and fistulae are not infrequent. The pathogenesis of these anomalies is different from that of other types of androgenic development and should be considered in the context of other forms of developmental field defects. Familial occurrence of nonadrenal female pseudohemaphroditism with multiple anomalies has been reported. Citrormegalmy may sometimes be the presenting feature of neurofibromatosis and may be more common in this neurologic disorder than is realized. The clitoris is richly innervated, and biopsies have confirmed the presence of neuromas when citrormegalmy occurs with neurofibromatosis. Surgical excision is not curative because of the tendency for recurrence of the neuromas.
Male Pseudohermaphroditism

Male pseudohermaphroditism is a heterogeneous condition in which the gonads are exclusively testes but the genital ducts and/or external genitalia are incompletely masculinized. The clinical spectrum varies from individuals with female external genitalia to those with mild impairment of masculinization of the external genitalia, as represented by hypospadias, cryptorchidism, and minimal ambiguity of the external genitalia.

With the advances in the knowledge of pathogenesis, systems of nomenclature based on eponyms and phenotype have become less important. There are at least six major etiologic categories of male pseudohermaphroditism, with many subtypes, all of which are associated with incomplete masculinization of the fetal genital tract and/or incomplete regression of the müllerian ducts.

In this section, forms of male pseudohermaphroditism in 46,XY individuals with relatively normal embryonic differentiation of the testes are discussed. In such patients, defective male development must be ascribed to a more specific failure of the fetal testes to overcome the inherent tendency toward feminization of the somatic sex structures. This failure may stem either from a secretory failure of the testes during the critical period of sex differentiation or from a failure of target tissues to respond normally to androgen stimulation or to AMH. Table 22-26 reflects an attempt to classify the many forms of male pseudohermaphroditism on the basis of cause, insofar as that is known.

The ability of the testes to virilize at adolescence is in many ways a recapitulation of their capacity to masculinize the external genitalia in utero. The greater the development of the phallus in an infant, the greater likelihood that male secondary sexual characteristics will emerge at the time of expected puberty. Individuals with ambiguous genitalia may remain eunuchoid, exhibit mild virilism, or develop breast enlargement and other female secondary sexual characteristics. Those with an external female phenotype usually either feminize or remain sexually infantile. These are only approximate guides, however, and the development of male sexual characteristics at adolescence may occur, especially in patients with partial androgen resistance, 17-hydroxysteroid dehydrogenase-3 deficiency, or 5-reductase-2 deficiency.

Male pseudohermaphroditism can result from (1) testicular unresponsiveness to hCG and LH and consequent Leydig cell aplasia or hypoplasia; (2) a specific enzyme defect in testosterone biosynthesis; (3) familial end-organ resistance to androgen caused by abnormalities in the cytosolic receptor for testosterone and DHT or by an enzyme defect in the intracellular metabolism of testosterone; (4) aberrations in testicular organogenesis (dysgenetic male pseudohermaphroditism); (5) defective synthesis, secretion, or response to AMH; (6) administration of progestagens during pregnancy; and (7) putative environmental exposures. Apart from dysgenetic male pseudohermaphroditism and the persistent müllerian duct syndrome, all other forms of male pseudohermaphroditism are characterized by the absence of müllerian duct derivatives. Except for some variants of dysgenetic male pseudohermaphroditism and the maternal ingestion of progestagens, virtually all forms of male pseudohermaphroditism are familial and characterized by genetic heterogeneity. No doubt many subtypes will be defined and characterized by molecular, genetic, and biochemical techniques. Although dysgenetic male pseudohermaphroditism and the group of disorders associated with defective organogenesis of the testes has already been discussed, it is included under male pseudohermaphroditism because this category of intersexuality must be considered by the clinician in the differential diagnosis of male pseudohermaphroditism. In Table 22-4 and Figure 22-15 genes implicated in sex determination (gonadogenesis) are shown; Table 22-19 lists genes involved in sex differentiation.

Defects in Testosterone Biosynthesis and Metabolism

Testicular Unresponsiveness to hCG and LH, LH/hCG Resistance (Leydig Cell Agenesis or Hypoplasia)

The production of testosterone by fetal Leydig cells is critical to male sexual differentiation of the Wolffian ducts and the
Increased gonadotropins postpubertally, decreased testosterone levels with decreased or absent response to hCG stimulation, decreased or absent hypoplasia and hypergonadotropic hypogonadism, and a sexually mature 46,XX female with elevated plasma LH levels and amenorrhea.

Phenotypically, the external genitalia vary, from those of a normal-appearing female to those of a male with micro penis and hypoplastic external genitalia. Male pseudohermaphroditism results from an LH/LH-receptor defect in fetal testes and includes a complete absence of female differentiation. The LH-receptor is responsible for the biosynthesis of testosterone, and it is also necessary for male sexual differentiation.

Phenotypic features of Leydig cell unresponsiveness to hCG/LH (Leydig cell aplasia or hypoplasia) include:

- Aplasia/hypoplasia of the testis (recognizable in the first trimester of pregnancy)
- Aplasia/hypoplasia of the seminiferous tubules
- Absent or decreased number of Leydig cells
- Absent or diminished binding of labeled hCG and LH to Leydig cells
- Absent or diminished testicular production of testosterone
- Absent or diminished hCG/LH response to LHRH-evoked responses
- Absent or diminished hCG/LH response to hCG/LH resistance

Male pseudohermaphroditism may result from an LH-receptor defect, which is responsible for the biosynthesis of testosterone in male testes and is also necessary for male sexual differentiation. The LH-receptor is responsible for the biosynthesis of testosterone, and it is also necessary for male sexual differentiation.

The LH-receptor is responsible for the biosynthesis of testosterone, and it is also necessary for male sexual differentiation. The LH-receptor is responsible for the biosynthesis of testosterone, and it is also necessary for male sexual differentiation.
Homozgyous mutation (Ser616Tyr) in the seventh trans-membrane domain of the LH receptor gene. The mutant receptor did not bind hCG. Homozygous mutations in eight 46,XY males analyzed resulted in fetal and postnatal testosterone deficiency and a spectrum in appearance of the external genitalia extending from female external genitalia to a micro penis and in hypogenital dystrophic hypogonadism. Wu and associates described a compound heterozygous loss of function mutation with a nonsense mutation (Cys545X) in exon 11 of the LH receptor in one allele and a 3 base-pair insertion in exon 1 on the other allele in two 46,XY females with Leydig cell hypoplasia and LH/hCG resistance. In 10 patients with clinical features of Leydig cell hypoplasia, only 2 patients had mutations in the coding region of the LH/hCG receptor, which suggests that mutations may occur in other regions of the gene or a mutation in other Leydig cell specific genes may produce the same phenotype. For example, in the mouse Desert hedgehog (DHH) a signaling protein and its receptor Patched 1 (Pch1) are critical factors in the differentiation of fetal Leydig cells in the mouse but do not affect cell migration from the mesonephros nor the contribution of interstitial cells from the coelomic epitheum. An XY DH-null mouse bred on a mixed strain background exhibited severely impaired fetal Leydig cell differentiation and female external genitalia. A homozygous mutation in DHH was reported in a 46,XY male pseudohermaphrodite with partial gonadal dysgenesis and polyneuropathy. These observations support the genetic heterogeneity of the syndrome and the importance of searching for genes involved in Leydig cell differentiation and function. Null mutations of the LH receptor (LH-R) would not be expected to result in feminization of 46,XY females because female secondary sexual characteristics are maintained in the absence of testicular androgens. In contrast, females with complete androgen insensitivity (Xg7,8) and with mutations of the androgen receptor have normal expression of female secondary sexual characteristics.

In patients with testicular unresponsiveness to hCG/LH, fetal testosterone deficiency impairs masculinization of the external genitalia, but müllerian duct regression is complete because the secretion of AMH by the fetal Sertoli cells is intact. Of interest is the paradoxical finding of Wolffian derivatives, which are testosterone dependent, in some patients with no or minimal masculinization of the external genitalia (only posterior labial fusion). One explanation, supported by the variation in masculinization of the external genitalia, is that the defect in the hCG/LH receptor is of variable severity. A second, more likely possibility is that during the early fetal period, sufficient testosterone may have been secreted locally and autonomously independently of circulating hCG to induce male duct development, but the concentration of testosterone in the fetal circulation was too low to evoke normal male differentiation of the external genitalia and urogenital sinus. hCG is necessary to sustain Leydig cell differentiation and growth and testosterone secretion by the fetal testes, at least by about the 10th week of gestation, but, as discussed previously, it may not be essential for initiation of these functions at week 8. Variation in the magnitude of hCG/LH resistance of the unresponsive embryonic and fetal Leydig cells would result in variable degrees of fetal testosterone deficiency and thus a variable degree of failure to develop normal male external genitalia. Therapy depends on the age at diagnosis and the degree of virilization. In the severe form of testicular unresponsiveness to hCG/LH with female external genitalia, sex assignment is usually female. The gonads are removed, and estrogen replacement therapy is instituted at the time of expected puberty. In the less extreme forms with predominantly male external genitalia, testosterone therapy augments phallic development and virilizes the patient at puberty. In the human male fetus, deficient fetal pituitary gonadotropin secretion associated with anencephaly, hypothalmic hypopituitarism, and isolated gonadotropin deficiency (including Kallmann syndrome) is not associated with ambiguous external genitalia (with one possible exception of the male/female ratio in this disorder appears to be 3:1. Enzyme defects common to adrenal and testicular biosynthesis include 3-HSD, CYP17, cholesterol side-chain cleavage, as well as abnormalities in the intracellular steroid transport protein, StAR. These have already been reviewed in the section on CAH. A fourth defect involves the biosynthesis of cholesterol (7-cholesterol reductase deficiency) and results in multisystem metabolic malformation syndrome.

Enzyme defects affecting both adrenal and testicular biosynthesis include CAH and StAR Deficiency (Congenital Lipoid Adrenal Hyperplasia). A single step involving enzymes, and the third, StAR, a protein that affects both glucocorticoid and gonadal steroid biosynthesis; these errors in steroid biosynthesis are discussed, in part, in the section on CAH. A fourth defect involves the biosynthesis of cholesterol (7-cholesterol reductase deficiency) and results in multisystem metabolic malformation syndrome.

Enzyme Defects of Testosterone Biosynthesis Affecting Both Adrenal Steroid and Testosterone Biosynthesis (Variants of Congenital Adrenal Hyperplasia)

Enzyme defects common to adrenal and testicular biosynthesis include 3-HSD, CYP17, cholesterol side-chain cleavage, as well as abnormalities in the intracellular steroid transport protein, StAR. These have already been reviewed in the section on CAH. Some additional features are described for the 17,20-lyase variant of CYP17 deficiency in view of the primary effect on testicular steroid biosynthesis and, hence, male pseudohyperpladioid.

Defects in testosterone biosynthesis (Fig. 22-70) have been described, one at each of the enzymatic steps required for the conversion of cholesterol to testosterone[916] (Fig. 22-71). Three of the defects (3-HSD, CYP17, CYP11A1 [P450,]) involve enzymes, and the third, StAR, a protein that affects both glucocorticoid and gonadal steroid biosynthesis; these errors in steroid biosynthesis are discussed, in part, in the section on CAH. A fourth defect involves the biosynthesis of cholesterol (7-cholesterol reductase deficiency) and results in multisystem metabolic malformation syndrome.

StAR Deficiency (Congenital Lipoid Adrenal Hyperplasia)

Infants with this defect (Table 22-28; see previous discussion in the section on CAH) present with severe adrenal insufficiency and accumulation of lipid in the cells of both the adrenal cortex and the gonads. The second most common form of CAH in Japan (the GnRH6X mutation was found in over 80% of Japanese patients studied) and the male/female ratio in the United States and Europe is 1:1. Affected females have female external genitalia with a blind vaginal pouch and hypoplastic male genital ducts but no uterus or fallopian tubes; the genitalia of affected females are normal. In males, the testes may be abdominal, inguinal, or in the labia. All reported patients are diffusely pigmented; glucocorticoid and mineralocorticoid insufficiency is severe; and adrenal crises in infancy can lead to death if untreated. Three male pseudohermaphrodites

---

Figure 22-70 Diagram of male sex determination and differentiation showing the consequences of an enzymatic block in biosynthesis of testosterone that results in male pseudohermaphroditism. Solid bar indicates defect (see legend for Figure 22-43).

Survived the perinatal period without therapy and presented at 6 weeks, 12 weeks, and 10 months of age; (see discussion of StAR and its mutations in the section on female pseudohermaphroditism). The patient reported by Haufla and co-workers (and in the previous editions of this chapter) is more than 35 years old and well maintained on glucocorticoid and mineralocorticoid replacement therapy. Sexual hair is absent unless small doses of testosterone are given; female secondary sexual characteristics are induced by estrogen replacement. As described in the section on CAH, no secondary sexual characteristics (either male or female) develop at the age of puberty in affected males, in contrast to females with this disorder. Wu and Pedigree analysis of families and DNA analysis of affected patients and parents indicate autosomal recessive transmission. The usual ratio of affected patients is yet to be explained and may represent, at least in part, ascertainment bias. The molecular genetics of StAR deficiency are illustrated in Figure 22-45 and 22-46.

The diagnosis of StAR deficiency should be suspected in patients with male pseudohermaphroditism, including all phenotypic female infants with evidence of adrenal insufficiency. The diagnosis can be confirmed by documentation of low or absent mineralocorticoids, glucocorticoids, and gonadal steroids and their metabolites in plasma and urine and an absent steroid response to corticotropin and hCG administration. The adrenals are large and lipid laden and displace the kidneys caudal on ultrasonography, CT, or MRI; the enlargement can
Persist for months after glucocorticoid therapy. Therapy requires replacement doses of glucocorticoid and mineralocorticoid from the time of diagnosis. All affected 46,XY males have been reared as females. Estrogen replacement therapy to induce female sexual characteristics at puberty and low-dose testosterone treatment to elicit development of sexual hair are indicated; prophylactic orchidectomy is appropriate.

P450c17 is the enzyme that converts cholesterol to pregnenolone, the first step in steroidogenesis. As noted in the section on CAH and female pseudohemaphroditism, null mutations in both alleles of this gene would lead to failure of placental production of progesterone, which in the human (unlike, for example, the rabbit) would be incompatible with continued gestation beyond the 8th to 10th week. Tajima and his associates described a hyperpigmented 4-year-old XY male pseudohemaphrodit with mild virilization of the external genitalia as evidenced by citoromegaly but no labial fusion, with a blind vaginal pouch, who had had bilateral inguinal testes removed. It was not until age 4 years that she experienced life-threatening adrenal insufficiency which with a low concentration of plasma cortisol, a high plasma ACTH and plasma renin activity, but normal concentrations of serum sodium and potassium.

**TABLE 22-28**  -- Clinical Features of SIAR Deficiency in 46,XY Males

| Karyotype: | 46,XY |
| Genitalia: | Female |

| Müllerian duct derivatives: | Absent |
| Gonads: | Testes |
| Habitus: | Severe adrenal insufficiency in infancy, no virilization at puberty |
| Hormone profile: | Decreased or absent glucocorticoids, mineralocorticoids, and gonadal steroids in plasma and urine; increased plasma LH and FSH; increased plasma renin |

LH, luteinizing hormone; FSH, follicle-stimulating hormone.

*46,XY male with heterozygous mutation of P450c17. Genitalia: Clitoromegaly separate vaginal and urethral openings, no labial fusion, no müllerian ducts, childhood onset of adrenal insufficiency.

**TABLE 22-29**  -- Clinical Features of 3-HydroxySteroid Dehydrogenase II Deficiency in 46,XY Males

| Karyotype: | 46,XY |
| Inheritance: | Autosomal recessive; mutations in 3HSD2 gene |
| Genitalia: | Ambiguous; hypospadiac male |
| Wolffian duct derivatives: | Normal |
| Müllerian duct derivatives: | Absent |
| Gonads: | Testes |
| Habitus: | Severe adrenal insufficiency in infancy; poor virilization at puberty with gynecomastia. Mild form: no mineralocorticoid deficiency, premature adrenarche mild virilization |

This rare autosomal recessive disorder is a consequence of mutations in the CYP11A1 genean in-frame insertion of Gly and Asp between Asp 271 and Val 272was identified that lacked P450c17 enzymatic activity. The suggestion that the P450 haplo-insufficiency eventually led to a late-onset type of congenital lipid hyperplasia is consistent with the two-stage model of pathogenesis proposed for SIAR deficiency. The discrepancy between the compromised function of the fetal testes and the resultant male pseudohemaphroditism and the relatively late onset of symptomatic adrenal insufficiency is incompletely understood. In contrast to the absent Müllerian duct derivatives in this patient, the male pseudohemaphrodit with adrenal insufficiency caused by haploinsufficiency of the SFT gene due to Gly35Glu mutation had a uterus as did the male pseudohemaphrodit with a homozygous mutation (arg92Gin).

3-HydroxySteroid Dehydrogenase II (3HSD2) Deficiency

This rare autosomal recessive disorder is a consequence of mutations in the HSD3B2 gene encoding the 3-HSD2, isomerase type 2 isozyme, which is expressed mainly in the adrenals and gonads. This enzyme catalyzes a crucial step in the biosynthesis of all steroid hormones, the conversion of 4,5-steroids. The type 1 isozyme is expressed predominantly in the placenta and in peripheral tissues (e.g., skin, breast), has 93% homology in structure with the type II isozyme, is about five times as active, and is closely linked to the type II isozyme (both are encoded by genes on chromosome 1p13). The type 1 isozyme is not associated with CAH, and mutations in the coding region of type I are probably lethal because they prevent or compromise progesterone synthesis by the placenta and, hence, survival of the fetus.

Males with 3-HSD2 deficiency have CAH associated with male pseudohemaphroditism with or without adrenal insufficiency (salt loss) (Table 22-29). The external genitalia in males are usually ambiguous, with a small phalic structure, second-or third-degree hypospadias, partial fusion of the labia, a urogenital sinus, and a blind vaginal pouch; rarely, the external genitalia are female in appearance. Wolffian duct differentiation is normal. The testes are usually in the scrotum or lower inguinal region, and, as with other blocks in testosterone biosynthesis and defects in androgen action, Müllerian structures are absent.
Newborns with severe deficiencies of the 3-HSD II (e.g., null mutations) have severe CAH and exhibit signs or symptoms of both glucocorticoid and mineralocorticoid deficiency after the first 5 to 7 days of life. In those infants with severe deficiency of the enzyme, adrenal insufficiency may result in death if the diagnosis is missed and therapy is delayed.\textsuperscript{1093} 46,XY males with partial deficiency of 3-HSD II are not salt losers; the mutant gene in these cases encodes an enzyme with 2% to 10% of residual 3-HSD II enzymatic activity in the adrenals and gonads, as assessed in intact transfected cells.\textsuperscript{1094,1095} This amount of enzymatic activity is apparently sufficient to prevent salt wasting and adequate for aldosterone synthesis but not enough to provide sufficient fetal testosterone to virilize the external genitalia.\textsuperscript{1096}

Gynecomastia can occur at puberty in both affected males and affected females.\textsuperscript{1097,1098} Presumably by peripheral conversions of $^{5}$-C$_{19}$-steroids to $^{4}$-C$_{19}$-steroids by the 3-HSD 1 isoform expressed principally in peripheral tissues and the subsequent aromatization of androgens to estrogens. Menses in treated females and fertility in males have been reported.\textsuperscript{1099} A 46,XY male had a null mutation in the HSD3B2 gene caused by a premature stop codon (Tyr171X) in one allele and a frameshift in the other allele.\textsuperscript{1100} This patient, who had male pseudhermaphroditism and adrenal insufficiency requiring replacement therapy for survival, virilized at puberty and developed gynecomastia and was sufficiently fertile to father two children.\textsuperscript{1101,1102} Paternity was confirmed in one child by DNA analysis.\textsuperscript{1103} The source of the 3-HSD enzymatic activity to enable the synthesis of testosterone to facilitate spermatogenesis was undetermined. However, the 3-HSD 1 enzyme in peripheral tissues and in small amounts in the testis is a likely candidate.\textsuperscript{1104,1105}

Simard and co-workers reviewed the molecular genetics of 3-HSD 2 deficiency in 17 patients, 10 of whom were salt losers.\textsuperscript{1106} They described eight different point mutations in the 10 latter patients. All of the mutations led to profound impairment of enzymatic activity (to <1%\textsuperscript{1107}) ; they were nonsense, missense, and frameshift mutations that clustered in the fourth exon of the gene (see Fig. 22-62).\textsuperscript{1108} Seven different mutations were found in patients with six families with the so-called nonsalt-losing form of 3-HSD deficiency (see Fig. 22-62).\textsuperscript{1109} All were missense mutations except for one mutation that produced a splice error.\textsuperscript{1110} These mutations resulted in 1% to 10% of the wild-type 3-HSD enzymatic activity in transfected cells.\textsuperscript{1111,1112} Additional studies of the molecular genetics and enzymatic activity of the mutant genes are reported.\textsuperscript{1113,1114} No mutations in either HSD3B1 or HSD3B2 have been found in patients with the putative “late onset,” “attenuated,” or nonclassic form of 3-HSD deficiency.\textsuperscript{1115}

Mendonca and colleagues described four patients in two families with an arginine-to-threonine substitution at amino acid 82 (Arg82Thr) in the HSD3B2.\textsuperscript{1116} Two males in one family were pseudohermaphrodites with differing degrees of mild salt loss. A 46,XX phenotypic female sibling homozygous for the same mutation had mild hypospadias and cryptorchidism.\textsuperscript{1117} No mutations in either HSD3B1 or HSD3B2 have been found in patients with the putative “late onset,” “attenuated,” or nonclassic form of 3-HSD deficiency.\textsuperscript{1118} Some individuals develop severe salt losses in early childhood. Patients with severe 3-HSD deficiency exhibit clinical findings that are consistent with severe glucocorticoid deficiency. A more subtle presentation may result in delayed diagnosis and inappropriate replacement therapy, which may precipitate episodes of adrenal crisis.\textsuperscript{1119}

Additional studies of the molecular genetics and enzymatic activity of the mutant genes are reported.\textsuperscript{1120,1121} No mutations in either HSD3B1 or HSD3B2 have been found in patients with the putative “late onset,” “attenuated,” or nonclassic form of 3-HSD deficiency.\textsuperscript{1115}

TABLE 22-30 -- Clinical Features of CYP17 Mutations with Both 17-Hydroxylase and 17,20-Lyase Deficiencies in 46,XY Males

| Karyotype: | 46,XY |
| Inheritance: | Autosomal recessive; CYP17 (P450C17) gene mutations |
| Genitalia: | Female ambiguous hypoplastic male; blind vaginal pouch |
| Wolffian duct derivatives: | Absent hypospadias |
| Müllerian duct derivatives: | Absent |
| Gonads: | Testes |
| Habitus: | Absent or poor virilization at puberty, gynecomastia |
| Hormone and metabolic profile: | Decreased plasma testosterone; increased plasma LH and FSH levels; increased plasma deoxy corticosterone, corticosterone, and progesterone concentrations; decreased plasma renin activity |

| Low renin hypertension with hypokalemic alkalosis |

LH, luteinizing hormone; FSH, follicle-stimulating hormone.

during the first few weeks of life and by the peripheral conversion of $^{5}$-3-hydroxysteroids to $^{4}$-3-ketosteroids by the type I enzyme in peripheral tissues. Newborn males with severe 3-HSD II deficiency can have elevated levels of 17-hydroxyprogesterone in infancy secondary to the peripheral conversion of 17-hydroxyprogesterone.\textsuperscript{1122} These infants usually present in the first week of life. In contrast, another unrelated 46,XX female from another family with the same mutation had acne and premature pubarche as well as elevated plasma 17-hydroxyprogesterone and DHEA levels.\textsuperscript{1123} Hence, as in patients with 21-hydroxylase deficiency, the same mutations may be “cryptic” in some individuals and severe clues in others result.

The diagnosis of 3-HSD II deficiency should be suspected in all 46,XY males with ambiguous genitalia and adrenal insufficiency. The hormonal characteristics are increased levels of $^{5}$-3-hydroxy C$_{19}$- and C$_{19}$-steroids (e.g., 17-hydroxyprogesterone and DHEA and their sulfates) and their metabolites in plasma and urine and striking increases in ACTH stimulated $^{17}$-17-hydroxyprogrenolone (>50 SD above controls) and $^{17}$-17-hydroxyprogrenolone to cortisol ratios (>30 SD above controls). However, the diagnosis in early infancy can be confounded by the elevated concentrations of $^{5}$-3-hydroxy C$_{19}$- and C$_{19}$-steroids normally seen in premature and full-term infants.
than 25% of normal enzymatic activity is necessary for normal fetal masculinization of the external genitalia. The tests may be intra-abdominal, in the inguinal canal, or in the labioscrotal folds. Inguinal hernias are commonly present. In one affected 46,XY patient, no gonads were found at laparotomy. Müllerian structures are absent, and wolfian derivatives are usually hypoplastic. Bone age is retarded during childhood and can lead to tall stature. Excessive secretion of DOC and corticosterone, the consequence of the failure of 17-hydroxylolation of the C21-steroids, usually leads to hypertension, hypokalemia, and alkalosis. The adrenal zona fasciculata is the source of the increased plasma concentration of DOC, corticosterone, 18-hydroxycorticosterone, and 18-hydroxydeoxycorticosterone. Salt and water retention, volume expansion, and hypertension suppress renin and, consequently, aldosterone secretion in the classic form (although aldosterone concentrations are normal or elevated in some patients). This process is reversible with cortisol therapy. Because gonadal sex steroid secretion is low, severely affected patients fail to develop secondary sexual characteristics, including pubic and axillary hair. Plasma and urinary FSH and LH levels are increased. One patient with a partial deficiency of 17-hydroxylase activity developed prominent gynecomastia and incomplete male secondary sexual characteristics at the expected time of puberty. As previously discussed in the section on CAH, mutations in the CYP17 gene (see Fig. 22-63) that are associated with less than 25% of normal 17-hydroxylase activity in intact transfected cells result in female (complete deficiency) or ambiguous genitalia in affected 46,XY males, whereas activity equal to at least 25% of that of the normal enzyme is associated with normal male genitalia. Smith-Lemli-Opitz Syndrome (7-Dehydrocholesterol Reductase Deficiency)

The Smith-Lemli-Opitz syndrome has a broad phenotypic spectrum but typically includes microcephaly, mental retardation, ptosis, upturned nose, micrognathia, polydactyly, syndactyly of toes, severe hypospadias, microopenis, and growth failure. The abnormalities of the external genitalia in 71% of XY patients vary from hypospadias to complete failure of masculinization, resulting in a female phenotype. It has now been established that the syndrome is caused by a deficiency of 7-dehydrocholesterol reductase (sterol 7-reductase, DHCR7), the phylogenetically conserved sterol-sensing domain-containing enzyme required for the last step in the biosynthetic path-way from acetaldehyde to cholesterol biosynthesis. This is the first characterized metabolic malformation syndrome; the defect in cholesterol metabolism acts as a multisystem teratogen perhaps related in part to defective signaling of Hedgehog proteins. The diagnosis is confirmed biochemically by demonstrating low plasma levels of cholesterol and elevated levels of 7-dehydrocholesterol; the plasma cholesterol concentration correlates negatively with severity. The gene encoding this enzyme (DHCR7) maps to 11q1213 and more than 70 different mutations have now been described. The Smith-Lemli-Opitz syndrome has a broad phenotypic spectrum, but typically includes microcephaly, mental retardation, ptosis, upturned nose, micrognathia, polydactyly, syndactyly of toes, severe hypospadias, microopenis, and growth failure. The gene encoding this enzyme (DHCR7) maps to 11q1213 and more than 70 different mutations have now been described.

The diagnosis of 17-hydroxylase deficiency should be suspected in male pseudohermaphrodites, including 46,XY phenotypic females, who have hyporeninemic hypertension and hypokalemia as well as low concentrations of testosterone and hydrocortisone. Plasma concentrations of corticotropin, DOC, corticosterone, and progesterone are high, and those of aldosterone, 17-hydroxyprogesterone, cortisol, and gonadal steroids are low. Replacement therapy with physiologic doses of glucocorticoids suppresses DOC and corticosterone secretion and causes return of serum potassium levels, blood pressure, and plasma renin and aldosterone levels to normal. At puberty, appropriate gonadal steroid replacement therapy is indicated, and gonadectomy should be performed in 46,XY patients who have been assigned a female sex of rearing.

The topology of -5-sterol reductase. Dark circles designate amino acid substitutions due to missense mutations in DHCR7. The two arrows indicate site of stop codons. (From Witsch-Baumgartner M, Loffler J, Utermann G. Mutations in the human DHCR7 gene. Hum Mol Hum Mutat 2001; 17:172182.)
activity can be demonstrated in the human testis or in cultured human theca cells. The conversion of 17-hydroxyprogrenolone to DHEA is about 50 times more efficient than the conversion of 17-hydroxyprogesterone to androstenedione. The control of 17,20-lyase activity in the adrenal appears to be independent of that in the gonad; adrenal 17,20-lyase activity is age dependent, as illustrated by adrenarche. Data suggest that the ratio of 17-hydroxylation to 17,20-lyase activity of the CYP17 enzyme is a function of the molar ratio of its electron transfer (redox) partners P450 oxidoreductase and of cytochrome b5. Increasing the amount of either NADPH-P450 reductase or cytochrome b5 increases the activity of 17,20-lyase sevenfold. Furthermore, the CYP17 enzyme undergoes post-translational modification through phosphorylation of serine and threonine residues by cyclic AMP-dependent protein kinase A. Phosphorylation of the enzyme increases 17,20-lyase activity, and dephosphorylation reduces or eliminates it. Both these mechanisms appear to play a role in control of 17,20-lyase activity in the adrenal and gonads. There have been about 18 case reports of putative isolated 17,20-lyase deficiency, despite the fact that one gene encodes a single enzyme with both 17-hydroxylase and 17,20-lyase activities. Isolated 17,20-lyase deficiency, however, is exceedingly rare; there are only two patients in whom the diagnosis has been established unequivocally by demonstration of the mutation and detailed functional and structural studies.

Zachmann and colleagues initially reported two first cousins with a familial form of male pseudohermaphroditism ascribed to a partial deficiency of 17,20-lyase in both the adrenals and testes. The patients had ambiguous genitalia, inguinal or intra-abdominal testes, and a 46,XY sex chromosome constitution. Both cousins had severe hypospadias with a male-type urethra and male duct development. Only urinary steroids were examined. A sample of testicular tissue from one cousin studied in vitro exhibited a defect in the conversion of C_{19}-steroids to C_{17,20}-steroids. Subsequent studies of the cousins at ages 12 and 15 years disclosed a partial defective partial in the conversion of 3α,5α-C_{19}-steroids to C_{17,20}-steroids. Analysis of the CYP17 gene in one cousin detected compound heterozygosity with two different mutant alleles. Transfection studies indicated combined 17-hydroxylation and 17,20-lyase deficiencies despite the clinical findings. Further study of the steroid pattern in this patient revealed that although 17-hydroxylation activity had been putatively normal in childhood, it was decreased in adulthood.

Two Brazilian male pseudohermaphrodites are described from consanguineous marriages with presumed isolated 17,20-lyase deficiency. Both had 46,XY karyotypes, microphthalmia, perineal hypospadias, bifid scrotum, a blind vaginal pouch, and cryptorchidism. Basal LH and FSH concentrations were elevated in the postpubertal case, and testosterone levels were low. The administration of hCG resulted in a marked rise in plasma 17-hydroxyprogesterone with a paucity of response in DHEA, androstenedione, and testosterone, consistent with isolated 17,20-lyase deficiency. Molecular modeling and site-directed mutagenesis indicated that the Arg347 Ala mutation selectively ablates 17,20-lyase activity in the rat or human enzyme while leaving 17-hydroxylase activation intact. Analyses of CYP17 in these patients showed one to be homozygous for an Arg347His mutation and the other to have an Arg356Gln mutation. These two mutations are located in the redox partner binding site of the CYP17 enzyme and therefore cause a decrease in 17,20-lyase activity by reducing electron transfer. These are the first patients with isolated 17,20-lyase deficiency defined by molecular analyses and the first example of prediction of the specific location for a mutation by site-directed mutagenesis and modeling. The role of redox partners in the regulation of 17,20-lyase is illustrated by a description of a male pseudohermaphrodite with congenital methemoglobinemia due to a mutation in cytochrome b5.

Depending on the degree of impairment in 17,20-lyase activity and its effect on fetal testosterone production during gestation, the external appearance may vary from female to ambiguous to hypoplastic male. The testes may be intra-abdominal, in the inguinal region, or in the scrotum. As with other defects in testosterone synthesis, the Wolffian duct derivatives are either hypoplastic or normal, depending on the severity of the testosterone deficiency, and müllerian duct derivatives are absent. Gynecomastia can occur at the age of puberty. In the 46,XX females, putative isolated 17,20-lyase deficiency leads to failure of pubertal development and elevated gonadotropin levels.

The diagnosis of 17,20-lyase deficiency should be considered in male pseudohermaphrodites with absent müllerian derivatives and in 46,XX females who have no abnormality in glucocorticoid or mineralocorticoid synthesis but fail to develop secondary sexual characteristics at the expected time of puberty and have elevated concentrations of FSH and LH. In prepubertal male pseudohermaphrodites, 17,20-lyase deficiency must be distinguished from the partial form of androgen resistance, 5-reductase deficiency, and 17,20-HSD type 3 deficiency. In the prepubertal patient, both corticotropin and hCG stimulation may be useful in unmasking the defect. Prenatal diagnosis is possible by the measurement of androgenic hormone (C_{19}-steroids to testosterone (C_{17,20}-steroids) in placental liver and endometrial microsomes and primarily oxidizes (inactivates) both androgens and estrogens. The 17-HSD 3, a microsomal enzyme, utilizes NADPH as a cofactor and it is encoded by a gene on chromosome 9q22 that is 23% homologous to the genes for 17-HSD 1 and 17-HSD 2 and is expressed primarily in the testes, where it favors the reduction of androstenedione to testosterone; male pseudohermaphroditism is a consequence of mutations in the gene encoding 17-HSD 3. The 17-HSD 3 gene is expressed in multiple tissues. 17-HSD 3 is encoded by a gene on chromosome 10p14 and favors the reduction of androstenedione to testosterone and of DHEA to androst-5-ene-3,17-diol in peripheral tissues and the ovary. 17-HSD 7 is expressed in the placenta, mammary gland, and kidney and efficiently catalyzes the conversion of E_{1} (DHEA) to E_{2} (Estradiol).

Male pseudohermaphrodites caused by 17-HSD 3 deficiency (also called 17-hydroxysteroid oxidoreductase or 17-ketosteroid reductase) was first reported by Saenz and colleagues (Table 22-32). Many patients have been described, including a cohort of 68 subjects from a highly inbred population in the Gaza Strip. Except for a few 46,XY individuals with ambiguous genitalia at birth, most affected 46,XY males have predominantly female external genitalia, testes (usually located in the inguinal canal), male Wolffian duct derivatives (epididymides, vas deferens, seminal vesicles, and ejaculatory ducts), and a blind vaginal pouch. Because of unambiguous female genitalia at birth, such individuals are usually assigned a female sex, raised

As females, and in some cases mistakenly assumed to have the complete androgen resistance syndrome. However, at the age of puberty, gonadotropin levels and plasma concentrations of androstenedione, estrone, and testosterone increase. The levels of testosterone in some cases approach the normal male range, and some virilization invariably occurs. **Hormone profile:**
- Increased plasma estrone and androstenedione; decreased ratio of plasma testosterone/androstenedione and estradiol/estrone after hCG stimulation test; increased plasma FSH and LH levels.

**hCG, human chorionic gonadotropin; FSH, follicle-stimulating hormone; LH, luteinizing hormone**

Figure 22-74 Diagram of the gene encoding 17-hydroxyxandrostenedione dehydrogenase type 3 with selected mutations reported to cause 17-HSD deficiency. The exons are the numbered black boxes and the missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and the three-letter abbreviation for the substituted amino acid. The position of the amino acid of the mutation from the amino terminus is indicated by the number. **The mutations included a frameshift, 3 splice site abnormalities, and 10 missense mutations. Expression of 8 of the 9 missense mutations revealed complete absence of 17-HSD 3 enzymatic activity.**

The Arg20Gln mutation in the Ghana Strip Arab patients resulted in an enzyme with partial activity. **Only mutations in the HSD17B3 gene that encodes the testis-specific enzyme cause male pseudohormonaphroditism. The gene is located on chromosome 9q22 and is composed of 11 exons.** The **gene that encodes the testis-specific enzyme cause male pseudohormonaphroditism. The gene is located on chromosome 9q22 and is composed of 11 exons.**

Ala56Thr, on kinetic analysis showed a 20-fold decrease in NADPH cofactor affinity and a 6-fold decrease in affinity for the androstenedione substrate.

**The presence of wolffian duct derivatives in these patients with homozygous mutations of the 17-HSD 3 isoenzyme that result in complete absence of enzymatic activity is unexplained.**

Analyses of 17 patients with classic 17-HSD 3 deficiency, including 4 from San Francisco, revealed 14 mutations in the HSD17B3 gene. **Twelve patients had homozygous mutations, 4 were compound heterozygotes, and 1 was a presumed heterozygote (see Fig. 22-74).** The mutations included a frameshift, 3 splice site abnormalities, and 10 missense mutations. Expression of 8 of the 9 missense mutations revealed complete absence of 17-HSD 3 enzymatic activity. **The Arg20Gln missense mutation in the Ghana Strip Arab patients resulted in an enzyme with partial activity.**

Little or no HSD 3 is expressed in the human ovary. **Women with homozygous or compound heterozygous mutations of 17-HSD 3 are asymptomatic.** A putative late-onset form of 17-HSD deficiency causing gynecomastia and hypogonadism in males has been reported but has not been confirmed by DNA analyses of the coding sequence of the HSD17B3 gene.

In the past, patients reared as females treatment involved castration followed by estrogen substitution therapy at puberty, but this approach needs to be reexamined, especially in view of the dramatic advances in neonatal diagnosis and DNA analysis. Patients with ambiguous genitilia in whom 17-HSD deficiency is detected in infancy should probably be reared as males; testosterone therapy to augment phallic size and genitoplasty are indicated in infancy. As noted previously, male pseudohormonaphroditism is caused by 17-HSD deficiency and is relatively common among Arabs of the Gaza Strip. The natural history in this isolated virilization at puberty; furthermore, a change in gender role behavior from female to male is the rule. Because of this, Gros and colleagues proposed that these patients should be given male gender assignment at diagnosis. They described seven young affected 46,XY males with female external genitilia who after biochemical confirmation were treated with testosterone enanthate, 25 to 50 mg each month for 3 months. Most patients received two or three courses of testosterone therapy, which resulted in an increase in phallic length into the normal range for age.

Although 17-HSD 3 activity appears to be completely deficient in infant, a progressive rise occurs in plasma testosterone from puberty to adulthood. This apparent "recovery" of 17-HSD 3 enzymatic activity is undoubtedly a result of the increase with puberty in gonadotropin and androstenedione secretion as well as the extraglandal activity of the other 17-HSD isozymes in converting androstenedione to testosterone. **However, the patients described from the Gaza Strip had a less severe enzyme block, with 15% to 20% of normal 17-HSD 3 activity and evidence of synthesis of testosterone by the testes at the expected time of puberty.**

The presence of wolffian duct derivatives in these patients with homozygous mutations of the 17-HSD 3 isoenzyme that result in complete absence of enzymatic activity is unexplained. Anderson and colleagues suggested that because the androgen receptor in the wolffian duct appears to be identical to the mature androgen receptor, there must be an alternate pathway for testosterone synthesis by 17-HSD in utero to induce wolffian duct stabilization. The diagnosis of 17-HSD 3 deficiency should be considered in (1) male pseudohormonaphroditism who have no abnormality in adrenal steroid biosynthesis, absent müllerian ducts, and normal wolffian duct structures and (2) male pseudohormonaphroditoids who virilize at puberty either with or without gynecomasia. The absence of müllerian duct derivatives generally distinguishes patients with defective testosterone biosynthesis or androgen resistance from those with dysgenetic male pseudohermaphroditism. In the prepubertal or young adolescent patient, basal androstenedione and estrone levels may not be elevated for age. However, at any age the defect in testosterone biosynthesis can be demonstrated best by a prolonged hCG stimulation test. In response to hCG, there is a disproportionate rise in plasma androstenedione and estrone levels, with testosterone and estradiol concentrations.

The ratio of plasma testosterone to androstenedione concentrations after hCG stimulation usually well distinguishes androgen insensitivity from 17-HSD 3 deficiency. A ratio less than 0.8 is typically found in 17-HSD deficiency; although similarly low ratios can be encountered in testicular dysgenesis, the absolute amount of plasma C19 and C18 steroids after the administration of hCG is strikingly different.

Hormone profile: Increased plasma estrone and androstenedione; decreased ratio of plasma testosterone/androstenedione and estradiol/estrone after hCG stimulation test; increased plasma FSH and LH levels.

**hCG, human chorionic gonadotropin; FSH, follicle-stimulating hormone; LH, luteinizing hormone**
Defects in Androgen-Dependent Target Tissues

A defect at any step in the mechanism of action of androgens on their target cells (see Fig. 22-29) (Figure Not Available) 5-reduction of testosterone, binding of DHT to the receptor, nuclear localization of the steroid receptor complex to hormone response elements on DNA and subsequent transcription, or translation can lead to impaired androgen action and result in male pseudohermaphroditism. Two major forms have been identified: end-organ resistance to androgenic hormones (androgen receptor defects) and errors in testosterone metabolism in target tissues (5-reductase deficiency).

End-Organ Resistance to Androgens (Androgen Receptor Defects)

The spectrum of phenotypes in 46,XY individuals with resistance to androgens varies from patients with normal female external genitalia through those with genital ambiguity to those with a normal male phenotype who have a small phallus and are fertile. The syndromes of androgen insensitivity are a paradigm of clinical disorders resulting from resistance to the action of normal or increased circulating concentrations of a hormone. 

Complete Androgen Insensitivity Syndrome and Its Variants (Androgen Resistance, Testicular Feminization, Feminizing Testes).

The term "testicular feminization," coined by Morris but no longer used, was applied to a highly distinctive X-linked disorder in which affected males are phenotypic females and develop female secondary sexual characteristics at puberty but fail to menstruate (Table 22-33). Affected individuals are genetic males as shown by the 46,XY karyotype and have testes. The prevalence of this disorder is estimated at between 1 in 20,000 and 1 in 60,000 live male births.

The syndromes of androgen insensitivity represent the most common identifiable cause of male pseudosexual disorder. Phenotypically, these patients have unambiguous female external genitalia, hypoplastic labia majora; a blind vaginal pouch; absent or, rarely, vestigial Müllerian structures (uterus and tubes); testes located in the labia, the inguinal canal, or the abdomen; and absent or vestigial Wolffian derivatives. Histologically, the testes are difficult to distinguish from normal before puberty. After puberty, there are Sertoli-cell-only seminiferous tubules within nodules, spermatogenesis are sparse, and spermatogenesis is absent. The Leydig

cells are hyperplastic and tend to form adenomatous clumps. The testes are predisposed to malignant transformation. Carcinoma in situ and seminoma have been reported, especially in patients with the partial form of androgen insensitivity. The overall risk of a testicular neoplasm in the affected adult has been estimated at 4% to 9%; however, the risk appears to be significantly less in those younger than 20 years of age.

At birth and in childhood the diagnosis should be suspected in phenotypic females with an inguinal hernia (particularly if bilateral) and a testis-like mass in the inguinal region or in the labia. It has been estimated that 1% to 2% of phenotypic females with inguinal hernias have the syndrome. Nevertheless, it is debatable whether a routine karyotype should be performed in all female infants with inguinal hernias. At adolescence, female secondary sexual characteristics develop and include normal breasts and female body habitus but no menses. Pubic and axillary hair is usually sparse and is completely lacking in about one third of patients. This was the case in a family with complete deletion of the androgen receptor, representing the null phenotype of this syndrome.

Pathophysiology and Hormone Profile

The Androgen Receptor

In 1950 Wilkins first suggested that failure of androgenization of the male fetus and the development of female rather than male secondary sexual characteristics at puberty could be explained by end-organ unresponsiveness to androgen based on lack of virilization with 50 mg of methyltestosterone administered daily . Studies by subsequent workers supported this contention by failing to demonstrate a clinical or metabolic response to testosterone administration in patients with the complete form of this syndrome.
A Japanese patient with the syndrome was reported to have a normal gene on sequencing and absence of a specific co-activator for transcription factors. ARA 70 cofactor, which appears to bind relatively specifically to the androgen receptor, was screened for mutations in a group of patients with partial androgen resistance.  

The role of co-regulator protein dysfunction in androgen action may be relevant in some forms of androgen insensitivity. Targeted disruption of the mouse androgen receptor gene led to a more functional interpretation of androgen-binding results. The lack of strict correlation between phenotype and receptor binding, as well as the undetectable or low amount of androgen receptor activity was subsequently demonstrated in cultured fibroblasts from the genital skin of karyotypic males with the syndrome. These observations were amply confirmed by others. The lack of androgen binding in genital skin fibroblasts from patients with this disorder provided an explanation for the observed failure of androgen action.

Extensive studies of the parameters of androgen binding in genital skin fibroblasts using DHT and synthetic androgens showed a range of quantitative and qualitative defects. Typically, there was absent specific androgen binding in patients with the complete androgen insensitivity. In contrast, there was detectable binding in the partial form of the syndrome, but this was qualitatively abnormal as based on characteristics such as decreased binding affinity, thermolability of binding, and increased dissociation kinetics. In some instances, there was curiously normal or increased androgen binding that was only adequately explained once the androgen receptor had been cloned. Knowledge of the functional domains of the androgen receptor protein as a result of characterizing the androgen receptor gene led to a more functional interpretation of androgen-binding results. The lack of strict correlation between phenotype and receptor binding, as well as the apparently normal binding found in patients with androgen resistance, was clarified by studies of the molecular biology of the androgen receptor and of mutations in the gene encoding the receptor.

A large number of androgen receptor gene mutations have been described in patients with androgen insensitivity, and they are recorded on an international database (see http://www.mcgill.ca/androgendb/). About 400 mutations distributed throughout the gene are now described. The vast majority are missense/nonsense nucleotide substitutions located predominantly in exons encoding the hormone-binding domain. There are also examples of splice site intronic mutations, small deletions and insertions, and, rarely, complete deletions of the gene. Mental retardation was an associated feature.

**Molecular Biology of the Androgen Receptor (see Hormonal Sex Differentiation)**

The androgen receptor gene is located at Xq11-q12, comprises eight exons, and encodes a 110- to 114-kd protein that varies in length from 910 to 919 amino acids. Exons 1 through 4 encode the DNA-binding region of the androgen receptor. Part of exon 4 (Fig. 22-77) encodes the hinge region of the androgen receptor, which contains a nuclear localization signal. The 3' end of exon 4 through exon 8 encodes the ligand (androgen)-binding region. A mutational hot spot is located in exon 5 and can cause both CAR and PAR. Not shown are nonsense, frameshift, and splice junction mutations and deletions that can cause either CAR or PAR. (Redrawn from Quigley CA, De Bellis A, Marschke KB, et al. Androgen receptor defects: historical, clinical and molecular perspectives. Endocr Rev 1995; 16:271321. © 1995, The Endocrine Society.)

Asterisks indicate mutations that have been found to cause both complete and partial androgen resistance. Each mutation is indicated by the three-letter abbreviation for the wild-type amino acid.

Germ line mutations have been reported in male breast cancer; the mutations affected adjacent arginine residues in the second zinc finger part of the DNA-binding domain in all three reported patients. Somatic mutations are described in prostate cancer, a disease that is androgen dependent in its initial stages. A common mutation is Thr877Ala, which is also found in the human prostate LNCAP cell line. A unique inactivating somatic mutation (Ty649Cys) has been identified that is transcriptionally inactive and appears to sequester the SRC1 co-activator protein, a pathophysiologic feature analogous to what occurs as a result of the increased triplet repeats in Kennedy’s disease.

Hormone Profile

The hormone profile is similar in all variants of androgen insensitivity but is best characterized in the complete form. The hallmark at puberty and in the adult is an elevated concentration of plasma LH and testosterone in the absence of virilization. However, plasma LH and testosterone levels were strikingly low in 9 of 10 neonates with the complete form of androgen resistance at 30 and 60 days of age as was the LH response to the administration of LHRH. In contrast, 5 similarly studied neonate with partial androgen resistance had plasma testosterone levels in the high normal range and exhibited a normal neonatal LH surge. The suggestion is that the normal postnatal range of testosterone and LH in male infants is abolished or attenuated by the lack of or very functionally defective androgen receptors in the hypothalamus whereas the less functionally defective androgen receptor abnormalities in the partial androgen resistance syndrome are sufficient for the expression of the characteristic surge.

The pattern of LH and testosterone at puberty and in the adult is much the same in the partial form of the syndrome. Indeed, elevated LH in the face of normal to increased adult male-related testosterone concentrations in men with reduced sperm counts may be a marker of mild androgen insensitivity secondary to an androgen receptor gene mutation. Estradiol levels are elevated, both as a direct effect of testosterone secretion and peripheral aromatization of androgens to estrogens.  

Feminization takes place at puberty amplified by estrogen action unopposed by androgens. Plasma FSH concentrations are generally within the normal range. When gonadectomy is performed, there is a further elevation of plasma LH and a rise in FSH concentration that suggests that both estradiol and inhibit play a role in the negative feedback of gonadotropins in patients with androgen resistance.

Sex hormone binding globulin (SHBG) levels are higher in adult females compared with males as a result of an estrogen effect. SHBG levels are in the female range in androgen insensitivity. The lack of SHBG response to the rise in testosterone concentrations after hCG stimulation has been proposed as a useful biochemical screen for androgen insensitivity before puberty. Furthermore, the absence of the androgen-steroid binding protein fails to suppress SHBG levels in complete androgen insensitive patients, whereas there was an intermediate response in patients with the partial form as compared with normal male controls. However, this bioassay is not useful in newborns because of the normal decrease in the concentration of SHBG in the neonate. Few confirmatory data have been published in older patients; an increased plasma level of AMH may be a marker of androgen resistance during the first year of life and after the onset of puberty.

Diagnosis

The diagnosis in the complete form of androgen insensitivity is relatively straightforward and can usually be established on clinical grounds. This is particularly so when there is a positive family history. It is not unusual to establish a history of an older "sister" having had surgery to repair bilateral inguinal hernias. The main differential in infancy is 17-HSD 3 deficiency and Leydig cell hypoplasia (LH/ICG resistance), hence the recommendation to perform an hCG stimulation test. Later, the differential is mainly with complete XY gonadal dysgenesis, where typically there is absent or poor breast development and the retention of müllerian structures.

The full form of the syndrome is much more of a diagnostic challenge; the disorders that can give rise to a similar phenotype have already been discussed. As yet there is no readily available, clinically practical, in vivo or in vitro assay of the trans-activational capacity of the androgen receptor; but new approaches are promising. It is mandatory to assess the androgen response to hCG stimulation, ensuring that androstenedione, testosterone, and DHT concentrations are measured in plasma. There is sometimes a response in growth of the phallicus after the hCG stimulation test, particularly if prolonged. Furthermore, a short course of testosterone injections is recommended as a diagnostic test. However, a response does not necessarily exclude partial androgen insensitivity because it is now known from trans-activation studies of mutant receptors in vitro that certain androgen receptor gene mutations are compatible with male sex of rearing. The phallic response to testosterone is an important assessment in the recommendation for sex assignment in the affected infant. In addition, the phallic response has been used as a predictive test of androgen responsiveness in utero. If the phallic growth, in some cases the results have been equivocal and a neonatal response has not invariably followed by a response to testosterone at puberty.

Management

The sex of rearing is female in the complete form of androgen insensitivity, and the gonads need to be removed, owing to a later risk of malignancy. The tests may be left in place (especially if they are not located in the labia major) until late adolescence to provide a natural source of estrogen. The patient may then elect to undergo orchidectomy, having undergone spontaneous pubertal feminization. Using laparoscopy it is feasible to repair an inguinal hernia in childhood without removing the testis. The status of the intra-abdominal part of the appendix is not removed in infancy or early childhood. There is also the question of a modest decrease in bone mineralization in patients with complete androgen insensitivity, although the risk does not seem to be related to when gonadectomy is performed. The limited data available on bone mineral density in partial androgen insensitivity indicate less of a deficit in bone mineralization.

A potential surgical problem in the complete form of androgen insensitivity is the shortened vagina. There are numerous techniques described to re-vagina a fashion, and the details are beyond the scope of this chapter. Most patients do not require surgery if graded vaginal dilators are used on a regular basis in adolescence. Estrogen treatment is required after gonadectomy; a transdermal patch is widely used but is expensive. It is generally thought that the lack of a uterus precludes the necessity for concomitant treatment with a progestogen. Outcome studies indicate that psychosexual development and sexual function are generally satisfactory in adult life. The practice of not disclosing full information to the patient about the nature of her medical condition is no longer acceptable. The authors recommend that with consent of the parents and the establishment of an appropriate psychosocial support system, the diagnosis, pathophysiology, quality of life issues, and in our view on a need-to-know basis. A potentially painful if not disasterous scenario is one in which the adult patient inadvertently discovers the diagnosis. Carrier detection for genetic counseling purposes is often requested and can be undertaken once the gene mutation within a family has been identified. The polymorphic CAG repeat sequence in exon 1 is useful to analyze segregation of the two X chromosomes in a carrier female. Furthermore, this linked marker can be useful to exclude the possibility of partial androgen insensitivity in familial hypospadias of unknown cause.

Management of partial androgen insensitivity syndrome is complicated by the major issue of predicting the likely response to androgens at puberty. The disorder is not different to other causes of severe undermasculinization (e.g., in 45X/46,XY karyotype) where decisions are often based on the response of the penis to a course of intramuscular testosterone. The surgical issues concerning creation a functional phallicus, which one. The surgery has been an important consideration, are no longer compelling in light of the remarkable advances in the surgical correction of severe degrees of hypospadias. There is evidence that male sex of rearing is increasingly chosen despite severe undermasculinization at birth. Some patients respond at least partially to high-dose androgen therapy. Outcome studies are sparse, but studies of males with microphoria reported heterosexual orientation and normal male sexual function in the majority. If the parents select a female sex assignment, it is necessary to inform them that a variable degree of masculinization as well as feminization will occur at puberty. In patients in whom the
assigned female sex and their gender identity are congruent, orchidectomy is usually advisable by early puberty.

Partial (Incomplete) Form of Androgen Resistance and Its Variants (Reifenstein’s Syndrome)

A heterogeneous group of 46,XY individuals have partial androgen resistance. The external genitalia range from perineoscrotal hypospadias with cryptorchidism and micropenis to clitoromegaly with partial labial fusion. The patients described in the past by Lubbs, Gilbert, Dreyfus, Reifenstein, Rosewater, Walker, and their associates quite likely had partial androgen resistance. The variable degree of masculinization of affected males within and between kindreds is well illustrated by one family studied by Wilson and colleagues. Eleven males were affected; two had a relatively mild defect in masculinization of the external genitalia (small penis and bifid scrotum), eight had peripheral hypospadias, and one had hypospadia, a urogenital sinus with a blind vaginal pouch, and an absent vas deferens. All lacked müllerian structures. In contrast, families with the complete form of androgen resistance exhibit little variability in expression of the mutant gene. The most common presentation in infancy is that of an apparent male with third-degree hypospadias (the urethral orifice located at the base of the phallus), a small penis, and, often, cryptorchidism. Müllerian duct derivatives are absent; Wolffian duct derivatives are usually present but hypoplastic. At puberty, pubic and axillary hair and gynecomastia usually develop, male secondary sexual characteristics are incompletely developed, and the testes remain small and exhibit azospermia because of germinal cell arrest beyond the primary spermatocyte stage. Less severely affected men may exhibit a bifid scrotum, infertility, and poor virilization at puberty. More severely affected males may have ambiguous genitalia, a blind vaginal pouch, and poorly developed Wolffian structures. As in other patients with androgen insensitivity, the concentrations of plasma LH and testosterone are elevated and the high LH levels are resistant to suppression by exogenous androgens. Estradiol and testosterone production rates are increased. However, the degree of feminization at puberty, despite elevated estradiol secretion, is less than in the complete form of androgen resistance.

Analysis of a large kindred with Reifenstein’s syndrome (partial androgen resistance syndrome) led to the detection of two phenotypically normal men who were infertile and lacked the clinical features of androgen resistance. These infertile males could not be distinguished endocrinologically or by androgen receptor studies from their more severely affected relatives. Subsequently, Aiman and co-workers reported infertility in three unrelated men with uninformative family histories and a quantitatively defective androgen receptor. Two of these men had a normal adult male phenotype, and one had mild feminine habits. In a study of the androgen receptor in 28 unrelated, phenotypically normal men with idiopathic azoospermia or oligospermia, Aiman and Griffin estimated the frequency of androgen receptor abnormalities in men with idiopathic infertility. Aiman and Griffin also studied 28 unrelated, phenotypically normal men with idiopathic azospermia or oligospermia. Using genital skin fibroblasts, they observed a partial deficiency of the androgen receptor. Further studies suggested the existence of both quantitative and qualitative abnormalities in infertile males.

Molecular analysis of the androgen receptor in transfected cells demonstrated a decrease in hormone and metabolic profile: Increased plasma LH and testosterone concentrations; increased estradiol (for men); FSH levels may be normal or slightly increased. Partial resistance to androgenic and metabolic effects of testosterone. Genetic heterogeneity; partial deficiency of normal receptor; mutations lead to qualitatively abnormal receptor.

| Karyotype: 46,XY |
| Inheritance: X-linked recessive; mutations in \( \alpha \) subunit gene |
| External genitalia: Ambiguous with blind vaginal pouch hypoplastic male normal male with infertility normal fertile male |
| Wolffian duct derivatives: Rudimentary hypoplastic normal |
| Müllerian duct derivatives: Absent |
| Gonads: Testes (usually undescended) |
| Habitus: Decreased to normal auxiliary and pubic hair, beard growth, and body hair; gynecomastia common at puberty |
| Hormone and metabolic profile: Genetic heterogeneity; partial deficiency of normal receptor; mutations lead to qualitatively abnormal receptor |

Androgen Resistance in Infertile Men

It was postulated that infertility in otherwise normal men was the most consistent and most subtle clinical manifestation of quantitative and qualitative defects in the androgen receptor. However, families have now been described that include men with normal male genitalia, postpubertal gynecomastia, and poor virilization in spite of elevated plasma testosterone levels. Studies of the androgen receptor in affected individuals detected several qualitative abnormalities, including receptor instability, failure of up-regulation, increased dissociation of receptor-synthetic androgen complexes, and thermal instability. Molecular analysis of the AR gene in one patient revealed a single nucleotide substitution in the androgen-binding domain, a leucine to phenylalanine change at amino acid 789 (Leu789Phe). Expression of the mutant gene in transfected cells demonstrated a decrease in trans-activational activity with this substitution compatible to that seen in this mild form of androgen resistance. Hence, subtle undervirilization (phallic length, 5 to 6 cm in two patients) with or without gynecomastia, rather than infertility, may represent the extreme of the phenotypic spectrum of subtle defects in androgen receptor function.

Defects in Testosterone Metabolism by Peripheral Tissues: Steroid 5-Reductase Type 2 Deficiency (Male Pseudohermaphroditism with Virilization at Puberty)

In 1961, Nowakowski and Lenzi described a familial type of male pseudohermaphroditism, which they called "pseudovaginal perineoscrotal hypospadias," that was transmitted as an autosomal recessive trait. The patients resemble those with other forms of male pseudohermaphroditism by having a 46,XY karyotype, normally differentiated testes, male internal ducts, and ambiguous external genitalia. At puberty, striking but selective signs of masculinization appear.

In 1974, Walsh and associates and Imperato-McGinley and colleagues reported a defect in the conversion of testosterone to its 5-reduced metabolite DHT in patients with this syndrome. Imperato-McGinley described a genetic isolate from villages in the southwestern part of the Dominican Republic. The classic clinical features of this form of male pseudohermaphroditism in infancy include a clitoris-like, hypospadic phallicus bound in chordee of variable degree, a bifid scrotum, and a urogenital sinus that opens on the perineum. A blind vaginal pouch opens either into the urogenital sinus or onto the perineum behind the
and seminal vesicle) are well differentiated; the ejaculatory ducts usually terminate in the blind vaginal pouch. If a vaginal pouch is not present, the Wolffian ducts terminate on the perineum next to the urethra. The prostate is hypoplastic. At puberty, plasma testosterone levels increase into the adult male range, whereas DHT levels remain disproportionately low but measurable. Affected males virilize to a variable degree without gynecomasia; the voice deepens, muscle mass increases; the phallus, although bound in chordee of variable severity, enlarges to 4 to 8 cm in length; libido ensues; and penile erections occur. The bifid scrotum becomes rugated and pigmented, and the testes enlarge and descend into the labioscrotal folds. However, none of the postpubertal affected males have acne, more than sparse facial or body hair, temporal hair recession, or enlargement of the prostate, nor do they develop gynecomasia. Histologic examination of the adult testes in affected males shows Leydig cell hyperplasia and decreased spermatogenesis. In general, spermatogenesis is either absent or profoundly impaired, which appears to be due to the cryptorchidism. Three male siblings in a Swedish family affected with 5-reductase-2 deficiency had successful hypospadias repair in infancy and two brothers were demonstrably fertile. All were compound heterozygotes for mutations in the SRD5A2 gene.

As with other forms of male pseudohermaphroditism, phenotypic variability has been described both within and between cohorts. Approximately 55% of patients have had a pseudovagina; the rest have a urogenital sinus, a hypospadiac phallus, or even a microphallus with a penile urethra. Eighteen of 19 46,XY patients with 5-reductase-2 deficiency from the Dominican cohort who were raised "unambiguously" as females changed their gender identity and gender role behavior to male after the onset of puberty. Similar observations were reported in 19 of 40 families with 5-reductase-2 deficiency, as well as in male pseudohermaphrodites with 17-HSD3 deficiency or XO/XY mosaicism. This phenomenon appears to be particularly prevalent, although not exclusively so, in 46,XY male pseudohermaphrodites whose gonads are retained and who produce testosterone that results in masculinization at puberty. An isolated case of 5-reductase deficiency was reported where the child was raised as a girl but on virilization at puberty the gender was changed to male. The parents were first cousins of Pakistani origin. These patients raise provocative questions about the effect of sex of rearing, social and cultural factors, and of learning and prenatal androgen exposure on the brain and Y-bearing genes on psychosexual development. A genetic isolate of individuals from New Guinea deficient in 5-reductase-2 was described by Herdt and Davidson. As in the Dominican cohort, a third category of sex was identified in this cultural isolate, the so-called Turnim man. However, sex reversal at puberty has not been as common in this cultural isolate as in others, where the sex reversal appears to be in part a consequence of social and cultural pressure rather than solely a sex hormone effect on behavior. Another cluster of cases has been described from Southern Lebanon. Again, affected individuals were unambiguously female at birth and remained so until puberty, when there was a change in gender role.

Females homozygous for 5-reductase-2 deficiency are phenotypically normal and undergo normal pubertal maturation except for delayed menarche. They have an absence of hair on the arms and legs and decreased axillary and pubic hair, which suggests an important effect of DHT on the growth of body hair. Fertility is normal, and two of the three homozygous females studied in the Dominican kindred gave birth to nonidentical twins, which suggests a role for DHT in the regulation of ovarian follicular maturation; the human ovary has 5-reductase-2 activity.

In infancy and childhood, patients with 5-reductase-2 deficiency have normal to elevated plasma concentrations of testosterone and decreased levels of DHT after the administration of hCG. In affected postpubertal patients, the testosterone/DHT ratio in peripheral blood is increased from 12 ± 3.1 (mean ± SD) to 35 to 84. Postpubertally, plasma LH levels are either normal or slightly elevated; plasma FSH levels are elevated in about 50% of patients. Studies of estrogen and androgen synthesis demonstrate normal male androgen and estrogen production; this explains the lack of gynecomasia postpubertally in these patients, compared with patients with partial androgen resistance. Additional biochemical features of 5-reductase-2 deficiency are a diminished ratio of urinary 5 to 5-reduced C19 and C18 steroids. Analysis of 5-reduced C19-steroid urinary products can be a useful diagnostic test if the gonads have already been removed. Deficient or abnormal 5-reductase-2 activity in fibroblasts cultured from genital skin is typically seen, but the range of activity in normal individuals is very wide and varies between cell passage number. This is no longer used for diagnosis now that molecular studies of the SRD5A2 gene are possible. Heterozygotes for 5-reductase-2 deficiency have
no clinical manifestations and have intermediate ratios of urinary 5-reduced to 5-reduced C17-steroids (e.g., androsterone/eiocholanolone).  

Genetics.  

The disorder is transmitted as an autosomal recessive trait. There are two steroid 5-reductase enzymes. Both isoforms, which share 50% homology, and catalyze the conversion of androsterone to the more androgentic DHT. Steroid 5-reductase-1 is encoded by a gene located on chromosome 5p15.23; the gene, SRD5A1, has five exons and four introns and encodes a protein with a neutral to basic pH optimum. It is expressed at birth in the liver and nongenital skin. Although the expression of the type 1 enzyme persists in the liver throughout postnatal life, its expression decreases in skin to unmeasurable levels after 2 to 3 years of age and remains low until puberty, when it is again present in nongenital skin, especially the sebaceous glands of the scalp. No mutations in the type 1 gene have as yet been described. Targeted disruption of the SRD5A1 gene in mice causes a defect in parturition that is caused by impaired cervical ripening.  

Steroid 5-reductase-2 is encoded by the SRD5A2 gene on chromosome 2p23, which, like the type 1 gene, contains five exons and encodes a 254-amino acid protein. The type 2 isozyme has a lower Michaelis constant (Km) for testosterone than does the type 1 isozyme; steroid 5-reductase-2 has an acidic pH optimum and is more sensitive to inhibition by finasteride. Most of the 5-reductase activity in the early fetus is caused by the type 2 enzyme. It is expressed in the primordia of the prostate and external genitalia before their differentiation, but it is not expressed in the embryonic Wolffian duct until after the differentiation of the epithelium, vas deferens, and seminal vesicles, which are induced by testosterone and not by DHT. Similar observations were found in the human male reproductive tract based on immunohistochemistry.  

Type 2 expression increases in liver and nongenital skin at birth. It persists in the liver throughout life but diminishes to unmeasurable levels in nongenital skin after 3 years of age. A pseudogene has been mapped to the long arm of the X chromosome at band q24-qter.  

Steroid 5-reductase-2 deficiency is inherited as an autosomal recessive trait and is genetically heterogeneous and more than 30 mutations have been detected in the gene (Fig. 22-82). Most are missense mutations and distributed throughout the coding region of the gene. In general, mutations involving the 3' end of the gene and the carboxyl terminus of the enzyme are associated with a decrease in the affinity for the cofactor NADPH, whereas mutations that affect the binding of testosterone involve exons that encode either the NH2 or COOH-terminal ends of the enzyme. About 35% of the mutation-positive cases are compound heterozygotes and there are relative "hot spots" in exons 4 and 5.  

Consanguinity has been described in approximately 40% of patients. The occurrence of the disorder in three genetic isolates in the Dominican Republic (Arg246Trp), the Sambia tribe of the New Guinea highlands (deletion of the SRD5A2 gene), and cohorts in Turkey is probably the result of a "founder effect." The severity of undermasculinization does not appear to be closely related to the type of mutation, especially in nongenetic isolates. The two mutations reported to cause either 17HSD3 or 5-reductase-2 deficiency are very similar. Consequently, the report of mutations in both HSD17B3 and SRD5A2 in a large isolated Turkish kindred with male pseudohermaphroditism is noteworthy. The results of molecular analysis were complex, with some members homozygous for the SRD5A2 mutation but heterozygous for the HSD17B3 mutation, and vice versa for other affected family members. There was some phenotypic distinction as judged by the presence of mild gynecomastia if an individual was homozygous for the HSD17B3 mutation. There is evidence that 5-reductase-2 deficiency may result from uniparental disomy (UPD). This is based on a report of two unrelated patients with the enzyme deficiency whose parents were heterozygous carriers for two different but identical mutations in the two families (Glu197Asp and Pro212Arg). One patient was a compound heterozygote for the two mutations, but the other was a homozygote for the paternal mutation (Glu197Asp). The reduction to homozygosity for this mutation suggested not only the first example of 5-reductase deficiency resulting from UPD but also the first case of paternal (as opposed to maternal) UPD involving chromosome 2.  

The finding of two 5-reductase genes with different tissue distributions and different temporal expressions has clarified the nature of the pubertal masculinization in the human male. The increase in plasma DHT levels at puberty and the chronic effect of adult circulating DHT levels are responsible for the masculinization at puberty.  

The incidences of 5-reductase-2 deficiency are consistent with a frequency of at least 1 in 20,000 live male births. The finding of two 5-reductase genes with different tissue distributions and different temporal expressions has clarified the nature of the pubertal masculinization in the human male. The increase in plasma DHT levels at puberty and the chronic effect of adult circulating DHT levels are responsible for the masculinization at puberty.  

The diagnosis of 5-reductase-2 deficiency can be difficult, especially before the age of puberty. It should be suspected in all prepubertal male pseudohermaphrodites, especially those with perineoscrotal hypospadias with or without a blind vaginal pouch, in males with hypospadias or microphallus, and in male pseudohermaphrodites who virilize at puberty without evidence of gynecomastia. Virilization at puberty and the absence of gynecomastia in male pseudohermaphrodites are not unique to 5-reductase-2 deficiency. For example, patients with 17-HSD3 deficiency or partial androgen resistance may present in this manner, but can be distinguished biochemically or by DNA analysis from patients with 5-reductase-2 deficiency. The diagnosis of 5-reductase-2 deficiency can be confirmed prepubertally and postpubertally by demonstration of an abnormally high testosterone/DHT ratio in peripheral blood before and/or after hCG administration. The testosterone/DHT ratio under basal conditions in postpubertal affected males is 35 to 84, whereas the ratio in normal men is 12 ± 3.1. In normal male infants, when there is active testicular steroidogenesis, the testosterone/DHT ratio ranges from 1.7 to 17 (mean ± SD, 4.9 ± 2.9). In view of the low levels of testosterone and DHT in prepubertal males, it is usually necessary to administer hCG (1500 U/m2 intramuscularly every 24 hours three times) to demonstrate the defect. Normal infants, when there is active testicular steroidogenesis, the testosterone/DHT ratio ranges from 1.7 to 17 (mean ± SD, 4.9 ± 2.9). Using both basal and hCG-induced increases in testosterone level and urinary analyses of 5α- and 5β-hydroxy metabolites, Imperato-McGinley and co-workers detected 5-reductase-2 deficiency in three infants between the ages of 1 and 3 months. Mutations in the SRD5A2 gene have been reported rarely in boys with isolated hypospadias. Two of the mutations (Ala49Thr and Leu113Val) have not been reported in patients with typical 5-reductase deficiency. A positive family history of hypospadias is not necessarily a pointer to a mutation being more likely.  

Early diagnosis of 5-reductase-2 deficiency is important because of its bearing on the assignment of sex in the affected infant. Although the majority of missense mutations in the SRD5A2 gene are associated with less than 0.4% of normal activity, mutations with 3% to 15% residual activity have been reported in 46,XY individuals with sufficient masculinization of the external genitalia at birth to be assigned a male gender. Masculinization in utero and the plasma testosterone/DHT ratio in early infancy correlate with the degree of residual 5-reductase-2 activity. The natural history of patients with this deficiency is that, in the propensity for patients to change to male gender role behavior and for virilization at puberty makes male assignment of neonatally diagnosed patients the recommendation of choice, especially in affected individuals with ambiguous or hypoplastic male genitalia. Therapy with DHT should increase phallic length into the normal range for age and enable repair of hypospadias. Carpenter and co-workers described a 9-month-old infant with 5-reductase-2 deficiency who had been assigned a male gender at birth. The genitalia exhibited penoscrotal hypospadias with a phallus 1.9 cm in length and bound down in choordee. Therapy was instituted with DHT, 25 mg/day (2% by weight in a cold cream base), applied to the patient's abdomen. Four months of therapy resulted in an increase of stretched phallic length from 1.8 to 3.8 cm. No advancement in bone maturation was noted. Hypospadias repair was undertaken, and a second course of DHT was given without consequence. Two affected siblings with very small phallices and a bifid scrotum containing palpable
gonads were treated with topical DHT cream applied to the external genitalia. There was significant phallic growth in both siblings, which also aided subsequent hypospadias corrective surgery. In adults with 5-reductase-2 deficiency, supraphysiologic doses of testosterone have resulted in normal DHT levels and partial masculinization; the conversion to DHT is mediated by the type 1 5-reductase isozyme. However, Mendonca and colleagues[246] report that treatment of late adolescents or adults with high doses of testosterone and/or DHT induced an increase in phallic size that remained more than 2 SD below the normal mean and usually did not exceed 5 cm. Should the patient inadvertently be assigned a female sex role or the parents elect to rear the infant or child as a female, we suggest that female genitaloplasty and orchidectomy not be performed until the age of puberty and only with the consent of the adolescent as well as the parents.

### Dysgenetic Male Pseudohermaphroditism (Ambiguous Genitalia Resulting from Dysgenetic Gonads)

Ambiguous development of the genital ducts, urogenital sinus, and external genitalia occurs in patients with dysgenic gonads. They usually present with evidence of AMH deficiency as well as androgen deficiency and therefore have müllerian duct derivatives and ambiguous external genitalia. Mutations and deletions of any and all of the genes involved in the testes determination and differentiation cascade (see Fig. 22-19 and Table 22-4) have been implicated in the etiology of dysgenetic male pseudohermaphroditism. The differential diagnosis encompasses a spectrum of abnormalities of the Y chromosome as well as

mosaicism involving a 45,X chromosome cell line and a cell line with Y chromosome DNA, which we have classified as "abnormalities of gonadal differentiation" (see sections on X-chromatin negative variants of the syndrome of gonadal dysgenesis and familial and sporadic XY gonadal dysgenesis). These patients, all of whom have in common a defect in testes differentiation, can present with the clinical syndrome of "dysgenetic male pseudohermaphroditism"[1378] (Fig. 22-83) .
